855 IMPAIRED AWARENESS OF ARM POSITION IN PARKINSON PATIENTS IN THE ABSENCE OF VISUAL FEEDBACK. J. D. Cooke, V. B. Brooks, J. Brown and G. Lucier. Depts. of Physiology and of Clin. Neurol. Sci., Univ. of Western Ontario, London, Canada, N6A 5C1.

Studies by Purdon Martin (1) on Parkinsonians and by Hore et al. (2) on monkeys with temporary dysfunction of the globus pallidus have revealed increased dependence on visual information for movement performance. We have studied tracking movements made with and without visual feedback of arm position by two non-medicated patients with idiopathic Parkinson's disease and two age-matched control subjects. Subjects were seated in a chair with their forearm supported on a horizontal handle and they grasped a vertical rod with their hand. The subjects' view of their operant arm was blocked by a sheet. A visual display of target and handle positions was presented on an oscilloscope at the subject's eye level approximately 1m in front of him. Two types of test were used: a) step tracking where the target switched every 2 sec between two positions separated by 32 deg of arc. Targets were not bounded by mechanical stops. b) continuous tracking where the target moved at constant velocity (6.5 or 13 deg/sec) between the same two target positions. After a familiarization period the subject was asked to follow the target movement with, and subsequently, without, the handle position being displayed on the oscilloscope.

Accuracy of arm positioning was assessed from the standard deviations (SD) of the holding positions (step tracking) or of the maximum flexion or extension positions (continuous tracking). Average SDs of arm position from 15-30 trials are given below (patients: BS, BM; controls: WS, JS). Removal of the visual display of handle position increased the variability of arm positioning by a significantly greater amount in the Parkinson patients. In one patient (BS) this increased variability was associated with a gradual drift of arm position towards flexion with no accompanying change in movement amplitude. The other patient (BM) showed an apparent random variation in arm position accompanied by a decrease in movement amplitude which was not significantly different from the control subject.

	STEPS		RAMP (13 deg/s)		RAMP (6.5 deg/s)	
SD(deg)	BS/WS	BM/JS	BS/WS	BM/JS	BS/WS	BM/JS
VISION	2.3/1.9	2.3/2.0	4.0/2.7	2.3/2.4	5.5/2.8	2.4/2.4

856 FIRING RATE CHARACTERISTICS OF SMUs IN THE HUMAN MASSETER MUSCLE. B. Derfler* and L.J. Goldberg. Sch. Dent., UCLA, L.A., CA 90024.

Intramuscular recording of spike trains from single motor units (SMUs) was obtained from the masseter muscle of humans while a force transducer positioned between the teeth simultaneously recorded bite-force. Subjects produced 10sec force steps that ranged between 1 and 48 kg. A total of 73 SMUs were triggered and identified for analysis; 41 of these could be followed over 2 or more consecutive force steps. Histograms of interspike intervals (ISIs) were generated for each force level; the mean ISIs ranged from 161-38 ms, and std. deviations (SD) ranged from 47-4 ms. The following observations were made. (1) When units could be triggered over several successive force levels after recruitment, the plots of force vs mean ISI were usually curvilinear and all tended to reach a "plateau phase" of maximum mean ISI, beyond which firing rate remained constant over further force steps. The slope of the curve (rate of change of mean ISI) and position on the Y-axis (indicating minimum and maximum mean ISI) were dependent upon the recruitment threshold of the units. (2) At the recruitment level, most units generated histograms that were asymmetric and positively skewed but as firing rate increased at higher force levels the histograms became progressively more symmetric and narrow, with some reaching even slight negative skew. (3) A plot of SD vs mean ISI was linear with significant positive correlation, except in the vicinity of the shortest mean ISIs where SDs asymptote to values of 4-7 msec. (4) Serial correlation between consecutive ISIs were calculated for 33 sequences of spikes. There were 19 sequences where the respective SMUs had entered their plateau phase of maximum firing rate and these all had negative correlation coefficients with 10 significantly so; the other 14 sequences were not from plateau phases and these had both negative and positive coefficients with none significantly different from 0.

The data can be interpreted according to criteria proposed by Segundo and Perkel (UCLA Forum Med. Sci., 11:349, 1969) as indicating that masseter motoneurons behave: (a) at low drive (threshold) as non-pacemaker cells receiving the equivalent of large, irregular EPSPs; (b) at "optimum drive" (maximum rhythmic firing rate) as non-pacemaker cells receiving the equivalent of many, small, regular or irregular EPSPs (c) at "supra-optimum drive" (strong enough to elicit spikes during the after-hyperolarization) as pacemaker cells receiving the equivalent of large, irregular EPSPs unsynchronized with the rhythmic pacemaker discharge. In addition, we interpret the observations as support for the hypothesis that after-hypolarization summation may provide the natural limit to firing rate for motoneurons in the trigeminal motor nucleus, where no recurrent collaterals have been identified. 857 MOTOR OUTPUT RESPONSE TO TRANSIENT DISTURBANCES OF THE HUMAN FOREARM. J. R. Dufresne*, J. F. Soechting and C. A. Terzuolo. Laboratory of Neurophysiology, Medical School, University of Minnesota, Minneapolis, MN 55455.

The dynamic properties of reflex mechanisms responsible for position control of the human forearm were analyzed by relating EMG activity of the biceps and triceps muscles to angular displacement and its derivatives during applied force perturbations. These were produced by a torque motor and consisted of pulses of torque whose amplitude and duration could be precisely controlled. The subjects were instructed to resist the applied perturbations. Either single pulses or a sequence of randomly occurring pulses were used. Modelling of these data using Fourier and cross-correlation analysis showed that the motor output was related primarily to the angular velocity consequent to the applied perturbation (for frequencies above 1 Hz), in agreement with previous results. The gain of this relationship was increased when the applied perturbations were superimposed on a constant level of torque resulting in a high maintained level of agonist activity. EMG output as predicted by modelling closely paralleled the experimental data. The behavior of these relationships during intentional movements was then studied by applying torque pulses while the subject tracked a sinusoid. Thus, reflex behavior could be studied while the biceps acted as agonist or antagonist. For slow movements (below 0.8 Hz), reflex gain is modulated roughly in parallel with the velocity of the movement. For fast movements (2 Hz; above resonance), instead, the reflex gain was maximum while the biceps was silent (being the antagonist and shortened). Throughout the cycle of movement, the gain varied by a factor of 3. These data imply that during fast movements a fusimotor dynamic bias is injected into the antagonist. (Supported by UPHS Grant NS-2567.)

858 BACLOFEN AND VERAPAMIL ON HEREDITARY MUSCULAR DYSTROPHY OF THE CHICKEN. Richard K. Entrikin, Gary T. Patterson*, C. Michael Cisson*, and Barry W. Wilson. Depts., Pharmacology and Avian Sciences, Univ. California, Davis, CA 95616.

In previous studies we found that phenytoin (DPH) improved righting ability and reduced acetylcholinesterase (AChE) activity in posterior latissimus dorsi (PLD) muscles of dystrophic chicks (Science 195:873, 1977), reduced repetitive firing to electrical stimulation in isolated PLD fibers (Fed. Proc. 36:499,1977), and produced a dose-related decrease in AChE activity in chick embryo muscle cultures (Fed. Proc. 36:498,1977). Since DPH affects both myotonia (Neurology 17:359,1967) and calcium metabolism (Science 183:671,1974), other drugs that affect either or both of these systems might also alleviate symptoms of avian dystrophy and decrease AChE activity in cultured muscle cells. We now present results of whole animal and preliminary cell culture experiments with baclofen (Lioresal; CIBA-Geigy) and verapamil (Isoptin; Knoll).

Baclofen (1-10 mg/Kg) was administered in a single i.v., injection (0.2 ml) to seven 25-day-old line 413 dystrophic chicks on two consecutive days. Control dystrophic chicks received saline injection (0.2 ml). Righting ability of each animal was expressed as the exhaustion score (consecutive number of times a chick can right itself from the supine position). Pre-drug all scores were zero. One day after the first injection, all baclofen-treated birds had increased exhaustion scores (range 1-8), and all control birds had scores of zero. After a second injection maximum scores were 10.4 $\pm$ 6.6 (range 4-22).

Single i.v., injections of verapamil (0.2-2.0 mg/Kg) had no effect on exhaustion scores, but chronic verapamil (1 mg/Kg, b.i.d. i.p.) on days 1-25 ex ovo improved scores in 3 of 6 chicks. The PLD and pectoralis major muscles were removed from the two verapamil-treated chicks with the highest exhaustion scores (11, 22). Both histochemical and biochemical determinations revealed decreased AChE activity in these muscles.

Baclofen (0.3-30.0 µg/ml) and verapamil (1-30 µg/ml) were added to 7-day-old cultures of embryonic chick muscle, and 48 hours later cells and medium were assayed for AChE activity. Total activity (Δ cell + Δ medium) was decreased by both verapamil and baclofen (10 and 30 µg/ml).

These results support our theory that antimyotonia drugs (such as baclofen and DPH) will produce acute increases in exhaustion scores of dystrophic chicks and reduce AChE activity of cultured muscle cells. The results suggest that drugs such as verapamil may increase exhaustion scores by a long-term effect on calcium metabolism. (We thank T. Arnold and S. Usoz for assistance. Supported by NIH Grants NS 05308, AM 16716, and the MDA).

859 MOTOR CORTEX UNITS DISCHARGING MOST INTENSELY WITH SMALL PRECISELY CONTROLLED ARM MOVEMENTS ARE MOST SENSITIVE TO SENSORY INPUTS ARISING FROM THE ARM. E. V. Evarts and C. Fromm*. Lab. Neurophysiol., NIMH, Bethesda, MD 20014.

A visual pursuit-tracking paradigm was used for training monkeys to position a handle within a small zone and rotate it by pronation-supination movements. Motor cortex unit discharge was examined in relation to movements carried out in this situation, with particular attention to large (20^0) ballistic movements as compared to small ($\sim 1^0$) precisely controlled movements. Among motor cortex units related to these pronation-supination movements, about half changed discharge frequency only with the large movement, whereas the other half showed changes both with the large and with the small movement. For many units in this latter group, intense discharge was found to occur during even the smallest movements made to achieve accurate positioning of the handle, and such units almost invariably responded (latencies: 20-60 msec) to small handle perturbations which pronated or supinated the forearm. The perturbations, caused by 50-msec torque pulses delivered to the handle, produced handle displacements of about 5^0. Typically, the neurons discharging intensely with precise fine movements were reciprocally related (increase vs. decrease of discharge rate) both to the two directions of movement and also to the two oppositely directed torque pulses. On the other hand, units active with ballistic supination-pronation movements and inactive with small movements were to a large extent uninfluenced by these kinesthetic stimuli. Activity with small movements and high sensitivity to kinesthetic inputs was particularly common in pyramidal tract neurons with more slowly conducting axons, and appears analogous to the high sensitivity to segmental inputs in those spinal cord motoneurons first to be recruited in the course of movement (cf. Henneman, E., Principles governing distribution of sensory input to motor neurons, In: The Neurosiences, Third Study Program, F.O. Schmitt and F.G. Worden (eds.), Cambridge: MIT Press, 1974 (pp. 281-291).

For any particular neuron, the responses to torque pulses delivered during postural stability (i.e., accurate holding of the handle) were compared with the responses to the same torque pulses when delivered immediately before the onset of a ballistic movement, when injected into ongoing ballistic movement, or when applied during precise fine movement. It was found that unit responsiveness to sensory input is relatively enhanced during accurate positioning and controlled small movement, but reduced before and during ballistic movements.

We suggest that sensory feedback continuously modulates motor cortex activity for units controlling precise fine movements and postural stability, while for large ballistic movements the effect of such sensory feedback is relatively attenuated.

860 DIRECT COMPARISON OF RECRUITMENT ORDER WITH NEURAL AND MUSCULAR PROPERTIES OF MOTOR UNITS. Joel S. Faden and Felix F. Zajac. Elect. Eng. Dept., Univ. of Maryland, College Park, Md. 20742.

There is a great deal of controversy regarding the hypothesis that motoneurons innervating a muscle are recruited in an immutable order based on cell size. Confounding this issue is the belief that cell size is correlated with axonal conduction velocity (CV) and contraction time, tension and other properties of the innervated muscle unit. The lack of a unifying solution has been due to the inference of motor unit properties during recruitment studies from a set of assumptions and a combination of experiments. We have been able to measure directly the neural and muscular properties of single units in a given experiment.

In decerebrate cats nerve fibers innervating plantaris (PL) muscle were functionally isolated by dissecting small, intact filaments (30-125μm in diameter; 5-12 mm in length) from the L7 ventral root, to ensure no disturbance of the discharge characteristics of the units as might occur with intracellular electrodes. Axonal CV and tension and EMG produced by the muscle unit to various stimulus trains were recorded using conventional techniques. The intact filaments were then cut distally and the proximal ends carefully preserved. Simultaneous recordings from these proximal filaments containing single PL nerve fibers were obtained during reflexes produced by homonymous muscle afferents to establish their pairwise recruitment order. The stimuli used to elicit reflexes were tendon taps, muscle stretches, repetitive shocks to the muscle nerve and single shocks after post-tetanic potentiation (PTP). PTP was generated by stimulating either the muscle nerve during a distal cold block or dorsal root(s) at 500 Hz for 5-12 seconds at maximum Ia intensity. In all eleven pairs of units studied the unit producing the largest tension, fatiguing the fastest and having the largest CV was recruited after the other unit. Further study of pairs of units showed that the unit in the pair with the largest CV had the largest tetanic tension (60/76), with the reverse (4/76) and with no differences (12/76). These results are consistent with the hypothesis that recruitment order is solely based on motoneuron size, which in turn is highly correlated with the "size" and fatiguability of the innervated muscle unit.

Our sample is perhaps small in order to make definitive judgements, though units defined as type S, FR, and FF are included. The use of other than homonymous input might also change the recruitment order. Further study with a variety of inputs to the motoneuronal pool, such as those occurring during locomotion will contribute to a better understanding of the relevance of the size principle hypothesis. (Supported by NIH grant NS 11518)

861 ORIGINS OF SPINAL PROJECTIONS FROM THE CAUDAL MEDULLA IN MONKEY. M.C. Gallaway*, A.J. Castiglioni*, R.D. Foreman and J.D. Coulter. Marine Biomed. Inst. and Depts. of Physiol. & Biophys. and Psyciat., Univ. of Texas Med. Br., Galveston, Texas 77550.

Retrograde labeling with the enzyme horseradish peroxidase (HRP) was used to identify the origins of descending spinal projections from the caudal medulla in 8 monkeys (M. mulatta and M. fascicularis). In different animals, injections of HRP were made unilaterally into the spinal gray matter of the cervical or lumbosacral enlargement, the thoracic spinal cord, or the upper cervical segments, C1-C3. Beginning at the spinal-medullary junction, medium to large multipolar neurons were found labeled bilaterally in the region of the nucleus supraspinalis, adjacent and just caudal to the decussating fibers of the pyramidal tract. Labeling of these neurons was most abundant following HRP injections in the upper cervical cord and cervical enlargement, but was virtually absent with injections in the lumbosacral cord. More rostrally in the medulla, a major population of labeled neurons was found ventrolaterally in the nucleus retroambiguus. The majority of these labeled neurons were contralateral to HRP injection sites and were labeled from the upper cervical and thoracic cord, as well as from the cervical and lumbosacral spinal enlargements. From the region of the nucleus retroambiguus, labeled neurons could be followed anteriorly where they were situated around and just dorsal to the nucleus reticularis lateralis, and continued forward in small numbers in a position immediately lateral to the inferior olive. At this level, an additional collection of labeled neurons was found dorsally in the lateral medulla beneath the trigeminal complex. These labeled neurons were medium sized, multipolar cells with their long axis directed dorsomedially. The labeling of this lateral medullary zone was heaviest following HRP injections in the upper cervical cord and cervical enlargement. Among other groups of labeled cells in the caudal medulla were scattered neurons in the ventral part of the dorsal column nuclei between the nucleus gracilis and cuneatus. In addition, labeled neurons were located in the caudal nucleus of the tractus solitarius with the heaviest labeling of this area appearing after thoracic spinal injections. The medial medullary reticular formation (nucleus gigantocellularis) and the midline raphe nuclei also contained large numbers of labeled neurons projecting to all levels of the spinal cord. These findings indicate, in the primate, that the caudal medulla contains a number of distinct cell groups which give rise to descending projections to the spinal cord. Presumably these different regions have separate functions in descending sensory and visceral or somatic motor control.

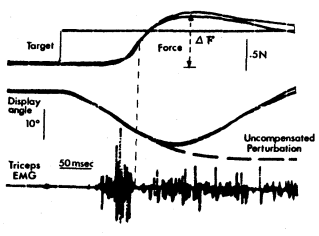
862 ISOMETRIC TRACKING IN THE CAT. C. Ghez and D. Vicario*, The Rockefeller University, New York, NY 10021.

Subjects tracking a rapidly moving target must estimate its trajectory from initial sensory information and scale their motor output to the subsequent position of the target. This study documents such a process in the cat and attempts to characterize the central commands which specify the magnitude of force output generated under isometric conditions.

Cats were trained to apply force isometrically to a strain gauge with their forearm to match a target force level which was stepped at random times. The difference between the target level and the cats' force determined the position of a visual display. Because of inertia and friction in the display device, the step perturbations took 150-200 msec. to be displayed fully (see uncompensated perturbation in figure) and the rate of its motion varied with the size of the step.

The cats responded to these perturbations by rapidly adjusting the force applied. A burst of EMG activity in agonist muscles preceded the force response and lasted until the peak rate of force change (dF/dt). The latency from the target step to this EMG activity was 60-90 msec. After a brief pause, the EMG resumed at a level dependent on the static force exerted. The magnitude of first force change (ΔF) was significantly correlated with the amplitudes of randomly varied target changes despite some overshoot. Both the peak dF/dt and the integrated value of the initial EMG were linearly related to ΔF. By contrast the duration of force change, the time to peak dF/dt and the duration of the initial burst of EMG activity remained essentially constant over the range of forces examined (0.1-2.5 N). We conclude that under isometric conditions the magnitude of intended force may be specified by the magnitude of a pulsatile central command of near constant duration.

The initial agonist "burst" and peak dF/dt specifying the ensuing ΔF are invariably complete before the target shift has been fully displayed. The animals thus extrapolate the full extent of motor output required from the initial parameters of display motion. (Supported by NIH grant 10705).



863 EFFECTS OF AXOTOMY ON NEURAL ACTIVITY DURING LOCOMOTION. J.A. Hoffer, R.B. Stein and Tessa Gordon*. Dept. Physiology, Univ. Alberta, Edmonton T6G 2H7, Canada.

The use of chronic recording electrodes in Silastic cuffs (Hoffer and Marks, Soc. Neurosci. Abstr. 300, 1974; Stein et al, Can. J. Neurol. Sci. 2:235, 1975) has allowed us to follow changes in peripheral nerve activity for long periods of time, prior to and following axotomy. Cuffs were implanted around the sciatic and lateral gastrocnemius -soleus, common peroneal, or posterior tibial nerves of cats. The amplitude and latency of compound action potentials in each branch were measured during stimulation of the sciatic nerve. When these values stabilized some weeks after implantation, the nerve branches were cut distally, and either tied off or sutured to their distal stumps or to nearby muscles which were denervated. Neural activity was recorded during controlled locomotion on a treadmill, and by using cross-correlation techniques the patterns of sensory and motor activity could be separated for each nerve.

Sensory activity declined abruptly following axotomy and did not recover unless reinnervation of sense organs occurred. Even several months after reinnervation, however, sensory activity did not return to control values. Incomplete recovery was accounted for, in part, by a decrease in fiber diameters (as evidenced by declining evoked amplitudes and longer latencies), but was also due to fewer nerve impulses, presumably because some fibers were unsuccessful in regenerating to appropriate sense organs.

Motor activity also declined over the first month following axotomy. This initial decline, greater than that expected from a decrease in fiber diameters alone, was probably attributable to a reduction in synaptic connections onto motoneurons (Mendell et al, J. Physiol. 255:67, 1976). When reinnervation was allowed, motor activity eventually recovered to near control levels, as a result of increasing fiber diameters and probable reformation of synaptic connections. Even when regeneration was prevented by tying off cut nerves, and there was no indication from compound action potentials that fiber diameters had increased, some recovery in motor activity was observed which was maintained for many months.

These findings suggest 1) that the changes undergone by motoneurons in response to axotomy may be partially reversed, even in the absence of reinnervation, and 2) that it may be practicable to record from motor nerves in human amputees and use these signals to control powered artificial limbs.

Supported by the Muscular Dystrophy Association of Canada and the Canadian Medical Research Council.

864 PATTERNS OF MOTOR-UNIT RECRUITMENT IN A SINGLE FOREARM MUSCLE OF MONKEY IN RELATION TO THE DYNAMICS OF VOLUNTARY CONTRACTION. D.R. Humphrey, M. Rowinski* & A.M. Budacz. Lab. Neurophysiol., Emory Univ. Sch. Med., Atlanta, GA 30322.

To understand better the neural mechanisms that are used in the voluntary control of joint position, we have studied patterns of motor-unit (MU) recruitment in the wrist extensor muscles of monkeys, who were trained to 'track' externally imposed forces and thus maintain a constant wrist position. The animals were required: (i) to generate steady muscle forces of various amplitudes; (ii) to generate triangular or ramp increases and decreases in muscle force, which were of constant amplitude but of variable speed (± 80-1200 g/sec); and (iii) to reposition the wrist following step force disturbances which stretched or shortened the muscle. Intramuscular leads were used to record the activity of small clusters of 3-6 MUs during performance of the various contraction patterns. The units were discriminated on the basis of amplitude, and spike-triggered averaging was used to obtain estimates of the relative amplitudes and durations of their associated twitch tensions. Our major observations were as follows.

(i) During the generation of steady or slowly varying muscle forces, the smallest units in each ensemble were always recruited into activity at lower force levels than were the larger units, and were inhibited last during contractions of the antagonist. These results are fully predictable from the previous work of Henneman and his colleagues.

(ii) When the animal was required to generate triangular force waveforms of constant amplitude but with progressively increasing rates of rise and decay, however, the smaller MUs reached a 'saturation' in their firing rates, so that at the higher rates of tension change their discharge modulated very little. Over this same range, the larger (faster-twitch) MUs exhibited a progressive increase in their firing rate modulation, appearing, at the higher tension rates (700-1200 g/sec), to be largely responsible for the observed modulation in muscle tension. Thus, there may be an order of recruitment from small, slow-twitch to large, fast-twitch MUs in relation to the required speed of a muscle's modulated force output, as well as in relation to the required amplitude.

(iii) MUs of different sizes also responded differently to step perturbations in wrist position. When the muscle was rapidly stretched, the initial, apparently segmental reflex response (latency = 15-25 msec) was most prominent and occurred first in the largest MUs. The response of the smaller MUs was, on the other hand, most prominent during the later period when transcortical reflexes and voluntary adjustments appear to dominate (latency = 60-200 msec). (Supported by NIH Grant NS 10183).

865 CATEGORIZATION AND COMPARISON OF CLINICAL EMG WITH MUSCLE PATHOLOGY BY OPEN BIOPSY EMG. E. R. Isaacs, A. J. Szumski and J. A. Martinez. Depts. Neurol. - Physiol. - Pathol., Med. Coll. Va., Richmond, Va. 23298

Discrepencies between the clinical interpretation of the electromyogram and the muscle biopsy from the same patient prompted the use of an open biopsy EMG technique. The resulting reduction in sampling error permitted more accurate correlations between physiological and anatomical data obtained. One hundred patients ranging in age from 3 to 82 years were selected for muscle biopsy because of suspected muscle pathology. All patients were evaluated neurologically, and with complete electromyographic testing prior to the biopsy. Muscle biopsies were obtained using usual sterile technique under local anesthesia. Muscle tissue was prepared for serial frozen sections and stained by routine histological and histochemical techniques. The electromyograms were categorized descriptively and divided into seven major categories based on motor unit amplitude, duration and potential configuration. Recordings of low amplitude, short duration polyphasic potentials alone, or mixed with normal amplitude, short duration polyphasic potentials showed an eighty-eight percent correlation with histological primary myopathic changes. Twenty one patients had EMGs which displayed a mixture of low amplitude polyphasic potentials and either normal motor unit potentials or normal amplitude but polyphasic potentials. Of these, 80% were associated with selective fiber type atrophy, most of which were Type II fiber atrophy. There was a 90% correlation between large polyphasic motor unit potentials and neurogenic atrophy. Overall, there was a 15% discrepency between the open biopsy EMG and the routine EMG of the opposite extremity. The open biopsy EMG most often correlated with the muscle pathology. It is suggested that selective fiber type atrophy can be reflected in the clinical EMG. Open biopsy EMG provides a reasonable and reliable method of correlating physiological changes with the observed muscle pathology.

866 AERODYNAMIC/TEMPORAL CHARACTERISTICS OF MOTOR SPEECH PRODUCTION IN NORMAL AND APRAXIC SUBJECTS. Thomas W. Jensen* (Spon: D.H. York) Dept. Phys. Med. & Rehab., Sch. Med., Univ. Mo., Columbia, Mo. 65201

Because of the potential neuromuscular diagnostic information that may be contained within the aerodynamic/temporal make-up of motor speech production, a study was designed to tap certain parameters of the normal speech product, and then to apply these data to a clinical population (apraxia of speech). Eighty (80) normal adult females, and two adult females with apraxia of speech, served as subjects for this study. Peak intraoral air pressure and duration of intraoral air pressure, of certain voiceless consonants, were temporally compared to voice termination time and voice onset time preceding and following the consonants of interest. Intraoral air pressure was collected via an open-ended tube placed in the oral cavity. The transduced signal was amplified and displayed on a multichannel recorder. Voice timing data was sensed by placement of a throat microphone on the external neck wall on, or adjacent to the lamina of the thyroid cartilage. The voicing data was amplified and displayed simultaneously with the pressure data. Results of normal subjects revealed consistent aerodynamic/temporal responses to the stimuli presented, within subjects, and across subjects, suggesting that glottal activity is time dependent on supraglottal activity, during speech production. Specifically, peak pressure (expressed in cm H_2O) and pressure duration (expressed in msec.) was dependent upon initiation and release of the intraoral pressure component. To demonstrate clinical application, two subjects, with apraxia of speech, were recorded using the above procedure. Inconsistent intraoral air pressure characteristics were displayed within subjects and across subjects with voice timing not being temporally related to supraglottal activity.

867 INPUTS FROM THE PERIPHERY TO THE MOTOR CORTEX IN THE CAT. K. Larsen*, P. Zarzecki and H. Asanuma. The Rockefeller University, New York, NY 10021.

Neurons in the motor cortex (M-Cx) have small somatosensory receptive fields, but the pathways which convey this sensory input are not known. We have approached the problem by recording cortical evoked potentials following stimulation of superficial (SR) and deep radial (DR) nerves in combination with lesions or cooling of selected spinal tracts and sensory cortex (S-Cx). Following extensive removal of S-Cx, including areas 1, 2, and 3a, the potentials were still evoked in M-Cx, although they were reduced to one-fourth the control amplitude. Cuneate nucleus cooling reduced only slightly the group II response from DR, reduced the SR-evoked response by less than 40%, and eliminated the group I response. Section of either the spinocervical or spinothalamic tract reduced only moderately the magnitude of the evoked potentials in M-Cx. When both tracts were sectioned, however, the M-Cx response was reduced greatly. When spinothalamic tract section was combined with cuneate nucleus cooling, the SR-evoked response was eliminated in S-Cx but remained, although reduced, in M-Cx.

The results altogether indicate that some inputs to M-Cx arrive independently of S-Cx. Some of the group II inputs travel directly to M-Cx through the spinocervical and spinothalamic tracts. The group I input to M-Cx is transmitted through the dorsal columns and probably through area 3a of the sensory cortex.

This research was supported by the NIH grant NS-10705.

868 FIELD POTENTIALS RECORDED FROM THE TRIGEMINAL MOTOR NUCLEUS AFTER LABELING THOSE NEURONS BY RETROGRADE TRANSPORT OF HORSERADISH PEROXIDASE. Visaka Limwongse*, Don Rigamonti, and Mark DeSantis. Dept. Anat., Georgetown Univ., Washington, D.C. 20007.

Sprague-Dawley rats received unilateral injections of horseradish peroxidase (HRP; Sigma, type VI; 5% in saline) into either the masseter or the mylohyoid and anterior belly of the digastric muscles. After 24 hr the animals were reanesthetized and electrodes were placed on the nerves to those muscles. With micropipettes, filled with 7% Fast Green in 2M NaCl and having an initial impedance of 1.8-2.2 MΩ, a systematic series of tracks through the ipsilateral trigeminal nuclei were made at intervals of 200 µm. Amplified potentials were recorded at 100 or 200 µm intervals along each track. The animals were sacrificed by perfusion with a buffered aldehyde fixative. Frozen sections of brain were incubated in 3,3' diaminobenzidine containing hydrogen peroxide to identify those cell bodies possessing the exogenous peroxidase. The recording sites were reconstructed from the histological sections containing the HRP labeled motor neurons and the Fast Green marks deposited from the micropipette at known intervals along the depth of electrode tracks.

Field potentials of negative polarity recorded from the trigeminal motor nucleus between 28 and 48 hr after the HRP injection into a muscle did not differ in amplitude, duration or latency from those recorded in uninjected rats. The size of the potential when the nerve to the injected muscle was stimulated was correlated with the distribution of motor neurons containing the HRP. The location of labeled masseter motor neurons and the largest field potentials recorded with stimulation of the nerve to that muscle were in the dorsal and lateral part of the nucleus. The same measures on the motor neuron pool innervating the mylohyoid and anterior belly of the digastric muscles showed them to be situated ventrally and medially in the caudal half of the motor nucleus. This confirms previous morphological studies on the organization of the trigeminal motor neurons in the rat (Mizuno et al., J. Comp. Neurol.,1976; Limwongse and DeSantis, Am. J. Anat., in press). The evidence that trigeminal motor neurons containing exogenous peroxidase conduct action potentials suggests that the simultaneous use of these morphological and electrophysiological techniques may prove a feasible approach to studying other neuronal populations. (Supported by Division of Research Resources, Biomedical Research Support Grant RR05360.)

869 EFFECTS OF UPPER RESPIRATORY TRACT STIMULI ON THE LARYNGEAL MUSCULATURE. G.E. Lucier and B.J. Sessle. Div. Biological Sciences, Fac. Dent., Univ. of Toronto, Canada M5G 1G6.

Although the laryngeal musculature is active in normal protective reflexes such as coughing and swallowing, it is also involved in other paroxysmal respiratory phenomena such as laryngospasm which has been implicated in the sudden infant death syndrome. The purpose of this study was to determine what effect upper respiratory tract stimuli, previously observed by us to have profound effects on respiration and respiratory neurones, especially in kittens, have on laryngeal motoneurones in adult cats. This would also provide data for comparison with effects of similar stimuli in future studies in kittens. The effects of various natural (e.g. saline, water, saturated bicarbonate solution applied retrograde through a laryngeal cannula) and electrical (superior laryngeal, recurrent laryngeal, glossopharyngeal and vagus nerve stimuli) modes of stimulation have been studied in over 80 laryngeal motoneurones. Their activity was monitored by (i) extracellular recording from single neurones in the nucleus ambiguus, (ii) single fibre recording of motoneurone efferents in the recurrent laryngeal nerve, and (iii) single motor unit recording from individual laryngeal muscles. Stimuli (both electrical and natural) which were most effective in modifying laryngeal motoneurone activity were those previously found to be highly successful in altering respiratory neurone activity, thus emphasizing the interrelationship of these two populations of brainstem neurones. Central and single fibre recordings demonstrated that superior laryngeal nerve sensory input is a dominant modifier of laryngeal motoneurone activity. Peripheral motor unit recording in individual laryngeal muscles revealed that superior laryngeal nerve stimuli and especially saturated bicarbonate solution produced, in addition to transient apnea, an inhibition of laryngeal abductor musculature (as recorded from the posterior cricoarytenoid muscle) and simultaneously excitation of laryngeal adductor musculature (as recorded from the thyroarytenoid muscle).

Although these effects reflect preparatory steps in the initiation of protective reflexes such as coughing in the adult animal, they may prove to be augmented in the neonatal animal to produce laryngospasm, accompanied by the prolonged apnea which we previously found to be characteristic of the kitten. Therefore, future studies will examine the effects of these stimuli in kittens.

870 COMPARISONS BETWEEN HISTOCHEMICAL PROFILES AND CONTRACTILE PROPERTIES OF SELECTED PIGEON MUSCLES. Alfred Maier. Department of Anatomy, University of Alabama, Birmingham, Alabama 35294.

Histochemical profiles were determined and compared to contractile properties in five muscles each of the forearm and leg. The muscles used were chosen for their diversity in fiber type composition, promising likely detection of differences in contractile properties. With the exception of the gastrocnemius, the most frequent fiber seen was a type high in myofibrillar adenosine triphosphatase (ATPase) and oxidative enzyme reaction products, comprising at least one third of the cross sectional area of a muscle. A type resembling the mammalian fast-twitch glycolytic fiber accounted from 11 to 48 per cent of muscle cross-sectional areas. The least frequently observed fiber, except in the gastrocnemius, was a type low in myofibrillar ATPase and moderate in oxidative enzyme reaction products. Of the muscles studied, three in the forearm had none of the latter type while in the leg they accounted for at least 15 per cent of the muscle's cross-sectional area. Leg muscles when stimulated at 5 Hz to give trains of single twitches retained, on the average, at least 85 per cent of their initial tension after 10 minutes of stimulation. In none of the forearm muscles declined the tension below 67 per cent. Tetanic tension/cm^2 bore no relation to the fiber type composition. Muscles of quite divergent histochemical profiles produced similar tensions. Fusion frequencies in muscles lacking fibers low in myofibrillar ATPase ranged from 41 Hz to 60 Hz, whereas in muscles with such fibers they ranged from 32 Hz to 42 Hz. Two muscles of the forearm which contained only fibers high in myofibrillar ATPase had significantly faster ($p<0.01$) time to peak tensions than muscles whose histochemical profiles also included fibers low in myofibrillar ATPase, even if few in numbers. However, the extent of the cross-sectional area composed of fibers which were high in myofibrillar ATPase reaction product showed a poor linear correlation ($r=0.15$) with time to peak tension. A better fit was obtained ($r=0.71$) when comparing the cross-sectional area comprised of fibers low in myofibrillar ATPase reaction product with time to peak tension. The linearity was further improved ($r=0.95$) by removing from consideration muscles with complex fiber distributions such as the gastrocnemius, extensor metacarpi radialis and flexor carpi ulnaris. It was only in muscles in which fiber types were randomly distributed that there was a well recognized trend for the time to peak tension to decrease as the number of fibers low in myofibrillar ATPase reaction product increased. Since complex muscles with restricted fiber type distributions did not altogether follow this pattern, it appears that the number of fibers low in myofibrillar ATPase present is not the only factor influencing time to peak tension.

871 THE ROLE OF STRESS RELAXATION OF MUSCLES IN FORCE DEVELOPMENT. Michael McCormack and Bernardo Dubrovsky. Neurophysiol. Lab., Allan Memorial Institue, McGill University, Montreal, Québec.

During flexion of the legs physical work is done on extensor muscles. This work is stored as elastic energy in the stretched muscles and can, therefore, be re-used. In order to evaluate the time-dependant mechanical properties of muscles, we varied the delay between flexion and extension of the legs of 8 male human subjects required to perform maximal vertical jumps from a force transducer platform, the output of which was registered on a polygraph. In this way the role of stress relaxation of the stretched muscles in force development could be assessed. The delay between flexion and extension of the legs was varied by requiring subjects to 'count from 1 to 5' following their flexion, and then to proceed to the extension (force development) phase of the jump. An objective quantitative estimate of the delay was obtained by analysis of the polygraph output. The delay was operationally defined as the time between the onset of the flexion and the onset of the extension phase. The magnitude of the delay was also varied. In order to more precisely evaluate the role of stress relaxation of muscles, three parameters must be controlled. First, the arms must not contribute to the development of momentum throughout the take-off procedure. This was accomplished by taping the arms of the subjects to their sides. Second, the position of a given subject must be constant in order that the stored elastic energy may be constant. The subject's position could be evaluated through cinematography. Third, it must be established that the force applied in the horizontal axes does not increase with increasing delay. The results showed that subjects raised their center of gravity (height=$\frac{1}{2}$ gt^2) 8-29% higher when the delay between flexion and extension was reduced to a minimum. Similar results have been reported by Asmussen and Bonde-Petersen (Acta Physiol. Scand., 91, 385-392, 1974) who suggested that the storage of elastic energy in muscles might explain the results. Further we find that, for a given subject, the height of jump varied inversely and exponentially with the delay. Interestingly, previous research on isolated muscles has shown that stress relaxation properties of muscles follow an exponential function, the tension decreasing with time (Abbott, B.C., and Lowy, J., Proc. Roy. Soc. London, Ser. B. 146: 280-288, 1957). However, it was found that the total force applied in the horizontal axes increases exponentially in proportion to the magnitude of the flexion - extension delay. We suggest then that the timing between flexion and extension of the legs in performing maximal vertical jumps is crucial to the obtained height of jump and, further, that force distribution is a critical parameter in assessing the importance of elastic storage of energy and stress relaxation in vertical force development.

872 ORGANIZATION OF THE FACE AREA OF MOTOR CORTEX IN MACAQUE MONKEYS. EveLynn McGuinness* and John Allman (SPON: C.B.G. Campbell). Dept. Psychol., Vanderbilt Univ., Nashville, TN 37240 and Div. Biol., California Institute of Technology, Pasadena CA 91125.

Macaque monkeys were surgically implanted with a head restraint bolt and a chamber over the face area of precentral motor cortex using aseptic procedures. After a recovery period, animals were lightly sedated with ketamine HCl and placed in a primate chair with the head immobilized. We stimulated the face region using glass insulated platinum-iridium microelectrodes at current levels of less than 20 µa (0.2 msec pulse duration, 3 msec interpulse interval, 50 msec train of pulses). Experiments were typically conducted 2 or 3 times a week for sessions of 8 to 10 hrs. Electrolytic microlesions were made at appropriate intervals and after a period of about 1 month the animal was killed, its brain sectioned, and electrode tracks reconstructed. Using this technique it was possible to explore the structure of motor cortex in fine detail by advancing the electrode through cortex in steps of 50 or 100 µ. After moving the electrode we waited for several minutes at each site before stimulating to allow the brain to settle. Our results suggest that motor cortex is arranged in fine columns (usually 200-800 µ across). The data were particularly striking in long penetrations parallel to the bank of the central sulcus in which we were able to move tangentially through cortex. As the electrode was advanced in these tangential penetrations, we encountered a series of discrete zones, each of which was related to the movement of a particular muscle in the face. The lowest stimulus threshold points were found in the center of each zone and as the microelectrode progressed toward the edge, thresholds rose slightly until there was a shift to a new muscle movement. The threshold then dropped and the pattern repeated. Typically changes in muscle movement were quite abrupt and successive stimulation points separated by as little as 50 µ could yield different responses. In favorable penetrations thresholds remained under 10 µa, usually ranging from 2 to 6 µa. We very rarely encountered simultaneous movements of more than one muscle when stimulating at threshold level currents. The general organization of the face area was roughly topographical with adjacent muscles clustered together; however, particular muscle movements were sometimes represented in several non-contiguous zones in tangential penetrations. Our data are compatible with the possibilities that these zones are either curving slabs of cortex representing a muscle movement or series of cylindrical columns.

873 EFFECTS OF COOLING VENTRAL LATERAL THALAMUS (VL) AND SENSORIMOTOR CORTEX ON LONG-LOOP REFLEXES IN MONKEYS. Alan D. Miller and Vernon B. Brooks. Dept. of Physiology, Univ. of Western Ontario, London, Ontario, Canada N6A 5C1.

Perturbations applied to a monkey's forearm can produce three successive EMG responses in upper limb muscles (M1, M2, M3 (1)). M1 (15-35 ms) occurs at the latency of a spinal stretch reflex while M2 (35-70 ms) and M3 (70-100 ms) are thought to depend on supraspinal participation (latencies from our exps). M2 is abolished by postcentral arm region lesions involving areas 1, 2, 3b, most of 3a, and some of 5 (1). Perturbations can produce precentral neuronal discharges at latencies that would permit their participation in the generation of M2 and M3 (2). The 1st precentral response (20-50 ms), preceding M2, does not depend on cerebellar input since it is unaffected by cerebellar nuclear cooling (3, 4). However, the 2nd precentral response (50-100 ms), which precedes M3, but probably occurs too late to appreciably contribute to M2, does depend on cerebellar nuclear function (4).

We examined the possible contribution of a transcerebellar pathway through VL to motor cortex to the generation of M2 and M3 by implanting VL with probes for local reversible cooling in three Cebus monkeys. The arm areas of pre- and postcentral cortex were also cooled for comparison in two of the same monkeys using thermoelectric Peltier modules implanted over the dura. Two monkeys were tranquilized with Atravet, and the arm contralateral to the cooling devices was firmly strapped to a manipulandum handle which was perturbed using a torque motor (5). A third monkey, with VL probe only, was trained to resist perturbations applied to a handle. Biceps EMG responses, obtained with fine-wire intramuscular electrodes, were full-wave rectified and filtered; 25-30 trials were averaged in 5 ms bins with a PDP-12 computer. Cooling VL or sensorimotor cortex delayed and reduced M2 and M3. (Our failure to abolish M2 (cf. (1)) may have been due to insufficient tissue affected by cortical cooling). VL cooling may have depressed M2 by tonic disfacilitation of motor cortex, since phasic discharges of most VL arm area neurons to perturbations occur too late to participate in most of M2 (6). Cortical cooling could have produced tonic as well as phasic disfacilitation of subcortical structures. Pathways through sensorimotor cortex may participate in spinal generation of M2 and M3, with a transcerebellar route via VL contributing mainly to M3.

874 MODULATION OF THE SPONTANEOUS ELECTROMYOGRAM (EMG) OF THE TEMPORAL MUSCLE IN THE ADOLESCENT RHESUS MONKEY. Arthur J. Miller, Karin Vargervik*, and George Chierici*. Center for Craniofacial Anomalies, School of Dentistry, University of California, San Francisco, CA 94143.

As part of a long-term study of muscle-bone interaction within the craniofacial region of the rhesus monkey, muscle function has been evaluated by monitoring the spontaneous activity of selected muscles. The temporal muscle as a jaw elevator and posture muscle of the mandible has been studied among these muscles. Spontaneous activity has been defined as that EMG activity exclusive of swallowing and mastication. This activity has been analyzed by one or both methods: 1) by counting the total number of spikes over time in the rectified signal, and 2) by spectral analysis to determine the power distribution of specific frequencies of the background EMG.

The temporal muscle was continuously active in the unanesthesized monkey sitting upright. The mean spike count averaged across 4 monkeys in 16 recording sessions was 160± 14 spikes/sec. Spectral analysis indicated that the mode frequency of the spontaneous EMG was 60 Hz. The spontaneous activity was altered under two short-term conditions which were originally hypothesized to alter the function of the temporal muscle. First, all monkeys were initially anesthesized with a dissociative drug, ketamine HCl (7-10mg/kg, IM). Administration of ketamine HCl increased significantly the power in all frequency bandwidths below 400 Hz within the first 30 minutes but demonstrated the normal distribution by 60 minutes. Secondly, suspension of weights from the mandible decreased significantly the mean number of spikes and the power of the frequency bandwidths below 400 Hz with the larger of two weights (i.e. 150, 300 gm).

The spontaneous activity of the temporal muscle was also evaluated under two long-term alterations. First, detachment of the temporal muscle increased significantly the mean number of spikes of the EMG through the first 24 days but only suggested a slight alteration in the spectral analysis. Comparison of 8 control monkeys with 8 established mouth breathing monkeys (i.e., for 2 years) indicated that the distribution of the spectral analysis histogram did differ significantly. The mouth breathing monkeys had demonstrated morphologically a greater vertical height and a lower jaw position.

875 CORRELATIONS BETWEEN HISTOCHEMICAL PROPERTIES AND USAGE PATTERNS OF HUMAN SKELETAL MUSCLES. A.W. Monster, H. Chan*, D. O'Connor*. Temple U., Health Sc. Cntr., Philadelphia, Pa. 19140.

Enzyme stains of human skeletal muscle biopsies indicate a number of differences between the metabolic properties of different muscles. There are good reasons to assume that metabolic differences reflect differences in the functional (usage) characteristics of skeletal muscles. These characteristics can be derived from the normal contractile and electrical activity patterns. It is, thus, possible to consider the question: "What aspects of the usage pattern are being expressed by the present histochemical methods?" Day-to-day variability in normal muscle usage as well as population and species differences in the available histochemical data, complicate the analysis of functional-histochemical correlations. In the present study we have tried to overcome the effects of usage variability by: 1) recording simultaneously from two or more functionally related, but histochemically different, muscles and 2) recording activity patterns continuously for day-long time periods using a portable multi-channel tape recorder. Muscular activity was based on the area integral of the rectified electromyogram (EMG). No restrictions were placed on the individuals daily activities but the subject population was somewhat restricted. The EMG recordings showed that a number of muscle usage parameters were highly correlated with the percent type I fibers (e.g., Fig. 1). Muscle pairs are identified by lines in Fig. 1. The gradients of the lines show that the muscles with a higher percent of the (fatigue-resistant) type I fibers were relatively more active. Other usage parameters, such as the amplitude distribution of activity levels, also were correlated with the percent type I fibers. The findings suggest that, taken over a wide range of human skeletal muscles, there is a continuum in the relationship between the usage pattern of a muscle and its histochemical make-up, even though the examined muscles are involved in very different motor activities.

876 ELECTROMYOGRAPHIC RESPONSES TO LOAD PERTURBATIONS IN PARKINSONIANS IN RELATION TO QUANTITATIVE MEASURES OF RIGIDITY AND TREMOR. James A. Mortimer and David D. Webster*. Dept. Neurol., V.A. Hosp. and Univ. Mn., Minneapolis, MN 55417.

The association between quantitative measurements of rigidity and tremor and the normalized magnitude of integrated EMG responses to suddenly-applied load perturbations to the forearm was studied in 17 Parkinsonian patients with varying degrees of clinical rigidity and tremor and in 8 normal subjects. Subjects were instructed to respond to load perturbations in one of four ways: 1) to return the forearm to its initial position as soon as possible, 2) to perform a ballistic flexion movement, 3) to perform a ballistic extension movement, or 4)to relax and allow the forearm to be passively moved. Sixty-four 500 ms. torque steps of 3 Nm. amplitude tending to extend or flex the forearm were presented in a random sequence for each test. Rigidity was measured by integrating the resistance torque as the forearm was passively extended and flexed at a constant velocity by a servo-controlled system.

Positive values of rigidity were associated with tonic stretch responses in both the biceps and triceps muscles. When EMG responses to load perturbations in normal and Parkinsonian subjects were compared, three significant differences were found: 1) Patients with Parkinson's disease had significantly larger responses between 50 and 100 ms. following the load change when the instruction was given to relax. 2) When the intended prime mover in a ballistic movement was stretched, Parkinsonians had a greater discharge than normals between 50 and 75 ms. after a change in load. 3) When the biceps was preloaded and the instruction was given to return to the initial position, normal subjects had a larger EMG response than Parkinsonians between 22 and 50 ms. following the load change. Significant positive correlations were found between the increased EMG activity from 50 to 100 ms. following the load change and quantitative measures of rigidity obtained during relaxation and during performance of a pursuit tracking task. With one exception, arm tremor was uncorrelated with the magnitude of the EMG responses to load changes.

The results add support to the hypothesis of Tatton and Lee that abnormal feedback in long-loop pathways is related to Parkinsonian rigidity by demonstrating a significant correlation between the magnitude of long-latency EMG responses to sudden muscle stretch and quantitative measures of rigidity in an unselected population of patients.

877 CORTICAL AND PERIPHERAL CONTRIBUTIONS TO THE GENESIS AND MODULATION OF THE RHYTHM OF MASTICATION. T. Murakami*, J.P. Lund and S. Rossignol. Fac. Méd. Dent. and Centre Rech. Sci. Neurol., Univ. de Montréal, Canada. (SPON: H.H. Jasper)

Repetitive electrical stimulation (3-500 Hz) of a large area of the anterolateral cortex of the rabbit evokes rhythmical movements resembling normal mastication. However the basic rhythmical pattern of alternating activity in antagonistic muscle groups is generated within the brain stem in response to the cortical input or to certain inputs arising from the mouth (Dellow and Lund, J. Physiol. 215: 1-13, 1971). This present study shows that, as well as acting as activators of the rhythm generator, these inputs are capable of modifying the resulting rhythm.

Stimulation of the upper lip during subthreshold cortical stimulation evokes a long duration burst of activity in the digastric muscle after long latency (100-400 msec). Such a burst may then be followed by a period of rhythmical mastication. When given during masticatory movements, the effect of a stimulus to the lip depends upon the phase of movement in which it occurs. When given during jaw closing and the early part of jaw opening, the cycle time is increased by up to 20%. Conversely, when the shock occurs during the final phase of jaw opening, the cycle is shortened by up to 10%. In the intervening period, it is unchanged.

With low frequency stimulation of the cortex, the mean frequency of mastication (2-5 Hz) is proportional to the frequency of stimulation. In addition, the cycle length is dependent upon the phasic relationship between the stimulus and the movement. When a stimulus is given at maximal jaw opening the cycle length is reduced to 75% of the mean. The gradual displacement of the stimulus away from that point leads to a progressive increase of the cycle length up to a maximum which is 25% longer than the mean. This occurs just before maximal jaw opening.

Stimuli occurring in the critical period at which jaw opening turns into jaw closing have their maximum effect on the cycle length. The displacement of the stimulus pulse by as little as 5% of the total cycle time within this critical period, can halve or double the masticatory cycle length.

878 CORTICOSPINAL PROJECTIONS FROM THE MEDIAL CEREBRAL HEMISPHERE IN MONKEY. E.A. Murray* and J.D. Coulter. Marine Biomedical Inst. and Depts. of Physiol. & Biophys. and Psychiat., Univ. Texas Medical Br., Galveston, Texas 77550.

The primate corticospinal tract has previously been shown to originate in the primary motor cortex (MI), corresponding to Brodmann's area 4, the first somatic sensory cortex (SI), comprised of areas 3a, 3b, 1 and 2, plus the adjacent area 5, the second somatic sensory region (SII), and the supplementary motor region (MII), corresponding to medial area 6. In addition to these four main functional zones, analysis of the medial hemisphere indicates the existence of an additional, separate, medial posterior parietal cortical region, corresponding to part of area 5 and the adjacent area 7, which contains a topographically organized projection to the spinal cord. Retrograde transport of horseradish peroxidase (HRP) from the spinal cord was used to identify corticospinal neurons in 16 monkeys (M. fascicularis and M. mulatta). With injections of HRP into the cervical enlargement, labeled neurons of cortical layer V were found in the lateral MI, SI and SII regions on the convexity of the hemisphere. On the medial buried aspect of the hemisphere, neurons were labeled in the anterior area 6 on the upper and lower banks of the cingulate sulcus in the supplementary motor region. A second population of labeled neurons was found in the posterior parietal cortex around the posterior end of the cingulate sulcus in Brodmann's area 5. The labeled neurons within this medial part of area 5 were clearly separated anteriorly from the labeled cells in area 6 and laterally from the cells in SI and area 5 on the convexity of the hemisphere. The intervening cortex, comprised of the medial MI and SI regions and immediately adjacent parts of area 6, anteriorly, and area 5, posteriorly was found to contain labeled neurons when injections of HRP were made in the lumbosacral spinal cord. Following injections in the upper cervical cord, labeled neurons in the supplementary motor region extended further anteriorly in area 6 in the medial hemisphere. In the medial posterior parietal zone, labeled neurons were located more posteriorly than those projecting to the cervical enlargement. Labeled neurons extended over the extreme end of the postcentral gyrus, area 5b of C. and O. Vogt, into area 7 on the medial aspect of the hemisphere and in the buried cortex forming the banks of the medial-most part of the intraparietal sulcus. The somatotopic representation in this medial posterior parietal zone thus appears approximately reversed in anterior-posterior orientation to that seen in the rostral supplementary motor region. These findings are consistent with the previous identification of this posterior parietal cortical zone as constituting a "supplementary sensory" region. Supported by NS 12481.

879 REFLEX EFFECTS ON THE DISCHARGE PATTERNS OF GAMMA MOTONEURONES. K.S. Krishna Murthy, James E. Marchand*and Philip L. Gildenberg. Div. Neurosurg. and Dept. Neurobiol. and Anat., Univ. Tex. Med. Sch., Houston, TX 77030.

Variability in the frequency of discharge from gamma motoneurones may increase due to loss of supraspinal control (Ellaway, P.H. and Pascoe, J.E., J. Physiol. 181:200-213, 1965). It is not known, however, whether significant differences exist in the regularity of impulses from gamma motoneurones when activated by various reflex pathways. Recordings have been made from lumbar (L7) ventral rootlets of cats under light sodium pentobarbital anesthesia. Gamma motoneurones were identified from their spontaneous background activity and confirmed from their conduction velocity determined by recording from the same ventral root filament at two points spaced 5-10 mm. (Conduction velocities were in the range of 17-48 m/sec.) Interval histograms were obtained over 2 minute periods with a Nicolet 1072 averaging computer and recorded on paper. The mean and standard deviation of interspike intervals were calculated for further analysis.

Gamma motoneurones were excited by a variety of peripheral stimuli through both segmental and inter-segmental pathways (Gilman, S. and Ebel, H.C., Brain Res. 21:367-384, 1970). Excitation from natural stimulation of ipsilateral proprioceptive afferents improved the regularity. Electrical stimulation of the ipsilateral sural nerve tended to increase the variability of the gamma motoneurones while simultaneously decreasing the mean interspike interval. This observation may have resulted from mixed effects of cutaneous afferents stimulated. It was often found that an initial inhibitory effect on the gamma motoneurone is reversed to an excitation on prolonged electrical stimulation of the sural nerve. Activation through propriospinal reflex pathways, when present, always increased the variability of interspike intervals. Most effective peripheral stimulation appeared to result from pressure applied locally at the joints. It was not unusual to find a single gamma motoneurone being driven to high discharge rates by pressure applied separately at ankle, knee and hip joints. It is suggested that slowly adapting afferents in the various joints may be responsible for this observation since an earlier study (Hunt, C.C. and Paintal, J. Physiol. 143:195-212, 1958) has discounted muscle and cutaneous receptors as a source of excitation for such stimuli.

880 THE ORGANIZATION OF MIDBRAIN-FACIAL SYSTEMS. W. Michael Panneton and George F. Martin, Dept. of Anatomy, The Ohio State University, Columbus, Ohio, 43210.

Since electrical stimulation of the midbrain elicits an array of complex behaviors in the cat and opossum and the facial motor nucleus (FN) is an integral part of many such behaviors, a study was undertaken to reveal the origin, course, and termination of midbrain-facial systems in the North American opossum. Horseradish peroxidase (HRP) placements were made in the FN in order to locate the midbrain neurons which project to it. All of the retrogradely labelled areas, as well as other areas devoid of back-filled neurons, were then submitted to autoradiographic study using tritiated leucine.

Midbrain regions containing HRP back-filling were the ventral periaqueductal gray (VPG), mainly ipsilateral; the contralateral nucleus Darkschewitz (DK); the interstitial nucleus of Cajal (IFLM), primarily rostral portions of the opposite side; and, more caudally near the midbrain-pontine junction, a contralateral group of perilemniscal cells. A few neurons were also labelled in the dorsal periaqueductal gray, but subsequent autoradiographic experiments suggested that their back-filling was the result of HRP spread beyond the facial nucleus into the reticular formation. Leucine injections delivered to the ventral periaqueductal gray and interstitial areas produced label over the medial divisions of the FN bilaterally, especially its caudal auricular and cervical subdivisions. More rostral placements which included the nucleus of Darkschewitsch, produced label over the medial division of the contralateral FN, while the labelling over the homolateral FN was barely above background. Leucine injections into the red nucleus caused light terminal labelling in lateral subdivisions of the contralateral FN. Although injections of more lateral tegmental areas labelled tracts which descend in ventromedial portions of the pontine reticular formation, grains were not found above background over the facial nucleus. Such results suggest that the absence of back-filled neurons in these areas after HRP cases was not artifactual.

In summary both retrograde and orthograde labelling methods have shown that the region ventral to the cerebral aqueduct is the principle source of midbrain-facial connections. This area includes the VPG, the DK and the IFLM. The red nucleus and perilemniscal region provide additional inputs to the FN which appear to be exclusively crossed.

881 RETICULOSPINAL ACTION ON CERVICAL, THORACIC AND LUMBAR MOTONEURONS. N.G. Pitts, K. Fukushima and B.W. Peterson. Rockefeller Univ., New York, N.Y. 10021.

We have previously shown that neck motoneurons receive monosynaptic excitation and inhibition via a pathway descending from the medullary reticular formation (RF) outside the medial longitudinal fasciculus (MLF). This study was to determine if the same pathway has similar actions on limb and back motoneurons.

Excitatory and inhibitory postsynaptic potentials (EPSPs and IPSPs) were intracellularly recorded from a diverse group of extensor and flexor motoneurons supplying the forelimb and hindlimb as well as extensor motoneurons supplying the back in cerebellectomized cats anesthetized with chloralose. Motoneurons were identified antidromically and were then studied to determine their responses to 100-200μA, 100μs pulses applied to the brainstem through bipolar concentric electrodes located 1-3 mm below the floor of the fourth ventricle. Arrays of 8-12 electrodes were used to stimulate points ranging from 1 mm posterior to 11 mm anterior to the obex and 3 mm to each side of the midline. Depolarizing current was injected routinely through the recording electrode to facilitate detection of IPSPs. PSPs that began within 0.7 msec after the arrival of the earliest descending volley and that exhibited little temporal facilitation were identified as monosynaptic.

In 28/38 hindlimb motoneurons monosynaptic excitation was observed following stimulation of the MLF. Monosynaptic EPSPs were also seen when the medial pontine RF was stimulated. Only 2 of 25 hindlimb motoneurons gave monosynaptic EPSPs to medullary RF stimulation and we generally failed to see any response to single pulses. Forelimb motoneurons behaved similarly: 27 of 34 exhibited monosynaptic EPSPs following stimulation of the MLF or medial pontine RF. Only 1 of 32 cells was monosynaptically excited by medullary RF stimulation. No monosynaptic IPSPs were evoked in limb motoneurons by RF stimulation.

Monosynaptic EPSPs were seen in 30 of 34 back motoneurons following stimulation of the MLF or pontine RF and in 10 of 32 motoneurons following medullary RF stimulation. Back motoneurons (13 of 43 cells) also received inhibition from this RF region which required multiple shocks and had a much longer latency suggesting that the inhibition descends primarily via a polysynaptic pathway.

These findings suggest that reticulospinal fibers originating in the medulla act on axial motoneurons at all levels but seldom on limb motoneurons. Therefore, the excitatory and inhibitory actions from the medulla are distinct from the excitatory projections that originate in the pontine RF and act on both limb and axial motoneurons. Supported in part by Grants NSF 75 00487 and NIH NS 02619.

882 PROPERTIES OF THE MOTOR PROGRAMS UNDERLYING VISUALLY TRIGGERED ARM MOVEMENTS IN MONKEYS. Andres Polit* and Emilio Bizzi. Dept. Psychol., M.I.T., Cambridge, MA. 02139.

These experiments were addressed to the problem of elucidating the organization of the nervous system underlying the performance of a simple motor act. Our basic preparation was a monkey trained to point at a target light. The monkey sat in a primate chair with its forearm fastened to a manipulandum which permitted flection and extension of the forearm about the elbow in the horizontal plane. The target lights were mounted on a 14" arc centered at the elbow and spaced at 5 degree intervals. The monkey was required to position its forearm within a 10-15 degree target zone centered about the lights, and hold a position for about 1 second. Four adult monkeys (Macaca mulatta) were used.

We tested their performance prior to and after bilateral dorsal rhizotomy (C2-T3). Movements were performed without the sight of the arm both before and after the surgical intervention. Consequently, after deafferentation the movements were performed "open loop". Remarkably, within five days postoperatively, the animals were able to perform the previously learned task.

In the first series of experiments we unexpectedly displaced the arm within the reaction time of the monkey, and observed the outcome of this displacement on movement termination. Our results indicated that in spite of the presence of unexpected proprioceptive responses, the arm moved accurately to the target. The same procedure was used in the deafferented monkeys, yielding qualitatively the same results, i.e., a displacement of the initial position did not affect the attainment of the intended final position. The electromyographic responses were carefully examined in the postoperative state to ascertain the lack of any short latency changes in EMG following the unexpected displacement of the arm.

These results are relevant to the question of what is being controlled by motor commands. It appears that the controlled variable is an equilibrium point resulting from the interaction of agonist and antagonist muscles. Consequently, a change in the equilibrium leads to movement. This view allows one to consider movement and the attainment of a posture as a result of a single process.

883 METABOLIC CHANGES IN RESPONSE TO STIMULATION OF SINGLE FROG MUSCLE FIBERS IN WHICH CONTRACTION IS UNCOUPLED FROM EXCITATION BY STRETCH AND HYPERTONIC SOLUTION. S. I. Rapoport, V. Nassar-Gentina* and J. V. Passonneau. Lab. Neurophysiology, NIMH and Lab. Neurochemistry, NINCDS, Bethesda, MD 20014.

At 15 °C, stretch of isolated single fibers of the semitendinosus muscle of R. pipiens, to sarcomere lengths (SL) of 3.8 μ or 4.7 μ from a rest SL of 2.3 μ, did not alter concentrations of PCr, ATP, glucose-6-P or glycogen. Stimulation of fibers at a SL of 2.3 μ, for 150 sec and at a frequency of 20 Hz, reduced PCr by almost 100% and ATP by one-third, elevated glucose-6-P and did not alter glycogen concentration. Fatigue was produced, and was evidenced by a reduced mechanical response to a 200-msec tetanus following the 150-sec stimulus train. Stimulation for 150 sec of fibers at a SL of 4.7 μ produced no tension, yet reduced PCr by 70%. ATP was unaltered and G-6-P was elevated. Tetanic stimulation of fibers at a SL of 3.8 μ produced contractile and metabolic changes between those at 2.3 μ and 4.7 μ, as well as fatigue. As fibers stretched to a SL of 4.7 μ consumed PCr but did not generate tension during stimulation, a large fraction of PCr consumption in stretched fibers was unrelated to force generation. On the other hand, stimulation of fibers in which excitation-contraction was abolished by a hypertonic soak resulted in no observed metabolic changes nor in fatigue. The soak by itself increased base line tension and PCr consumption. The findings indicate that stretch uncouples contraction from excitation differently than does a hypertonic soak, at a later step that involves reduction of actin-myosin overlap. PCr consumption in stimulated, stretched fibers may be required for reuptake of calcium that is released by excitation, and calcium may be released to a lesser extent when fibers are stimulated in a hypertonic soak. Furthermore, as fatigue occurs in fibers with an approximately normal ATP concentration, fatigue probably is due to failure of excitation-contraction coupling.

884 A MORPHOLOGICAL DESCRIPTION OF MOTONEURONS IN THE UPPER CERVICAL SPINAL CORD OF THE ADULT CAT. P.K. Rose and F.J.R. Richmond*. Dept. of Physiology, Queen's University, Kingston, Ontario, Canada K7L 3N6.

Most descriptions of motoneuron morphology are based on Golgi stained neurons found in the cervical and lumbosacral enlargements of young animals. Little is known, however, about the organization of motoneurons in the upper cervical spinal cord. In the present experiments therefore, intracellular injection of horseradish peroxidase (Snow, Brown, and Rose, 1976) was used to examine the morphology of electrophysiologically identified motoneurons in the upper cervical spinal cord of the adult cat. Cats were anaesthetised with chloralose (60 mg/kg) and paralysed with gallamine triethiodide. Motoneurons were identified by antidromic action potentials elicited by stimulation of dorsal neck muscle nerves. Other neurons, not antidromically excited, were also stained and frequently these neurons were found to have axon projections to the ventral root. These neurons were included in the population of motoneurons to be described.

The somas of motoneurons in the upper cervical spinal cord were usually found in Rexed's lamina IX, but were not restricted to this region and several were located in the nucleus commissuralis on the medial wall of the ventral horn. Axons were darkly stained and usually followed a simple, direct trajectory to the ventral root. Several motoneurons also projected to laminae VIII and IX via axon collaterals.

Dendritic trees of motoneurons in the upper cervical spinal cord were substantially larger than those of motoneurons located in the lumbosacral enlargement and stained with Procion Yellow (Barrett and Crill, 1974). The rostral caudal extent of dendritic trees ranged from 2150 μm to 3500 μm. Dorsally directed dendrites usually spread to lamina VII. Two motoneurons had dendrites which crossed into the contralateral spinal cord via the ventral commissure. All motoneurons had fine dendrites which extended into the lateral and ventral funiculi. Distinct swellings were frequently seen along these dendrites and at their termination.

These results suggest that motoneurons found in the upper cervical spinal cord differ morphologically from those found in the lumbosacral spinal cord (Barrett and Crill, 1974). Whether this difference arises from the different technique used to stain the motoneurons or is related to the different connections of upper cervical spinal cord motoneurons must now be determined.

885 THE CONTROL OF CROSSED EXTENSOR AND CROSSED FLEXOR RESPONSES. S. Rossignol. Ctr. de Recherche en Sciences Neurologiques, Faculté de Médecine, Dept. Physiologie, U. de Montréal, Québec, Canada, H3C 3T8.

Painful skin stimuli of a hindlimb evoke long latency, long duration contractions of ipsilateral flexor muscles in acute low spinal cats pretreated with Clonidine, a noradrenergic stimulant. In the contralateral limb however, contractions occur in the extensors if the limb is initially flexed or in the flexors if initially extended (S. Grillner and S. Rossignol, IIId Int. Symp. Motor Control, Bulgaria, Abs. 28, 1976). What is the contribution of the contralateral limb afferents to this reflex reversal? A progressive dorsal rhizotomy of the contralateral side was performed from S1 to L4 inclusively. Section of S1 did not alter the phenomenon. Section of L7 abolished almost completely the flexor responses when the limb was kept extended. However with the limb in flexion, extensor responses were not only present but increased. This pattern was further enhanced by cutting L6. Following section of L5, large extensor responses appeared both with the limb in flexion or in extension. This remained after cutting L4. Thus crossed extensor responses in absence of peripheral afferents are not only present but are larger both in amplitude and duration. Preparations with weak or absent crossed extensor responses developed large extensor responses after deafferentation. Crossed flexor responses, on the other hand, were never observed after deafferentation and thus their occurrence depends on peripheral afferents. Preliminary results in cats with intact dorsal roots indicate indeed that, with the limb in flexion, a position that would favor extensor responses, stretching the cut tendon of an ankle flexor (tibialis anterior) inhibits extensor responses and leads to flexor responses. With the limb in extension, however, stretching of the ankle extensor Gastrocnemius does not block the flexor response. It is concluded that when the limb is kept in extension the stretch of flexor muscles causes an inhibition of the crossed extensor responses and a facilitation of crossed flexor responses. On the contrary, when the limb is flexed thus removing the stretch of flexor muscles crossed extensor responses appear. Such peripheral control of crossed limb reflexes may be useful during locomotion. During most parts of a step cycle, the position of the limb is such that crossed extension could be used to support weight during a contralateral flexion. However at the end of the stance phase, when the limb is being fully extended and the flexor muscles stretched a crossed flexor response preceding extension would be more appropriate. Peripheral afferents would then be essential to signal such condition during the step cycle.

886 TRANSCORTICAL FACILITATION OF THE H- (MONOSYNAPTIC) REFLEX IN MONKEYS. D. G. Rüegg*, J.-M. Lachat* and M. Wiesendanger. Institut de Physiologie, Pérolles, CH-1700 Fribourg, Switzerland.

The recovery curve of the monosynaptic spinal reflex (H-reflex) is characterized by an early and a late facilitation which is superimposed on a long-lasting inhibition. The mechanism of the late facilitation is not known. The hypothesis was tested that a transcortical loop for low threshold muscle afferents could be responsible for the late facilitation.

Four monkeys were trained, with a leg fixed in a fiberglass cast, to maintain a prescribed background activity in the soleus muscle. Under these conditions H-reflexes of large amplitude were obtained with little variability. A conditioning stimulus was used which was just subthreshold for the H-reflex whereas the test stimulus was adjusted to elicit H-reflexes without contamination by a direct motor response (M-wave). We found that the late facilitation started at a latency of 50 to 60 msec and reached a maximum at about 100 msec following the conditioning stimulus.

Blocking of the motor cortex by reversible cooling or an irreversible lesion abolished the late facilitation without changing the early facilitation and the long-lasting inhibition. A transcortical pathway was also indicated by the following latency measurements: a cortical potential was evoked in the somatosensory cortex at a latency of 15 msec, and in the motor cortex at a latency of 25 msec. Motor responses in the soleus muscle occurred 25 msec following stimulation of the motor cortex. The sum of these latencies was compatible with the onset of the late facilitation and the long-lasting inhibition.

We conclude that the late facilitation produced by stimulation of the low threshold muscle afferents is mediated via the motor cortex.

887 MECHANISMS OF THE CLASP-KNIFE REFLEX. W.Z. Rymer, J.C. Houk and P.E. Crago. Dept. Physiol., The Johns Hopkins Univ. Sch. of Med., Baltimore, Md. 21205. (Supported by NIH06828 and NIH57240).

The clasp-knife reflex is the abrupt yield in force provoked by flexion of a spastic limb. Although classically attributed to tendon organs, it has recently been ascribed to the inhibitory actions of secondary spindle receptor afferent fibers (1). However, several key issues remain unresolved. Specifically the autogenetic basis of this reflex has not been demonstrated directly, the apparent inhibition has not been adequately distinguished from withdrawal of excitation, and the receptor basis has not been established with fiber recordings. We used a model of the clasp-knife reflex provided by stretch of the soleus muscle in the mid-collicular decerebrate partly spinalized cat (2). The soleus muscle was subjected to ramp stretch of varying amplitude, initiated at several different muscle lengths. Measured variables included muscle length, tension and EMG, together with the discharge of single muscle afferent fibers, teased from dissected small dorsal root filaments. The dorsal roots were otherwise intact. In 5 preparations, dorsal hemisection of the thoracic cord converted a classical soleus stretch-reflex response to a clasp-knife pattern. Specifically, when soleus stretch exceeded some threshold length (typically near -10mm), the initial stretch-induced excitation was converted to inhibition. The degree of this inhibition was most clearly related to absolute muscle length, rather than incremental length change. When muscle stretch was superimposed upon the tonic vibration reflex, the inhibition was reproduced, thus the effects are unlikely to have resulted from withdrawal of Ia afferent excitation.

Although the EMG declined as a function of absolute muscle length, the decrement in EMG was also correlated with initial and peak force levels, behavior not consistent with observed secondary spindle receptor action. Furthermore, a profound inhibition of EMG and force was produced by gentle manipulation of the tendon and muscle aponeurosis. In a limited preliminary examination we isolated several slowly conducting nerve afferents which were not derived from spindle or tendon organ receptors but which responded to muscle manipulation and maximal muscle stretch.

The generation of the clasp-knife reflex in a separated soleus, within an otherwise denervated limb verifies the autogenetic basis of this response. However, the dependence of this effect on initial force levels together with its' prolonged time course are not in keeping with either secondary ending or tendon organ action. It is suggested, tentatively that the clasp-knife reflex is the outcome of stretch induced activation of free nerve endings, presumably of groups II and III diameter.

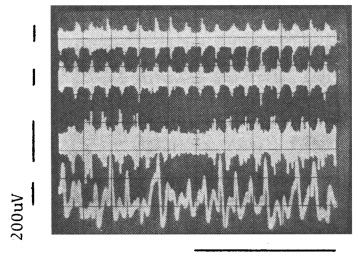
888 EXCITATION AND INHIBITION OF PROXIMAL MUSCULATURE BY MICROSTIMULATION OF PRECENTRAL CORTEX. Edward M. Schmidt and Joan S. McIntosh. Lab. of Neural Control, NINCDS, NIH, Bethesda, MD 20014.

Chronic recording intracortical microelectrodes implanted in the precentral gyrus of monkeys were used for single cell recording and microstimulation. The electrodes were implanted to a depth of 1.5mm (approximately layer V). Single unit activity from the same neuron was recorded before and after microstimulation with trains (5 to 35 pulses, 400Hz) of capacitively coupled 0.2msec pulses up to current levels of 20μa, indicating that stimulation did not permanently damage neurons near the electrode. Both excitation and inhibition have been produced in different muscles, revealed by EMG activity, from the same cortical site. Inhibition was more difficult to demonstrate unless the inhibited muscle was tonically active prior to stimulation or a rebound excitation occured at the end of the stimulus train. Both proximal as well as distal musculature can be activated in the awake monkey with the stimulation parameters we have employed. Either prior to or after microstimulation, through a specific microelectrode, single cell operant conditioning techniques were employed to modify the firing rate of the recorded cell. The movements made by the monkey in controlling the cell firing rate were usually associated with the muscle that was activated by microstimulation. When the cortical cell could be activated by peripheral stimulation, such as stroking the hair and skin overlying the external oblique m, microstimulation produced excitation of this muscle. These findings indicate a somatotopically organized input-output relation.

889 NATURALLY-OCCURRING FACIAL "TREMOR" SYNCHRONIZED WITH RHYTHMICAL THALAMIC NEURONAL ACTIVITY IN RATS. K. Semba*, H. Szechtman*, and B. Komisaruk. Inst. Anim. Behav., Rutgers U., Newark, NJ 07102

A fine (approx. 9 c/sec) passive tremor of the jaw and/or vibrissae was observed in normal rats when they stood still after being placed into a novel environment. The tremor was distinctly different in frequency, intensity, and behavioral context, from movements involved in gnawing, tooth chattering, or exploratory sniffing. Individual tremor movements (recorded as EMG) occurred in synchrony with individual bursts of multiunit activity (MUA) recorded in the ventrobasal complex of the thalamus and with individual "spikes" in the cortical (frontal-occipital) EEG (see figure). Single trains of this rhythmical activity often lasted more than a minute. The phase relationships between EMG and MUA differed among individuals, but tended to remain consistent within each individual. Movement artifacts were discounted since 1) the moment of occurrence of individual tremor movements and MUA bursts were interdigitated rather than simultaneous, and 2) during high amplitude EMG bursts accompanying sniffing (associated with EEG theta rhythm), tooth chattering, eating or licking, no corresponding activity in the MUA was observed. We also discounted the possibility that the neural activity was generated by reafference, for 1) during vigorous non-tremor sniffing movements of the vibrissae, or chattering or chewing movements of the jaws, the rhythmical MUA was absent (although the units did discharge if the vibrissae contacted an obstacle or were brushed by the experimenter), 2) rhythmical MUA often continued both during brief pauses in the motor tremor, and in its absence, 3) injection of Xylocaine subcu into the face abolished sensory responses of the thalamic units, but the rhythmical MUA persisted. Since this rhythmical neuronal activity is apparently not simply a sensory correlate of the tremor, it may be involved in its central production, and is therefore potentially of value in understanding Parkinsonism.



890 DISCHARGE CORRELATES OF FTG UNITS DURING SPONTANEOUS BEHAVIORS. J. M. Siegel, D. J. McGinty and S. M. Breedlove*. V. A. Hospital, Sepulveda, CA 91343 and University of California, Los Angeles, CA 90024.

We have previously reported that discharge in pontine gigantocellular tegmental field (FTG) neurons recorded in unrestrained cats is closely related to motor activity (Science 196: 678-680, 1977). We now report further observations on the activity of these cells during a variety of behavioral states. Cell discharge was monitored during quiet immobility, alert immobility, eating, grooming, lapping, exploration and sleep.

FTG discharge did not relate to any specific behavioral state, but rather related to directionally specific movements which could occur during a variety of behaviors. Of 45 units tested, 30 were related to head and neck movements, 4 to ear movements, 1 to forepaw movements, 3 to tongue movements and 4 to facial movements. FTG discharge was not correlated with directionally specific eye movements observed during head restraint. Units showed no evidence of habituation during repetitive motor activities. Most FTG units discharged during REM sleep, a time of intense internal motor system activation. Unit discharge could often be seen to occur in conjunction with the muscle twitches of REM sleep. We saw no relationship between FTG firing and level of arousal or alertness. Movement correlations seen during grooming activity were the same as those seen during play or attack behavior.

Sensory stimuli often elicited unit discharge whose intensity was correlated with obvious motor responses provoked by the stimuli. Forced acceleration of the cat's head produced intense discharge in many FTG units. However, the maximum response was associated with induced head acceleration in a direction opposite to that which produced maximum unit firing during spontaneous head movements, i.e., a unit which responded maximally when the cat made spontaneous head movements to the right would fire preferentially when the experimenter twisted the cat's head to the left. Response to repeated head movement was variable with irregularities in response correlated not with the velocity of head movement, but rather with the cat's active resistance to the manipulation. During complete head restraint unit discharge remained correlated with specific motor activities associated with struggling.

These results support our previous findings that in the unrestrained cat FTG discharge is closely related to specific motor activities. A film of FTG unit discharge in the unrestrained, behaving cat will be shown.

891 THE ACTIVITY OF NEURONS IN THE SUPPLEMENTARY MOTOR AREA DURING A MAINTAINED PRECISION GRIP. Allan M. Smith. Centre de Recherche en Sciences Neurologiques, Université de Montréal, Québec, Canada.

Monkeys were trained to grasp a hand-held force transducer and maintain specified pressures between the thumb and forefinger for a one-second duration ("the maintained precision grip"). The activity of single neurons was recorded in the hand region of the supplementary motor area (SMA) described by Woolsey et al. 1950. Although microstimulation (300Hz. for 300msec. up to 50uA.) through the recording electrode failed to evoke twitches in the muscles of the wrist and fingers, 60 neurons were found that showed reliable changes in activity related to performance of the precision grip. These units were located in the medial convexity of area 6 between the tail area of primary motor cortex and the face area of the SMA in agreement with the original description given by Woolsey et al. (1950). Many of these neurons were extremely sensitive to light touch and the receptive fields often covered the entire arm from the shoulder to the fingers. Some SMA neurons in the hand area discharge prior to EMG activity recorded in the flexor and extensor muscles of the wrist and fingers. The discharge patterns of SMA neurons appear, on initial analysis, to resemble the discharge patterns of neurons in the hand region of area 4 (Smith et al. 1975). The majority of units were more active during the dynamic phase of force application as opposed to the period of static maintained force. The activity of the flexor and extensor muscles of the wrist and fingers is also correspondingly greater during this period. The preliminary results suggest that a substantial number of neurons in the supplementary motor area are involved in the motor function of the hand.

892 CROSS-CORRELATION ANALYSIS OF EXTENSOR EMG'S AND HAND TREMORS FROM NORMAL AND PARKINSONIAN SUBJECTS. Robert N. Stiles and Robert S. Pozos. Dept. of Physiol. and Biophysics, Univ. Tenn. Cntr. Hlth. Sci., Memphis, TN, 38163.

Cross-covariance analysis was performed on simultaneously-obtained 16-sec records of wrist extensor EMG's and postural hand tremor oscillations from normal and parkinsonian subjects. Bipolar, surface EMG's from the extensor digitorum communis muscle were digitized at 1024/sec, full-wave rectified and smoothed, resulting in an amplitude demodulated EMG signal with equivalent sampling rate of 64/sec. Hand tremor was detected with an AVR-250 accelerometer mounted at 16 cm from the wrist, and the voltage analog of this acceleration was digitized at 64/sec (Stiles and Pozos, J. Appl. Physiol. 40: 990-998, 1976). The cross-correlation (time domain) and coherence (frequency domain) functions were calculated for values of root-mean-square (rms) displacement amplitude of the tremor that ranged between about 30 and 30,000 μm. (These amplitude levels of tremor from normal subjects occurred as each subject maintained the hand extended horizontally for periods of 15-45 min.) Results obtained for both groups of subjects indicate that, for rms displacement levels above about 100 μm, the amplitude demodulated EMG's are highly correlated with the tremor (at the tremor frequency), with coherence values generally between 0.6 and 0.8. For displacement levels below about 100 μm, the coherence between these two variables decreased to values as small as 0.2 at rms displacements of 20-30 μm.

These data are consistent with the hypothesis that the large-displacement postural hand tremor of parkinsonian subjects is an exaggerated normal tremor. The relatively high correlation between the demodulated extensor EMG and hand tremor having rms displacements greater than about 100 μm suggests that additional cross-spectral analysis, resulting in values of gain and phase between these two variables, may be warranted. (Supported in part by USPHS Grants HE-05612 and NS-08692).

893 INPUT TO PRIMATE MOTOR CORTEX FROM POSTERIOR PARIETAL CORTEX. P.L. Strick(1), P. Zarzecki(2), and H. Asanuma(2). (1) Veterans Administration Hospital, and Depts. of Neurosurg. and Physiol., Upstate Med. Ctr., SUNY, Syracuse, NY 13210; (2) The Rockefeller Univ., New York, NY 10021.

The characteristics of some of the neurons in the posterior parietal cortex (areas 5 and 7) suggest that this region may be involved in the control of limb movement (Mountcastle et al, 1975). Using anatomical and physiological methods, we now demonstrate a direct projection from area 5 to the motor cortex (area 4). Small injections of HRP were restricted to the gray matter of the motor cortex 'arm area'. Retrogradely labeled neurons were found in the anterior bank of the intraparietal sulcus in area 5. These neurons occurred in layer III. They were largely pyramidal shaped and 10-30 μm in diameter. The injections labeled at least as many, or more, neurons in area 5 as in the primary somatic sensory cortex. HRP injections placed more laterally in the 'arm area' labeled neurons more laterally in the intraparietal sulcus.

Physiological experiments were performed in unanesthetized monkeys. An array of up to ten stimulating microelectrodes was implanted into superficial layers of the 'arm area' of the motor cortex as identified by muscle contraction to minimal intracortical microstimulation. Single microstimulating pulses antidromically activated neurons of area 5 in the depths of the intraparietal sulcus. Only the anterior bank was explored. Our sample includes only those neurons where a liberal estimate of the spread of threshold current ruled out white matter activation. The relation between effective stimulation sites and the location of antidromically activated neurons was consistent with the topography seen in the HRP studies.

Ten neurons of area 5 projecting to the motor cortex were tested for input from the periphery. Two of these gave weak, phasic responses to abrupt, large amplitude joint movements. Possible contributions of active movements to the responses were not assessed in these alert, untrained animals, which were at times uncooperative. No other responses to peripheral manipulation or spontaneous movements were observed.

The direct connection from area 5 to the motor cortex described in this study could be an important route by which area 5 influences motor cortex output and limb movements. (Supported by the Medical Research Service of the Veterans Administration and by NIH grant 10705).

894 A NEW HYPOTHESIS ON THE FUNCTIONAL ROLE OF MUSCLE RECEPTORS IN SEGMENTAL MOTOR CONTROL. D. G. Stuart and M. D. Binder. Dept. of Physiology, University of Arizona, College of Medicine, Tucson, Arizona, U.S.A.

A relatively small, but influential body of data is now available on the discharge patterns of muscle receptor afferents from cat hindlimb muscles during controlled and unrestrained locomotion. Analogous data exist from a variety of other animal and human muscles during their participation in natural movements. Collating these results, together with those depicting the responses of spindles and tendon organs to single muscle unit contractions and with those delineating the central connections of their afferent fibers, illustrates that traditional models of the functional role of muscle receptors are inadequate and in need of revision. This report presents a new hypothesis on the role of muscle receptors in segmental, spinal motor control mechanisms, together with the evidence on which it is based and the experimental approaches required to test it. We propose that fundamental to the role played by muscle spindles and tendon organs in motor control are their individual capabilities, at the peripheral level, to monitor the activity of a select number of muscle units within the parent muscle and, at the central level, to provide stronger synaptic input to motoneurons innervating the muscle units to which they are responsive than to other motoneurons within the homonymous and functionally related pools. A key corollary to the peripheral component of this hypothesis suggests that rather than acting as generalized, whole muscle length (spindles) and tension (tendon organs) sensors, each individual receptor monitors the activity of a discrete set of muscle units within the parent muscle. The resultant afferent signals are modulated by the overall length-tension status of the muscle and, in the case of spindles, by fusimotor input as well. A key corollary at the central level suggests that all three muscle afferent types (Ia, Ib and spindle group II) contribute to motoneuronal post-discharge inhibition. The Ib afferents do so through polysynaptic inhibition and the spindle afferents through "relative disfacilitation" (i.e., transient reduction in excitatory input to a motoneuron following its muscle unit's contraction). Our presentation will also address the functional distinctions between the information content of single afferent channels and that of the collective input from all receptor afferents from a given muscle. (Supported in part by the Fan Kane Foundation and USPHS Grant NS 07888.)

895 EFFECTS OF ACUTE CORTICAL INJURY ON THE ACTIVATION OF THE MOTOR CORTEX IN THE CAT. Floyd J. Thompson. Dept. Neurosci., Col. Med., Univ. Fla., Gainesville, FL.

The effects of acute cortical injury on the general pattern of sensory transmission to and activation of motor cortex neurones were investigated in the following experiments. Two fundamental questions were examined: are changes in the pattern of cortical neurone activation related only to the degree of proximity to the lesion or are changes in the pattern of cortical activation also related functionally to the cortical region injured? The motor corteces of cats were exposed and covered with a closed chamber. Bipolar concentric electrodes were placed stereotaxically into the contralateral dentate nucleus and in the ipsilateral medullary pyramidal tract. A bipolar concentric electrode was also placed in the posterior intermediate sulcus in the upper cervical spinal cord to activate the contralateral gracile and cuneate tracts. These electrode placements provided cortical evoked potentials elicited by three functionally different but powerful activators of the motor cortex neurones. Effects of acute cortical injury on cortical activation were determined by analyses of the averaged cortical evoked potentials recorded from several cortical positions before and following the production of a focal (radio frequency) lesion at one of the recording sites. These experiments have shown that the cortical evoked potentials (P_1-N_1 amplitudes) recorded from cortical positions proximal to postcruciate lesion sites are significantly larger following the lesion. However, cortical evoked potentials recorded from a more remote medial precruciate region are decreased in amplitude, particularly in the cortical evoked potential elicited by dentate nucleus stimulation. On the other hand, cortical evoked potentials recorded from both proximal (precruciate) and remote (postcruciate) recording sites are significantly larger following focal lesion at the medial precruciate position. These experiments indicate that following focal cortical lesion, the pattern of cortical neurone activation is altered in both the proximal and more remote cortical regions. The nature of the alteration is functionally related to the region of cortex injured and not simply to proximity to the lesion site.

896 THE FORCES PRODUCED BY HINDLIMB MUSCLES IN FREELY MOVING CATS. B. Walmsley*, J. A. Hodgson* and R. E. Burke. Lab. of Neural Control, NINCDS, NIH, Bethesda, MD 20014.

Forces produced by individual muscles [medial gastrocnemius (MG) and soleus (SOL)] were measured in the respective tendons of insertion using chronically implanted devices. The device consists of a semiconductor strain gauge bonded along one side of a 1 mm thick stainless steel form (Fig. 1; 8-14 mm long, 5-7 mm wide) which has two slots to permit placement on the intact tendon (Fig. 1, stripes) and insulated with Parylene C and Silastic rubber which prevents the gauge from slipping off the tendon. Its output was led to a connector on the cat's back. Gauges that respond linearly to forces up to 10 kg have been used. Muscle electrical activity (EMG) and force data were recorded on FM tape synchronized with videotape records of movements. The results demonstrate that SOL produces virtually the same peak force (1.5-2.0 kg) over the entire range of hindlimb action (from quadripedal standing to 1.2 m vertical jumps) and obviously plays a major role in locomotion (Fig. 2). In contrast, the peak forces from MG vary more widely over the same range of movements, from <500 gm in standing to 10 kg in jumps. Peak MG force was clearly graded with speed of walking (Fig. 2) while that from SOL was not. This difference in the range of movements over which peak MG and SOL forces are graded is very likely related to the differences in the motor unit populations making up these two muscles.

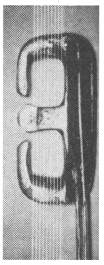

Fig. 1 Photograph of strain gauge device.

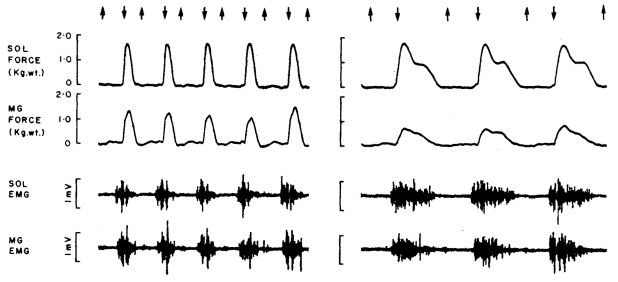

Fig. 2. Fast (left; 1.6 m/sec) and slow (right; 0.8 m/sec) walks in a 2.7 kg cat. ↑ = foot lift; ↓ = foot contact; duration of left record is 2 sec.

897 LINEAR HEAD MOVEMENTS OF WALKING AND TROTTING CATS. Douglas G. D. Watt and Mary C. Wetzel. Aviation Med. Res. Unit, McGill Univ., Montreal, Quebec, Canada H3G 1Y6 and Dept. Psych., Univ. of Ariz., Tucson, Ariz. 85721

Previous work in the cat has demonstrated that natural stimulation of the vestibular otolith organs leads to changes in lumbosacral spinal cord excitability. It has been suggested that vestibulo-spinal reflexes resulting from the cyclical linear accelerations experienced during normal locomotion might contribute to motor control. However, the relationships between head and limb movement have not been examined systematically.

The purpose of this study was to measure the linear head movements of walking and trotting cats, and to relate these to the simultaneously occurring footfall patterns. A light-weight 3-axis linear accelerometer package was mounted on the heads of 6 cats trained previously to walk and trot on an enclosed treadmill. Limb and shoulder movements were measured from high speed movies filmed at the same time.

Stable walking gaits were recorded on 33 occasions, with treadmill speeds ranging from 0.4 to 1.6 m/sec. Trotting was seen 12 times, from 1.2 to 2.7 m/sec. Stride frequency increased linearly with treadmill speed, being 1.28 strides/sec at 0.4 m/sec, and 3.03 strides/sec at 2.7 m/sec. Lateral head accelerations were generally minimal, but those in the fore-aft and vertical directions were substantial and highly reproducible, increasing in amplitude as the rate of progression of the cat increased. A detailed computer-based analysis of head and shoulder vertical movements determined that most of these occurred at twice the stride frequency. The relationship between head and hindlimb movement was not constant within or between cats. However, head movement was closely tied to shoulder, and hence forelimb, movement while the cats walked or trotted.

Otolith-spinal responses could contribute, therefore, to the control of neck and forelimb muscles during locomotion, but would be less likely to participate directly in hindlimb activity. This conclusion is compatible with the finding of Wilson (Int. Rev. of Neurobiol. 15: 27, 1972) that monosynaptic vestibulospinal projections to motoneurons are largely limited to the cervical and upper thoracic spinal cord.

(Supported by USPHS Grant NS-11491)

898 THE AVIAN RUBROSPINAL TRACT: ITS CELLS OF ORIGIN, COURSE AND SITES OF TERMINATION. J. Martin Wild*, John B. Cabot, David H. Cohen, and Harvey J. Karten. Dept. of Physiol., Sch. Med., Univ. of Virginia, Charlottesville, VA 22901 and Dept. Psychiat., Sch. Med., SUNY, Stony Brook, NY 11794.

As part of a series of anatomical studies of the major descending projections to the spinal cord of the pigeon (Columba livia) we have described the cells of origin, course and sites of termination of the rubrospinal tract (RST).

In Nissl-stained material the nucleus ruber of the pigeon cytoarchitectonically resembles the mammalian nucleus ruber, consisting of both magnocellular and parvocellular divisions. The large neurons (40-50 μ) defining the magnocellular portion of the nucleus are located dorsomedially and ventrolaterally at the more caudal nuclear levels, while the small and medium sized neurons (15-35 μ) comprising the parvocellular portion are more prominent at rostral levels. It should be emphasized, however, that neurons of all sizes are present throughout the entire rostrocaudal extent of the nucleus, and at intermediate levels it can be difficult to distinguish magnocellular and parvocellular divisions.

The course and sites of termination of the RST were investigated using either anterograde degeneration or autoradiographic techniques. From such material the axons of rubral neurons could be traced across the midline where they pass the ventrocaudal aspect of the contralateral nucleus ruber and then form a compact bundle which sweeps laterally and rostroventral to the nucleus tegmenti pontinus. The RST continues ventral to and distinctly separate from the brachium conjunctivum and passes ventral to the entering radix of the trigeminal nerve. At rhombencephalic levels the RST lies on the ventrolateral aspect of the brainstem and, more caudally, is situated dorsomedial to the ascending fibers of the dorsal spinocerebellar tract. The RST then enters the spinal cord as a well-defined bundle in the dorsal portion of the lateral funiculus, and its terminations within the spinal gray are limited to the base of dorsal horn in laminae V and VI of Leonard and Cohen (J. Comp. Neurol., 1975, 163:149-180.)

A possible topographic organization of this projection was then investigated by means of the retrograde transport of horseradish peroxidase following injections into the lateral funiculus at brachial, thoracic or lumbar levels of the spinal cord. Regardless of injection level, labelled neurons were prominent throughout the rostrocaudal extent of the contralateral nucleus ruber in both its magnocellular and parvocellular divisions. Thus, if a topographic projection does exist, it is a subtle one with a substantial degree of overlap.

899 ELECTROMAGNETIC STRETCH OF INDIVIDUAL MUSCLES IN BEHAVING PRIMATES. Jonathan R. Wolpaw* and Theodore R. Colburn* (SPON: H. C. Lansdell). Laboratory of Neurophysiology and Section on Technical Development, NIMH, Bethesda, MD 20014.

This report describes a technique for stretch of individual muscles in awake behaving primates by direct application of calibrated force unaccompanied by other stimuli. An external electromagnet applied force to a small piece of permeable metal permanently imbedded in the musculotendinous junction.

A 3 x 5 x 18 mm coated steel implant was sutured inside flexor carpi ulnaris of Macaca mulatta 30% of the way from distal to proximal insertion with its long axis parallel to that of the muscle. A coil was wound on a longitudinally split hollow aluminum spool. Current was supplied either by an operational power supply or by an AC transformer. The monkey sat in a primate chair, elbow flexed to 90^0, and forearm passing through the spool so that the implant was half inside the proximal end of the coil and as near to its longitudinal axis as possible. The major component of the force applied to the implant by the coil was thus directed distally parallel to the long axis of the muscle. Its maximum value was 90 gm for the operational power supply and 158 gm for the AC transformer. The monkey grasped a movable handle and received a periodic liquid reward for maintaining the handle in the mid-position, wrist neither flexed nor extended. Steady state torque, tending to move the handle out of the mid-position, could be applied to the handle via a torque motor. Flexor carpi ulnaris EMG activity was recorded via intra-muscular wire electrodes.

Activation of the coil appeared to cause no distress to the animal nor did it produce any response other than that accompanying elicitation of a stretch reflex. Tendon jerks of 10-14 msec latency followed the onset of 100 msec (7 msec rise time), 90 gm, DC stretch delivered at pseudo-random 3-6 sec intervals. Their amplitude was greater when the muscle was active, opposing external extensor torque on the handle, than when it was inactive. Both an initial stretch reflex and a subsequent tonic vibratory response occurred in response to 3.6 sec, 77 gm, 60 Hz full wave rectified stretch.

The range of possible applications of this technique to research at peripheral, segmental, and suprasegmental levels depends on theoretical and practical considerations concerning the design of the electromagnet, current supply and control, and implant form and magnetic properties.

900 OPERANT CONDITIONING OF MONKEYS FOR TONIC CONTROL FIRING PATTERNS OF NEURONS IN MOTOR CORTEX. Allen R. Wyler. Dept. Neurological Surgery, Univ. of Wash., Seattle, Wash., 98195.

A paradigm has been developed which allows monkeys to be trained with operant conditioning to operantly control the firing patterns (rather than rate) of cortical pyramidal tract neurons. This requires the monkey to change phasic firing patterns to tonic firing patterns for reward. This paradigm also allows quantification of operant behavior such that operant control may be compared between neurons, as well as between monkeys. Factors which might predict which neurons were most easily conditioned were phasic firing patterns, and those neurons involved in movement of distal arm muscles. Factors not predictive were initial firing rate or variance. The application of this paradigm to studying central nervous system pathology, i.e. epilepsy, is discussed.

NARCOTICS AND DRUGS OF ABUSE

901 EFFECTS OF CHRONIC THALAMIC, LIMBIC, AND CORTICAL LESIONS ON NARCOTIC DEPENDENCE AND ABSTINENCE IN THE RAT. M.W. Adler, P.B. Beeton*, E.B. Geller*, and P.L. Gildenberg. Temple Univ. Sch. of Medicine, Phila., Pa. 19140.

Although considerable effort has been directed towards studying areas of the brain involved in the analgesic actions of narcotics, relatively little attention has been focused on elucidating the neuronal pathways mediating narcotic dependence and abstinence. One effective means of investigating the different anatomical pathways that subserve the variety of signs which characterize abstinence is the use of brain lesions. Previous studies have generally been restricted to 1 or 2 areas of the brain, a design which tends to preclude the type of comparative analysis of data necessary to study so complex a picture as narcotic dependence and abstinence. The present experiment is an attempt to clarify the interrelationships between a number of brain structures, the production of dependence, and the abstinence syndrome.

Male Sprague-Dawley rats (270-310g) received either bilateral anodal d.c. lesions (subcortical), tissue aspiration (cortical), or sham operation under pentobarbital anesthesia. Animals were then housed in groups of 4 or 5, and a minimum of 3 months elapsed before narcotic administration was begun. This period was allowed in order to obviate any changes caused by non-specific factors such as edema, anesthesia, altered blood-brain barrier, and altered food and water intake resulting from surgery. Animals were implanted with 2 pellets of M (75 mg. M base each) under light ether anesthesia. After 72 hr, naloxone (N) was injected i.p. (1.0 mg/kg) and the abstinence syndrome assessed on a blind basis. Each brain was removed, and lesion locations verified using luxol blue, cresylecht violet stained serial sections. Histology was the determining factor in the decision to include an animal in a group.

Lesion groups were centre median, parafascicularis, other thalamic areas (primarily ventral and dorsomedial), amygdala (primarily cortico-amygdaloid), lateral septum, hippocampus, posterior cortex (primarily area 17 and parts of 18 and 18a), and frontal cortex (primarily area 10). Signs of abstinence scored included weight loss, jumping, teeth chattering, wet-dog shakes, writhing, chromodacryorrhea, diarrhea, ptosis, flat posture, salivation, and rhinorrhea. Groups were compared with appropriate controls and with each other. Differences in frequency of occurrence of each of the abstinence signs varied little and weight loss did not show any significant differences between groups.

We conclude that once recovery from any acute effects of brain damage is complete, lesions in thalamic, limbic, and cortical areas do not markedly alter M dependence or the N-precipitated abstinence syndrome. (Supported by DA 00049 & DA 00376).

902 $H_3{}^{32}PO_4$ AND (^{3}H)-AMINO ACIDS INCORPORATION DURING MORPHINE WITHDRAWAL. Alemán, V., Camacho, J.L.* Centro de Investigación y de Estudios Avanzados del I.P.N., México 14, D.F. MEXICO.

We were interested to know if protein phosphorylation activity is modified in the nervous tissue during morphine abstinence in morphine dependent rats. If it is modified we wanted to know if this change in protein phosphorylation activity may produce a change in the metabolism of some proteins of the cell.

Groups of six female rats, 25 days old were made morphine addicted by twice dayly injections of increasing doses of morphine for six days.

Fifty µCi of ^{3}H-amino acids mixture was administered intraperitoneally 10, 6 and 2 days before the last morphine injection. In a similar fashion 350 µC of $H_3{}^{32}PO_4$ was given 6 and 2 days before the last morphine injection.

Groups of rats were killed at different times after the last morphine injection and the radiactive precursors incorporated, were quantified.

The morphine treated rats showed a significantly higher incorporation of both radioactive precursors as compared with control animals. Both the nuclear and the mitochondrial fractions showed higher specific activities than other cell fractions.

On time, kinetics of both $H_3{}^{32}PO_4$ and (^{3}H)-amino acid uptake were similar. For most of the cell fractions incorporation was maximum at 24 hours; a second maxima was observed on the fourth day.

Radioactive phospho-L-serine was isolated from protein hydrolyzates and the amount of labelled phosphate was determined. In the morphine treated animals the amount of labeled phospho-L-serine was higher, indicating that protein has been phosphorylated.

903 CHANGES IN THE DURATION OF THE ELECTROENCEPHALOGRAPHIC RESPONSE TO COCAINE DURING CHRONIC ADMINISTRATION OF THE DRUG. H. L. Altshuler, N. R. Burch*, M. Hubler*, and R. Dossett*. Texas Research Institute of Mental Sciences and Baylor College of Medicine, Texas Medical Center, Houston, TX 77030.

The electroencephalographic (EEG) response to intravenous challenge doses of cocaine was measured in rhesus monkeys during a study in which the animals were treated chronically with the drug for two years or longer. The animal subjects were 4-6 kg male rhesus monkeys, which had been implanted with cortical electrodes. The responses were measured during experiments in which pre and post dose spontaneous and photically driven EEG were recorded and the resulting EEG analyzed with period analysis. Previous work from our laboratory has shown that the responses to intravenous challenge doses of cocaine change during chronic drug administration such that the first part of the biphasic EEG response becomes potentiated and the second part of the biphasic response becomes attenuated after long term cocaine therapy. Detailed analysis of the first part of the biphasic response revealed that the response became greater in magnitude and also showed increases in response duration following the intravenous cocaine dose. These changes were most pronounced in the frontal and temporal cortex. Detailed analysis of the increase in duration of the first part of the biphasic response to cocaine provides support for the hypothesis that certain responses to cocaine become greater during chronic drug administration; that is, develop reverse tolerance. The second part of the biphasic response decreases both in magnitude and duration after chronic administration, especially in the temporal and occipital cortex. The observation of reduction in magnitude and duration of that part of the response provides support for the hypothesis that certain aspects of the response to cocaine develop tolerance during chronic administration.

904 EFFECT OF ETHYL ALCOHOL ON BRAIN CYCLIC GMP. William E. Askew and K. D. Charalampous. Department of Psychiatry, Baylor College of Medicine, Houston, Texas 77030.

Cyclic GMP has been implicated as a cholinergic mediator in discrete areas of the mouse brain and has also been identified as specifically involved in GABA-nergic transmission in the cerebellum. Ethanol presumably acts in the central nervous system via major mediators. The effect of acute and chronic ethanol on murine c-GMP, such an mediator, is now presented. Acute administration of ethanol decreased cerebellar C-GMP in a dose-related manner but did not affect pons-medulla C-GMP. Chronic administration of ethanol via the pyrazole inhalation model resulted in a decrease in cerebellar C-GMP at 24 hours which returned to normal levels at 48 and 72 hours. Cyclic GMP levels in the cerebral cortex, pons-medulla, and forebrain were not affected by chronic treatment. The decrease in cerebellar C-GMP was partially due to increased phosphodiesterase activity; however, other factors apparently contributed indirectly to the decrease.

905 ENDORPHIN LEVELS IN RAT PITUITARY. Eugene R. Baizman*, Osman Hassan Osman*, and Brian M. Cox*. (Spon.: Avram Goldstein) Addiction Research Foundation, Palo Alto, CA 94304.

Extending our original studies of endorphin from bovine pituitary gland (Brain Res. 124:523, 1977) to the rat, we have applied a similar glacial acetic acid:acetone extraction procedure to freshly microdissected single lobes of rat pars intermedia, pars nervosa and pars distalis. The extracted material was assayed for inhibition of stereospecific binding of ^{3}H-Etorphine in the standard opiate receptor binding assay. Distribution studies generally confirmed earlier results in bovine glands; pars intermedia has approximately 17-fold greater endorphin content than pars nervosa. Females exhibit a 2-fold higher total endorphin content in the anterior lobe than males (14 ± 2 ID50 units/gland-females, vs 6.5 ± 0.7-males; $p<0.01$, reflecting the larger gland weight. No significant differences were observed between neurointermediate lobes. Total endorphin content in pars distalis from male rats appears maximal at about 10 weeks of age, with a decline at 25 weeks, despite an increase in gland weight. Neurointermediate lobe endorphin content increased significantly from 5 to 10 weeks of age, a trend which continued to 25 weeks, and paralleled the increase in gland weight. Whole pituitaries of neonatal rats were also examined for endorphin content. Administration of 2% NaCl in drinking water, electrolytic lesioning of several hypothalamic regions and continuous 30 or 60 min footshock were among attempts to alter pituitary endorphin levels. 12 h, 48 h, and one week following initiation of NaCl drinking, endorphin activity in both anterior and neurointermediate lobe shows a substantial reduction over controls. These experiments, together with footshock and hypothalamic lesioning will be discussed in terms of chronic, stressful stimuli as potential activators of the pituitary endorphin system. (Supported by Natl. Inst. on Drug Abuse grant DA1199).

906 ARE ENDOGENOUS OPIATES INVOLVED IN THE ANALGESIC ACTION OF NITROUS OXIDE? Barry Berkowitz*, A. Donald Finck* and S. H. Ngai* (Spon: C. Neurath). Roche Inst. Molec. Biol., Nutley,N. J. 07110 and Depts. of Anesthes. and Pharmacol. Columbia Univ. College of Phys. and Surg., New York, New York 10032

In an initial study of nitrous oxide analgesia, we utilized the phenylquinone writhing test in mice and observed some similarities between the effects of nitrous oxide and morphine (Science 194: 967-968, 1976). The objective of this study was to further characterize the nature of nitrous oxide analgesia using other tests and to establish if tolerance to nitrous oxide occurs. In mice, nitrous oxide was analgesic in the acetic acid writhing test. Aspirin and very high doses of alcohol were also active in these tests, however, only nitrous oxide induced analgesia was antagonized by narcotic antagonists. These data indicate the mechanism of action of nitrous oxide analgesia differs from that of the other two drugs. A similar phenomenon of analgesia and antagonism by naloxone occurred in rats. Nitrous oxide produced a dose-related analgesic response in rats (ED50, 67%) as measured by the tail-flick method. Naloxone, 5-30 mg/kg, antagonized nitrous oxide analgesia in rats. A 1 mg/kg dose of the antagonist was not effective. It should be emphasized that when naloxone is used alone, it never produced any hyperalgesia in any of the analgesic tests.

Tolerance developed to the analgesic action of nitrous oxide in both rats and mice. Animals exposed to 75% nitrous oxide for 18-24 hours had a reduced analgesic response to subsequent exposures of the gas. These data show that nitrous oxide is analgesic in a variety of tests and lend support to the hypothesis that nitrous oxide and opiates have a significant pharmacologic resemblance. Ultimately, these drugs may produce similar molecular events in the brain lending to relief of pain. A possibility which we are actively considering is that there is an interaction between nitrous oxide and the opiate receptor-endorphin system.

907 REGIONAL DISTRIBUTION OF β-ENDORPHIN AND ENKEPHALIN IN RAT BRAIN: A BIOCHEMICAL AND CYTOCHEMICAL STUDY. F. Bloom, J. Rossier, E. Battenberg, T. Vargo*, S. Minick*, N. Ling* and R. Guillemin. The Salk Inst., La Jolla, CA 92037

Radioimmunoassays (RIA) for β-endorphin (β-end) and Leu^5-enkephalin (Leu-enk) were developed. β-end RIA shows negligible cross-reaction with α-end, Met-, and Leu-enk. Leu-enk RIA shows a 3.7% cross-reaction with Met-enk and the standard curves for Met- and Leu-enk were completely parallel, therefore this RIA cannot discriminate between Leu- and Met-enk. Values given below (Table I) assume that all enkephalin immunoreactivity was due to Leu-enk. If the rat brain contains no Leu-enk but only Met-enk, the Leu-enk values will reflect cross reactivity, and correct Met-enk concentrations will be obtained by multiplying the Leu-enk by 27.

Table I: Regional distribution of β-end and Leu-enk

Tissue	β-end, ng/gm	Leu-enk, ng/gm wet tissue	
Pituitary	269,000. ± 20,000.	75. ± 5.	n = 11
Hypothalamus	490. ± 30.	119. ± 6.	n = 5
Septum	234. ± 34.	85. ± 7.	n = 5
Midbrain	207. ± 15.	29. ± 2.	n = 5
Striatum	< 200	64. ± 9.	n = 5
Medulla + Pons	< 200	19. ± 3.	n = 5

For immunocytology, brains (rats, mice) were fixed by perfusion with 5% p-formaldehyde. Sections were cut on a cryostat and prepared with the PAP method of Sternberger using antisera (AS) to β-end or to enk. With either AS discrete nerve fibers and terminal boutons were observed throughout the CNS. With β-end AS, innervations was most intense in the ventral septum, the preoptic area of the hypothalamus, the paraventricular hypothalamus, the peri-aqueductal grey regions of the thalamus and midbrain and was also observed within portions of the substantia nigra and locus coeruleus. Globus pallidus and caudate nuclei, which show intense staining for enk, do not stain with β-end AS. With the β-end AS, labelled synaptic terminals have been seen by electron microscopy. Neuronal perikarya stained with β-end AS have been seen in the ventral hypothalamus and in the amygdala. These results as well as other endocrine and pharmacological experiments in progress suggest that endorphin-containing neuronal systems exist separately from those containing enkephalin.

908 OPIATES REGULATE ADENYLATE CYCLASE AND PROTEIN SYNTHESIS IN RAT FOREBRAIN REGIONS. K.A. Bonnet and S. Gusik.* New York University Medical Center, New York 10016.

Opiate analgesics and opioid peptides act through specific receptors to effect changes in cyclic nucleotide regulation in brain. In vivo, initial morphine injection results in lowering of midbrain cAMP and cGMP levels and an elevation of cAMP levels in the caudate and thalamus(Life Sciences, 16: 1877, 1975). In vitro, morphine and enkephalin stimulate caudate-thalamus adenylate cyclase activity only in the presence of Ca^{2+}. Morphine microinjected into the thalamus results in substantial analgesia with tolerance development on repeated microinjection. Systemic injection of theophylline (50mg/Kg) elevates cerebral cAMP and cGMP levels somewhat, and significantly potentiates morphine analgesia only if given 30 minutes prior to morphine. Ro20-1724 injected systemically significantly elevates cerebral cAMP only, and produces mild analgesia; injected 30 minutes prior to morphine the result is significantly greater than additive analgesia. By in vivo labelling studies using a double isotope technique we find significant alterations in the populations of high molecular weight RNA in forebrain regions 2.5 hours after the initial encounter with morphine, but not in the pons-medulla or in the cerebellum. These alterations are not the result of changes in RNA synthesis rates. None of these alterations in RNA populations are evident on challenge morphine injection in morphine tolerant (72 hour morphine pelleted) animals. These data provide biochemical evidence for the role of protein synthesis in the development of tolerance to narcotic analgesics. Such alterations appear to be qualitative rather than quantitative, and appear to result from opiate-receptor mediated alterations in cAMP levels since morphine in combination with either phosphodiesterase inhibitor resulted in accelerated tolerance development.

(Supported by NIDA grant DA 01113, KAB,PI)

909 EFFECTS OF CHOLINE ON MORPHINE ANALGESIA IN THE RAT. L. J. Botticelli, L. D. Lytle, and R. J. Wurtman. Massachusetts Institute of Technology, Cambridge, MA 02139.

The administration of choline has been shown to increase levels of acetylcholine in peripheral tissues and brain. Indirect pharmacological evidence suggests that these increases may be associated with a change in the amount of neurotransmitter actually released. Considerable evidence suggests that some actions of morphine and its congeners may be mediated in part by acetylcholine. We therefore studied the extent to which choline, as a precursor of acetylcholine, might modify the response to morphine in the rat. Latency in response to a thermal stimulus was used as the criterion for analgesia. The time required for characteristic lifting of a hindlimb was measured on a modified hot plate device. Difference between latency of the withdrawal response and the altered latency after morphine administration was used as a measure of the analgesic effect. Groups of 10-12 adult male rats received choline chloride (15, 30, or 60 mg/kg, i.p.) and, after 30 minutes, morphine sulfate (10 mg/kg, s.c.). Analgesia was examined 15, 30, 60, and 120 minutes after morphine injection. To evaluate the antinociceptive response, the area under each curve relating drug dose to time and response latency was calculated. Data are given as this area, in minute-seconds, ± S.E.M.

Drug		Analgesic area
Choline Cl (mg/kg)	Morphine SO_4 (mg/kg)	(minute-seconds)
0	0	12 ± 16*
60	0	66 ± 24*
0	10	1285 ± 81
15	10	1022 ± 98
30	10	693 ± 40*
60	10	243 ± 47*

*P < 0.001 differs from group receiving morphine alone.

Results suggest that choline, by increasing acetylcholine release at cholinergic synapses, produces a dose-related antagonism of the analgesic effects of morphine. (Supported in part by U. S. Public Health Service Grant MH-28783.)

910 Δ^9-TETRAHYDROCANNABINOL BLOCK OF 5-HYDROXYTRYPTAMINE STIMULATED RELEASE OF PROLACTIN IN MALE RATS. Bruce L. Bromley, J. H. Gordon and E. Zimmermann, Department of Anatomy and Brain Research Institute, University of California, Los Angeles, CA 90024.

The acute administration of Δ^9-tetrahydrocannabinol (Δ^9-THC) lowers resting levels and blocks the ether-induced rise in plasma prolactin (PRL) in male rats (Bromley et al, Fed. Proc. 36: 1026, 1977). To further study the mechanism(s) by which Δ^9-THC inhibits PRL release, adult male rats received ip injections of 5 or 30 mg/kg Δ^9-THC (2 hrs prior to sacrifice) and 1 hr later they received either a dopamine (DA) receptor blocker (pimozide, 2.5 mg/kg, haloperidol, 1 mg/kg, or chlorpromazine, 25 mg/kg) or a 5-Hydroxytryptamine (5-HT) agonist (fenfluramine, 5 mg/kg, or quipazine, 10 mg/kg). In a second series of experiments male rats received either reserpine (5 mg/kg, 5 hrs prior to sacrifice) or α-methyltyrosine (250 mg/kg 3 hrs prior to sacrifice) followed by Δ^9-THC at 2 hrs prior to sacrifice. All drug doses were selected on the basis of either preliminary studies or published values which produced a significant elevation in plasma PRL. All animals were decapitated, within 30 sec following cage opening, and trunk blood was collected for radioimmunoassay of PRL. In the absence of Δ^9-THC treatment each of the drugs caused a significant ($p<0.05$) elevation of plasma PRL levels. Δ^9-THC treatment failed to alter the prolactin response to pimozide and chlorpromazine, but partially reduced the response to haloperidol. In contrast, Δ^9-THC completely abolished the PRL response to fenfluramine (which releases central stores of 5-HT) and quipazine (which directly stimulates 5-HT receptors). Δ^9-THC treatment did not antagonize the PRL elevating effects of α-methyltyrosine and only partially antagonized the effects of reserpine.

Both DA and 5-HT have been implicated in the regulation of PRL release. DA has been proposed to act as a PRL release inhibiting factor (PIF) at the level of the pituitary; conversely, 5-HT has been proposed to stimulate the release of a PRL releasing factor (PRF). When either the level of DA is reduced (reserpine and α-methyltyrosine) or its effectiveness at receptor sites is reduced (pimozide, haloperidol and chlorpromazine) then the Δ^9-THC treatment at best only partially inhibited the drug induced rise in plasma PRL. Conversely, when 5-HT agonists were used to stimulate a PRL release, then Δ^9-THC was a potent inhibitor of PRL release. These data suggest that Δ^9-THC either inhibits the action of 5-HT or the release and/or action of PRF. (Supported by USPHS grants DA826 and DA5010).

911 BEHAVIORAL CHARACTERIZATION OF THE EFFECTS OF ß-ENDORPHIN, NEUROLEPTICS AND OPIATES. Ronald G. Browne and David S. Segal. Dept. Psychiat., Sch. Med., UCSD, La Jolla, CA 92093.

Recently Bloom et al. (Science 194: 630, 1976) reported that intraventricular administration of ß-endorphin in rats produces a profound state of immobilization characterized by the absence of movement, loss of righting response and extreme generalized muscular rigidity. However, Jacquet and Marks (Science 194: 632, 1976) reported that injections of ß-endorphin into the periaqueductal gray (PAG) elicit a "cataleptic-like" state similar to that produced by most neuroleptics. Differentiation of the effects of ß-endorphin as rigid immobility or neuroleptic-like catalepsy may be crucial, both with respect to mechanistic considerations as well as possible clinical implications. Therefore, we have extended our earlier studies to characterize more completely the state of immobility produced by ß-endorphin and to compare it with the behavioral profile produced by opiates and neuroleptics. Following the systemic, intraventricular or PAG administration of these drugs, rats were tested for: rigidity, immobility on a vertical grid, righting reflex and gross behavioral and physiological changes. A dose-response analysis of intraventricular or PAG administered ß-endorphin revealed that this neuropeptide induced a state of immobility characterized by general muscular rigidity, loss of righting reflex and negative response on the vertical grid test. In contrast, haloperidol (0.5 - 12 mg/kg, s.c.) treated rats did not exhibit rigidity, maintained their righting reflex and remained stationary for at least 60 sec on a vertical grid. Pharmacological interactions further differentiated the effects of these two drugs. All the effects of ß-endorphin, but not those produced by haloperidol, were reversed by naloxone (0.1 - 2 mg/kg, s.c.). Furthermore, animals made rigid with ß-endorphin and later injected with haloperidol (2 mg/kg) became flaccid. In rats rendered flaccid by this combined treatment, naloxone administration resulted in the emergence of the typical spectrum of haloperidol effects. These results do not support the contention that ß-endorphin is an endogenous neuroleptic (Jacquet and Marks, 1976). We also found that the synthetic opiate methadone produced a pattern of effects which closely resembles the ß-endorphin-induced syndrome, indicating that the similarity between ß-endorphin and opiates such as methadone extends beyond their analgesic properties, and therefore that they may exert their effects through the same spectrum of neurochemical actions.

912 ETONITAZENE AS A REINFORCER FOR RATS: TASTE, OLFACTORY, AND POSTINGESTIONAL FACTORS. Marilyn E. Carroll* and Richard A. Meisch* (SPON: M.E. Ruggero) Department of Psychiatry, University of Minnesota, Minneapolis, MN 55455.

Previous studies have demonstrated that etonitazene HCl (ETZ) may function as a reinforcer for rats. Since etonitazene (5 or 10 µg/ml) is believed to be a relatively tasteless compound, in most studies the drug has been tagged with a taste additive or paired with visual stimuli. The present study investigated the reinforcing properties of ETZ with and without auditory discriminative stimuli. ETZ and water were concurrently available to 6 rats during daily 1-hr sessions in operant conditioning chambers equipped with 2 levers and 2 liquid dippers. A food-induced acquisition procedure was used whereby ETZ rapidly served as a reinforcer (i.e., is preferred to water) for food-deprived rats. Drug and water positions and liquid containers were alternated on a random basis.

Etonitazene maintained significantly higher response rates than water in the presence and absence of auditory discriminative stimuli even as ETZ concentrations were reduced logarhythmically from 10.00 µg/ml to .078 µg/ml. Drug intake (µg/kg) increased directly with concentration, whereas dipper presentations first increased and then decreased. Even at the lowest concentrations, the rats reliably chose the drug-lever from the onset of the session. These results suggest that drug choice was made on the basis of taste or olfaction rather than postingestional factors. The role of taste vs. olfactory factors were studied by presenting full vs. empty dippers at the start of the sessions. Also, an extinction test was conducted in which dipper operation was prevented but liquid reservoirs were present.

913 ASSAY OF METHIONINE- AND LEUCINE-ENKEPHALIN IN HUMAN BRAIN AND CEREBROSPINAL FLUID. Steven R. Childers* and Solomon H. Snyder. Depts. of Pharmacology and Psychiatry, Johns Hopkins Univ. Sch. Med., Baltimore, MD. 21205

Levels of opioid peptides were measured in human brain to determine whether the enkephalin pentapeptides are the predominate opioid peptides and to determine the ratios of methionine-enkephalin (met-enk; H_2-TYR-GLY-GLY-PHE-MET-OH) to leucine-enkephalin (leu-enk; H_2-TYR-GLY-GLY-PHE-LEU-OH). Adult human brain samples obtained 6-12 hours post-mortem were dissected, extracted in 0.1 N HCl, neutralized and lyophilized. Total opioid peptide levels were determined by rat brain opiate radioreceptor assay using ^{3}H-naloxone as ligand. Levels of met-enk and leu-enk were determined by radioimmunoassays utilizing specific antisera directed against each peptide. Regional dissection studies revealed that highest levels of enkephalin occurred in basal ganglia: globus pallidus > putamen $\geq$ caudate. In the caudate nucleus, enkephalin was concentrated in the head region, with lower amounts in the caudate body and tail. In the basal ganglia, levels of met-enk + leu-enk approximately equaled total opioid peptide levels, indicating that enkephalin is the predominate opioid peptide. Met-enk was higher than leu-enk, with met-enk:leu-enk ratios between 4 and 12. Hypothalamus and periaqueductal gray contained lower enkephalin levels. All cortex and cerebellum areas, along with thalamus, amygdala, medulla, and pons contained negligible opioid peptide levels. Inferior colliculus contained large quantities of opioid peptides by radioreceptor assay, but negligible enkephalin by radioimmunoassay. Therefore, this area may contain significant amounts of non-enkephalin opioid peptide (s).

Radioimmunoassays of human CSF revealed no detectable activity of either met-enk or leu-enk (< 1 pmole/ml). Radioreceptor assay detected only a small amount of opioid peptide activity which eluted from Biogel P-2 columns with higher molecular weight than enkephalin. (Supported by USPHS grants DA-00266 and MH-33128).

914 A COMPARISON OF DIBUTYRYL CYCLIC GMP AND MORPHINE INDUCED ANTINOCICEPTION. Major L. Cohn and Marthe Cohn*, Dept. Anesthesiology, Magee-Womens Hosp., Univ. Pgh. Sch. Med., Pittsburgh, PA 15213.

The analgetic properties of the opiates are not dissociable from systemic and central nervous system depression. We have previously reported the original findings that unlike morphine, the dibutyryl analog of the nucleotide guanosine 3':5' cyclic monophosphate (db cyclic GMP) is a potent analgetic devoid of systemic and central nervous system depression. In the present study, we examined whether db cyclic GMP induces dependence and suppresses the acute morphine abstinence syndrome. Following microinjections in specific sites of the brain, we also compared the analgetic responses and behavioral events produced by db cyclic GMP and morphine. Groups of Sprague-Dawley male rats (200-250 g) were stereotaxically implanted with cannulae either in the lateral ventricle of the brain (ICV), in the periaqueductal gray matter (PAG) or in the mid-brain reticular formation (MRF). Either db cyclic GMP (5-200 µg), morphine sulfate (5-30 µg) or saline vehicle was administered through the cannulae. Analgesia was tested by a gradient increase of temperature on a hot plate. While rats treated with db cyclic GMP (150-200 µg) exhibited no alteration of either behavior or locomotor activity (recorded on Stoelting Activity Monitor), they tolerated temperatures up to 60°C without any signs of discomfort or sedation. Of considerable potential is our finding that all db cyclic GMP treated rats survived temperatures beyond 54°C whereas rats treated with morphine died within 1 to 4 hours after the experiment. Naloxone (1 mg/kg) injected subcutaneously (s.c.) did not alter the analgetic properties of db cyclic GMP. The continuous ICV perfusion of db cyclic GMP for three days (total dose 8 mg/rat) produced no behavioral alteration. Neither the abrupt cessation of the perfusion nor naloxone (1 mg/kg) injected s.c. precipitated withdrawal symptoms. In rats addicted with morphine (150 mg/kg) and challenged with naloxone (1 mg/kg) s.c. db cyclic GMP (200 µg) did not suppress withdrawal symptoms. Microinjections of db cyclic GMP (200 µg) into PAG or MRF did neither suppress noxious stimuli nor produced behavioral events induced in these sites by microinjections of morphine. Our evidence suggests that db cyclic GMP 1) is a potent analgetic devoid of systemic and central nervous system depression; 2) protects against death secondary to heat exposure; 3) does not induce dependence; 4) is not blocked by naloxone; 5) does not produce analgesia at the same sites as morphine; 6) does not induce the same behavioral events as morphine. In conclusion, the mechanism of action of db cyclic GMP seems mediated through a pain inhibitory pathway distinctly different of that upon which morphine acts.

915 ACUTE EFFECT OF ETHANOL ON HIPPOCAMPAL CA1 FIELD POTENTIALS RECORDED IN VITRO. William A. Corrigall, Peter L. Carlen and Allan L. Staiman. Dept. Medicine (Neurology),Addiction Research Foundation, Toronto, Ontario, Canada, M5S 2S1.

The effect of ethanol on field potentials recorded in the CA1 region of the transverse hippocampal slice from the rat has been examined. Potentials were evoked by stimulation in the stratum radiatum (orthodromic) or in the alveus (antidromic). Ethanol was bath-applied over a concentration range of 0-600mM (0-4.6%).

At the highest concentrations (consistently at 600mM), the field potential evoked by orthodromic stimulation was abolished within several minutes. Stimulation of the alveus would, however, still give rise to an antidromic field potential, although reduced in amplitude by 40 to 75% of control. Recordings of activity following stratum radiatum stimulation occasionally included a small negative spike which preceeded the population spike by approximately 1 msec and which, unlike the population spike, did not facilitate following tetanus. This spike may represent activity in the presynaptic fibers. Ethanol at 600mM completely blocked this spike indicating that, if the above assignment is correct, the effects on the orthodromic field potential at this concentration may be due exclusively to conduction block in the afferent fibers.

At 400mM ethanol, the radiatum-evoked field potential was reduced in amplitude by 25-50% and occurred at longer latency. In addition, in those cases in which responses in control medium consisted of several spikes, the longest latency spikes were frequently abolished. The "presynaptic spike" also was reduced at this concentration but to a lesser extent than the post-synaptic potential. The antidromic field potential was reduced by approximately 25%.

At 100mM ethanol, reductions of as much as 25% of the amplitude of the orthodromic field potential could still be observed, although the "presynaptic spike" appeared to have been unaffected at higher concentration (200mM).

All of these effects were reversible upon return to control medium.

Preliminary data at the low concentrations (100-200mM) does not indicate any greater sensitivity to ethanol of post-tetanically or double-pulse facilitated responses, although subtle effects at lower concentrations may be more evident in data obtained intracellularly.

(supported by The Medical Research Council of Canada)

916 ABRUPT WITHDRAWAL OF BUPRENORPHINE, ETHYLKETOCYCLAZOCINE, KETOCYCLAZOCINE OR PENTAZOCINE IN THE RAT: EFFECT ON SEIZURE SUSCEPTIBILITY AND BODY WEIGHT. A. Cowan* and M.W. Adler. (SPON: D.L. Margules). Temple Univ. Sch. of Med., Philadelphia, Pa. 19140.

Whereas acute doses of morphine (M) increase the threshold to flurothyl-induced convulsions in rats, the M primary abstinence syndrome in this species is associated with a decrease in the threshold (Adler *et al.* Psychopharm. *35*:243,1974). How useful is the latter finding in the evaluation of those analgesics that are claimed to possess only low physical dependence capacities? This question seemed particularly pertinent since, in our hands, analgesics of current interest could be differentiated after acute injection i.e. buprenorphine (B) was anticonvulsant, pentazocine (P) was proconvulsant, and ethylketocyclazocine (EK) and ketocyclazocine (K) had no marked effect. We now describe the effect of abrupt withdrawal of these compounds on seizure threshold (S.T.) and on body weight, a commonly reported sign of withdrawal in the rat.

Groups of 8-10 male, albino Sprague-Dawley rats (300-350 g) were injected s.c. at 0800 and 1700 h daily for 10 days with either saline (S), B, EK (both 1.0-16 mg/kg), K (0.50-8.0 mg/kg), P (2.0-32 mg/kg), or morphine (10-160 mg/kg). Each rat was weighed at 0900 and 1700 h daily during the withdrawal period. The flurothyl challenge took place 40 h after the last injection.

Seizure threshold and mean % weight change during withdrawal

	% wt change +40 h; 9 am	S.T. at +40 h mean ± s.e. (sec)	% wt change +64 h; 9 am
S	4.9	332 ± 13	6.4
M	-14.1	276 ± 10*	-14.9
B	2.8	389 ± 14*	1.7
EK	-4.9	336 ± 16	-2.2
K	1.4	295 ± 9	1.9
P	1.7	338 ± 23	1.6

*P<0.05 (Dunnett's method for multiple comparisons)

To summarize our major findings: a) pronounced effects on both S.T. and body weight were only obtained with rats undergoing withdrawal from M; b) in rats treated with B, EK, K, or P and then withdrawn there was no significant decrease in S.T.; indeed, there was a marked increase after B; c) rats treated chronically with EK lost weight during withdrawal.

This pilot study has shown that by recording weight loss and seizure threshold it may be possible to characterize the withdrawal syndromes of analgesics with low physical dependence capacities. (Supported by grant DA 00376 from NIDA. AC is the recipient of a Wellcome Travel Grant).

917 SELECTIVE OPIATE DEPRESSION OF SENSORY-EVOKED SYNAPTIC NETWORKS IN DORSAL-HORN REGIONS OF SPINAL CORD CULTURES. Stanley M. Crain, Edith R. Peterson*, Bea Crain* and Eric J. Simon*. Depts. of Neuroscience and Physiology, Albert Einstein Coll.Med., Bx., N.Y. 10461; Dept. of Medicine, New York Univ. Coll.Med., N.Y. 10016.

Prominent sensory-evoked synaptic networks develop in dorsal horn regions of fetal mouse spinal cord cross-sectional explants, with attached dorsal root ganglia (DRGs), cultured in high NGF (Cr.&Pet., Br.Res.79:145,'74; Soc.Neurosci.'75,'76). Focal DRG stimuli elicited complex negative slow-wave responses restricted to dorsal cord loci, with latencies of 2-3 msec and duration often > 500 msec, resembling primary and secondary sensory-evoked synaptic network responses in situ. These DRG-evoked dorsal cord responses are maintained or augmented in 10^{-3}M GABA, whereas ventral cord discharges are rapidly depressed. Recordings were made via saline-filled pipettes, 3-5 μ tips; electric stimuli (0.5 msec) were applied via 10 μ pipettes.

Morphine sulfate at 10^{-7}-10^{-6}M often led to sustained depression of major components of the DRG-evoked negative slow-wave responses in dorsal cord within 3-10 min, whereas ventral cord discharges were either unaltered or enhanced. Etorphine produced similar selective depression of the dorsal cord responses at still lower concentrations (10^{-8}-10^{-7}M). Levorphanol was comparable in potency to morphine, whereas dextrorphan was ineffective at 10^{-6}M. Introduction of naloxone at 10^{-8}-10^{-6}M restored opiate-blocked cord responses within minutes, whereas recovery in BSS required much longer periods. Naloxone also prevented effects of subsequent addition of morphine or etorphine. In many cultures, naloxone elicited increases in amplitude and duration of the DRG-evoked dorsal cord responses even when introduced without prior opiate exposure.

The concentrations of morphine which depressed sensory-evoked dorsal-cord networks in vitro compare well with analgesic levels in situ, and the antagonist effects of low concentrations of naloxone support the validity of this tissue culture model for studies of opiate mechanisms in the CNS. Localization of opiate sensitivity in dorsal horn regions of cord-DRG explants is consonant with studies in situ and with evidence of high opiate receptor binding levels in these cultures, especially in DRG neurites (Simon et al., this vol.). This study is the first to demonstrate that sensory-evoked synaptic networks in the dorsal horn regions of spinal cord tissue cultures can be selectively depressed by exposure to opiates. Furthermore, naloxone-enhancement of DRG-evoked dorsal cord responses in cultures not exposed to exogenous opiates suggests that these sensory CNS networks may develop localized opioid inhibitory control systems as in situ.

918 DEGRADATION OF ENKEPHALINS. Gale L. Craviso* and José M. Musacchio. Dept. Pharmacol., Sch. Med., NYU, New York, NY 10016.

We have studied the degradation of enkephalins by the guinea pig myenteric plexus-longitudinal muscle (MPLM) strip in order to isolate the endogenous ligand which is released by the electrical stimulation of the same preparation (Puig et al., Science 195: 419,1977). MPLM strips were incubated with ^{3}H-Met^5-enkephalin or ^{3}H-Leu-enkephalin (2 x 10^{-8} M) in Krebs bicarbonate at 37°. At the end of the incubation, the strips were removed and HCl added. Enkephalin and its degradation products were analyzed by TLC. Almost all the enkephalin degraded could be accounted for as free tyrosine, indicating that the enkephalin pentapeptides were cleaved at the Tyr-Gly bond.

We found that even after extensive washings of the MPLM strips, considerable peptidase activity leaches out of this preparation into the Krebs medium. We studied this leaching enzyme and compared it to the peptidase activity of guinea pig serum and brain subcellular fractions. The peptidases were incubated in Hepes buffer at pH 7 and 37° with ^{3}H-Met-enkephalin (2 x 10^{-8} M). After the addition of HCl, aliquots were analyzed by TLC. The major degradation product obtained by each source of the peptidases was free tyrosine. Boiling at 100° for 2 min destroyed peptidase activity in all cases. As can be observed in the following table, the peptidase activity of the various sources was different as indicated by the percent inhibition produced by certain inhibitors. The concentration of enzyme from the different sources was adjusted so that the control samples degraded 40% of the enkephalin added.

	100,000 x g Brain Sup	MPLM Sup	Serum	MPLM Leaching
Met-Enkephalin 10^{-4} M	73	78	42	51
Bacitracin 100 γ/ml	97	99	21	68
Lima Bean Trypsin Inhib. 100 γ/ml	65	75	4	18
o-Phenanthroline 10^{-3} M	100	100	100	100

From this table, it can be concluded that the peptidases of the 100,000 x g sup from brain and MPLM are similar and that they are different from the serum and MPLM leaching peptidases.

919 NORADRENERGIC ROLE IN THE SELF-ADMINISTRATION OF ALCOHOL BY RATS. W.M. Davis, S.G. Smith and T.E. Werner. Department of Pharmacology, School of Pharmacy, University of Mississippi, University, MS 38677.

The acquisition by rats of a lever-response reinforced by intragastric (i.g.) infusions of alcohol has been described previously (Davis et al., Proc. West. Pharmacol. Soc. 19: 346, 1976). The role of noradrenergic processes in such self-administration behavior was assessed in rats allowed to lever-press for 25 mg/kg i.g. doses of alcohol. Cannulation for i.g. infusion was by an esophageal approach (Smith et al., Physiol. Psychol. 3: 220, 1975). Access to infusions of saline for establishing an operant baseline was followed by sessions on acquisition contingencies for alcohol or for sweet milk (sweetened condensed milk diluted to half strength). Following acquisition of the lever-press response, the saline contingency was reintroduced, i.e., extinction was imposed. Prior to a reacquisition session, rats were treated with saline, with an agent depleting both norepinephrine (NE) and dopamine (DA), α-methyltyrosine (225 mg/kg), with an agent depleting only NE, 1-phenyl-3-(2-thiazolyl)-2-thiourea (U-14,624; 600 or 300 mg/kg), or with an agent blocking DA receptors, haloperidol (3.5 mg/kg). Results showed that both the control subjects (i.e., the saline-pretreated alcohol group and the sweet milk groups with all three pretreatments) and the haloperidol-treated subjects all reacquired lever-press behavior, whereas the other groups did not. The latter results are attributed to abolition of the reinforcing effect of the infusion of alcohol. The results with the sweet milk reinforcer indicate that the effects on alcohol self-administration of drugs altering central neuroamine functions are not caused by an abolition of all appetitive behaviors and reinforcement. Brain levels of NE, DA and serotonin (5-HT) were measured following administration of the amine-depleting compounds employed in the reacquisition tests. NE was depleted by both compounds, DA was depleted only by α-methyltyrosine, and 5-HT was elevated by 600 mg/kg of U-14,624, but unaffected by 300 mg/kg. As the lower dose of U-14,624 had the same behavioral effect as the higher one, but without elevating 5-HT, it seems unlikely that the behavioral effect involves 5-HT. These results suggest that NE has an important function in the reinforcing action of alcohol, whereas DA does not. (Supported by research grant AA 01217-02 from NIAAA, and in part by the Research Institute of Pharmaceutical Sciences, the University of Mississippi).

920 CORRELATION OF OPIATE LOCALIZATION AND PHARMACOLOGICAL ACTION IN THE MYENTERIC PLEXUS OF THE GUINEA PIG ILEUM. Ihsan M. Diab, Bruce H. Wainer* and Lloyd J. Roth* (SPON: J. de la Torre). Depts. of Pharmacological and Physiological Sciences, Psychiatry, and Pathology. University of Chicago, Chicago, IL 60637.

Morphological localization of three narcotic agonists was determined autoradiographically and compared with their pharmacological effects on the electrically stimulated longitudinal muscle-myenteric plexus preparation.

Concentrations of 100nM ^{3}H-morphine, 0.100nM ^{3}H-etorphine, or 1550nM ^{3}H-met-enkephalin resulted in 90-100% inhibition of the ileal contractile response in each case. These inhibitions were reversed by the presence of 10nM naloxone in the bath or by washing the preparation.

Various experimental manipulations were performed following the addition of each agonist. At the termination of each manipulation the tissue was removed from the organ bath, the longitudinal muscle-myenteric plexus strips were separated from the intact ileal segments and processed for autoradiography.

Autoradiograms of plexus preparations removed from the bath at maximum inhibition by ^{3}H-morphine, without washing, showed high radioactivity over the longitudinal muscle with little activity over the myenteric plexus proper. Occasional satellite cells were found to be labeled. Autoradiograms from strips maximally inhibited by ^{3}H-morphine and reversed by naloxone, without washing, showed a radioactive distribution pattern similar to ^{3}H-morphine autoradiograms described above. Autoradiograms of tissue maximally inhibited by ^{3}H-morphine followed by washing and allowed to recover full contractility, showed silver grain density which was considerably reduced over the longitudinal muscle. Within the plexus proper, occasional satellite cells were radioactively labeled. Autoradiograms from tissue maximally inhibited by ^{3}H-morphine and reversed by naloxone, followed by washing, showed a low distribution of silver grain density on the longitudinal muscle with no radioactivity associated with satellite cells. In no autoradiograms was there any definite neuronal labelling observed in the myenteric plexus. Similar autoradiographic results were obtained with ileal myenteric-plexus preparations treated with either ^{3}H-etorphine or ^{3}H-met-enkephalin. The present studies show no correlation between labelling of a particular cell type and the contractile state of the smooth muscle. Furthermore, there appears to be a selective barrier to the penetration of narcotic agonists into the myenteric plexus of the guinea pig ileum. This barrier may reside in the basal lamina sheath that envelops the plexus, and the narcotic agonist action may be mediated at the surface of the sheath. Supported by grants USPHS RO1 DA00393-05 & RO1 DA00397-05.

921 A COMPARISON OF THREE METHODS FOR PRODUCING PHYSICAL DEPENDENCE ON MORPHINE IN THE RAT. William A. Dickinson, Robert A. Levitt, and Beth L. Eskanazi*. Dept. Psychol. and Sch. Med., Southern Ill. Univ., Carbondale, Il. 62901

The laboratory rat is a popularly employed subject in the study of narcotic dependence. Three main methods for the production of physical dependence on morphine in rats have evolved to date. These methods can be categorized according to the routes of administration and include parenteral injection, oral ingestion, and pellet implantation. This study compares the effectiveness of these three methods in producing physical dependence on morphine in the rat as measured by the severity of the withdrawal syndrome during naloxone precipitated abstinence.

Three groups of 10 rats were made physically dependent on morphine. Group 1 received twice daily injections (IP) of 25mg. morphine/kg. body weight for a period of 3 days. Group 2 was provided with an ad lib choice between water and a morphine-sucrose solution (0.25mg. morphine/cc in 10% sucrose) for 10 days. Group 3 recieved their morphine for 3 days via a 75mg. morphine-base pellet implanted subcutaneously in the cervical region of the back. Withdrawal was precipitated at the end of the dependence periods by an I.P. injection of 5mg. naloxone hydrochloride/kg. body weight. Six similarly treated groups (N=10) were added as controls. Groups 4, 5, and 6 were administered morphine as in groups 1, 2, and 3 respectively, but were injected with physiologic saline solution rather than naloxone on the withdrawal day. Groups 7, 8, and 9 did not receive morphine at any time, but were injected twice daily for three days (group 7), provided with unadulterated sucrose solution (group 8), and implanted with placebo pellets (group 9). These latter 3 groups were injected on the withdrawal day with 5mg./kg. naloxone as a control for its effects. Immediately following the precipitation of withdrawal all subjects were placed in 1 gal. size "mayonaise type" jars for a period of 1 hr. during which 13 behavioral signs of withdrawal were recorded.

Analysis of the results indicated no significance difference between the severity of the naloxone-precipitated withdrawal syndrome produced by the 3 different methods of administering morphine. There was a significant difference ($p<.001$) between the groups treated with morphine followed by naloxone (groups 1-3) and the control groups (groups 4-9).

It appears, from the results of this study, that the major consideration in choosing which of these three popular methods of producing physical dependence on morphine in the rat are ones of convenience and economy since all three methods consistently produce a relatively severe withdrawal syndrome.

922 STUDIES ON THE GENERALITY OF CALCIUM ENHANCEMENT OF ALCOHOL AND HYPNOTIC DRUG INTOXICATION IN RATS. C.K. Erickson, L.K. Beck*, K.L. Duensing*, and R.M. Huff*. Dept. Pharmacol. Toxicol., Sch. Pharm., Univ. Ks., Lawrence, KS 66045.

Earlier studies (Harris, Fed. Proc. 36: 285, 1977; Tyler and Erickson, ibid. 36: 331, 1977) have shown that calcium chloride (Ca^{2+}) and some other cations will significantly enhance ethanol-induced sleeping-time in mice. Ca^{2+} also enhances sleeping-time produced by tertiary butanol, chloral hydrate, and pentobarbital in mice. To test the generality of the enhancement in another species, and with lower doses of these hypnotics, rats were given the same four CNS depressants intraperitoneally at various times after intracerebroventricularly-administered Ca^{2+}. High (sleep-inducing) doses and low doses which produced motor incoordination were used. Motor coordination was measured by the moving belt ("treadmill") apparatus of Gibbins et al. (J. Pharmacol. Exp. Ther. 159: 236, 1968). The results in the sleeping-time studies were identical to those seen earlier in mice, when a range of Ca^{2+} doses was used, and when the Ca^{2+} doses were adjusted for brain weight. Furthermore, the Ca^{2+} effects on ethanol-induced sleeping-time were increased by pretreatment with Ca^{2+} ionophores (X537A and A23187) in rats as reported earlier in mice. In the treadmill studies, various doses of Ca^{2+} shift the ethanol dose-response curve dramatically to the left; i.e., Ca^{2+} potentiates low doses (1.0-1.7 g/kg) of ethanol. Finally, intracerebroventricularly-administered Ca^{2+} did not change blood ethanol levels compared with no cation treatment. This study expands the generality of Ca^{2+}-depressant drug enhancement reported earlier, and supports the evidence for involvement of a brain Ca^{2+} pool in behavioral intoxication in rodents. (Supported in part by USPHS, NIAAA Grant No. AA01417).

923 EFFECT OF MORPHINE ON SPONTANEOUSLY ACTIVE SINGLE UNITS OF CAT MYENTERIC PLEXUS. David N. Erwin, Toshiaki Ninchoji* and J. D. Wood. Depts. of Physiol. & Neurosurg., KUMC, Kansas City, Kansas 66103.

We recorded spontaneous action potentials extracellularly from neurons of cat Auerbach's plexus, using 20 micron teflon-coated platinum wires. Longitudinal muscle was removed from mounted sections of duodenum or jejunum to expose Auerbach's plexus, but the circular muscle, Meissner's plexus and submucous plexus were intact. A six minute control recording from each neuron was followed by six minutes of morphine sulfate at 1 to 5 x 10^{-5} g/ml final conc. in Tyrode's solution. In five experiments, Naloxone was added at 1 x 10^{-5} g/ml either before, during, or after the addition of Morphine. Types of cells recorded included mechano-sensitive neurons, bursting cells and single spike cells. Drug studies were only performed on bursters and single spike cells.

We measured the spike frequency of single spike cells in terms of the mean interspike interval. For burst cells, we measured the mean interspike interval (within bursts), the mean interburst interval, and the mean number of spikes per burst. The results are tabulated below:

29 Burst-Type Cells

Parameter	# Increase	# Decrease	# Unchanged
Mean Interspike Interval	8	19	2
Mean Spikes/Burst	6	16	2
Mean Interburst Interval	13	9	7

Columns indicating a change include only those experiments for which there was a significant difference according to Student's t-test between Control and Morphine. In most cases, the changes in interspike intervals were correlated with the appropriate change in spikes per burst. That is, the latter spikes in a burst tended to have the greatest interspike intervals; so that, if the number of spikes increased, the mean interspike interval also tended to increase.

We also recorded from five single spike cells. Three of these increased their spike frequency upon addition of morphine and two of the three were eventually blocked. Two single spike cells decreased their spike frequency upon addition of morphine. Naloxone had no detectable effect upon any of the cells at the dosage used.

In contrast to previously published work on the guinea-pig ileum, these results indicate that morphine has no consistent direct effect upon spontaneously active neurons of Auerbach's plexus in the cat. It is possible that the effects of morphine upon motility are mediated by other neurons not sampled by our recording methods.

Supported in part by KUMC Grant #1571 to DNE and NIH Grant #2R01 AM 16813 to JDW.

924 EFFECTS OF MORPHINE ON SELF-STIMULATION THRESHOLDS TO THE SUBSTANTIA NIGRA AND THE LOCUS COERULEUS IN THE RAT. R. Esposito* and C. Kornetsky*. (Spon: A. Peters). Boston University School of Medicine, Boston, MA 02118.

Acute administration of morphine in low to moderate doses (4mg/kg - 8mg/kg) has previously been found to reduce the threshold for intracranial self-stimulation (ICSS) to the medial forebrain bundle at the level of the lateral hypothalamus (MFB-LH) (Marcus and Kornetsky, Psychopharmacologia, 38: 1, 1974). Further, we have found no evidence that there is tolerance to this threshold lowering effect with chronic administration of morphine (Esposito and Kornetsky, Science, 195: 189, 1977).

Since the catecholamines have been implicated as critical substrates for both the phenomenon of ICSS (German and Bowden, Brain Research, 73: 381, 1974) and the self administration of rewarding drugs, particularly morphine (Davies and Smith, Life Sciences, 12: 185, 1973), it was decided to investigate whether morphine may lower or in other ways modulate ICSS thresholds to other "rewarding" brain sites, and to determine to what degree the morphine effect on MFB-LH stimulation may reflect differential catecholamine activity. Rats were implanted with bipolar stainless steel electrodes aimed at the substantia nigra (SN) or the locus coeruleus (LC) and trained on a modified method of limits to determine reinforcement thresholds from these brain sites.

At low doses (2mg/kg - 6mg/kg) morphine lowered the ICSS threshold to both the LC and the SN. Higher doses (8mg/kg - 12mg/kg) increased the threshold with the animals manifesting some degree of sedation. As with stimulation to the MFB-LH, there was no tolerance to the threshold lowering effect of the low dose in the SN animals. At the present time, the chronic administration of morphine to the LC animals has not been completed so that no statement regarding tolerance to these animals can be made at this time.

These data indicate that when rate-free measures of the reinforcing value of ICSS are employed, morphine will (within a narrow dose range) enhance the reinforcing value of stimulation to catecholamine rich areas of the brain. Further, and probably of most importance, to date we have failed to find tolerance to these threshold lowering effects.

These results suggest that the ICSS threshold lowering effects of morphine may represent a model for the study of the reinforcing properties of the narcotic analgesics.

(Supported by NIDA Grant DA00377 and Research Scientist Award MH 1759 - C.K.).

925 MORPHINE FACILITATION OF SHUTTLE-BOX SELF-STIMULATION IN THE RAT: FAILURE TO FIND TOLERANCE. Timothy M. Evers, Donald J. Stilwell*, and Robert A. Levitt. Dept. Psychol. and Sch. Med., Southern Ill. Univ., Carbondale, IL 62901.

In a shuttle-box self-stimulation paradigm, a rat is able to control the onset and duration of rewarding electrical brain stimulation by crossing from one side of the cage to the other. Animals with lateral hypothalamic electrodes have been reported to leave the stimulation on about 10sec and off about 2sec per crossing. Systemic injections of an analgesic dose (10mg/kg) morphine were found to produce an immediate increase in average ON time per crossing (to about 20sec) without altering average OFF time. In this experiment we investigated the development of tolerance to this action of morphine.

One week after surgery, 16 adult rats, each implanted with one electrode in the lateral hypothalamic area, were tested in cages measuring 35x20x20cm, set on a fulcrum at the center, and with a microswitch at one end. Mean ON and OFF times per crossing during nine-ten minute periods per day were recorded on ten consecutive days. Days 1 and 2 were control days. On days 3-7, the 8 experimental animals were injected IP with 10mg/kg morphine sulfate immediately before placement in the shuttle-box. Days 8-10 were post drug control days. A second group of 8 animals received IP injections of isotonic sodium chloride solution on days 3-7.

ON times averaged about 8sec per crossing, while OFF times averaged about 2sec per crossing for both groups on training days 1 and 2. The shuttling behavior of the control animals did not change during the subsequent 8 days. On the first day of morphine injection, the experimental animals increased their mean ON times to about 25sec, but their mean OFF times remained near 2sec. This facilitative effect of morphine did not show tolerance over the subsequent 4 days of drug injections. ON and OFF times for the experimental group returned to baseline levels on day 8.

In the standard self-stimulation (SS) paradigm, morphine first depresses bar press rates for up to 3 hours and then facilitates SS for about 4 hours. With daily morphine injections tolerance develops to the initial suppression of SS but not to the later facilitation. The immediate facilitation of shuttle-box self-stimulation by morphine also does not show tolerance and seems analogous to the delayed facilitation found in bar-press SS. This action of morphine on shuttle-box self-stimulation may provide a useful model of the mood-enhancing effects of narcotic drugs in humans.

926 IONTOPHORESIS OF OPIATE ALKALOIDS AND ENDORPHINS ACCELERATES HIPPOCAMPAL UNIT FIRING BY A NON-CHOLINERGIC MECHANISM; CORRELATION WITH EEG SEIZURES. E. D. French*, G. R. Siggins, S. J. Henriksen and N. Ling*. The Salk Institute, La Jolla, CA 92037

In previous iontophoretic studies on anesthetized rats, normorphine and the opioid peptides Met^5-enkephalin (Met-enk) and β-endorphin generally inhibit neurons of most brain regions, while they markedly excite dorsal hippocampal (HPC) neurons (Nicoll et al., PNAS, 1977, in press). HPC excitations are also seen with iontophoresis of $(D\text{-}Ala^2)\text{-}Met^5$-enk amide, γ-endorphin and s.c. morphine (50 mg/kg). On rare occasions the excitations of HPC cells to iontophoretic β-endorphin are accompanied by large (2-5 mv) voltage deflections (interictal spikes) in d.c. microelectrode recordings. In agreement with iontophoretic studies, subcortical EEG recordings from HPC show dramatic non-convulsive seizures 1-2 min after intraventricular injection of 1-10 nM of morphine, Met-enk or β-endorphin; such seizures are blocked by naloxone (Henriksen, this vol.). These seizures are also associated with large (3-20 mv) interictal spikes in recordings from single-barrel micropipettes (1μ tip size), in correlation with the unit HPC excitations to iontophoresis of opiates.

The opiate excitations could result from presynaptic release of an excitatory neurotransmitter, such as acetylcholine (ACh) derived from cholinergic septal-HPC pathways. Although iontophoretic ACh excites HPC neurons, excitations to normorphine, Met-enk and β-endorphin are not diminished by iontophoretic currents of atropine or scopolamine sufficient for total blockade of ACh. Conversely, the opioid excitations, but not ACh responses, are blocked by iontophoretic or s.c. naloxone (2-8 mg/kg). Moreover, electrocoagulation lesions of medial septum, the origin of cholinergic fibers to the dorsal HPC, do not diminish excitations of dorsal HPC neurons to β-endorphin, morphine or Met-enk. This correlates with EEG recordings showing persistence of β-endorphin HPC seizures after i.p. scopolamine (4 mg/kg). These results support the hypothesis that opiate-induced excitations and seizures in HPC are independent of ACh release.

927 ENKEPHALIN-INDUCED CORTICAL SEIZURES IN THE RAT. Hanan Frenk, Gideon Urca, and John C. Liebeskind. Dept. Psych., Los Angeles, CA 90024.

We have recently reported (Urca et al., Science, in press) that intracerebroventricular (ICV) injections of 200 μg met-enkephalin into the lateral ventricle induced powerful cortical epileptic activity in the EEG of rats. These injections also produced potent but short-lived tail-flick analgesia in 50% of the animals. In the present study we compared the effects on cortical EEG of ICV injections of met-enkephalin, leu-enkephalin, and morphine, all administered in a dose of 100 μg in 10 μl of Ringer's. In these quantities all substances elicited pronounced and morphologically similar seizure activity, which was blocked or greatly attenuated by the prior intraperitoneal injection of 10 mg/kg naloxone. It was noted that the duration of the seizures caused by leu-enkephalin (median = 13 min) was significantly longer than that caused by met-enkephalin (median = 6 min). The convulsant potency of enkephalin was underlined by the finding that ICV injections of doses as low as 25 μg leu-enkephalin still reliably caused seizures.

At doses of 100 μg, ICV injections of morphine elicited powerful and long-lasting tail-flick analgesia, but analgesia was only rarely observed after injections of the enkephalins at this same dose.

In a separate study, 120 μg of met-enkephalin in 1 μl of Ringer's was injected directly into, or in the immediate vicinity of the periaqueductal gray matter of rats. Seizures were not observed in any of these animals. Analgesia was found in those rats that were injected into sites ventral, but not dorsal to the aqueduct. On the basis of these experiments it was concluded that both the epileptic and analgesic effects of the enkephalins and morphine are mediated by opiate receptors. It seems likely, however, that the analgesic effect is mediated by receptors in the midbrain, whereas the EEG effect is mediated by receptors in other anatomical locations, most likely in the forebrain. A study aimed at locating these receptor sites is currently in progress.

928 IN VITRO EFFECTS OF PHENCYCLIDINE ON RAT STRIATAL TYROSINE HYDROXYLASE AND ADENYLATE CYCLASE. Richard E. Garey, Carl W. Christensen,* Andrew D. Howard* and Morris A. Spirtes. Depts. of Psych. & Neurol., Physiology and Pharmacology, Tulane School of Medicine and Veterans Administration Hospital, New Orleans, La. 70112.

Utilizing whole brain homogenates, Domino and his colleagues (Arch. int. Pharmacodyn. 202: 252-258, 1973) concluded that phencyclidine (PCP) caused a relative lowering of catecholamine (CA) synthesis and an increase in CA metabolism. Further data by this group indicated that the biochemical steps from dihydroxyphenylalanine (DOPA) onward in the synthesis of CA were probably not involved. Thus tyrosine hydroxylase (T-OH) activity or substrate availability for this enzyme could have been altered by the drug. We now present evidence that PCP at 10^{-7} M stimulated T-OH activity in the striatum by at least 30% so that the statistically significant lowering of dopamine and norepinephrine found by the original group must have been due to an even greater increase in CA metabolism. This interpretation is supported by the finding of Garey and Heath (Life Sci. 18: 1105-1110, 1976) that PCP is a potent, competitive inhibitor of CA reuptake in the striatum. Such an inhibition could lead to the increase in O-methylated metabolites previously reported by the Domino group. In addition, we have found another effect of PCP, also in the striatum, namely, that it stimulates brain adenylate cyclase (AC) directly by at least 60% at a concentration of 10^{-8}M; i.e. a concentration 10x smaller than that required for T-OH stimulation. The question now is raised as to whether the AC effect is the primary action of PCP. This drug-induced increase in AC activity would also help in explaining the increased T-OH activity which we found. The latter could be due to activation of the T-OH enzyme via a phosphoprotein-kinase, a possibility suggested by Roth et al. in 1975 (In: Pre- and Post Synaptic Receptors ed. Usdin and Bunney, Marcel Dekker, Inc., New York. p. 18).

929 POTENTIATION OF MORPHINE BUT NOT MEPERIDINE ANALGESIA FOLLOWING SEROTONIN (5HT) REUPTAKE INHIBITION. G.F. Gebhart and S.A. Lorens. Dept. of Pharmacol., Univ. of Iowa, Iowa City, IA 52242.

The hot plate (55±0.5°C) and tail flick (60±0.5°C) methods were used to determine the effects of a new selective 5-HT uptake inhibitor, Zimelidine (Ross and Renyi, Neuropharmacol., 1977, 16: 57), on morphine and meperidine analgesia. Control paw lick (60 sec. maximum) and tail flick (15 sec. maximum) latencies were obtained. The rats (n=42; 258-345 g.) then received Zimelidine (Z; 10 mg/kg) or saline (S; 1 mg/kg) i.p., followed 1.5 hr. later by morphine sulfate (MOR; 3.0 mg/kg, as the base), meperidine HCl (MEP; 10.0 mg/kg, as the base) or saline (S; 1.0 ml/kg) s.c., and were retested 30 min. after the second injection.

No group differences in control response latencies were found. The post-injection latencies of all MEP and MOR groups were significantly (Wilcoxan test) longer than control. Z did not affect paw lick or tail flick latency, but potentiated the analgesic effect of MOR as measured by the hot plate but not the tail flick procedure. In contrast, Z pretreatment reduced (46%) the analgesic effect of MEP. The response latencies of the S-MEP and Z-MEP groups, however, did not differ significantly (see Table).

The effect of Z on meperidine HCl (MEP-24; 24 mg/kg, as the base) analgesia was re-examined in a new group. The schedule was as above, except that only the hot plate test (120 sec. cut off) and 2 groups were employed. The paw lick latencies (sec.) of the S+MEP-24 group (n=6) were significantly (T=0) longer post-injection (control, 7.4±0.9; post-drug, 60.3±20.1). In contrast, the pre- and post-injection response latencies (control, 9.1±2.0; post-drug, 30.5±11.8) of the Z+MEP-24 group (n=7) did not differ significantly ($T=2\frac{1}{2}$). Z thus produced a 49% reduction in paw-lick latency. The two groups, however, did not suffer significantly (U=11), primarily because of the variance observed.

5-HT uptake inhibition following Zimelidine injection can potentiate morphine analgesia but attenuate meperidine analgesia, suggesting that different 5-HT systems may be involved in mediating the analgesic effect of morphine and meperidine.

Mean (± S.E.M.) Response Latencies (Sec.)

	Paw Lick		Tail Flick	
Treatment	Saline	Zimelidine	Saline	Zimelidine
Saline	9.2±1.3	11.3±1.3	4.2±1.9	3.2±0.5

930 DIFFERENTIAL EFFECTS OF NARCOTICS AND RELATED COMPOUNDS ON THE FLUROTHYL SEIZURE THRESHOLD IN RATS. E.B. Geller*, A. Cowan*, B. Melamed* and M.W. Adler (SPON: R.C. Truex). Temple University School of Medicine, Philadelphia, Pa. 19140

Acute doses of morphine produce anticonvulsant effects in rats (Adler *et al.* JPET *198*:655,1976). To investigate the generality of this finding, we have compared the effects of several strong analgesics on the seizure threshold of rats challenged with flurothyl. Male, albino Sprague-Dawley rats (300-350 g; n=10-20) each received one of at least 3 doses of test compound s.c. 30 min prior to being exposed to flurothyl. The convulsant (a 10% solution in 95% ethanol) was infused onto a gauze pad fixed beneath the lid of a glass jar and the time to onset of a clonic convulsion with loss of posture was noted. Rats (n=50) pretreated with saline convulsed after 355 ± 5 (s.e.m.) sec. From the results, test compounds could be divided into 3 groups.

1. Compounds producing dose-related anticonvulsant effects: buprenorphine (0.0008-0.02 mg/kg; mean max. % increase in seizure threshold = 15%), levorphanol (2.5-20 mg/kg; 16%), morphine (12.5-50 mg/kg; 18%), phenazocine (0.50-5.0 mg/kg; 18%), N-allylnorphenazocine (SK&F 10,047) (10-40 mg/kg; 21%), and cyclazocine (1.0-5.0 mg/kg; 27%).

2. Compounds producing dose-related proconvulsant effects: meperidine (6.25-25 mg/kg; -12%) and pentazocine (12.5-50 mg/kg; -32%).

3. Compounds without dose-related effects: ketocyclazocine (0.50-5.0 mg/kg; 4%), ethylketocyclazocine (0.50-12.5 mg/kg; 5%), nalorphine (25-100 mg/kg; 10%), and ℓ-BL-4566 [(-)-3-cyclopropylmethyl-8-hydroxy-11-α-methoxy-1,2,3,4,5,6-hexahydro-2,6-methano-3-benzazocine] (12.5-50 mg/kg; 7%).

It is of interest that doses of buprenorphine higher than 0.02 mg/kg (*i.e.* 0.10-12.5 mg/kg) had slightly less effect (range 7% - 10%) on seizure thresholds. Also, optimal anticonvulsant doses of cyclazocine (2.5 & 5.0 mg/kg) and SK&F 10,047 (20 & 40 mg/kg) caused head swaying and trembling of the forepaws. This behavioral syndrome was likewise observed after ℓ-BL-4566 (25 & 50 mg/kg) but was not associated with a marked increase in seizure threshold.

We conclude that a) the anticonvulsant action previously reported for morphine is shared by at least 3 other strong analgesics; certain psychotomimetic narcotic antagonists, at doses causing bizarre behavioral patterns in the rats, are also anticonvulsant, b) benzomorphan analgesics can have either pro- or anti- convulsant actions or no effect, c) three compounds, ethylketocyclazocine, ketocyclazocine, and nalorphine, presumed to have little or no intrinsic activity at so-called μ receptors (Martin *et al.* JPET *197*:517,1976) do not markedly influence seizure threshold. (Supported by grant DA 00376 from NIDA).

931 INTRAVENOUS SELF-ADMINISTRATION OF MORPHINE BY RATS: BEHAVIORAL FEATURES OF ADDICTION AND WITHDRAWAL. Philip L. Gildenberg, K.S. Krishna Murthy, Kevork G. Chatmajian* and Martin W. Adler. Div. Neurosurg., Univ. Tex. Med. Sch., Houston, TX 77030 and Dept. Pharm., Temple Univ. Sch. Med., Philadelphia, PA 19140.

Chronic intravenous self-administration of morphine by male Sprague Dawley rats (200-225 grams) was achieved after a 4-day schedule employing automatic hourly infusions of morphine sulfate (in a volume of 0.2 ml.) through a cannula inserted into the right external jugular vein. The cumulative daily dose of morphine during the 4-day schedule was 48, 72, 120 and 192 mg./kg. respectively. On day 5 the infusions were programmed for self-administration (activated by pressing a lever by the animal) on an FR 1 schedule for 5 days and then an FR 3 schedule. After 5 days on the FR 3 schedule the rats were subjected to abrupt withdrawal by substituting Ringer's solution for morphine. Behavioral features exhibited during the period of withdrawal were measured 24 and 48 hours after abrupt withdrawal.

The lever presses and infusions were tabulated. The body weight of each animal was monitored daily. Rats which self-administered morphine tended to press the lever considerably more frequently than necessary for the number of infusions recorded. A difference in the means of the daily lever presses of the morphine group compared to the control group became significant at the 0.05 level on the third day of self-administration and at the 0.01 level the fourth day of the FR 1 schedule. The significance increased to the 0.005 level after the start of the FR 3 schedule. Withdrawal symptoms were more pronounced at 24 hours when compared to 48 hours after abrupt withdrawal of morphine. The most prominent symptoms of abrupt morphine withdrawal were teeth chatter, diarrhea, rapid breathing, ptosis and loss of body weight (mean 14.9% ± 3.4 S.D.).

932 CARDIOVASCULAR AND VENTILATORY EFFECTS OF METHIONINE AND LEUCINE ENKEPHALINS ADMINISTERED BY INTRAVENOUS OR CLOSE-ARTERIAL INJECTION IN THE CAT. A.H.Hassen and M.K.Kindred*. Div. Allied Health & Life Sciences, Univ. of Texas, San Antonio, TX 78285.

Enkephalins are endogenous ligands for the morphine receptor. The effects of systemically or locally administered enkephalins upon various physiologic parameters have been examined in a variety of animal species. These studies have demonstrated similarities and differences in the responses to enkephalins as compared with the responses to morphine. As part of an on-going study of the actions of narcotics on brainstem regulation of autonomic activity, we have examined the cardiovascular (CV) and ventilatory (VENT) responses produced by MET- and LEU-enkephalin. In order to describe in a more precise manner the nature of enkephalin activity, these compounds were administered both systemically, and locally to the brainstem. All experiments were performed on decerebrate cats. Ventilation was monitored by means of a pneumotachograph connected to a tracheal cannula, providing direct measurements of ventilatory flow and rate. Tidal volume was derived from the integrated flow using a Narco GPA-10 Integrator. Blood pressure was monitored from the RT femoral artery. Systemic injections were made via an indwelling cannula, into the RT femoral vein. Close-arterial injections were made via an indwelling cannula into the subclavian artery, with all branches except the vertebral ligated. Systemic administration of enkephalins (2.0mg/kg) produced a drop in both diastolic and systolic blood pressures. These changes frequently were associated with bradycardia. VENT responses were variable among the different animals. In general, CV responses were much more consistant than VENT responses. All responses were of short duration (less than 5 minutes) and could be blocked by prior administration of Naloxone (0.2mg/kg). Close-arterial injection of enkephalins (0.25-1.0mg/kg) produced responses comparable to those observed following systemic injection, but at 12% to 50% of the systemic dose. CV responses were again more consistant and of longer duration than VENT responses. While the injection of enkephalins consistantly produced a predictable CV response, with morphine the predictable response was ventilatory.

In conclusion, it is noted that enkephalins alter CV and VENT activity in the cat, in a manner different from morphine, and appear to do so primarily as a result of an effect on central brainstem mechanisms.

933 INDUCTION OF LIMBIC SEIZURES BY ENDORPHINS AND OPIATE ALKALOIDS: ELECTROPHYSIOLOGICAL AND BEHAVIORAL CORRELATES. S. J. Henriksen, F. E. Bloom, N. Ling* and R. Guillemin. The Salk Inst., La Jolla, CA 92037.

Rats were prepared with cortical and subcortical electrode arrays and chronic indwelling ventricular cannulae. Following at least 3 days recovery from surgery, beta-endorphin (BE), ($D\text{-}Ala^2$)-Met^5-enk amide (DAME), a potent enkephalin derivative, and opiate alkaloids all precipitated complex limbic seizures in unrestrained rats when injected in nanomolar (nM) doses. Beta-endorphin (5-10 nM) precipitates multiple ictal spiking episodes (duration 30-90 sec.), starting 90 sec. to 2 min. following the injection. During these ictal episodes high frequency spike discharges are observed simultaneously in the dorsal hippocampus, amygdala, and other limbic loci. Behaviorally, the animals maintain a frozen posture, stare, chew, and occasionally orient rapidly, but no frank convulsions are observed. The ictal episodes are also punctuated by violent shaking of the torso ("wet-dog-shakes"). Following the initial ictal episodes, animals show increased exploration with constant sniffing. Multiple ictal episodes are followed by tonic inter-ictal spike activity in the amygdala and hippocampus at a spike frequency of 10-20/min. Fifteen to thirty min. post injection high amplitude cortical slow-waves dominate the EEG, and analgesia (corneal reflex and tail pinch) develops with catatonia soon ensuing. Inter-ictal spiking continues during the entire catatonic episode lasting for up to 6 hrs. Lower doses of BE (< 3 nM) produce little or no analgesia nor catatonia, but ictal and inter-ictal spiking episodes persist. Using equimolar (3×10^{-9}M) doses, BE produces the most prolonged seizure episodes with DAME-amide and morphine sulfate producing correspondingly less potent effects. Naloxone (1-2 mg/kg, I.P.) results in a rapid but temporary reversal of the behavioral and electrographic signs. These results suggest that opiates and endorphin peptides produce profound and lasting electrophysiologic disturbances in limbic structures at doses below the threshold for their anti-nociceptive actions.

Supported by grant number NIDA-01785, NICHD-09690 and NIAMDD-18811. S.J.H. is a recipient of a Sloan Foundation Fellowship in the Neurosciences.

934 NALOXONE EXCITATION OF DORSAL HORN UNITS IN THE SPINAL CAT. James L. Henry. Dept. of Research in Anaesthesia, McGill University, Montreal, P.Q. Canada. H3G 1Y6

Naloxone has been shown to have actions in the central nervous system independent of those as an antagonist of centrally or systemically administered opiates. This has led to the suggestion that these actions are due to an antagonism of endogenous opioid substances, likely peptides, which are being released continuously. Microiontophoretic studies have demonstrated an action of opiates and of endogenous opioid peptides in the spinal cord, and other studies have revealed the abundance in the spinal cord of stereospecific "opiate receptors". Thus the endogenous opioids may be released in the spinal cord and depress activity in nociceptive pathways. The following investigation was done therefore to see whether naloxone modifies the activity of spinal nociceptive neurones. Cats were anaesthetised with alpha-chloralose (60 mg/kg). The spinal cords were transected at the level of the first lumbar vertebra and segments L5-L7 were exposed for recording. Extracellular unit spikes were recorded using glass micropipettes filled with 2.7 M NaCl. Single units responding in a reproducible way to regular periodic applications of noxious radiant heat were selected for study. The intravenous administration of naloxone (0.05-0.1 mg/kg) caused an increase in the on-going discharge rate of all units tested. This effect began within one minute, reached its maximum at three to five minutes and persisted for more than one hour. In addition, naloxone facilitated the response to noxious heat. This facilitation followed a similar time course to the increase in ongoing activity. These observations support the suggestion that an endogenous opioid is being continuously released in the spinal cord which reduces transmission of nociceptive information at this level. However, these experiments do not exclude the possibility that naloxone itself may be causing excitation in spinal nociceptive pathways, perhaps as an opiate agonist.

(Supported by grants from the Quebec MRC and the Canadian MRC.)

935 AMPHETAMINE-ETHANOL INTERACTION ON ACTIVITY AND MAZE PERFORMANCE IN RATS. Joan A. Holloway Dept. of Psychiatry and Behavioral Sciences, Univ. of Okla. Health Sciences Center, Oklahoma City, Oklahoma 73190.

The effects of single or combined doses of d-amphetamine sulfate and ethanol were studied in rats. Jiggle platform activity as well as photocell activity counts were measured simultaneously. Additionally, performance on a previously learned Y-maze-discrimination-avoidance-task was measured. Measurements were taken after drug administration at two times in the 24 hour light-dark cycle, at the peak circadian susceptibility to amphetamine and when susceptibility had fallen off sharply.

Results indicated a significant drug interaction as well as a significant drug by time-of-administration effect for activity measures. The results were different for the two activity measures. Photocell measurements were best at differentiating between ethanol and ethanol-amphetamine combinations and jiggle platform measurements were best at differentiating between amphetamine and ethanol-amphetamine combinations.

Performance measures further indicated a drug interaction. Performance was best with low-dose combinations of the drugs compared to single administration of the same drugs as reflected by number of correct avoidance responses and start latencies.

These data indicated that the drug interaction between ethanol and amphetamine was not antagonistic but synergistic at low doses and the extent of the interaction depended on the time in the light-dark cycle the drugs were administered.

936 INCREASE IN STRIATAL METHIONINE ENKEPHALIN CONTENT CAUSED BY CHRONIC ADMINISTRATION OF CATALEPTOGENIC ANTIPSYCHOTICS. J. S. Hong*, H.-Y. T. Yang*, W. Fratta* and E. Costa. Lab. Preclin. Pharmacol., NIMH, Saint Elizabeths Hosp., Washington, D.C. 20032.

In an attempt to obtain some indication on the regulation of met-enkephalin containing neurons by other neuronal systems, antipsychotic drugs were chronically administered to rats for 7 to 21 days and met-enkephalin content of striatum and hypothalamus was determined by radioimmunoassay. Acute administrations of haloperidol (1 mg/kg) failed to alter met-enkephalin levels. Following chronic treatment with haloperidol (1 mg/kg, twice daily), the met-enkephalin concentration in striatum gradually increased from 10 ng/mg protein (control) to 14 ng/mg (one week), 17 ng/mg (two weeks) and 20 ng/mg (3 weeks). In the same rats, neither hypothalamic met-enkephalin nor striatal substance P content was changed. This supports the possibility that the increase in striatal met-enkephalin content elicited by haloperidol is specific. An increase of met-enkephalin concentration in striatum was also observed after two weeks chronic administration of pimozide (0.75 mg/kg) or chlorpromazine (3.0 mg/kg). On the other hand, chronic treatment with a non-cataleptogenic antipsychotic, clozapine (5.0 mg/kg), failed to change striatal met-enkephalin content. The selective increase of striatal met-enkephalin content which appears after chronic, but not acute, haloperidol treatment and fails to appear after chronic treatment with a non-cataleptogenic antipsychotic suggests that a relationship may exist between tolerance to extrapyramidal side effects, supersensitivity of DA receptors to the agonist and striatal met-enkephalin content.

937 β-ENDORPHIN: DEVELOPMENT OF TOLERANCE AND ITS REVERSAL BY 5-HYDROXYTRYPTOPHAN IN CAT. Y. Hosobuchi*, J. Meglio*, and C.H. Li*. Dept. of Neurosurg. and Hormone Research Lab., Univ. of Calif., San Francisco, CA 94143.

β-endorphin is a potent analgesia when administered intraventricularly (icv) in cat. Repeated injections of this peptide produce acute tolerance, as well as cross-tolerance to morphine. This study was undertaken to analyze the development of tolerance to β-endorphin in cat, and the reversal of tolerance by systemic administration of the serantonin precursor, 5-hydroxytryptophan (5-HTP). Synthetic β-endorphin was administered icv through stereotactically placed third-ventricle cannulas. The extent or absence of analgesia was determined by stimulating tooth pulp and measuring the jaw opening reflex (JOR), and by observing the response to pinches applied with a tooth forceps to the cat's tail, limbs, and ears. In all cats, 25 μg β-endorphin icv was the minimum effective dose (MED) required for analgesia. Acute tolerance was observed when administration of β-endorphin was repeated within the first 24 hr, even if the initial dose administered was below MED (12.5 μg) or if the second was above MED (50 μg). The analgesic effect returned to its original potency if the second dose was administered after 48 hr.

In four cats, 50 μg β-endorphin was injected icv within 24 hr after an initial injection of 25 μg (MED); no analgesic effect was observed, although behavioral alterations occurred. Tests made for 1 hr after the second injection confirmed that there was no delayed analgesic response. 5-HTP (10 mg/kg) then was administered intraperitoneally (ip) to these cats. Within 10 min, a marked analgesic effect was noted in the response of all four cats to JOR and peripheral pinch tests; the effect generally lasted 3-6 hr. When 5-HTP was injected 40-60 min after icv administration of 12.5 μg (below MED) β-endorphin, a 3- to 4-fold increase in JOR and decreased or absent responses to pinch were observed. The analgesic effect was totally reversed by naloxone.

These results confirm our previous observations that a single icv administration of β-endorphin produces acute tolerance to its analgesic effect in cat. They show that tolerance is reversed by systemic administration of 5-HTP, which also potentiates the analgesic effect of β-endorphin. Several investigators report that 5-HTP has similar effects in reducing development of tolerance to, and potentiating the analgesic action of, morphine in mice.

Since 5-HTP is known to elevate intracerebral seratonin content, our results suggest that analgesia produced by β-endorphin may be related to activation of a seratonergic pathway. If the first dose of β-endorphin produces reduction of seratonin in a given brain area, a second dose might be expected to be ineffective; its effect could be restored by administration of the seratonin precursor, 5-HTP.

938 STEREOSPECIFIC AND NON-STEREOSPECIFIC EFFECTS OF (+) AND (-) MORPHINE. Yasuko F. Jacquet, Werner A. Klee*, Kenner C. Rice* and Ikuo Iijima*. NY State Res. Institute for Neurochem., Ward's Isl., NY 10035, and NIMH and NIAMDD, Bethesda, Md 20014.

Unnatural (+)-morphine synthesized from natural (-)-sinomenine was evaluated in several standard opiate assay systems to ascertain whether all opiate actions are mediated by stereospecific receptors. In 3 in vitro assays, i.e., binding to rat brain homogenates, inhibition of adenylate cyclase activity in neuroblastoma x glioma hybrid cell homogenates, and inhibition of electrically-induced contraction of the guinea pig ileum, the unnatural (+)-morphine had no activity either as agonist or antagonist. Microinjection of 80 ug of (+)-morphine into the periaqueductal gray (PAG) of unanesthetized rats resulted in at most weak analgesia, and did not abolish the corneal reflex. However, the explosive motor behavior usually seen following microinjection of natural morphine was observed at this dose of unnatural morphine. This high dose of (+)-morphine added to a standard dose (10 ug) of (-)-morphine injected into the PAG, or naloxone given intraperitoneally (10-mg/kg) resulted in some deaths. Thus, the toxic effects of morphine in the PAG appear to be non-stereospecific. Microinjection of (+)-morphine into the midbrain reticular formation (a site previously shown to mediate potent and morphine-specific rotation of up to 2-3/sec (Jacquet, Carol and Russell, Science 192:261, 1976) which was not blocked, reversed or mimicked by naloxone injected locally or intraperitoneally) also resulted in a dose-dependent, non-naloxone reversible rotation behavior. These results indicate the existence in the CNS of at least 2 classes of opioid receptors, one which stereospecifically mediates analgesia and is reversible by naloxone, and another which is not stereospecific and not blocked by naloxone. Furthermore, the receptors assayed in the in vitro assay systems, i.e., brain homogenate binding assay, the cyclase inhibition assay and the guinea pig ileum assay, appear to be of the former class.

939 COCAINE LEVELS IN PLASMA AND RED BLOOD CELLS AFTER INTRAVENOUS AND INTRANASAL ADMINISTRATION IN MAN. J. I. Javaid, M.W. Fischman*, J. M. Davis, H. Dekirmenjian, and C. R. Schuster*. Ill. State Psychiatric Inst., Chicago, Ill. 60612 and University of Chicago, Ill. 60637

Cocaine is a short acting central stimulant, the pharmacology of which has not been studied in man. In the present studies cocaine Hcl was inhaled intranasaly (i.n.) or dissolved in physiological saline and injected intravenously (i.v.) over a period of one minute to adults with a long history of illicit intravenous cocaine use. All subjects signed a consent form which indicated that psychomotor stimulant drugs would be administered. Blood samples were withdrawn at different time intervals following different doses of drug administration and processed immediately for cocaine levels. Cocaine was determined by gas chromatography using an electron capture detector. Systolic and diastolic blood pressure were monitored on an Automatic Blood Pressure Monitor. Subjective effects of the drug were measured by the stimulant sections of the Addiction Research Center Inventory (ARCI) questionnaire and the Profile of Mood Scales (POMS). Cocaine levels were correlated to subjective and physiological responses.

Peak plasma and RBC levels were reached in five minutes after i.v. administration with RBC to plasma ratio of greater than one. Peak plasma levels after 16 mg i.v. administration were 221±41 ng/ml (n = 12) with a range of 120-586 ng/ml. After 32 mg i.v. administration the peak plasma levels were 283±23 ng/ml (n = 8) and ranged between 207-409 ng/ml. Increase in heart rate, blood pressure and subjective ratings was dose related although the onset of action did not have any relation to dose. There was a positive relationship between plasma levels and subjective ratings at both doses.

The individuals with higher peak levels at a given dose generally gave higher subjective response compared to the subjects who had lower peak levels at the same dose.

Peak plasma levels after i.n. administration of cocaine were reached in 10 to 60 minutes and ranged between 21-75 ng/ml at 16 mg dose; 106-276 ng/ml at 32 mg dose; 181-195 ng/ml at 64 mg dose and 129-296 ng/ml at 96 mg dose. The time of peak plasma level after i.n. administration correlated with the peak level of subjective response. Significant amounts of cocaine were present at higher doses even 2 hours after i.n. administration (156±64, n=2, at 96 mg dose).

940 LONG TERM SUPPRESSION OF NARCOTIC DEPENDENCY IN THE PRIMATE. Frederick W. L. Kerr. Dept. Neuro. Surg., Mayo Foundation, Rochester, MN 55901.

Macaque monkeys maintained in restraint chairs were trained to self-administer morphine (M.S.) by bar pressing on a fixed ratio of 10:1; each cycle provided 10 mg M.S. via a spring loaded self-refilling syringe connected to a right atrial catheter. They also obtained 1 gm food pellets on a 10:1 ratio. Dependence on morphine reached levels which were relatively stable for individual animals of 250 to 500 mg/day or approximately 60 to 125 mg/Kg B.W./day.

Intense withdrawal signs, graded on a 0 to 4+ scale, were precipitated by administration of naloxone, or by withholding morphine.

Fine cannulae were then implanted stereotaxically and under X-ray control in the lateral hypothalamus bilaterally and 7 to 10 days later 6-OHDA administered in doses of 50 to 125 μg on each side.

In all instances in which the cannulae were correctly positioned a pronounced fall in morphine demand occurred. However, to obtain complete suppression it was necessary to vary the position of the cannulae over a vertical distance of 2 to 2.5 mm and administer 6-OHDA on repeated occasions, demand for morphine decreasing in a stepwise manner with each successful injection.

Demand for food pellets dropped in parallel with that for narcotics, but after 2 to 3 days of anorexia, recovered progressively and returned to normal levels.

Complete suppression of narcotic dependence has been obtained in two monkeys, the effect persisting at 4 and 9 months after the lesions were completed. Both animals appeared to be neurologically intact and showed normal behavioral patterns when placed in a group situation. Growth hormone and prolactin levels in blood were within the normal range. Reduction of dependence to less than 10% of prelesional levels was obtained in other monkeys. Whether the 6-OHDA effect is specific or non-specific is uncertain in view of the doses employed.

941 MORPHINE EFFECTS ON THREE TYPES OF AVERSIVE MIDBRAIN STIMULATION IN RATS. R.S. Kiser, D.C. German, and R.M. Lebovitz. Depts. of Psychiat. & Phys., Univ. of Texas Health Sci. Cntr., Dallas, TX 75235.

The present study examined the effects of morphine and its antagonist, naloxone, on decremental bar-pressing performance in rats stimulated at three aversive midbrain sites. The three types of aversion can be differentiated on the basis of stimulation site and the elicited gross behavior. One type of aversion is produced by stimulation in the dorsal central gray (DCG) area. Stimulation here produces frantic rearing, jumping, and running, along with attempts to escape the behavioral chamber. Another aversive site is located in the ventral reticular formation (VRF), ventrolateral to the central gray area. VRF stimulation induces a stereotyped circling behavior, usually ipsiversive. A third type of aversive behavior is elicited from the dorsolateral tegmentum (DLT). DLT stimulation produces wincing, shaking, and shuddering behavior often accompanied by whimpering and crying. Rats stimulated at these sites can be trained to bar press for escape in a decremental bar-pressing paradigm. In this paradigm, each bar press decrements the stimulation current by 5% of its initial level. Rats were implanted with a bipolar stimulating electrode in one of the aversive midbrain sites described above and trained in decremental bar pressing. The brain stimulation consisted of 100 msec. duration trains of negative square wave pulses (0.5 msec. pulse duration, 60 Hz, capacity coupled) at the rate of 5 trains per second. Mean current intensities at all 3 sites was approximately 10-15 μa, RMS. Immediately after acquisition of baseline decremental bar-pressing performance, DCG, VRF, and DLT rats were injected intraperitoneally with either morphine (15 mg/kg), naloxone (2 mg/kg), morphine (15 mg/kg) and naloxone (2 mg/kg), or normal saline. The effects of the injections on decremental bar-pressing performance were assessed in data runs one hour later. In subsequent experiments separated by at least one week, all animals eventually received all of these injections in random order. No change in bar-pressing performance was seen in the saline-injected control animals. Morphine given alone inhibited decremental bar pressing in all three classes of animals, and naloxone alone had no effect. Naloxone given with morphine, however, blocked the inhibitory effect of morphine in all three groups. At no time were signs of impairment of motor function or level of consciousness observed. These results suggest that the antinociceptive effects of opiates are complex and involve multiple aversive neural systems.

942 OPIATE-LIKE, NALOXONE-REVERSIBLE EFFECTS OF ANDROSTERONE SULFATE IN RATS. F. S. LaBella, V. Havlicek, C. Pinsky* and L. Leybin* Dept. of Pharmacol. and Ther. and Dept. of Physiol., Univ. of Man. Fac. of Med., Winnipeg, Canada, R3E 0W3.

Androsterone, androstan-5a-3a-ol-17-one (A), androsterone-3-SO_4 (AS), and some related compounds show weak binding (IC_{50} = 10^{-5}M) to the opiate receptor, in contrast to 150 steroids which are completely inactive. The in vitro Na effect indicates A to be an antagonist and AS an agonist. AS was infused over 5 min in 10 ul of 10% ethanol in saline to male rats via intracerebroventricular (ICV) cannulae with simultaneous EEG recording. The vehicle was inactive even at 25 ul. Less than 1 ug AS (3 nmoles) was threshold for EEG changes and slight behavioral effects. 3 ug caused EEG seizure activity in all animals and motor seizures in some; this dose also caused Straub tail, wet dog shakes, teeth chattering, circling, hypermotility, and hyperreactivity to auditory and tactile stimuli. 10 and 25 ug AS in most animals caused violent tonic seizures, and escape behavior and extreme aggression persisting for several hours. 5 and 10 ug promoted analgesia in the hot plate test. These effects of AS were reversed or blocked by naloxone (NAL). NAL given ICV inconsistently diminished drug-induced EEG or behavioral responses, and large doses were required to antagonize analgesia. However, pretreatment with NAL (5 mg/kg) given i.p. 15 min prior to AS consistently antagonized the steroid. Within 30 min after AS the NAL pretreated rats were asleep, with corresponding slow wave sleep or REM pattern of the EEG and having demonstrated little or no EEG or behavior changes. In contrast, saline pretreated animals showed the full blown opiate-like syndrome over the entire period of observation. This study supports our hypothesis that opiates and steroids share a common mechanism of action in the CNS (Life Sci. 16: 1783; 16: 1785, 1975). We find that 2 ug beta-endorphin given ICV produces similar behavioral and EEG effects but no motor seizures. Higher doses of the peptide, 10 and 50 ug, yield EEG hypersynchrony and catatonia rather than electrical and behavioral seizures seen with AS. Epiandrosterone, androstan-5a-3b-ol-17-one-3-SO_4 (ES), is considerably more potent than AS and promotes more violent seizures and aggression. NAL reversal of ES has not been tested. 10 ug of 17b-estradiol-3-SO_4 or androst-4-ene-3-one-17b-SO_4 were inactive. Results with AS resemble findings on somatostatin which shows weak in vitro but potent in vivo opiate activity and is blocked by NAL. AS may act on a family of receptors distinct from those binding recognized morphine-like compounds and/or it may mobilize endogenous opiates. (Supported by MRC, Non-Medical Use of Drugs Directorate, and the Sellers Foundation).

943 MORPHINE AND SHUTTLE-BOX SELF-STIMULATION IN THE RAT. Robert A. Levitt, John H. Baltzer, Timothy M. Evers, Donald J. Stilwell*, and John E. Furby*. Dept. Psychol. and Sch. Med., Southern Ill. Univ., Carbondale, IL 62901

One interesting apparatus for the study of narcotic drug effects on SS is the shuttle-box. In this apparatus the animal moves back and forth across a cage to turn brain stimulation on and off. The animals not only self-regulate the time of onset of ON and OFF periods, but also the duration of such periods. This type of SS may be particularly sensitive to the interaction of the rewarding and aversive components of brain stimulation.

Adult rats served as subjects. Each animal was implanted with one electrode in the lateral hypothalamic area. Testing occurred in cages measuring 35x20x20cm, set on a fulcrum at the center, and with a microswitch under one end. Electrical stimulation was provided by a square wave stimulator. Beginning one week after surgery, animals were tested in the shuttle-box for 90 minutes a day on six consecutive days. Mean ON and OFF times during each of the nine-ten minute periods per day were recorded. On days 2, 4, and 6 additional control 90-minute self-stimulation tests were given in the shuttle-box. On days 3 and 5 animals received drug injections immediately before being placed in the shuttle-box. Half of the animals received a dose of morphine on day 3 and isotonic sodium chloride solution on day 5; for the other half of the animals this order of treatments was reversed. Eight animals each were run at the 1.0, 2.5, 5.0, 10.0, and 20.0 mg/kg doses.

Control ON times averaged about ten seconds, while OFF times averaged about two seconds. Sodium chloride injections, and the injections of 1.0 or 2.5 mg/kg morphine did not significantly affect the animal's shuttling behavior. Injections of 5.0 or 10.0 mg/kg morphine, however, increased average ON time, while having little effect on OFF time (90 minute average; 5 mg/kg: ON time = 21 seconds, OFF time = 2 seconds; 10 mg/kg: ON time = 21 seconds, OFF time = 2 seconds). Injections of 20 mg/kg produced an even further increase in average ON time (64 seconds), together with a similar large increase in average OFF time (70 seconds). These findings were confirmed statistically.

In this shuttle-box SS paradigm analgesic doses of morphine (5 or 10 mg/kg) produced a large increase in the amount of time the animals left the stimulation on, without affecting OFF times. When coupled with the evidence that animals turn off initially-rewarding brain stimulation because it becomes aversive, we wish to suggest the notion that morphine enhances brain stimulation reward by inhibiting its aversive component. This action of morphine on shuttle-box self-stimulation in the rat may also prove to be a useful model for the mood-enhancing action of narcotic drugs in the human.

944 SIGNAL DETECTION THEORY ANALYSIS OF NOCICEPTION IN RHESUS MONKEYS. Charles G. Lineberry and Albert T. Kulics. Dept. Pharmacol., Sch. Med., Univ. of Pittsburgh, Pgh. PA 15261

In previous work, we have demonstrated a signal detection theory (SDT) model for assessing sensory functions in rhesus monkeys, and evaluated this model in direct comparisons between human and monkey subjects engaged in the same experimental task. SDT analysis of discrimination performance provided relative operating characteristic (ROC) functions and sensory sensitivity estimates (d' and d'_e) which were virtually identical for both species. This approach was used to determine the effects of morphine, diazepam, local injections of lidocaine and the presentation of conditioned stimuli on responses to noxious electrical cutaneous stimulation in rhesus monkeys. The conditioned stimuli were designed to be analogous to the implicit instructions that accompany placebo administration in humans. Separate groups of subjects were trained to either discriminate between noxious stimulus intensities in a go, no-go discrimination task, or to rate stimuli according to noxiousness by responding to terminate stimulation in an intensity rating task. Binary decision probabilities and response latencies (used as certainty ratings) were used in the discrimination task, and escape probabilities and response latencies (used as intensity ratings) were used in the intensity rating task to construct ROC functions. These ROC functions were used to obtain estimates of pain sensitivity (d') and response bias (β).

Estimates of d' were obtained for both tasks which: a) reliably reflected stimulus intensity differences, b) varied little within subjects upon replications in control sessions, and c) were insensitive to large differences in response bias (overall response tendency) that were observed within and between subjects. Diazepam (.125 and .250 mg/kg), lidocaine (1 and 2%) and the conditioned placebo stimuli reduced the tendency for subjects to respond to noxious stimuli (i.e., produced a change in response bias). Morphine (.125 to .500 mg/kg) had minimal effects on response bias (in general slightly increased responding) and none on pain sensitivity. Only lidocaine was effective in reducing pain sensitivity.

These studies demonstrate that psychophysical measures of pain perception can be obtained in monkeys using SDT techniques that: a) are directly analogous to those used in human subjects, and b) are capable of distinguishing manipulations which affect pain perception from those that affect only the response to pain.

945 UNIT RESPONSES OF MEDIAL THALAMUS TO LOW DOSES OF MORPHINE AND NALOXONE IN DRUG-NAIVE AND MORPHINE-DEPENDENT RATS.
M. A. Linseman and L. A. Grupp. Addiction Research Foundation and Department of Pharmacology, University of Toronto, Toronto, Canada.

Previous lesion (Teitelbaum et al., Science 185, 1974) and chemical stimulation studies (Wei et al., Science 177, 1972) have pointed to the possible importance of the medial thalamic area in morphine tolerance and physical dependence. In the present study, the spontaneous activity of medial thalamic units was recorded prior to and following an i.v. injection of 0.625 mg/kg morphine (M) in drug-naive, chronically-prepared, paralyzed rats. Previous experiments established this dose to be near threshold for producing a change in spontaneous firing rate. Of the 15 units studied successfully, 14 showed a decrease in rate in response to morphine with one showing no change. This decrease in firing rate generally began to occur about one minute following the beginning of the drug injection (duration=30 sec.), with recovery beginning between 10 and 30 min. post-injection. In 13 of the 15 units, a decrease was evident prior to appearance of spindle-like activity in the simultaneously recorded fronto-cortical EEG. A dose of 0.1 mg/kg naloxone, which was sufficient to reverse morphine-induced depression, by itself had no effect on unit rate. In the case of 3 units, a second injection of the same dose was given following recovery from the first. A smaller decrease in firing rate and a shorter duration of response indicated that some tolerance had developed to the drug.

When the unit responses to 0.625 mg/kg M were compared to those of 8 previously recorded responses to 5 mg/kg M, it was found that while the maximum decrease in unit rate was not different, the degree to which the EEG changed was greater at the higher dose. This suggests that the medial thalamic units were near maximally affected at 0.625 mg/kg M, and that additional elements were affected at the higher dose to contribute to the increased EEG response.

Preliminary data from morphine-dependent animals (1-75 mg pellet implanted s.c. for 3 days), indicates that the threshold dose of naloxone required to produce an increase in medial thalamic unit activity is near 0.025 mg/kg. However, doses below this have nevertheless been effective in reversing the high amplitude fronto-cortical EEG to continuous fast activity, suggesting that at least this effect might be mediated by factors other than a change in frequency of medial thalamic units.

946 EFFECTS OF PAIN, AND THE IONTOPHORESIS OF MORPHINE AND ACETYLCHOLINE ON NEURONS IN RAT NUCLEUS RAPHE MAGNUS.
Michael Lobatz*, Herbert K. Proudfit and Edmund G. Anderson. Dept. Pharmacol., Univ. Ill. Med. Ctr., Chicago, IL 60612.

The involvement of the nucleus raphe magnus (NRM) in pain and opiate analgesia is indicated by the blockade of morphine (M) analgesia following destruction of the NRM in the rat (Proudfit and Anderson, Brain Res. 98, 612, 1975). In examining nocisponsive neurons in the cat NRM we observed that iontophoretically applied M did not alter unit nocisponsiveness or baseline spontaneous activity, but systemic opiates did affect activity (Lobatz et al., Pharmacologist 18, 213, 1976). These findings suggest that, in the cat, M does not act directly on the NRM. To determine if NRM neurons in the rat react to pain and opiate analgesics in a similar manner, spontaneously active NRM units of intact, urethane-anesthetized rats were recorded, and frequency changes were measured following a painful pinch and iontophoretically applied M. Seventy-four % of the tested units responded to pinch. Of those responding, 87% were facilitated and 13% were inhibited. Morphine (25-100 nA) altered baseline activity in 61% (of those altered, 57% were facilitated and 43% were inhibited) and blocked pinch in 47% of the nocisponsive NRM units. These data show that rat NRM neurons are affected by noxious stimulation and the direct application of M. The effect of M is in contrast to data previously obtained in the cat and may reflect a species difference. Since acetylcholine (ACh) may play a role in M analgesia (see review by Mehta, Neuropharmacology 14, 893, 1975), we examined the effects of iontophoretic ACh on rat NRM neurons and its interaction with M. It was observed that iontophoretically applied ACh excited 85% of the nocisponsive NRM neurons, but the application of M did not block the ACh response. These data indicate that the NRM cells are highly responsive to ACh, and that M does not block this action. (Supported by USPHS Grant NS 12649.)

947 ROLE OF THE BLOOD-CEREBROSPINAL FLUID BARRIER IN THE DEVELOPMENT OF TOLERANCE TO THE RESPIRATORY DEPRESSANT EFFECTS OF MORPHINE.
J. Douglas Mann,* Elizabeth Young,* and Norman H. Bass. Department of Neurology, University of Virginia 22901 and University of North Carolina 27514.

Tidal volume, respiratory rate, and minute volume were measured during continuous intravenous infusion of morphine sulfate (0.4 mg/kg/min) in morphine tolerant (10 day incrementing dose schedule reaching 400 mg/kg/day), naloxone pretreated (0.5 mg/kg, IV), and naive adult albino rats. After ten minutes of intravenous infusion, naive controls showed a depression in respiratory function while tolerant and naloxone pretreated animals were resistant to this morphine-induced effect. Respiratory depression in naive animals appeared to be regulated via a transport site in the choroid plexus which allowed nanomole amounts of morphine to penetrate into CSF and then by diffusion, into periventricular opiate receptors in brain stem. Tolerant rats showed a blockade of morphine-induced respiratory depression associated with a 48% decrease in the rate of penetration of the opiate into both CSF and brain stem. A similar pharmacologic change was not found in naloxone-pretreated animals, although complete blockade of morphine-induced respiratory depression was observed. Although tolerance to the respiratory depressant effects of morphine was completely abolished by intraventricular infusion, showing a profile similar to that seen in naive controls, this direct route of opiate administration failed to depress respiratory function in animals pretreated with naloxone.

In conclusion, evidence has been obtained suggesting that tolerance to the CNS respiratory depressant effects of morphine may be mediated, at least in part, by active transport sites regulating penetration of the drug from plasma into the CSF system, thereby decreasing access of nanomole amounts of the opiate to receptor sites of respiratory neurons located near the subependymal zone at the floor of the IVth ventricle. Naloxone, although successfully blocking morphine-induced respiratory depression does not appear to exert its effect on the blood-CSF barrier, but presumably either displaces the opiate from the receptor site or changes the agonist configuration of such receptors on brain stem respiratory neurons.

948 ENKEPHALIN AND ENDORPHIN BREAKDOWN: STRUCTURE-ACTIVITY RELATIONSHIPS USING D-AMINO ACID ANALOGS.
Neville Marks* Alice Grynbaum. Institute for Neurochemistry and Drug Addiction Rockland Res. Institute. Ward's Island, N.Y. 10035.

The analgesic potency of endorphin (LPH 61-91) has been attributed to its relatively slower breakdown as compared to shorter enkephalin (LPH 61-65) sequences (Jacquet and Marks, Science 194, 632, 1976). To provide direct evidence for this we compared breakdown of analogs stabilized against degradation with activity in vivo following intracisternal injection. Analogs used in this study were:

Tyr-D-Ala-Gly-Phe-Met	Tyr-D-Ala-Gly-Phe-Met.NH_2
Tyr-Gly-D-Ala-Phe-Met	Tyr-Gly-Gly-Phe-Met.NH_2
Tyr-Gly-Gly-D-Phe-Met	D-Ala^2-LPH 61-76 (α-endorphin)
Tyr-Gly-Gly-Phe-D-Met	D-Ala^2-LPH 61-77 (γ-endorphin)
	D-Ala^2-LPH 61-91 (β-endorphin)

Peptides were incubated with an ultrafiltrate of mouse brain and breakdown products separated on columns or polyamide sheets as previously described (Marks, Grynbaum and Neidle, BBRC 74, 1552, 1977).

Enkephalins: at shorter incubation brain aminopeptidases were blocked by D-Alanine in position 2 but not in position 3, or with D-Phe in position 4, and D-Met in position 5. Substitution in positions 3-5 blocked action by carboxypeptidases but not that of aminopeptidases. The presence of Met.NH_2 retarded C-terminal cleavage but in combination with D-Ala gave a peptide that was completely resistant to hydrolysis by brain enzymes. Injection of this analog 125 μg (100 g nonanesthetized rat) induced analgesia reversible by naloxone (2 mg/Kg) but with no overt behavioral changes. These data unequivocally show that biodegradation is an important factor in evaluating the activity of enkephalins in vivo since unsubstituted peptide was without marked effects.

Endorphins: insertion of D-Ala in position 2 of endorphins retarded the release of Tyr at short incubation periods but failed to block release of Tyr from β-endorphin at longer periods. For α- and γ-endorphins the pattern of release indicated action by carboxypeptidases at long (60 min) but not at short (5 min) incubation periods. In the case of β-endorphin the low yield of Gln and Gly indicated that the C-terminal is not readily susceptible to action by brain carboxypeptidases present in soluble extracts. D-Ala^2-endorphin when injected intracisternally in low doses gave a marked analgesic response accompanied by catatonia. Intraperitoneal injection of naloxone reversed these effects and resulted in wet-dog shaking behavior.

Supported in part by grant NIH NS-12578.

949 AGE AND GENOTYPE DEPENDENT CHANGES IN MORPHINE INDUCED LOCOMOTOR ACTIVITY AND BRAIN HISTAMINE LEVELS. David E. McClain*, George N. Catravas and Herman Teitelbaum. Biochemistry Department, Armed Forces Radiobiology Research Institute, Bethesda, MD 20014.

Previous work (Lee and Fennessy, J. Clin. Exp. Pharm. Physiol. 3:179, 1976) has shown an inverse relationship between morphine induced changes in brain histamine levels and changes in locomotor activity in the same mouse strain (Commonwealth Serum Laboratories). We have been able to confirm this relationship using the C57BL/6J and DBA/2J strains of inbred mice approximately three months of age.

Morphine produces a dose dependent decrease in histamine levels in the C57BL/6J strain associated with a dose dependent increase in locomotor activity; in contrast, increased histamine levels and decreased locomotor activity are seen when the DBA/2J strain is given increasing doses of morphine.

When these experiments were replicated using six to seven month old mice the behavioral response to morphine was reproduced; whereas, the changes in brain histamine levels could not be replicated in the DBA/2J strain.

These findings suggest no causal relationship between morphine induced locomotor activity and brain histamine levels.

950 PHYSICOCHEMICAL CORRELATES OF ALCOHOL INTOXICATION. Michael J. McCreery* and Walter A. Hunt*. (SPON: J. Ribas). Neurobiol. and Behav. Sci. Depts., Armed Forces Radiobiol. Res. Inst., Bethesda, MD. 20014.

The precise way in which alcohols interact with membranes thus creating alterations in neuronal function remains unknown. Although the literature on the biological effects of alcohols is vast, most studies have dealt with only the anesthetizing properties of this broad class of depressants. Comparison of their actions as intoxicants in intact animals has remained unaddressed largely because of the absence of a suitable animal model. Previous studies of *in vitro* systems using a limited number of alcohols have suggested that their potency is directly related to their lipid/water partition coefficients (P). In the present effort, a broad range of structually divergent alcohols, diols, and other monofunctional alkanes were tested for their ability to intoxicate in whole animals. Male Sprague-Dawley rats were injected i.p. with several doses of a given drug and evaluated for the most severe signs of intoxication using behavioral endpoints described by Majchrowicz (Psychopharmacologia 43, 245 (1975)). From dose-response curves, the effective dose (ED) needed to produce ataxia 2 was determined. Of over 60 compounds tested, almost all induce a behavioral spectrum of intoxication virtually identical to that of ethanol. This includes amphiphilic compounds which are not alcohols such as propyl chloride and propanethiol. A plot of [log P] vs. [log ED] yields a straight line with a correlation coefficient equal to -0.9 indicating a high degree of predictability. The membrane concentration, the volume occupied within the membrane, and the thermodynamic activity have been successfully utilized by past workers to predict the anesthetic potency of a compound. In order to determine whether these physicochemical parameters could also be used as correlates of alcohol intoxication, partition coefficients were used to estimate the concentrations of each drug within the aqueous and nonaqueous regions of the animal. From these calculations each of these parameters was found to remain remarkably constant even though the ED varied over two orders of magnitude. Among the few exceptions were several alkanes which were ineffective in inducing intoxication even though their lipid solubility is very high. These data suggest that amphiphilicity of a compound is essential for inducing intoxication. Moreover, the three-dimensional structure of a compound is important in influencing its intoxicating efficacy only to the extent that its partition coefficient is affected.

951 CHANGES IN BRAIN TRYPTOPHAN AND TYROSINE FOLLOWING ACUTE AND CHRONIC MORPHINE. R.B. Messing, C. Flinchbaugh* and J.C. Waymire*. Dept. Psychobiol., Univ. Calif. Irvine, Irvine, CA 92717.

Morphine increases the turnover in brain of catecholamines and serotonin. Furthermore, synthesis of serotonin, and possibly of catecholamines, can be influenced by availability of their amino acid precursors, tryptophan and tyrosine. Therefore, we investigated the effects of morphine on these amino acids.

Morphine sulfate (5-20 mg/kg) increased brain concentrations of tryptophan and tyrosine 1-2 hr. after administration in a dose-dependent manner in male rats. Concentrations of these amino acids in blood serum decreased 30-45 min. post-injection, and then rose towards control values. The rise in brain amino acids could be antagonized by pretreatment with naloxone (1 mg/kg). Rats were made addicted to morphine by administration of 150 to 600 mg/kg of morphine sulfate in a slow release preparation in increasing doses, over a 10 day period. In these rats there was only a slight increase in brain tryptophan and no increase in tyrosine. Thirty min. after naloxone-precipitated withdrawal (0.5 mg/kg), tryptophan and tyrosine concentrations were increased in brain, in contrast to the decrease in these amino acids seen after naloxone is given to acutely morphinized rats.

The antagonistic effects of morphine and naloxone on brain tryptophan and tyrosine, and the differences in addicted and non-addicted rats, suggest that the changes in these amino acids in brain are due to specific effects of the drug.

These data support the hypothesis that increased amino acid precursor availability for serotonin and catecholamine biosynthesis may be involved in alterations of the metabolism of these neurotransmitters following morphine. (Supported by grant DA-01685.)

952 PERIAQUEDUCTAL GRAY AND THE MORPHINE ABSTINENCE SYNDROME IN THE RAT. James A. Mikula, Richard E. Wilcox, and Robert A. Levitt. Dept. Psychol. and Sch. Med., Southern Ill. Univ., Carbondale, IL 62901

The periaqueductal gray (PAG) of the midbrain has been implicated in the analgesic action of narcotic drugs. It has also been found to contain a high concentration of opiate receptors and of endogenous morphine-like substances. The PAG may, therefore, be expected to play a major role in the abstinence syndrome which accompanies the chronic administration of narcotics. This syndrome results from drug withdrawal in an organism whose body has homeostatically adjusted to the presence of the narcotic. In the rat it includes hyperalgesia, climbing, jumping, "wet-dog" shakes, diarrhea, salivation and rhinorrhea. Since there is good evidence that the PAG is involved in narcotic analgesia we would expect the PAG to be involved at least in hyperalgesia.

There were 8 groups of 8 animals in the experiment. Four groups were first implanted with a cannula in the PAG. All animals then had a pellet implanted under the skin of the back. For half of the animals the pellet contained 75 mg of morphine while the other animals were implanted with a placebo pellet. 72 hours later withdrawal was precipitated by injecting naloxone either into the PAG (1 µg in 1.0 µl of water) or systemically (IP; 5 mg/kg) or by injecting saline either into the PAG or systemically. Pain sensitivity was assessed by means of the flinch-jump technique while the other signs of the abstinence syndrome were assessed by behavioral observation. All testing and histological analyses were done "blind" as to the animal's previous treatment.

Injection of naloxone, either into the PAG or systemically, produced hyperalgesia in morphine-dependent rats. In both cases the change in jump threshold was a reduction of about 30 percent. Systemic naloxone injections also produced a "full-blown" abstinence syndrome in morphine-dependent animals consisting of all of the common signs. None of these other signs were found in morphine-dependent animals injected with naloxone in the PAG. Neither hyperalgesia nor the other abstinence signs were produced by saline injections in morphine-dependent animals nor by naloxone or saline in placebo-implanted animals.

Similar amounts of hyperalgesia were produced by the PAG and IP naloxone injections, while the other abstinence signs were only produced by IP naloxone. Therefore, the PAG may be involved in the homeostatic adjustments responsible for hyperalgesia but not in the adjustments responsible for the other signs. These other adjustments may involve other CNS sites, and/or sites in the periphery. These results suggest the possibility of separating different effects of the narcotic drugs.

953 DIFFERENTIAL EFFECTS OF ETHANOL ON UNIT ACTIVITY IN CEREBELLUM AND OTHER BRAIN AREAS IN THE RAT. J. Mitra. Harrison Dept. Surgical Research, Division of Neurosurgery, Sch. Med., Univ. of Pennsylvania, PA 19104.

The effects of acute administration of ethanol on activities of single units were studied in rats. Units were recorded from the cerebellum (cortex and nuclei), the caudate n., Deiters n. and the reticular formation (RF). It was found that with a low dose of ethanol (100 mg/kg), units in the RF (rostral and caudal brain stem), the cerebellar nuclei and the caudate nucleus were activated while units in Deiters n., showed no appreciable change. With the same dose of ethanol, cerebellar Purkinje units showed a slight decrease followed by a transient increase in activity. A large dose (500 mg/kg) of ethanol initially depressed units in all structures under study. However, units in Deiters n. and in the cerebellar nuclei showed depression that was more prolonged than in other structures (cerebellar cortex, caudate n. and RF). Recovery from a large dose of ethanol was first evident in the RF (caudal followed by rostral). During recovery from the initial depression due to ethanol, units in Deiters n., the RF (rostral) and the cerebellar nuclei often showed periodic increases and decreases of unit discharge which lasted from 2-15 min. Our data suggest that a low dose (100 mg/kg) of ethanol activated units in the RF, the caudate n. and the cerebellar nuclei while a large dose (500 mg/kg) had a prolonged depressive effect on units in Deiters n. and the cerebellar nuclei. (Supported by P.H.S. Research Grant NIAAA 00902.).

954 EFFECT OF ALPHA-METHYL-P-TYROSINE ON ABSTINENCE INDUCED, SPONTANEOUS CONVULSIONS IN BARBITAL DEPENDENT RATS. William W. Morgan. Dept. Anat., Hlth. Sci. Cntr. at San Antonio, San Antonio, TX 78284.

Barbiturate dependence was produced in adult male Sprague-Dawley rats following the long term consumption of increasing concentrations of barbital in the drinking water. The highest concentration of barbital consumed was 4 mg/ml. Sodium saccharine was added to the drinking water to disguise the bitter taste of barbital. Equal concentrations of saccharine were provided to both control rats and barbital consuming rats. At the end of the drug regimen the barbital was abruptly withdrawn from the rats by the substitution of water which contained only saccharine. Just before barbital withdrawal and again at 16 hours after withdrawal, groups of control and barbital dependent rats were treated with 0, 30, 60, 125 or 250 mg/kg of alpha methyl-p-tyrosine (αMPT), intraperitoneally. All the animals were observed continuously during the first 48 hours following barbital withdrawal, and the incidence of spontaneous convulsions in each animal was recorded. Core temperatures were monitored with tele-thermometers at 12 hour intervals following barbital withdrawal. Only the highest dosage of αMPT produced hypothermia. After 48 hours of withdrawal the animals were sacrificed, and brains were collected for subsequent analysis of dopamine (DA) and noradrenaline (NA) concentration utilizing spectrofluorometric procedures. A dosage related decrease in spontaneous convulsions was observed in αMPT treated, barbital dependent rats. In a separate study these dosages of αMPT did not affect the incidence of convulsions induced by pentylenetetrazol administration or thyroparathyroidectomy-pinealectomy. All of the dosages of αMPT that were administered significantly decreased the synthesis of catecholamines as evidenced by a statistically significant decrease ($p<0.001$) in both DA and NA content. The cumulative data indicate that the effect of αMPT on convulsion incidence following withdrawal of barbital from dependent rats is related to the suppression of catecholamine synthesis. These results suggest that brain catecholamines may have a role in the expression of the barbital abstinence syndrome.

955 INTRASEPTAL INJECTIONS: A PROCEDURE FOR STUDYING THE MODULATION OF THE CHOLINERGIC NEURONS PROJECTING TO THE HIPPOCAMPUS. F. Moroni*, S. E. Robinson*, D. L. Cheney and E. Costa. Lab. Preclin. Pharmacol., NIMH, Saint Elizabeths Hosp., Washington, D.C. 20032

Intraseptal injections of agonists and antagonists of two classes of putative neurotransmitters (opioid and catecholamine) have been performed in rats chronically implanted with cannulae. The acetylcholine (ACh) turnover rate (TR_{ACh}) has been monitored in the hippocampal formation and in other brain areas. The TR_{ACh} is calculated by measuring the incorporation of deuterium into ACh and choline mass-fragmentographically following the infusion of deuterated phosphorylcholine.

Morphine (35 and 70 nmoles) and β-endorphin (0.7 nmoles) injected directly into the septum fails to cause analgesia or electrical signs of convulsive activity but decreases the TR_{ACh} by approximately 50% in the hippocampus, leaving the ACh and Ch content unchanged. The TR_{ACh} in the cortex and striatum is not affected. The effect in hippocampus is antagonized by i.p. naltrexone (15 μmoles/kg). Furthermore, naltrexone (15 nmoles) directly injected into the septum, partially antagonizes the decrease of hippocampal TR_{ACh} induced by i.p. morphine (35 μmoles/kg). These data suggest that opiate agonists decrease the firing rate of cholinergic neurons projecting to the hippocampus.

On the contrary, intraperitoneal injections of amphetamine (27 μmoles/kg) increases the TR_{ACh} in the cortex, hippocampus and diencephalon by approximately 40%. Phenoxybenzamine (15 nmoles) injected into the septum curtails the increase of cortical TR_{ACh} elicited by amphetamine, but does not modify the increased TR_{ACh} in diencephalon.

Our data suggest that the α-adrenergic receptor agonists facilitate the ACh metabolism in septal cholinergic neurons and that opioid receptor agonists inhibit TR_{ACh} in these neurons. Intraseptal injections and measurement of TR_{ACh} is a useful pharmacological research tool to elucidate the structural organization of the septum.

956 EFFECT OF MORPHINE ON INTRACRANIAL SELF-STIMULATION IN RATS. William T. Nelson, Martin Brutus*, James E. Wilson, Jr.*, Robert A. Farrell*, Douglas R. Ocheret*, Steven J. Ellman and Solomon S. Steiner*. Dept. Psychology, The City College, New York, NY 10031.

The purpose of this study was to determine which sites in the brain yield an increase in intracranial self-stimulation (ICSS) response rates under morphine.

Twenty-five rats were subjects. Stimulation parameters and training procedures were similar to those of Bodnar et al. (Neuroscience Abstr., 1, 481, 1975). Each bipolar electrode was used in a monopolar fashion, allowing a comparison between each tip serving as cathode to a cortical screw anode.

After response rates stabilized, each animal received 7 days saline, 7 days morphine, 1 day morphine + naloxone, and 6 days post-drug saline. The first days of both pre-drug saline and morphine were discarded. Morphine doses were 2.5 and 5.0 mg/kg injected sc; naloxone dose was 1.0 mg/kg. ICSS rates were sampled 20 minutes post-injection.

Those electrode tips located in the locus coeruleus (LC) and those just lateral or ventral to it showed large facilitations under morphine. This area is delimited on either side by ICSS electrode tips which showed response depressions under morphine. Lateral hypothalamic (LH) placements yielded facilitations under morphine. Sites medial to the LH area, however, showed depressions under morphine. Substantia nigra (SN) placements were located throughout the zona compacta (SNC) and zona reticulata (SNR) and yielded facilitations and depressions in response rate which were not interpretable on an SNC/SNR distinction.

The facilitations occurred at the low C-T intervals only. The effect is an opiate-specific effect, in that naloxone reversed the observed morphine effect, whether facilitation or depression. The effect is not due to differences in individual animals' sensitivity to the drug, since there are animals which simultaneously showed a facilitation from one site and a depression from another site under the influence of morphine. There were two instances in which we obtained different drug effects from the two tips of the same electrode, thus indicating that each electrode tip is stimulating a discrete neural area. These results indicate that morphine exerts its reinforcing effect at very specific brain loci.

957 ANTAGONISM BY PROSTAGLANDIN (PG) OF MORPHINE-INDUCED EFFECTS IN THE PERIAQUEDUCTAL GRAY (PAG). G. A. Oltmans, J. E. Comaty*, and S. Ehrenpreis. Department of Pharmacology, Chicago Medical School, Chicago, IL 60612.

Ferri et al. (Psychopharmacologia 39:231, 1974) reported that PGE_1 injected intraventricularly reversed the analgesic effects of morphine. Ehrenpreis et al. (Nature [New Biol.] 245:280, 1973) have shown that PGs can antagonize narcotic action in vitro and postulated a common site of action for PGs and narcotics both in the periphery and CNS. We have now demonstrated that PGE can antagonize the analgesic and behavioral effects of morphine injected into the PAG, a site in the CNS directly implicated in opiate action (Jacquet and Lajtha, Science 182:490, 1973). Male albino Sprague-Dawley rats were stereotaxically implanted with a single chronically indwelling cannula aimed at one side of the PAG (AP=0.6; anterior L=0.75; V=6.5 below skull; Pellegrino and Cushman). Analgesia tests consisted of pinching both ears, pinching all paws, tail compression, and the hot plate. All measurements were quantitated, and each animal was given all four tests at various times following drug injections. In general, it was found that unilaterally administered morphine in PAG (in doses as low as 10 µg) produces a dose-dependent change from baseline in all tests except the tail-compression, which was all or none. At time of maximum analgesic response (20 µg morphine), infusion of as little as 2 µg PGE_2 or PGE_2-16,16 dimethyl ester in the same site immediately attenuated the morphine-induced analgesia. The PGs also rapidly reversed morphine-induced catatonia when it occurred. Effectiveness of the PGs was approximately equal to, and parallelled that of, an equimolar amount of naloxone infused into the PAG. These results support the previous reports that the PAG is a site of narcotic analgesia and behavioral effects and provides direct evidence for the involvement of PGE in opiate action in the CNS. 958 EFFECT OF ETHANOL ON MEMORY STORAGE PROCESSES. Elizabeth S. Parker* and Ronald L. Alkana* (SPON: R. M. Julien). NIAAA, Rockville, MD 20857, School of Pharmacy, USC, Los Angeles, CA 90033, and Department of Psychobiology, UCI, Irvine, CA 92717.

It has been suggested that consolidation decrements underly the ethanol-induced deficits in memory storage that have been found in human and animal studies. Two preliminary experiments were conducted in which ethanol was administered pre- or post-training on a "step-through", one-trial, inhibitory avoidance task with mice. Retention was tested in the non-drug state in both experiments. In Experiment 1, immediate, post-trial, ip, ethanol (15% w/v) administration did not significantly affect retention at either 24 hours or 1 week after training. For example, median retention latencies were: Footshock (450 µA)-Saline (FS-S), 182 sec; Footshock-1.5 g/kg Ethanol (FS-1.5 g/kg E), 300 sec; FS-3.0 g/kg E, 300 sec; FS-4.5 g/kg E, 300 sec; and FS-6.0 g/kg E, 300 sec. Post-trial ethanol administration in the absence of footshock (NFS-E) did not significantly change latencies over NFS-S controls indicating that the ethanol injection was not aversive. In Experiment 2, 3 groups were added to examine the effects of pre-trial ethanol administration. In addition, the FS was lowered to 300 µA to try to reduce the ceiling effect seen in the retention latencies of the FS-E groups in Experiment 1. Injection of subanesthetic doses of ethanol (1.5 g/kg or 3.0 g/kg) 10 min pre-training produced a significant and virtually total amnesia compared to saline controls when retention was tested 1 week later. Even with the lowered footshock, however, there were no significant effects of post-trial ethanol administration. In summary, pre-trial ethanol administration impaired retention, whereas, immediate post-trial injections did not. These data do not support the consolidation hypothesis of ethanol's acute amnestic effects.

959 EFFECTS OF OPIATES AND OPIOID PEPTIDES ON RAT MOTILITY FOLLOWING INTRAVENTRICULAR AND INTRACEREBRAL INJECTIONS. Agu Pert, Jim Mitchell*, and Carlos Sivit*. Adult Psychiat. Br., NIMH, Bethesda, MD 20014.

Opiates have been found to exert complex effects on spontaneous motility in rodents. Low doses of morphine generally increase spontaneous activity while high doses have a biphasic action--an initial depression followed by hyperactivity. The purpose of the present studies was two fold: (1) to characterize and compare the effects of β-endorphin, $[D\text{-}Ala]^2$-met-enkephalin (D-Ala) and morphine on motility following intraventricular injections and (2) to localize the brain structures involved in mediating the effects of opiates on motility. Rats were implanted with either intraventricular or intracerebral cannalae guides. Following recovery they were injected with saline, varying doses of β-endorphin, D-Ala, morphine or naloxone and then tested in a photocell activity apparatus. Following intraventricular injections (25 µg), we found that all three opiate agonists produced an initial depression followed by excitation. The depressive phase lasted 1-2 hrs for D-Ala and approximately 3 hrs for morphine and β-endorphin. Tissue injections (5 µg bilateral) revealed differential effects of opiates on motility depending on the injection site. Injections into the nucleus accumbens produced only hyperactivity without a depressant component, while injections into the periaqueductal gray matter, surrounding tegmentum and pontine reticular formation produced only depression without excitation. Preliminary results indicate that injections into the thalamus, amygdala and caudate nucleus are relatively ineffective in modifying motility. Naloxone (10 µg bilateral) injected into the nucleus accumbens produced a transitory depression of activity. Systemic administration of naloxone (0.1 - 10 mg/kg) was also found to produce a dose-dependent depression of activity. These findings indicate that endogenous opiate peptides in brain may play a role in some aspects of motility. In addition it appears that the differential effects of opiates on activity are determined through different brain structures. Species and dosage differences in the action of opiates on motility may depend on the relative sensitivity of one system over the other.

960 CONSUMPTION OF A TRYPTOPHAN-DEFICIENT, CORN-BASED DIET ALTERS THE ANALGESIC DRUG POTENCY OF MORPHINE. Lee Phebus*, Philip Rowley*, Laurel Fisher*, and Loy D. Lytle. MIT, Dept. of Nutrition and Food Science, Cambridge, MA 02139.

We have previously shown that rats fed a tryptophan-deficient, corn-based diet (supplemented with normal amounts of vitamins, minerals, carbohydrates and fats) are hyper-reactive to presentations of noxious electric foot shock. The time course for the development of the electroshock hyperalgesia parallels that of the diet-induced depletion of brain tryptophan and serotonin, suggesting that brain serotoninergic neurons may play a role in nociception. The diet-induced hyperalgesia and reductions in brain serotonin can be reversed by: 1) offering animals previously fed the corn-based diet a casein based diet that contains adequate concentrations of tryptophan; 2) offering animals a corn-based diet that is supplemented with normal concentrations of tryptophan; or 3) injecting corn diet fed animals with various doses of tryptophan, or other drugs known to increase brain serotoninergic neurotransmission (Science 190: 692 (1975); Life Sciences 18: 707 (1976)).

In the present experiments, different groups of rats were fed either the tryptophan-deficient, corn-based diet or the nutritionally adequate casein control diet for 3 weeks; their "jump" responses to presentations of different intensities of electric foot shock were then determined following intraperitoneal injections of different doses of morphine sulfate (2.5, 5.0, or 10.0 mg/kg; salt weight) or the 0.9% saline vehicle (1 ml/kg).

	JUMP THRESHOLD (mA)	
Drug Treatment	Casein-Fed	Corn-Fed
Saline	0.79±.07	0.42±.06**
2.5 mg/kg Morphine	1.05±.16	0.50±.07*
5.0 mg/kg Morphine	1.46±.17*	0.60±.06*
10.0 mg/kg Morphine	1.33±.11**	0.59±.09

*All values are means ±S.E. (N=6). *p<.05; **p<.01 compared to casein-fed, saline injected group.*

Animals fed the casein control diet showed dose-related increases in the shock intensity necessary to elicit the jump response following morphine; in contrast, animals fed the corn-based diet did not show significant analgesia at any of the morphine test doses. Pharmacological or surgical reductions in brain serotoninergic neurotransmission also produce hyperalgesia and antagonize morphine analgesia, and suggest a role for these neurons in normal or opiate-induced alterations in nociception.

961 ANALGESIA FOLLOWING MICROINJECTION OF MORPHINE INTO THE NUCLEUS RAPHE MAGNUS OF ACUTELY DECEREBRATE RATS. Herbert K. Proudfit. Dept. Pharmacol., Univ. Ill. Med. Ctr., Chicago, IL 60612.

Previous observations have shown that destruction of the n. raphe magnus (NRM) blocks morphine-induced analgesia (Proudfit and Anderson, Brain Research 98, 612, 1975) suggesting that the NRM is an essential part of the neuronal pathway mediating morphine's analgesic actions. However, it is unclear from these results whether morphine acts directly on the NRM or on some other part of the neuronal system. To distinguish between these possibilities, morphine was applied directly by microinjection into the NRM of acute decerebrate rats. Analgesia was tested using the tail-flick assay before and after microinjection of morphine in doses of 2.5-to-40.0 µg in 0.5 µl of saline. Within 1-to-9 minutes after morphine injection, the tail-flick response was maximally inhibited, and this effect was reversed by systemically administered naloxone (1.0 mg/kg, sc). In addition, analgesia induced by systemic administration of morphine (5.0 mg/kg, sc) was antagonized within 1-to-2 minutes by microinjection of naloxone into the NRM (0.4 µg/1.0 µl saline). Saline microinjected into the NRM (0.5 µl) had no effect on tail-flick latency. Also, microinjection of morphine in doses as high as 80 µg in a volume of 2 µl into areas of the brain stem rostral and dorsal to the NRM did not alter tail-flick latency. These results suggest that morphine acts directly on the NRM to produce inhibition of the tail-flick response to radiant heat. (Supported by USPHS Grant NS 12649.)

962 EFFECTS OF MET^5-ENKEPHALIN AND MORPHINE ON NEURONS OF THE TRIGEMINAL BRAINSTEM NUCLEAR COMPLEX. E. Puil, R.K. Andersen* and J.P. Lund. Dept. Pharmacology, University of British Columbia, Vancouver, and Centre de Recherches en Sciences Neurologiques, Université de Montréal, Montréal, Canada.

Since the analgesic effect of morphine is presently believed to be due to its interaction with opiate receptors in the neuraxis, it was of interest to compare the effects of this alkaloid with those of met^5-enkephalin, an endogenous opioid, on second order neurons activated by noxious inputs. There is considerable evidence that the subnuclei oralis (n. oralis) and caudalis (n. caudalis) of the spinal trigeminal complex are the major sites of reception for incoming nociceptive afferents. Extracellular recordings were made in these subnuclei of decerebrate cats, through one barrel of an assembly of glass micropipettes or with a tungsten microelectrode attached alongside. The remaining barrels of the micropipette were used for extracellular drug application by iontophoresis. Stimulation of the tooth pulp which has long been accepted to cause pain almost in pure form, was used as the main noxious input. The effects of the substances were also observed upon stimulation of the infra-orbital nerve (I.O.). The modality and size of the sensory receptive field which affected the particular cell were determined. Neurons which had a tactile receptive field but which did not appear to respond to "painful" inputs were generally unaffected by iontophoretically applied enkephalin. Others which received "painful" inputs were usually strongly inhibited by enkephalin. The inhibition was slow to develop but outlasted the period of application by as long as 20 minutes. These effects could be prevented by extracellular or intravenous administration of naloxone. The effects of morphine did not always resemble those of enkephalin; a depression of the amplitude of spikes was often observed upon application of morphine particularly in the n. oralis. Compared with enkephalin, morphine appeared to produce a weaker depression of neurons, whether firing spontaneously, activated by stimulation of tooth pulp or I.O. The inhibition by morphine was sometimes followed by an excitation lasting several minutes. These experiments suggest the presence of receptors for endogenous opioids in trigeminal neurons. Activation of such receptors appears to be responsible for the observed depression by enkephalin of cells responding to noxious stimulation. The data also indicate that the mechanism of action of morphine may not be identical to that of enkephalin on these cells. Alternatively the analgesic effects of morphine on facial and oral structures may not be mediated through direct activation of these receptors within the trigeminal spinal nucleus.
Supported by Medical Research Council of Canada.

963 THE ROLE OF CATECHOLAMINES IN SELF-INJECTION OF COCAINE AND APOMORPHINE. David C. S. Roberts*, Michael E. Corcoran, Ronald M. Clavier, and Hans C. Fibiger. Div. Neurol. Sci., Univ. of British Columbia, Vancouver, Canada V6T 1W5.

There is evidence to suggest that self-administration of amphetamine and cocaine is reinforced by the central catecholaminergic agonist properties of these drugs. However, there is little known concerning the relative importance of specific catecholaminergic fiber systems in this behavior. The present experiments were designed to evaluate the role of two major noradrenergic (NA) and dopaminergic (DA) projections in intravenous self-injection of cocaine and of apomorphine, a direct DA agonist. Stereotaxic infusions of 6-hydroxydopamine (6-OHDA) were used to destroy either the DA innervation of the n. accumbens or the NA projections innervating the hypothalamus, hippocampus, and cortex.

Twenty rats were used, each fitted with a chronic intravenous cannula. During daily 4-hr sessions, each depression of a lever produced an intravenous injection of 0.20 ml of drug. Cocaine self-injection was maintained at a dosage of 0.75 mg/kg/inj. Some rats were also allowed to self-inject apomorphine at a dose of 0.06 mg/kg/inj.

Lesions of the dorsal and ventral NA bundles that reduced hippocampal and cortical NA by 96% and hypothalamic NA by 80% failed to have any effect on self-injection of cocaine. In contrast, 6-OHDA-induced lesions of the n. accumbens significantly altered the intake of cocaine. This effect was dependent upon the degree of DA depletion in the accumbens: In the five rats in which the greatest depletion of DA was achieved (90%), intake of cocaine was reduced to 20 to 40% of prelesion levels. Typically these rats would respond at a low rate, and only in the first 1 to 2 hrs of the session. The same animals showed no change in rate or pattern of self-injection of apomorphine after the lesion. Identical lesions of the n. accumbens had only transient effects upon food-reinforced operant responding, suggesting that the prolonged disruption of cocaine self-injection was not the result of motor deficits. The results suggest that DA terminals in the n. accumbens may mediate some of the positive-reinforcing properties of cocaine.

964 EFFECTS OF BARBITURATE ON SPINAL CORD INHIBITORY PATHWAYS. Howard C. Rosenberg and Michiko Okamoto. Cornell Univ. Med. Coll. New York, N. Y. 10021.

The segmental reflex system of the lower spinal cord has long been an important model system for studying drug effects on the CNS. Barbiturates are important since other depressant drugs are often compared to barbiturates in order to ascertain any selectivity that such drugs might possess. Pentobarbital effects on 3 types of spinal cord inhibitory pathways have been studied. Cats were anesthetized with halothane and a tracheotomy, C1 section and carotid artery ligation were performed. Respiration on room air was then begun. The spinal cord was exposed by laminectomy from L4 to S1 and a hindleg was dissected to allow stimulation of specific nerves. Reflex activity was recorded from appropriate ventral roots that had been sectioned near their exits from the spinal column.

In agreement with published reports, pentobarbital enhanced presynaptic inhibition. Doses required to do so were about the same as needed to depress the unconditioned 2N response.

Postsynaptic (direct) inhibition has been reported not to be specifically affected by pentobarbital (Weakly et al., Arch. Int. Pharmacodyn. 171, 1968). Effects of pentobarbital doses from subthreshold to those that almost abolished the 2N response were studied by adjusting the strength of the test stimulus in many steps, and then by stepwise infusion of many doses of pentobarbital in the same animal. Decreased inhibition could be demonstrated over a wide dose range in contract to the apparent changes that are only secondary to decreased size of the unconditioned 2N response (decreased synaptic drive).

Recurrent (Renshaw cell-mediated) inhibition has been reported to be prolonged by barbiturates, although no consistent change in the maximum degree of inhibition was stated (Wilson and Talbot, J. Gen Physiol. 502, 1960). No specific effect of pentobarbital on the magnitude of recurrent inhibition was noted. There was an apparent increase which was secondary to decreased synaptic drive throughout the range of doses from threshold to those causing almost total loss of the 2N response. In most experiments there was a prolongation of this inhibition.

Thus, acutely administered barbiturate increases presynaptic, decreases postsynaptic and prolongs recurrent inhibition. These data are of interest to compare with those obtained during barbiturate withdrawal showing recurrent and presynaptic, but not postsynaptic, inhibition to be decreased (Rosenberg and Okamoto, Fed. Proc. 35, 1976). (Supported by ADAMHA grant #DA-00591).

965 COMPARISON OF MORPHINE ACTION ON SENSORY INPUT RECORDED IN FIVE BRAIN SITES. J. Salamy S. Sands and N. Dafny
Departments of Psychiatry and Neurobiology and Anatomy, The University of Texas Medical School, Houston, Texas 77030.

Certain brain structures including the central gray (CG), mesencephalic reticular formation (RF), nucleus parafasicularis (PF), and caudate nucleus (CN) have been implicated in morphines effect on pain, analgesia, tolerance, and motor disturbances respectively. Those structures were therefore selected for the present study. Specifically, the influence of morphine upon these sites was determined by its ability to modify the averaged evoked response to visual stimulation. The lateral geniculate body (Lgb) was employed as a sensory control site. Permanent electrodes (60 μ diameter) were implanted several days prior to experimentation in 11 Sprague-Dawley rats (200-300g). After 1 hour adaptation to the recording cage 4 consecutive pre-drug control averages consisting of 32 visual evoked responses (VERs) each, were obtained at 10 minute intervals. Similarly, 4 sets of VERs were obtained following the successive administration of morphine in each of 1, 5, 10 and 30 mg/kg i.p. doses and one dose of naloxone (1 mg/kg i.p.). The incremental doses of morphine followed by naloxone were injected at one hour intervals. The first average of each set was initiated 15 minutes following injection. Subsequent averages were obtained at 10 minute intervals. VER modification was regarded as an alteration in the amplitude of one or more of the P_2, N_2, or P_3 components of $\pm$ 2 standard errors from control values for each animal. The Lgb responded in a dose related fashion with increasing dosages modifying more and more responses. The CG appeared most sensitive to the influence of morphine. The VERs were maximally altered at the lowest dose (1 mg/kg) with little further change associated with higher doses. The responses of the RF and PF displayed comparable sensitivity. Only a few VERs were modified at the lowest dose (1 mg/kg) and the maximum effect was attained at 10 mg/kg. The CN exhibited the least responsiveness to morphine. However, the direction of response changes (increases or decreases of the various components) were dose related. Naloxone reversed the effect of morphine in all structures studied. These results indicate that the effects obtained were a specific result of morphine and that morphine influenced these structures differentially. Supported by USPHS Grant No. DA 00803.

966 IMMUNOHISTOCHEMICAL LOCALIZATION OF ENKEPHALINS IN RAT BRAIN. Madhabananda Sar*, Walter E. Stumpf, Richard J. Miller*, Kwen Jen Chang*, and Pedro Cuatrecasas*. Depts. Anat. and Pharma., Sch. Med., UNC-CH, Chapel Hill, N.C. 27514, and Burroughs-Wellcome Co., Research Triangle Park, Durham, N.C. 27709.

The distribution of enkephalins in rat brain was investigated by immunohistochemical staining technique using antisera to leucine-enkephalin and methionine-enkephalin. Adult male Sprague Dawley rats were perfused through the aorta with 3% paraformaldehyde and 0.5% gluteraldehyde in sodium phosphate buffer. Brains were removed. Forebrain, midbrain, pons and medulla oblongata were dissected out, dehydrated through alcohol and xylene, and embedded in paraffin. 4 μm sections were cut, deparaffinized and stained immunohistochemically by a modified immunoperoxidase bridge technique.

Immunoreactive staining for enkephalin (leu or met) was observed in nerve fibers and terminals in many regions of the brain. The localization was similar when antisera to met or leu-enkephalin were used. The localization is specific for enkephalins since antisera to leu or met enkephalin previously absorbed either with leu or met enkephalin fail to produce a positive staining in brain sections. The regions of localization include in the forebrain: lateral septum, amygdala, hippocampus, globus pallidus, nucleus caudatus, and nucleus accumbens; in the midbrain: nucleus interpeduncularis and periaqueductal gray; and in the lower brain stem: nucleus parabrachialis, nuclei raphes, locus ceruleus, nucleus tractus solitarii and formatio reticularis. The results of the histochemical staining reveal that certain structures which stain positively for enkephalin, closely correspond to the distribution of opiate receptors in the brain.

967 PUPILLARY CHANGES FOLLOWING MICROINJECTIONS OF OPIOIDS, SYMPATHOMIMETICS AND CHOLINOMIMETICS INTO THE OCULOMOTOR NUCLEUS IN THE DOG. Lawrence G. Sharpe, Wallace B. Pickworth* and William R. Martin. NIDA, Addiction Research Center, Lexington, KY 40511

Male and female beagle-type dogs had indwelling guide cannulae (19 ga) implanted with the tips located above the oculomotor nuclear complex (OMN). All animals were acclimated to sling restraints and during experimentation a concentric chemitrode (30 ga inner, 23 ga outer, insulated except at the tips) was lowered into a site where electrical stimulation (20 Hz, 0.5 msec duration, 2-6V) produced marked miosis without ocular movements. Drugs dissolved in sterile saline were then injected in a 0.5 μl volume over 1 min into this site. Pupil diameter was measured photographically. Morphine (5 μg), normorphine (5 μg), WIN 35,197-2 (0.5-2 μg), but not SKF 10,047 (5 μg), produced miosis lasting 45 min or longer. The rapidly metabolized sympathetic amines, dopamine (10-20 μg), norepinephrine (5 μg) and epinephrine (5 μg) produced transient miosis, whereas the longer acting α-adrenergic agonists, clonidine (5 μg) and methoxamine (5 μg) produced a prolonged miosis. Acetylcholine plus physostigmine (5 μg each) and carbachol (0.5 μg) produced marked mydriasis whereas atropine (0.5 μg) produced miosis. In another study in which decerebrate dogs were used, carbachol (10-20 μg) also caused mydriasis when microinjected into the OMN. These data suggest that there is a cholinergic inhibitory and possibly a catecholaminergic facilitatory mechanism modulating the visceral nuclei of the OMN.

968 DEMONSTRATION OF STEREOSPECIFIC OPIATE BINDING IN CULTURES OF FETAL MOUSE DORSAL ROOT GANGLIA AND SPINAL CORD. Eric J. Simon*, Jacob M. Hiller*, Stanley M. Crain and Edith R. Peterson* (SPON: C.S. Raine). Dept. Med., New York Univ. Coll. Med., N.Y. 10016; Dept. Neurosci., Albert Einstein Coll. Med., Bronx, N.Y. 10461.

Sensory-evoked synaptic networks in the dorsal horn regions of fetal mouse spinal cord cross-sectional explants with attached dorsal root ganglia (DRGs) can be selectively depressed by exposure to analgesic concentrations of morphine and other opiates, and these effects are reversed by naloxone (Crain et al., this vol.). Correlative analyses have been made of the opiate receptor binding levels in these cord-DRG cultures as well as in cultures of isolated DRGs and deafferented cord explants. Profuse neuritic outgrowths developed, primarily due to NGF-stimulated DRGs, extending for several mms beyond the explant zone on a collagen gel substrate (which thinly coated the 22 mm culture coverslips). Prior to some of the assays, the explants (ca. 1 mm diam.) were extirpated for separate analyses of the explants and the neuritic outgrowth zones. The latter were collected together with the entire remaining collagen substrate after removal of the explants. All assays were made on pooled groups of 8 cultures.

Homogenates of these explants (1-3 weeks in vitro), were found to exhibit stereospecific binding of the potent opiate antagonist, diprenorphine. Four times as much ^{3}H-diprenorphine was bound by homogenates of isolated DRG cultures (2500 cpm/mg protein) than by deafferented spinal cord cultures (700 cpm/mg). (All protein determinations were corrected for collagen substrate.) Similar cultures of non-neuronal explants exhibited no stereospecific binding of opiates. It was further found that the neuritic outgrowth zones of DRG cultures had four times the binding of the DRG explants (i.e. 2000 cpm/mg protein vs. 600 cpm/mg). On the other hand, the binding per mg protein in explants of spinal cord extirpated together with their attached DRGs was more than twice that of entire cultures of deafferented cord, and the binding by the neuritic outgrowths of these co-cultures was less than that of isolated DRG outgrowths. This shift in opiate receptor localization may be due to the growth of many receptor-bearing DRG neuritic processes into the spinal cord explants, consonant with bioelectric and histologic evidence of NGF-enhanced DRG-innervation of dorsal cord in these cultures (Crain and Peterson, Brain Res. 79:145,'74).

This report presents the first demonstration of opiate binding on neurites of dorsal root ganglion cells and the first direct evidence of presynaptic binding of opiates.

969 MORPHINE EFFECTS ON PROTEIN SYNTHESIS IN NORMAL AND REGENERATING FACIAL NUCLEUS NEURONS. Raymond S. Sinatra* and Donald H. Ford. Dept. Anat. Cell Biol., Downstate Medical Center SUNY, Brooklyn, N.Y. 11203

In addition to specific interactions at regional binding sites opiates induce numerous secondary alterations in CNS biochemistry including pronounced inhibition of neuronal RNA and protein synthesis. Axotomy has been associated with an altered metabolic state and the effects of morphine on the increased synthetic drive of axotomized neurons has not been previously reported.

Acute morphine effects on the accumulation of ^{3}H-l-lysine was studied by LM radioautography in normal and regenerating facial neurons. At predetermined intervals post axotomy, radioactivity present in various compartments within regenerating and normal neurons from adult male Wistar rats was compared with similar cells from rats receiving 30mg/kg morphine sulfate I.V. At 14 and 21 days post axotomy, regenerating neurons were larger and their grain count/unit area increased significantly when compared with unoperated controls. In unaxotomized neurons, the accumulation of lysine into the nucleus and nucleolus was decreased significantly 60 min after morphine administration. In regenerating neurons, morphine inhibition of lysine incorporation appeared even more pronounced. Nuclear lysine uptake was significantly depressed at 3 and 7 days, while maximal inhibition of cytoplasmic incorporation occurred at 14 days post axotomy. Morphine administration decreased nucleolar lysine incorporation at all time intervals observed.

Electron microscopic examination of normal and regenerating neurons suggested that chronic morphine administration induces ultrastructural alterations in organelles associated with RNA and protein synthesis. In nonoperated cells and regenerating cells 3 days post axotomy, shrinkage of RER cisternae with a con-comitant aggregation of polysomes within the intercisternal cytoplasmic matrix was observed. The characteristic nucleolar enlargement observed in the control regenerating cells did not occur after morphine treatment.

970 CONSEQUENCES OF MORPHINE PELLET IMPLANTATION IN NEONATAL FEMALE RATS. Theo Sonderegger, Sue Overing* and Emery Zimmermann. Dept. Anat. and Brain Res. Inst., Sch. Med., UCLA, Los Angeles, CA 90024.

Previous studies of effects of neonatal exposure of rats to morphine have employed daily injections of the narcotic to produce addiction. Since repeated handling early in life may confound drug effects upon neuroendocrine and behavioral responses, the present study investigated long-lasting consequences of early morphine exposure utilizing a modified pellet-implantation procedure developed by us to minimize handling of the pups (Proc. Soc. Exp. Biol. & Med. 154: 435-438, 1977).

Charles Rivers CD strain albino rats with 8 pups each were used in a split litter design. On Day 1 of life female pups were weighed and assigned to a treatment group. On Day 5 or Day 11 pups were anesthetized briefly with ether and implanted subcutaneously with a morphine (M) or a lactose placebo (P) or no pellet (NP). Pups were not further handled until they were weighed, weaned and separated into treatment groups on Day 21.

Surviving pups totaled 59 (Day 5) and 47 (Day 11); overall mortality was 15%. Body weights of M-treated groups were depressed below those of P- or NP-groups through Day 63. Open-field testing on Days 28-30 did not differentiate between treatment groups. After being put on 23-hr food deprivation and tested in the Lashley III maze at approximately 72 days of age, the M-treated animals made significantly more errors and took longer to complete the daily trials ($p<0.01$).

At Day 90, littermates were bred to the same male and all animals became pregnant. Litter sizes, birth weights and sex ratios of the offspring did not differ between groups. These offspring are being studied further.

At 150 days of age Day 5 animals were anesthetized with ether and a blood sample was quickly taken from the jugular vein and the plasma was assayed fluorometrically for corticosterone. Resting levels of corticosterone for the M, P and NP groups did not differ significantly. On Day 215, animals were subjected to a 3-min ether stress and blood samples taken 30 min later. The M group exhibited a smaller ($p<0.05$) steroid rise in response to ether than did the other groups.

These results are comparable to those obtained previously using injection techniques and further indicate that neonatal exposure to M produces long-lasting growth, behavioral, and neuroendocrine deficits.

971 DIRECT, INTRACEREBRAL SELF-ADMINISTRATION OF OPIATES IN THE RAT. Elliot A. Stein and James Olds.[1] Div. of Biology, Calif. Inst. of Technology, Pasadena, CA 90025.

It has long been realized that opiate agents possess powerful reinforcing properties. This has been readily demonstrated by animals which rapidly learn to press a lever to obtain an intravenous injection of morphine (Weeks, J.R., Science 138, 143 [1962]). However, little is known of the central loci or mechanisms by which these drugs produce their hedonic effect.

In an attempt to determine which areas within the central nervous system subserve the reinforcing properties of opiates, a series of experiments have been designed to allow rats to self-administer drugs into discrete subcortical nuclei. Male, Holtzmann rats are surgically prepared with 26 g guide cannulas aimed stereotaxically to lie just dorsal to the area of interest. Sites chosen include those known to support electrical self-stimulation as well as those implicated as sites of morphine action from binding studies. During experimental sessions, a 31 g drug cannula is lowered into the chosen area and rats are placed into a rectangular plexiglass box with a pedal at each end. One pedal is arbitrarily chosen as the active one with each press resulting in a single injection (0.1 µg) of drug (volume per injection = 10 nl). The opposite pedal is inactive and serves as a control for changes in general activation. Experiments are run over a twenty hour period with retests performed three days later.

Results indicate that only those structures which contain both high opiate receptor density as well as those which support electrical self-stimulation will support opiate self-administration. These include anterior lateral hypothalamus, preoptic region, septum, and lateral hypothalamus. Inactive regions include lateral thalamus, caudate nucleus and central gray. Locus coeruleus sites have resulted in equivocal responding, although motor seizures have been seen in two of these animals from injections in this area.

These data indicate that there may be specific central structures subserving opiate hedonic actions which appear to overlap areas known to be rewarding to electrical stimulation. Results are discussed as significant factors in repeated addict relapse phenomena. (Supported by NIH Postdoctoral Fellowship DA05030 and Grant DA 01541 from NIDA)

972 METHIONINE ENKEPHALIN QUANTIFICATION: A SPECIFIC RADIOIMMUNOASSAY. Sue Sullivan*, Huda Akil*, Stanley Watson and Jack D. Barchas. Nancy Pritzker Lab. Behav. Neurochem., Dept. Psych. Behav. Sci., Stanford Univ. Sch. Med., Stanford, CA 94305.

An antibody directed against methionine enkephalin has been raised in rabbits. The antigen used was met-enkephalin coupled to BSA using a glutaraldehyde reaction. The antibody has been used for an immunoassay and for immunohistochemical localization of met-enkephalin in rat brain. The following substances were found not to cross react in the immunoassay at concentrations of 1 µM: Gly-Gly-Phe, Gly-Phe, Gly-Gly, Tyr-Gly, Tyr-Gly-Gly, Phe-Leu, β-endorphin, β-lipotropin, α-endorphin, leu-enkephalin, naloxone, levorphanol, morphine, and the individual amino acids of met-enkephalin. The assay detects from 0.5 to 100 pmoles of met-enkephalin. Using this RIA, levels of met-enkephalin in normal human CSF were found to be 3.1 ± 1 pmoles/ml, which correlated well with enkephalin levels measured in the opiate receptor assay. Supported in part by DA 01207 and DA 01522.

973 A PARADOXICAL "AVERSIVE" PROPERTY OF LEUCINE-ENKEPHALIN: CONDITIONED TASTE AVERSION IN RATS. L. Switzman*, L. Hammer*, P. Shizgal and Z. Amit (SPON: Z. Amit) Centre for Research on Drug Dependence, Psychology Department, Concordia Univ., Montreal, Canada.

Belluzzi and Stein (Nature, in press) have demonstrated intraventricular enkephalin self-administration in rats. Morphine is also self-administered intraventricularly (Amit et al., Psychopharmacology, 1976, 48, 291-294) and, paradoxically, it can induce a conditioned taste aversion (CTA) to a saccharine-water solution (Switzman et al., in prep.). We investigated the ability of leucine-enkephalin (100, 200 or 300μg), methionine-enkephalin (100, 200 or 300μg) and d-alanine-enkephalinamide (25, 75 or 148μg) to induce a CTA in rats. All animals were placed on partial fluid deprivation for seven days such that water was presented for 2 successive ten-minute periods each day. On the eighth day, a saccharine-water solution was presented for ten minutes followed one minute later by an infusion of either of the enkephalins, the vehicle control solution (Ringer's) or a pH control solution. The rats were maintained on the partial deprivation schedule for the subsequent five days and on the sixth day, saccharine solution was again presented for ten minutes (test day). Fluid intake was recorded on all days. Only the leucine-enkephalin (200μg) group significantly decreased saccharine intake on the test day (83.13% of baseline compared to an increase of 109.89% for the Ringer's controls, $t=2.446$, $df=18$, $p < .05$), thus demonstrating a leucine-enkephalin induced CTA to saccharine flavored water. These results are interesting in light of the report by Belluzzi and Stein (ibid) in which leucine-enkephalin was self-administered at a higher rate than that of methionine-enkephalin. It is worthwhile to note that only the middle dose of leucine-enkephalin induced a CTA. This parallels the inverted U-shaped dose response relationship which we have observed for CTAs induced by both systemic and intraventricular morphine injections.

974 ETORPHINE-INDUCED ANALGESIA AND CATATONIA IN THE RAT. Beverly E. Thorn, Robert A. Levitt and Lisa M. Ohotzke*. Dept. Psychol. and Sch. Med., Southern Ill. Univ., Carbondale, IL 62901.

Etorphine hydrochloride is a fast-acting narcotic analgesic, several thousand times more potent than morphine. The increase in potency of etorphine compared to morphine is accounted for both by increased blood-brain barrier affinity and by increased receptor binding. We studied the analgesic and catatonic properties of etorphine both when administered systemically and when microinjected into the periaqueductal gray (PAG) region of the midbrain.

The flinch-jump technique was used to assess pain sensitivity (five series of ascending and descending shocks administered for 1.0 sec every 30 secs.), and the bar test to study catatonia (the forepaws are placed across a bar 4 inches off the floor). Increases in jump thresholds indicate analgesia, while increases in time on the bar indicates catatonia.

Each group consisted of 8 rats. Systemic doses of etorphine were 5,10,50, or 100 μg/kg. PAG doses were 1.0 or 3.0 μg. Each animal was used only once in one experiment and was administered etorphine only one time. The animals received a flinch-jump test followed by a bar test (taking 10 min.). They were then injected with drug (either water or etorphine, either IP (0.25-0.35 ml.) or into the PAG (1.0 μl)). While systemic Ss received only one injection (water or one of the doses of etorphine), PAG animals received both water and one dose of etorphine, presented in a counterbalanced order and separated by a four-day interval.

Rats injected with water or 5 μg/kg etorphine IP were neither analgesic nor catatonic. 10, 50 and 100 μg/kg IP etorphine produced a progressively greater analgesia, with a progressively greater catatonia also being produced by the 50 and 100 μg/kg doses. The jump threshold increase and the catatonia test results correlated .85. PAG injections of 1.0 μg etorphine produced both analgesia and catatonia in half the animals, while 3.0 μg etorphine produced both analgesia and catatonia in all the animals. Mean jump threshold scores increased from .132 ma to .329 ma for the 1 μg group, and to .503 ma for the 3 μg group. With PAG injections the jump threshold increase and catatonia test results correlated .77.

These studies show that the effective doses for producing analgesia and catatonia in the PAG are much lower than the effective systemic doses. Moreover, the high correlations between degree of analgesia and presence of catatonia for both systemic and PAG injections may suggest a common mechanism and substrate for these two actions of the narcotic drugs.

975 POSSIBLE RELATIONS BETWEEN BRAIN OPIATES AND SOCIAL BEHAVIORS. Tom Vilberg*, Noel Bean*, Paul Bishop*, Ken Porada* and Jaak Panksepp. Dept. Psych., BGSU, Bowling Green, OH 43403.

The functions of endogenous opiate systems in the brain are yet to be conclusively identified, however the increasing number of endogenous morphine mimetics and the widespread distribution of opiate binding sites in the brain suggests that more than the modulation of pain is involved.

Possible similarities between the dynamics of narcotic addiction and the formation of social bonds in animals (i.e. speed of development, strength and persistence) has led us to test the hypothesis that one function of these systems is the elaboration of social behaviors. Since acute morphine often has debilitating effects, we employed the receptor blockade strategy to test this possibility. Effects of naloxone were tested in opiate naive animals on diverse measures of discrete social behaviors in several species.

Naloxone severely disrupted pup retrieval in mice. The mother would repeatedly pick up pups and drop them without returning them to the nest. Infant (11 day old) mice showed higher levels of separation-induced activity (55.3% increase) following naloxone (1 mg/kg) than saline treatment. Naloxone-induced activity increases were not seen in adults. In 1 day old chickens, naloxone (5 mg/kg) increased latency to sleep induced by simulated maternal contact by 108%. Tonic immobility, a response linked to social fear, was decreased by 10.2% in duration in juvenile chickens. Three to five day old chicks increase the frequency of their distress vocalizations in response to social separation by 585% when treated with naloxone (2.5 mg/kg) as compared to control conditions. Adult cats were found to vocalize 52% more when given naloxone (1 mg/kg). All these effects were statistically reliable and usually visually obvious.

These findings stand in contrast to the difficulty which has previously been encountered in demonstrating any behavioral effects of naloxone in opiate naive animals. So far naloxone has had reliable effects on every innate social behavior we have analyzed, suggesting that endogenous opiate systems may modulate emotional or motivational functions underlying social behavior in many species. In general it appears that naloxone exacerbates the distress that results from social isolation and reduces the comforting effects of social contacts. Accordingly, these data are consistent with the possibility that endogenous opiate systems mediate social reward processes in the CNS. However, since we have presently only tested innate behaviors, the results are also consistent with the possibility that endogenous opiate systems merely modulate the expression of species-typical behaviors.

976 IMMUNOCYTOCHEMICAL LOCALIZATION OF OPIATE PEPTIDES AND β-LIPOTROPIN IN RAT BRAIN. Stanley J. Watson, Huda Akil* and Jack D. Barchas. Nancy Pritzker Lab. Behav. Neurochem., Dept. Psych. Behav. Sci., Stanford Univ. Sch. Med., Stanford, CA 94305.

With the discovery of the opiate peptides in mammalian brain, a number of questions have arisen concerning their physiology, biochemistry and anatomy. The substance β-lipotropin (β-LPH) has been proposed as a precursor peptide for methionine-enkephalin and several of the endorphins. Using specific antisera directed against these substances (β-LPH antisera obtained from Dr. C. H. Li--Hormone Res. Lab., UCSF), we have carried our immunohistochemical localization studies in rat brain. Generally the opiate peptides (e.g., enkephalins) and β-LPH are distributed variably throughout the brainstem. Relatively little of any of these substances can be seen in cortex, cerebellum, or hippocampus. High concentrations of both the enkephalins and β-LPH are seen in hypothalamus, amgydala, periaqueductal central grey, and paraventricular nucleus of the thalamus. Certain areas, such as median eminence and the arcuate nucleus, contain more β-LPH and much less enkephalins, whereas areas such as the lateral septal nucleus and certain cranial nerve nuclei contain more of the enkephalins and very little β-LPH. The existence of β-LPH in specific neurons in brain lends weight to its hypothesized role as an opiate peptide precursor. Supported in part by DA 01207 and DA 01522.

977 CHRONOTOXICITY OF BARBITURATES AND CHLORAL HYDRATE IN MICE. *Ulysses G. Whitworth, *Alvin Sermons and Charles A. Walker, School of Pharmacy, Florida A and M University, Tallahassee, FL 32307.

Twenty-four hour LD_{50} values of secobarbital, pentobarbital, phenobarbital, hexobarbital, and chloral hydrate were determined in Swiss Webster mice. Three experimental groups of animals were adapted for three weeks in an environmental room equipped with an automatically-timed light cycle lasting from 0800 to 2000 hours daily. For group A, injections for toxicity analysis were made intraperitoneally at D-0600, L-1200, L-1800 and D-2400. Group B were injected with hexobarbital and pentobarbital every three hours of the 24 hour cycle, (D-0600, L-0900, L-1200, L-1500, L-1800, D-2100, D-2400 and D-0300). Group were injected every three hours before the injection. Peak toxicity has reached at 0600 with all drugs studied except chloral hydrate which was 180 degrees out of phase. The drugs were least toxic at 1200 hours at a time when the animals were sleep, with the exception of chloral hydrate which was least toxic at 0600 hours. The greatest percent change in toxicity occurred during the hours of 1800 and 1200. Chloral hydrate changes may be explained by a different mechanism of biotransformation. This investigation probably indicates the existence of a circadian and food dependent biological rhythm with sedative-hypnotic drugs. (Supported by a Grant from the Office of Naval Research).

978 BRAIN SITES OF NALOXONE REVERSAL OF MORPHINE CATATONIA IN THE RAT. Richard E. Wilcox and Robert A. Levitt. Dept. Psychol. and Sch. Med., Southern Ill. Univ., Carbondale, IL 62901.

Analgesic doses of morphine in rats produce sedation. Higher doses result in more profound decreases in spontaneous activity culminating in a catatonic-like state. Previous work in our lab suggested a correlation between brain sites having many opiate receptors and the ability of naloxone to reverse morphine-catatonia when administered via chemical brain stimulation (CBS).

Subjects were 24 Long-Evans male rats weighing between 250 and 400 grams at the start of the experiment. Each rat was implanted with one 23 gauge guide shift aimed at head of the caudate nucleus (HC; n=8), periaqueductal gray (PG; n=8), or cerebellar white matter (CB; n=8). Drugs used for CBS were naloxone hydrochloride (10 µg) dissolved in sterile isotonic saline and isotonic saline. Previous work in our lab has demonstrated that the ED50 for systemic naloxone reversal of catatonia induced by 80 mg/kg morphine is 400 µg/kg. All CBS were administered in 1 µl of solution. Subjects were used as their own controls, receiving naloxone or saline in counterbalanced order on two test days separated by one week.

Behavioral testing was as follows. Animals were stimulated with 80 mg/kg morphine sulfate i.p. Thirty minutes later animals were tested for catatonia with a bar test. Animals keeping both forepaws on the bar for 30 seconds were given a CBS with naloxone or saline. At the time of testing the experimenters were not aware of the identify of the solutions used for CBS. Ten minutes later the bar test was repeated. On the second test day drug conditions for CBS were reversed. Thus, half of the animals in each brain site received naloxone the first time they were run and half received saline. Thus each animal received both naloxone and saline in the same brain site. Histological verifications were done without knowledge of the behavioral results.

No reversals occurred following saline stimulation in any of the 24 animals. Naloxone in the PG produced 5 reversals (out of 8 animals; 10 seconds or less on the bar after naloxone) while naloxone in the HC produced 4 reversals (out of 8 animals). Zero out of 8 animals responded to naloxone stimulation in the CB. A chi-square test comparing the number of reversals and failures to reverse at the sites of brain stimulation revealed significant differences at the $p<.025$ level.

Catatonia reversal is the first behavioral effect of morphine found to be mediated by the HC. Reversal of catatonia in HC and PG but not in CB supports the contention that high concentrations of opiate receptors are required for this action. This suggests that morphine-catatonia is a direct effect of the narcotic on opiate receptors in the brain.

979 ETHANOL PREFERENCE IN GENETICALLY SELECTED HYPERTENSIVE AND HYPOTENSIVE MICE. W. Gibson Wood, Merrill F. Elias* and Clyde A. Pentz*. Dept. Psych. Syracuse Univ., Syracuse, N.Y. 13210.

Mice selected for hypertension and hypotension were tested for ethanol preference using 8 different concentrations (Experiment 1). Hypertensive mice showed a greater preference for ethanol than hypotensive mice at 7 of the 8 ethanol concentrations used. Subsequent ethanol preference testing (Experiments 2 & 3) using hypertensive and hypotensive mice from a segregating F_2 generation, derived from the crossing of hypertensive and hypotensive hybrids ($F_1 \times F_1$) demonstrated that the greater preference shown by the hypertensive mice in Experiment 1 was not related to blood pressure phenotype in a casual manner (e.g., pleiotropic or linked genes). Results of the three experiments emphasized the importance of genetic tests designed to determine whether relationships between blood pressure phenotype and ethanol preference do, in fact, reflect casual relationships or mere artifacts of selection.

980 NALOXONE REVERSAL OF MORPHINE ANALGESIA: AN ANATOMICAL ANALYSIS. Randall D. Young, Robert A Levitt, and Maxine Weyant*. Dept. Psychol. and Sch. Med., Southern Ill. Univ., Carbondale, IL 62901.

One reliable procedure for measuring the response to pain in the rat is the jump-flinch technique. Using this procedure, it is possible to obtain a baseline measure of pain sensitivity, a measure of morphine analgesia, and a measure of naloxone reversal of morphine analgesia; all in the same animal and during the same testing session.

Adult rats served as subjects. Each animal was implanted with a 23g cannula aimed at the periaqueductal grey (PAG) of the midbrain. On the test day each subject was given a baseline measure of jump-flinch responding then injected with 10mg/kg morphine-sulfate. After a 30 min. period for drug onset the animal was retested for pain sensitivity and the animal was injected with either 1.0µg or 0.1µg of naloxone in the PAG (in 1µl water) or 1µl distilled water. Following a 10 min. period the animal was retested for pain sensitivity.

Each jump-flinch measurement was composed of 5 trials of 1 sec foot shock delivered in an ascending and descending series at 30 sec intervals.

The ascending series was continued until a "jump" response was elicited, then the series was reversed until the foot shock failed to elicit a response. A jump response is a highly agitated motor response consisting of two or more paws being off the grid floor simultaneously. The five shock intensities eliciting jump responses were averaged to give the jump threshold.

Morphine injections were effective in raising jump thresholds by about 100%. 1µg naloxone was effective in returning jump thresholds to baseline while 0.1µg returned the jump thresholds only half-way back to baseline. Distilled water was ineffective in reversing morphine analgesia. These results were confirmed statistically.

This paradigm appears promising for investigating brain areas mediating morphine analgesia. Such investigations have already been started in this lab, focusing on the caudate nucleus, amygdala, and hippocampus; brain areas shown to be high, medium, and low in opiate-receptor density.

981 ABNORMALITIES IN THE UNTREATED OFFSPRING OF FEMALE RATS TREATED NEONATALLY WITH MORPHINE. E. Zimmermann, Theo Sonderegger and Sue Overing*. Dept. of Anat. and Brain Res. Inst., Sch. of Med., UCLA, Los Angeles, CA 90024.

Previous studies demonstrated long-lasting growth, behavioral and neuroendocrine effects of neonatal exposure to morphine (M) in female rats (Zimmermann et al, Life Sci. 20: 639, 1977). Friedler recently called attention to diminished size of the offspring of rats treated with M prior to conception (Fed. Proc. 36: 1001, 1977). To investigate possible cross-generational effects of neonatal M treatment, Sprague-Dawley female rat pups (Charles Rivers) were implanted with a M, placebo (P) or no pellet (NP) on Day 5 or Day 11 of postnatal life using a split-litter design. On Day 90 these animals were bred with the same sire for each treatment block. A total of 319 pups were produced. Litter sizes (4 to 17), sex ratios and birth weights were similar for the M, P and NP groups. Excluding the 5 pups described below, pups of M-treated mothers weighed less than controls on Day 28. Female offspring of Day 5 M-treated mothers showed unaltered sensitivity to M when tested on the hot plate on Day 67. On Day 92 female pups of Day 11 M-treated mothers showed decreased sensitivity to the analgesic action of M (10 mg/kg s.c.) but exhibited unaltered sensitivity to the hot plate prior to M injection. Offspring of both Day 5 and Day 11 M-treated mothers exhibited diminished ($p<0.05$) plasma corticosterone elevations 30 min after acute injection of M (30 mg/kg) on Day 138.

Five female pups from 3 litters manifested a striking syndrome of growth, sensory and motor deficits. They had significantly lower body weights and lacked peripheral pain sensation and fine motor control. The hindlimbs were normally held in full extension and locomotion was achieved by trunk movements with awkward forelimb assistance. They showed both diminished resting and ether stress-induced levels of corticosterone, but evidenced normal vaginal cyclicity. When challenged with naloxone (5 mg/kg) these animals, unlike controls, showed no elevation of corticosterone levels.

These findings are consistent with those of Friedler and indicate that exposure of female rats to M early in life may produce M tolerance as well as serious growth, neurological and endocrinological deficits in their progeny. The basis for such effects is not known, but may involve a drug action on the immature germ cell which becomes evident after fertilization and development. (Supported in part by USPDHS grant DA826 and NIH RR-07055).

NEUROCHEMISTRY

982 CHARACTERIZATION OF RNA SYNTHESIS WITH RABBIT AND GERBIL BRAIN SLICES IN VITRO. J. Albrecht* and T. Yanagihara, Dept. of Neurol., Mayo Clinic and Mayo Med. School, Rochester, MN. 55901

In order to characterize the newly synthesized RNA, rabbit and gerbil brain slices were incubated with [^{3}H] uridine and radio-labeled RNA was investigated with nuclear, rough endoplasmic reticulum membrane and free polyribosomal fractions. TCA-insoluble specific radioactivity was highest in the nuclear fraction. The specific radioactivity of the membrane fraction was twice as much as the free polyribosomal fraction. Actinomycin D (up to 0.1 μg./ml. incubation medium) inhibited [^{3}H] uridine incorporation to similar extent (up to 40%) in these subcellular fractions, while the higher concentration of Actinomycin D resulted in more selective inhibition of the free polyribosomal fraction. The results were similar in rabbit and gerbil. Polyribosomal RNA was then extracted with phenol and further fractionated with oligo (dT) cellulose chromatography. The results indicated that 52% of labelling of rabbit and 26% of gerbil RNA were associated with poly(A)-containing (messenger) RNA. In contrast to the cell culture system or the in vivo system reported in the literature, low concentration of Actinomycin D (up to 0.08 μg./ml.) did not increase the relative labelling of poly (A+) RNA. There was even relative decrease of poly (A+) RNA with rabbit brain. Polyribosomal RNA was further characterized with continuous sucrose density gradient (15 to 30%) ultracentrifugation. In both rabbit and gerbil system, the major radio-labelling occurred in non-ribosomal RNA even with the fractionation of poly (A-) RNA. The poly (A+) RNA showed the major peak just ahead of 18S RNA while the large portion of poly (A-) RNA sedimented faster than 28S RNA. Though the messenger activity of poly (A-) RNA remains to be established, both poly (A+) RNA and poly (A-) non-ribosomal RNA were vulnerable to Actinomycin D. The present results demonstrated that RNA synthesis with brain slice in vitro favors synthesis and/or nucleocytoplasmic transport of messenger RNA, and that this system provides a convenient tool for studying the fate of messenger RNA under various physiological and pathological conditions. (Supported by the grant NS-06663 from NIH)

983 SPECIFIC (^{3}H)OUABAIN BINDING TO DIFFERENT AREAS OF BRAIN AND SOME PERIPHERAL ORGANS OF CAT: EFFECT OF CHRONIC ETHANOL TREATMENT. Shailesh P. Banerjee and Virendra K. Sharma*. Department of Pharmacology & Toxicology, University of Rochester, School of Medicine & Dentistry, Rochester, New York 14642.

Chronic ethanol treatment of cats, increased specific (^{3}H)-ouabain binding by 63% in cerebral cortex, 47% in cerebellum, 84% in amygdala and 100% in hippocampus when the binding assays were performed in the presence of 160 nM (^{3}H)ouabain. There was no significant change in specific (^{3}H)ouabain binding in hypothalamus, thalamus, corpus striatum and brain stem following chronic ethanol ingestion. Specific (^{3}H)ouabain binding to microsomal fraction derived from ethanol-treated cat heart, liver, spleen and kidney increased by 70%, 75%, 63% and 42% respectively as compared to that found with microsomal fractions obtained from control animals. Scatchard analysis revealed that enhancement of specific (^{3}H)ouabain binding following chronic ethanol treatment in several peripheral organs and some areas of cat brain is primarily due to changes in densities of ouabain binding sites. Since ouabain is a specific inhibitor of ($Na^+ + K^+$)-ATPase the present observations suggest that the molecular mechanism for the enhancement of ($Na^+ + K^+$)-ATPase activity after chronic ethanol ingestion may be due to increased net rate of synthesis of ($Na^+ + K^+$)-ATPase molecules or exposure of non-functional enzyme system following conformational change of plasma membrane. (Supported by the American Heart Association and H.L. 18185.)

984 COMPARISON OF IN VIVO AND IN VITRO PHOSPHORYLATION OF SYNAPTIC MEMBRANES. Robert F. Berman*, John P. Hullihan* and John E. Wilson. Department of Biochemistry, University of North Carolina, Chapel Hill, North Carolina 27514.

In vivo and in vitro phosphorylation patterns of synaptic membrane proteins were compared. In vivo phosphorylation was carried out by injecting 1 mCi of ^{32}P-orthophosphate into the ventricles of adult rats via chronically implanted cannulas and sacrificing after 40 minutes. Brains, minus brainstem, cerebellum and olfactory lobes, were homogenized and synaptosomal fractions were isolated by ultracentrifugation of the P_2 pellet on a continuous sodium diatrizoate gradient. The synaptosomes were osmotically disrupted, and the resulting ^{32}P-labeled synaptic membranes were further fractionated by SDS-polyacrylamide (7.5%) slab-gel electrophoresis. Unlabeled synaptic membranes from non-injected rats were phosphorylated in vitro by incubation with [γ^{32}P]ATP (4μM) for 2 minutes prior to SDS-polyacrylamide electrophoresis. Following electrophoresis, the gels were stained (Coomassie blue) and the resultant protein patterns were scanned by densitometry. The protein patterns for in vivo and in vitro labeled synaptic membranes were identical. In contrast, autoradiograms of these gels demonstrated striking differences in the phosphorylation patterns between in vivo and in vitro labeled synaptic membranes. While similarities were apparent, several protein bands which were labeled by ^{32}P by the in vivo phosphorylation procedure, did not appear to be labeled when phosphorylation was carried out in vitro. Cyclic-AMP (10μM) was found to maximally stimulate the in vitro phosphate labeling of two protein bands which were not labeled by the in vivo procedure. These results suggest the possibility that the regulation of phosphorylation of synaptic membrane proteins differs between the in vivo and in vitro states. (Supported in part by NIH Grant NS-07457 and by The Alfred P. Sloan Foundation).

985 TWO FORMS OF RAT CEREBRAL MICROSOMAL ($Na^+ + K^+$)-ADENOSINETRIPHOSPHATASE WITH DIFFERING SUSCEPTIBILITY TO PERIODATE INHIBITION John M. Bertoni* and George J. Siegel. Dept. Neurology, Sch. Med., Univ. of Mich., Ann Arbor, Mich. 48109.

50% inhibition of rat cerebral ($Na^+ + K^+$)-adenosinetriphosphatase [($Na^+ + K^+$)-ATPase] and K^+-paranitrophenylphosphatase (K^+-pNPPase) activities occurred reproducibly after 30 minutes of preincubation of NaI-extracted microsomes (0.1 mg protein/ml) in 25 μM periodic acid and 150 mM imidazole HCl (pH 7.4) at 23°C. Inhibition of Mg^{++}-ATPase or Mg^{++}-pNPPase activities under the same conditions was only 20% and 8%, respectively. ($Na^+ + K^+$)-ATPase activity was inhibited by 40% after 1 minute of exposure to periodate under these conditions. Thereafter, the inhibition progressed more slowly, reaching 60% after 80 minutes preincubation. Microsomes were preincubated with various concentrations of periodate for 30 minutes under these conditions. Inhibition of ($Na^+ + K^+$)-ATPase activity reached 40% at 10 μM periodate and thereafter progressed to 50% and 70% at 25 μM and 100 μM periodate, respectively. A similar periodate concentration response curve was obtained for inhibition of K^+-pNPPase activity under the same conditions. At least 95% inhibition of ($Na^+ + K^+$)-ATPase activity was produced by ouabain indicating that the measured activity represents the cation transport enzyme. Increasing the microsomal protein concentration in the exposure medium reduced the inhibition produced by 25 μM periodic acid. Inhibition of K^+-pNPPase activity could not be reversed by two washes of the periodate treated microsomes. To explore the possibility that a soluble oxidation product was inhibitory, microsomes were preincubated with 50 μM solutions of formic acid, formaldehyde, acetaldehyde, and glyceraldehyde and no inhibition was found under conditions in which 25 μM periodate produced 40% inhibition. These findings indicate that the cation transport enzyme in rat cerebral microsomes exhibits at least two forms distinguished by their sensitivity to periodate. The relative protection of half the enzyme activity may be related to enzyme conformation or orientation within the microsomal membrane. The ($Na^+ + K^+$)-ATPase and K^+-pNPPase activities show the same biphasic response suggesting that the same periodate-sensitive group(s) may be involved.

987 REGULATION OF PHENYLETHANOLAMINE N-METHYLTRANSFERASE SYNTHESIS AND DEGRADATION. Roland D. Ciaranello. Dept. Psychiatry, Stanford University Medical Center, Stanford, CA 94305

Adrenal medullary phenylethanolamine N-methyltransferase (PNMT) is under dual control by impulses from the splanchnic neurons, and by glucocorticoids from the adrenal cortex. Several lines of evidence suggest that these regulators operate by different biochemical mechanisms. Administration of reserpine and 6-hydroxydopamine, drugs which cause a reflex activation of the splanchnic nerves causes a marked increase in adrenal PNMT activity in both normal and hypophysectomized rats. In contrast, dexamethasone or ACTH have no effect on PNMT in normal rats, although both drugs will restore to normal the profound decrease in PNMT levels brought about by hypophysectomy.

After hypophysectomy PNMT levels fall markedly; this is associated with a decrease in immunotitratable PNMT molecules. Dexamethasone partially restores PNMT activity and immunotitratable enzyme levels, suggesting that the in vitro measurement of enzyme activity reflects the number of PNMT molecules present. Dual radioactive amino acid labelling studies show that the fall in PNMT levels after hypophysectomy is the result of accelerated degradation of the enzyme. PNMT turnover studies in dexamethasone-treated hypophysectomized rats show that dexamethasone restores PNMT levels by inhibiting the accelerated degradation caused by hypophysectomy. Dexamethasone has no apparent effect on the rate of PNMT synthesis.

Studies on the kinetic properties of PNMT from hypophysectomized and normal rats fail to disclose differences in affinity of PNMT for its substrates. Stability of PNMT at 50° is profoundly accelerated after hypophysectomy, however, suggesting an in vitro as well as in vivo susceptibility of the enzyme to denaturation after hypophysectomy. Thermal stability of PNMT appears to depend on the presence of an endogenous stabilizing factor which binds to the enzyme, protecting it against heat denaturation. This factor is present in control rats, is lost after hypophysectomy, and can be restored by dexamethasone treatment. Thus this endogenous factor may act in vivo to stabilize PNMT against intracellular proteolysis as well as acting in vitro to protect the enzyme against thermal denaturation. Intracellular PNMT proteolysis may, then, be regulated by this endogenous substance.

988 ACTIONS OF PHENYTOIN ON AChE SYNTHESIS IN CULTURED CHICK EMBRYO MUSCLE TREATED WITH PARAOXON. C. Michael Cisson*. Richard K. Entrikin, and Barry W. Wilson. Univ. of Calif., Davis, CA 95616.

The combination of phenytoin (diphenylhydantoin, DPH) and exercise alleviated functional disabilities of dystrophic chicks and reduced characteristically high muscle AChE activities (Entrikin et al., Science 195:873, 1977). In addition, 15 µg/ml DPH reduced the total AChE production of chick embryo muscle cultures by 34% and AChE released into the medium by 40%. Cellular AChE levels and net protein synthesis were not altered (Cisson et al., Fed. Proc., 36:498, 1977). These studies suggested DPH decreased net synthesis of AChE activity. To further study this question, we briefly treated cells with 3×10^{-8}M paraoxon (which inhibited 90% of the AChE activity) and then measured synthesis of new AChE in a normal medium or in one containing 15 µg/ml DPH. During the first 2 hours of recovery, cells treated with paraoxon + DPH produced significantly less AChE activity and maximal recovery was delayed by 30 minutes compared to cells treated with paraoxon alone (Table 1). Eight hours after treatment, net synthesis of AChE activity (Δcell + Δmedium) by cells treated with paraoxon + DPH was also significantly less compared to cells that were treated with paraoxon alone. DPH did not affect general cell protein synthesis. The results show that DPH decreases AChE activity in cultured chick embryo muscle by reducing net synthesis of AChE activity. (Supported by NIH grants ES 00202, AM 16716, and NS 05308, and the MDA).

989 DOPAMINE-SENSITIVE ADENYLATE CYCLASE IN RETINA: SUBCELLULAR DISTRIBUTION. Yvonne Clement-Cormier* and Dianna Redburn (SPON: G.A. Robison). Dept. of Neurobiology and Anatomy and Dept. of Pharmacology, Univ. Tex. Med. Sch., Houston, Tx. 77025.

Biochemical and pharmacological analysis of subcellular fractions from rabbit retina demonstrated the presence of an adenylate cyclase activity which is selectively stimulated by low concentrations of dopamine. The highest specific activity of adenylate cyclase was found in the P_2 fraction which is enriched in synaptosomes from amacrine and perhaps to a lesser extent from bipolar and horizontal cells. Adenylate cyclase activity was also observed in the P_1 fraction which contains synaptosomes from photoreceptor cells; however, adenylate cyclase sensitivity to dopamine was not associated with this fraction. A half maximal increase in the activity of the enzyme in the P_2 fraction occured in the presence of 4×10^{-6} M dopamine. A high degree of pharmacological specificity was demonstrated for the receptor-cyclase complex. Chloropromazine, a dopamine antagonist, competitively inhibited the activity of the enzyme in this fraction with a calculated inhibition constant of 5×10^{-8} M. A study of the relative effects of the cis-trans isometric forms of the thioxanthene, flupenthixol showed that the -isomer of flupenthixol was a more potent dopamine antagonist of adenylate cyclase activity in the retina than the -isomer. In addition, the (+) isomer of butaclamol was more potent than the (-) isomer in blocking the stimulation of adenylate cyclase by dopamine. The inhibition constant for (+) butaclamol was calculated to be 4.5×10^{-8} M. Dopamine agonists, apomorphine, N-methyldopamine (epinine) and 2 amino-6,7-dihydroxy-1,2,3,4-tetrahydronapthlene (ADTN) mimicked the action of dopamine on adenylate cyclase activity in retinal homogenates and subcellular fraction P_2. Dopamine has been previously localized by histofluoresence within the amacrine cells of the retina. In addition, we have demonstrated the localization of ^{3}H-dopamine uptake and release systems specifically within the amacrine (P_2) synaptosomal fraction. These data suggest that amacrine cells may stimulate adenylate cyclase systems within bipolar and/or ganglion cells by interacting with dopamine receptors which are pharmacologically similar to those previously characterized in the rat striatum. (Supported in part by a grant from the Pharmacuetical Manufacturer's Association.)

990 THE EFFECTS OF LEAD INTOXICATION ON THE BRAIN UPTAKE OF CALCIUM IN ADULT ALBINO RABBITS by S.L. Cookson*, J.D. Mann*, C.S. Kim*, J.T. Gatzy* and L.A. O'Tuama, (SPON: Troy A. Reaves, Jr.,) Depts of Neurology, Medicine and Pharmacology, Univ. North Carolina, Sch. Med., Chapel Hill, N.C. 27514

A technique for rapidly assessing the passage of solutes across the blood-brain barrier during a single circulatory pass has been successfully developed and extensively used (Oldendorf, Brain Research, 24:372-376, 1970). In the present study, this method has been applied to investigate the brain uptake of calcium in lead poisoned rabbits. Lead intoxication was induced in 30 day old albino rabbits by the oral administration of lead carbonate, 165mg/day for 5 days. Controls consisted of age matched non-lead exposed rabbits. Experimental procedures were carried out under ether anesthesia at the end of the lead exposure period. ^{45}Ca and [^{3}H] water were made up in buffered Ringers lactate to a total volume of 0.4cc and rapidly injected as a single bolus into the left carotid artery through a 27 ga. needle. Final calcium concentration in the injectate was 1.531 mM of which 0.031 mM was ^{45}Ca. Ten seconds after injection, animals were sacrificed by decapitation. This time for sacrifice was chosen on the basis of ^{14}C-inulin indicator dilution studies which show that transit time through rabbit brain for an intravascular marker is 8 seconds or less. In each experiment, the brain was quickly removed and the left hemisphere divided into cortical gray and deep white matter for determination of ^{45}Ca and [^{3}H] water by liquid scintillation spectroscopy. A portion of the right hemisphere was analyzed for lead content by atomic absorbtion spectroscopy. A brain uptake index (BUI) (Oldendorf, Loc. cit.) was calculated for left hemisphere samples. Final values were corrected for residual blood volume. Brain lead content was found to be 0.035μg/gram and 0.377 ± 0.10μg/gram for control and lead intoxicated groups respectively. The BUI for cortical gray matter was 0.98 ± 0.06 (SEM)% for controls and 0.72 ± 0.04% for lead poisoned animals ($p<0.01$); for deep white matter the values were 1.45 ± 0.10 (SEM)% and 1.37 ± 0.09% for controls and experimentals (NS). Other studies have suggested that a primary effect of lead intoxication is disruption of transport systems associated with the neural barriers (Lorenzo, A.V., Gewirtz, M.:Proc Am Soc Neurochemistry, 231, 1977; Kim et al, Environ Health Perspectives, in press, 1977). The finding in this study of a 24% decrease in calcium uptake in cortical gray matter suggests that lead intoxication may also disrupt systems for transport of calcium at the blood-brain barrier.

991 EFFECTS OF LIPID INTERMEDIATES, ALIPHATIC ALCOHOLS AND DETERGENTS ON SYNAPTOSOMAL LYSOPHOSPHOGLYCERIDE : ACYL-CoA TRANSFERASE ACTIVITY. D. R. Corbin*, R. MacQuarrie*, and G. Y. Sun. Sinclair Comp. Med. Res. Farm, Univ. of MO, Columbia, MO 65201.

The enzymic transfer of arachidonyl groups to 1-acyl-glycerophosphorylinositol (GPI) and 1-acyl-glycerophosphorylcholine (GPC) has been shown to occur in the synaptosomal fraction of mouse brain. This enzyme has been implicated as being important in regulating the turnover of polyunsaturated acyl groups of membrane phosphoglycerides, especially those present in the synaptic vesicles and synaptic plasma membranes. This membrane-bound enzyme was found to be greatly inhibited by Triton X-100 (0.01% or higher), a non-ionic detergent. On the other hand, sodium taurocholate, an ionic detergent, gave slight stimulation at the 0.01% level but exerted an inhibitory effect at higher concentrations (0.1% or higher). Excess bovine serum albumin (BSA) added to the incubation system also inhibited the transfer of (1-^{14}C)-arachidonate to the lyso acceptor molecules. This effect may be due to an excessive binding of the fatty acid substrate to BSA. A number of lipid intermediates with a free hydroxyl group, such as 1-acyl-phosphatidic acids, diacylglycerols and monoacyl glycerols were found to exert an inhibitory effect (25%) to arachidonyl transfer to 1-acyl-GPI and GPC. Furthermore, arachidonyl groups were not appreciably transferred to these lipid intermediates, further indicating the specificity of the substrates for acyl transfer. Ethanol at low concentrations (0.5-1.0%) gave slight stimulation to the acyl transfer system but became inhibitory at higher concentrations. Aliphatic alcohols with increasing chain length gave increasing inhibition to the enzymic system, a phenomena consistent with the fact that membrane-bound enzymes are greatly affected by changes in the hydrophobic regions of the membranes. (Supported in part by USPHS Research Grant NS12906 and NSF BNS76-24338).

992 RECIPROCAL MODULATION OF AMINO ACID AND SUGAR UPTAKE BY NOREPINEPHRINE AND EXTRACELLULAR K+ IN ASTROCYTES IN VITRO. C. J. Cummins, O. Z. Sellinger, and R. A. Glover (SPON: S. Winans). The University of Michigan, Ann Arbor, Mich. 48109.

We (CJC and RAG) presented details of a new technique for the cultivation of rat brain astrocytes at the last Neuroscience Meeting. By morphological, cytochemical, histochemical and biochemical criteria, this technique produces highly purified populations of astrocytes.

It is generally known that extracellular concentrations of K+ affect the membrane potential, oxygen uptake and ATP levels in preparations of astrocytes in vivo and in vitro. Uptake into confluent cultures of astrocytes of 2-deoxy-d-glucose (2-DOG) and methionine was observed in a buffer composed of 5.3 mM KCl, 150 mM NaCl, 1.0 mM $CaCl_2$, 0.6 mM $MgCl_2$, 1.6 mM KH_2PO_4, 4.3 mM Na_2HPO_4, at pH 7.2. To test the effects of elevations in extracellular K+ concentrations, K+ was replaced isoosmotically by Na+. At 11.9 mM K+, the uptake of 2-DOG was increased over control levels (at 6.9 mM K+). Increases in K+ above 11.9 mM were without effect. Norepinephrine (NE) and serotonin (5-HT) at 1.0×10^{-6} M decreased 2-DOG uptake. GABA diminished uptake, but not significantly. These effects do not appear secondary to alterations in cAMP levels or intracellular ionic perturbations, since dibutyryl cyclic AMP and ouabain were without effect.

Methionine was transported linearly for 150 seconds up to 2.4×10^{-6} M, yielding distribution ratios (met_{in}/met_{out}) of approximately 2.0. K+ concentrations of 11.9 mM decreased uptake of methionine at most methionine concentrations. NE at 50×10^{-9} M increased the uptake 2-fold while ouabain and dibutyryl cAMP had opposite effects.

These observations indicate that extracellular K+ concentrations and NE may act as reciprocal regulators of amino acid and hexose uptake in vitro, and they may suggest that in vivo K+ and NE regulate the levels of extracellular metabolites in brain by modulation of astrocytic uptake.

(CJC is a predoctoral trainee, NIMH grant 013034; this work was also sponsored by a H. H. Rackham Disertation Grant, and by a NINCDS grant 06294 to OZS).

993 POTENTIATION OF STIMULUS-SECRETION AND STIMULUS RESPIRATION IN ISOLATED CORTICAL TISSUE BY CYCLIC AMP (cAMP) AND ISOPROTERANOL Joseph T. Cummins and Elizabeth Keller, V.A. Hospital, Sepulveda, CA 91343, and Dept. Med. Pharmacol. Therup., Univ. California, Irvine.

Rat brain cortical slices were maintained in Krebs-Ringer bicarbonate and depolarized by electrical pulses (100Hz, 10 V). Stimulus-respiration was measured by changes in the steady-state level of reduced pyridine nucleotides [NAD(P)H] after electrical pulses. Stimulus-secretion was measured by following the rate of endogenous glutamate release before and after the application of electrical pulses. Isoproteranol (10^{-5}M), cAMP (10^{-3}M), and the phosphodiesterase inhibitor RO 20-1724 (10^{-5}M) potentiated by 75% of the increase in NAD(P)H due to electrical pulses. The potentiation by cAMP is inhibited by the β-adrenergic blocker propranolol (10^{-5}M), but not the α-adrenergic blocker phenoxybenzamine (10^{-5}M). In parallel experiments on superfused cortical slices cAMP potentiated by the 80% release of endogenous glutamate by electrical pulses. Thus cAMP potentiated stimulus-respiration and stimulus-secretion to the same extent. These observations imply that brain respiration and secretion is directly controlled by components of a β-adrenergic-adenylate cyclase system. These biochemical reactions of stimulus-respiration and stimulus-secretion may be a measurement of a potentiated state in which adrenergic neurones exert functional control over brain respiration and neurosecretion.

994 ENZYMIC DEGRADATION OF DIACYL-GLYCEROPHOSPHORYLINOSITOLS BY BRAIN SUBCELLULAR MEMBRANES. O. C. Der* and G. Y. Sun. Sinclair Comp. Med. Res. Farm, Univ. of MO, Columbia, MO 65201.

The implications of important functional roles of the acidic phospholipid, diacyl-glycerophosphorylinositols (GPI), in metabolism of excitable membranes has prompted us to study the biochemical characteristics of enzymes degrading this type of molecule in brain. The substrate, 1-acyl-2-^{14}C-arachidonyl-GPI, was prepared by enzymic transfer of 1-^{14}C-arachidonate to 1-acyl-GPI which in turn was obtained by degradation of diacyl-GPI by phospholipase A_2. Incubation of the labeled diacyl-GPI (app. 40,000 cpm, 5 nmole) was performed in a system containing 0.5-1 mg of membrane proteins (0.32M sucrose with 50mM Tris, pH 7.4) and sodium taurocholate and deoxycholate (1 mg each) in a total volume of 0.5 ml. Approximately 25-30% of the labeled substrate were hydrolyzed in 1 hr at 37°C. Hydrolysis was reduced 60% when incubated without detergents. Maximal hydrolysis was observed in the presence of both detergents but Triton X-100 (0.1%) gave nearly complete inhibition. Enzymic degradation proceeded linearly up to 1 hr of reaction time and the products formed (mainly diacylglycerols) were proportioned to the externally added substrate as well as the amount of enzymic protein (up to 2 mg). The enzyme was specific for degradation of diacyl-GPI since 1-acyl-2-^{14}C-arachidonyl-GPC (choline) could not serve as an active substrate. Under the present incubation condition, very little degradation of diacyl-GPI by phospholipases A_1 or A_2 was found. Further assay of the enzyme with various purified subcellular and subsynaptic fractions indicated that activity of the enzymes was 1 1/2 times higher in the microsomal than in the synaptosomal fractions. Very little activity was found in the myelin. Upon subfractionation of the synaptosomal fraction, the hydrolase activity seemed to reside mainly in the synaptic vesicles and synaptic plasma membranes with little or no activity in the mitochondria fraction. (Supported by USPHS Research grant NS12960).

995 MEASUREMENT OF NEWLY SYNTHETIZED ^{3}H-3-METHOXYTYRAMINE AS INDEX OF NERVE IMPULSE FLOW DEPENDENT DOPAMINE RELEASE IN RAT STRIATUM. A.M.DiGiulio*, A.Groppetti*, F. Cattaben*, A.Maggi* and S.Algeri* (SPON: T. C. Westfall) Inst. of Pharmacology; Inst. of Pharmacology and Pharmacognosy, Univ. of Milan and M.Negri Inst. for Pharmacological Research, Milan, Italy.

It has been proposed that changes of 3-Methoxytyramine (3-MT) concentrations give a reliable index for Dopamine (DA) release into the synaptic cleft. In fact drugs known to reduce neuronal DA activity (i.e. γ-Butyrolactone and Apomorphine) produce a decrease of striatal 3-MT concentrations.

However, administration of d-Amphetamine (AMPH)(1mg/kg i.v.), a drug also reported to inhibit firing rate of DA cell bodies in Substantia Nigra, results in an increase of striatal 3-MT. This suggests that AMPH may release DA by mechanisms not dependent upon nerve impulse flow. It has been suggested by several investigators that newly synthetized DA is preferentially released and that this release is nerve impulse flow dependent. We have therefore studied the effect of AMPH on newly formed ^{3}H-3-MT. AMPH treated rats were injected intraventricularly with ^{3}H-Tyrosine and killed 10 min thereafter by microwave radiations. In contrast to cold 3-MT the striatal concentrations of ^{3}H-3-MT were decreased by AMPH. This finding leads to the following conclusions: 1) cold 3-MT and ^{3}H-3-MT reflect two distinct mechanisms of DA release; 2) it is possible that ^{3}H-3-MT reflects the nerve impulse dependent DA release, being the firing of DA neurons decreased by AMPH. This hypothesis seems to be supported by the observation that when AMPH is given to rats with monolateral lesions of the crus cerebri, a condition that depresses the effect of this drug on firing of DA neurones, no changes of ^{3}H-3-MT levels have been found.

Another experimental condition in which cold 3-MT and ^{3}H-3-MT levels are differently affected, is represented by their post mortem variations. In fact, while the striatal concentrations of cold 3-MT measured 20 min after decapitation of the animals showed a 30 fold increase, ^{3}H-3-MT levels were only slightly affected. Since 20 min after decapitation nerve impulse flow is unlikely present, these data give further evidence that cold 3-MT derives from DA released by mechanisms not dependent upon nerve impulses, while the opposite might be true for ^{3}H-3-MT.

996 DEVELOPMENTAL CHANGES IN THE PHOSPHOLIPID COMPOSITION OF C6 ASTROGLIOMA CELLS IN VITRO Robert V. Dorman and Barry Festoff V. A. Hospital, Kansas City, MO 64128

The maturation of C6 astroglioma cells in culture is correlated with the development of a phospholipid pattern. We followed C6 cells as they developed and reached confluency. The phospholipid composition of these cells changed significantly and the importance of these changes is discussed.

C6 astroglioma cells were grown in MEM with 10% fetal calf serum. The cells were trypsinized prior to passage. Cells were harvested at 3, 6, 24, 48, 72, 96 and 168 hours post-passing. The phospholipids were extracted according to Folch, separated by thin layer chromatography and quantitated by lipid phosphorus. [^{3}H]-thymidine corporation was used to indicate mitotic activity.

The results indicated that ethanolamine plasmalogens (1-alk-1'-enyl-2-acyl-sn-glycero-3-phosphoryl ethanolamines) accounted for approximately 20% of the total phospholipids, considerably more than previously reported. The ratio of plasmalogen to diacyl form of the ethanolamine phosphoglycerides increased from 1.06 at 3 hours to 4.82 at 7 days, indicating considerable changes in ethanolamine phosphoglyceride metabolism as the astroglioma cells pass from growth to stationary phase. During the same time course the mole % of choline phosphoglycerides decreased relative to the other lipid classes. The absolute increase of ethanolamine phosphoglycerides and decrease of choline phosphoglycerides are larger than indicated by the mole % values, because the phospholipid content per cell increased approximately 50% between 3 and 72 hours post-passing. The increasing phospholipid content parellels a decreasing mitotic activity (^{3}H-thymidine incorporation).

These changes in C6 phospholipid composition during growth in culture are summarized as follows: 1) development, as described by the change from exponential growth to stationary phase, correlates with a significant increase in ethanolamine plasmalogens; 2) this alteration is initiated by a dramatic reduction of ethanolamine plasmalogens which coincides with the effects of trypsinization; 3) a relative reduction of choline phosphoglycerides occurs during this same developmental course. The enrichment of choline phosphoglycerides during growth phase and ethanolamine phosphoglycerides during stationary phase may be related to the fluidity or stability of the cell membranes as required for different metabolic states.

997 TRANSPORT OF META-TYRAMINE, PARA-TYRAMINE AND DOPAMINE IN RAT STRIATAL SLICES. L.E. Dyck* (SPON: A.A. Boulton), Psychiatric Research Division, University Hospital, Saskatoon, Saskatchewan, Canada S7N 0W8.

The high affinity uptakes of tritiated meta-tyramine (m-TA), para-tyramine (p-TA) and dopamine (DA) into rat striatal slices (0.2 mm thickness) have previously been shown to be inhibited by 3,4-dinitrophenol (5×10^{-4}M) and ouabain (10^{-4}M). Cocaine (5×10^{-6} M) and low Na^+ (25mM) were also found to inhibit the uptakes of these three amines. Thus, a Na^+-dependent, carrier-mediated transport system, utilizing metabolic energy, perhaps derived from Na^+-K^+ATPase may be involved.

Efflux of a previously accumulated amine was studied by a rapid transfer technique in the presence of nialamide (12.5 μM). The spontaneous efflux curve exhibited a characteristic initial rapid rate of wash-out followed by a secondary slow phase. During this latter phase, if the slices are depolarized with 50mM K^+, a typical release peak was observed. The effect of removal of Ca^{2+} (replaced by 2mM EDTA) from the Krebs Henseleit medium was assessed in the following manner: (1) the removal of Ca^{2+} during both the initial rapid wash-out phase and during the K^+-depolarization; (2) the removal of Ca^{2+} during the K^+-depolarization only; (3) the removal of Ca^{2+} during the second phase in the absence of K^+-depolarization; (4) the addition of cocaine (5×10^{-6}M) during the second phase also in the absence of K^+-depolarization. The first procedure (i.e. expt. 1) was found to cause increased rates of spontaneous efflux of all three amines; but the K^+-elicited effluxes of the tyramines were completely suppressed (i.e. Ca^{2+}-dependent), whereas that of dopamine was only partially suppressed (i.e. partially Ca^{2+}-dependent). This apparent Ca^{2+}-dependency in the case of tyramines was due to the virtual washout of all accumulated amine prior to the depolarization. In expt. 2, the K^+-elicited effluxes of both tyramines were not suppressed, whereas the K^+-elicited efflux of dopamine was again partially suppressed. In expt. 3, the spontaneous effluxes of m-TA and DA were moderately increased, whereas that of p-TA became as large as the K^+-elicited efflux in the first experiment. From the above, it is difficult to assess whether or not the removal of Ca^{2+} suppresses K^+-elicited effluxes. In expt. 4, no change in the spontaneous efflux of DA occurred, and only a small increase was observed for the tyramines. It appears, therefore, that a Ca^{2+}-dependent re-uptake is not responsible for the increased spontaneous efflux caused by Ca^{2+} removal. It may be that Ca^{2+} plays some role in tissue retention of the amines and that this function of Ca^{2+} is of greater importance for p-TA than for m-TA and DA.

998 OCTOPAMINE: A SUBSTRATE FOR TYPES A AND B MONOAMINE OXIDASE. David J. Edwards and Mark C. Venetti*. Western Psychiatric Inst. & Clinic, Dept. Psychiatry, Univ. Pittsburgh, School of Medicine, Pittsburgh, PA. 15261.

Octopamine was previously reported to be a substrate for only the type A species of monoamine oxidase (MAO) (Houslay & Tipton, Biochem. J. 139:645 [1974]). The recent finding that imipramine, a tricyclic antidepressant drug, causes an increase in octopamine concentrations in rat brain (Harmar & Horn, J.Neurochem. 26:987 [1976]) prompted us to reexamine the substrate specificity of A and B types of MAO towards octopamine, since tricyclics are known to selectively inhibit type B MAO (Edwards & Burns, Life Sci. 15: 2045[1974]). MAO was assayed with [2-^{3}H]-DL-octopamine in .04 M phosphate buffer at pH 7.5. Varying concentrations from 10^{-10} to 10^{-3}M of clorgyline (a selective inhibitor of type A MAO) were preincubated with the enzyme and the reaction was initiated by the addition of substrate. When either rat brain or liver homogenates were used, biphasic inhibition curves were obtained. The clorgyline-sensitive (type A) activities of both the brain and liver enzymes were inhibited 50% at a concentration of $5x10^{-9}$M of the inhibitor. The clorgyline-insensitive (type B) activities of these enzymes were inhibited 50% at an inhibitor concentration of 10^{-5}M. The plateaus of the inhibition curves occurred at 88% and 70% inhibition for the brain and liver enzymes, respectively. In contrast, a single sigmoid curve occurring at high clorgyline concentrations (I_{50}=$7x10^{-5}$M) was obtained for human platelet MAO, a pure type B enzyme. These experiments were repeated with deprenyl, a selective inhibitor of MAO-B. As with clorgyline, the inhibition curves were biphasic for both rat brain and liver MAO and sigmoidal for human platelet MAO. The apparent K_m for octopamine was determined to be $4.8x10^{-4}$M for rat liver MAO. When MAO-A was completely inhibited by preincubation with 10^{-7}M clorgyline, the apparent K_m for the remaining activity was 3.9x 10^{-4}M, indicating that the apparent K_m for octopamine toward MAO-A and MAO-B are similar. In conclusion, these data demonstrate that octopamine is a substrate for both types A and B MAO. Consequently, deamination of this amine may be affected by inhibition of either enzymatic form.

	I_{50} (clorgyline)		I_{50} (deprenyl)	
Enzyme	MAO-A	MAO-B	MAO-A	MAO-B
Human Platelet	-	$7x10^{-5}$M	-	$2x10^{-8}$M
Rat Brain	$5x10^{-9}$M	10^{-5}M	$6x10^{-6}$M	$5x10^{-8}$M
Rat Liver	$5x10^{-9}$M	10^{-5}M	$6x10^{-6}$M	$5x10^{-8}$M

999 INCREASED BRAIN CYCLIC AMP FOLLOWING FOOTSHOCK AGGRESSION IN THE RAT. B. Eichelman, T.M. McMurray*, G. Davis* and A. Qureshi*. Laboratory of Behavioral Neurochemistry, Dept. of Psychiat., Univ. Wisconsin and VA Hospital, Madison, WI 53705.

Rats subjected to electric footshock display two disparate behaviors, escape or aggressive attacks, depending on whether the rat is shocked alone or with a conspecific. Previous work (Eichelman et al., 1976) has shown that whole brain levels of cAMP are increased 100% over control levels for rats subjected to three days of shock-induced fighting (50 footshocks/day of 2 mA intensity, 0.4 s duration, presented every 7.5 s). An increase in whole brain cAMP of only 20% over control levels is present in isolated rats receiving similar footshock.

With paired rats in the footshock paradigm there is a stepwise increase in brain cAMP with each day of shock-induced testing (50 footshocks/day); the increase plateaus at day 3. This elevation, after three days of shock-induced fighting, returns to baseline levels in two weeks. For example, rats footshocked for three days with the parameters described above have brain cAMP levels of .45 pmoles/mg. Unshocked controls have levels of .22. Recovery levels after 1, 3, 5, 10, and 14 days, respectively are: .36, .35, .33, .26, and .27. All animals were sacrificed by focused microwave irradiation. cAMP was assayed by a modification of the protein-binding method of Tovey et al., 1974. Regional changes based on the sevenfold dissection of Glowinski et al. (1966) demonstrated greatest increases of cAMP in regions of the hypothalamus and caudate nucleus. These studies were accomplished with male Holtzman rats of 200 g wt.

Non-fighting Holtzman female rats (180-200 g) do not show the increase in cAMP following paired shock. Rats treated with a monoamine oxidase inhibitor (pargyline, 20 mg/kg/day) show increased levels of shock-induced fighting (Eichelman & Barchas, 1975). Similarly treated rats show an increase in brain cAMP. The time course of this increase over a three day period parallels the development of the facilitated aggression seen with pargyline. (This work was supported by grants from the Medical Research Service of the Veterans Administration Hospital and intramural grants from the University of Wisconsin.)

1000 CYCLIC GMP: A PROPOSED ROLE IN THE PHOTOTRANSDUCTION PROCESS OF PHOTORECEPTOR CELLS. Debora B. Farber and Richard N. Lolley. Dept. Anatomy, UCLA School of Medicine, Los Angeles, CA 90024, and Devel. Neurology Lab., V.A. Hospital, Sepulveda, CA 91343.

Dark-adapted retinal rod outer segments (ROS) of photoreceptor cells possess high levels of cyclic GMP. Upon bleaching of rhodopsin by light, cyclic GMP-phosphodiesterase is activated and the concentration of cyclic GMP falls rapidly. We have investigated purified preparations of bovine ROS in order to evaluate the role of cyclic GMP in modulating the functional biochemistry of ROS. We find protein kinase (PK) activity in the 100,000g supernatant fraction of ROS, which is increased by cyclic nucleotides and which selectively phosphorylates a soluble protein (apparent MW: 30,000 daltons) in a cyclic nucleotide-dependent manner. In the particulate membrane fraction, PK activity phosphorylates opsin independently from cyclic nucleotides. This particulate PK can be solubilized with Lubrol PX and, when in soluble form, it becomes cyclic nucleotide dependent. Conversely, the soluble PK can be reassociated with PK-depleted ROS membranes where it phosphorylates opsin in a cyclic nucleotide-independent manner. Several lines of evidence indicate that the membrane PK and phosphorylation of rhodopsin are associated with sensitivity changes in the ROS (dark/light adaptation). We propose that the soluble PK-30,000 dalton phosphoprotein complex links the light-induced changes in cyclic GMP concentrations with ion permeability changes in the ROS plasmalemma. A model will be presented which illustrates how high levels of cyclic GMP in dark-adapted ROS could allow for the ready access of sodium ions across the plasma membrane (dark-current) and how low levels of cyclic GMP in light-adapted ROS could facilitate a reduction of the dark-current and cause hyperpolarization of the photoreceptor cell. (Supported by NIH Grant EY00395, NSF Grant BMS 74-14784, and the Medical Research Service of the Veterans Administration.)

1001 THE EFFECT OF MAXIMAL ELECTROSHOCK ON ENERGY METABOLITES AND CYCLIC NUCLEOTIDES IN LAYERS OF THE CEREBELLAR VERMIS. G. K. Feussner*, D. W. McCandless*, W. D. Lust and J. V. Passonneau. Laboratory of Neurochemistry, NIH, Bethesda, MD. 20014

Previous studies have shown that maximal electroshock (MES) caused a reproducible seizure response in mice which was reflected in changes in energy metabolites and cyclic nucleotides in the cerebellum. These investigations have been extended to a study of the cerebellar layers to determine whether there was a differential response. The mice were shocked through corneal electrodes with 50 mA for 0.2 sec. The seizure response is characterized by a tonic extensor phase, 0-13 sec; followed by a clonic phase, 13-25 sec, and a subsequent postictal depressive phase. At selected intervals during these periods, the animals were frozen in liquid nitrogen. The dorsal cerebellar vermis was dissected at -30° and sections were cut and frozen-dried according to the method of Lowry and Passonneau (A Flexible System of Enzymatic Analysis, Academic Press, 1972). Samples 0.2-1.2 ug were dissected from the molecular, Purkinje cell-rich, granular and white layers; all samples were from lobultes VI-VII after Larsell. The analyses were made using oil well techniques and enzymatic cycling (Lowry and Passonneau, 1972). Measurements were made of ATP, P-creatine, glucose, glycogen, lactate, GABA, cyclic AMP and cyclic GMP. In general, the response to MES was significantly less in the white matter. P-creatine concentrations showed the most dramatic decrease, falling to 15% of the control values during the excitable phase of the seizure (10 sec). The changes were comparable in all the layers except white matter. The pattern of ATP changes was similar; the maximum decrease at 10 sec was 50% of control. Glucose concentrations decreased only slightly during the excitable phase; however, there was a 2.5-fold increase in glucose 10 min after MES in all layers. The changes in glycogen were delayed, falling to 65% of control value in all layers at 30 sec after MES. Lactate concentrations increased in all layers at 10 sec and continued to increase up to 30 sec after MES. Even after 10 min lactate levels had not returned to control values. There were no significant changes in GABA in any of the layers. Cyclic AMP concentrations in all layers increased 4-fold during the tonic phase and remained elevated at 30 sec after which the levels returned to normal. In contrast, cyclic GMP levels did not change until the postictal depressive period, when the concentrations increased 10-fold. The absolute levels of cyclic GMP and the increases after MES were greatest in the molecular layer. The maximum increases observed 60 sec after MES and were near normal values at 10 min. The effect of phenytoin on metabolite changes after MES was investigated.

1002 DOPAMINERGIC RECEPTORS IN THE CORPUS STRIATUM AND SUBSTANTIA NIGRA-REGIONAL ALTERATIONS IN HUNTINGTON'S DISEASE, J.Z.Fields*, T.D.Reisine*, P.C.Johnson*, L.Z.Stern, and H.I.Yamamura, Univ. of Arizona Health Sciences Center, Tucson AZ 85724.

Neuronal activity in the circuitry connecting the substantia nigra(SN) and corpus striatum(CS) modulates extrapyramidal control of motor function. Progressive loss of neurons as well as biochemical changes have been demonstrated in and may be critical to the tremor and rigidity of Parkinson's Disease and the choreiform movements of Huntington's Disease(HD). In one current model, these symptoms are due to hypo- and hyper-activity, respectively, of nigro-striatal dopaminergic(DA) neurons which synapse on and inhibit cholinergic interneurons in the CS.

Using ligand binding assays, DA receptors have been demonstrated in the CS but not in the SN. Recently(Fields et al., 1977, Trans.Amer.Soc.Neurochem., 8, 193) we developed an assay to label brain DA receptors using (+)-butaclamol-displaceable ^{3}H-spiroperidol binding. We have measured DA receptors in rat brain(CS=540 fmol/mg prot; SN=1.24 fmol/mg tissue) and in human brain(CS=245 fmol/mg prot; SN=16 fmol/mg prot). Although evidence has been accumulating suggesting that, within the SN, dopamine is released from the dendrites of nigro-striatal DA neurons onto axons of incoming striato-nigral neurons, the functions of these DA sites in the SN are uncertain.

In HD, the density(but not ligand affinity or sensitivity to (+)butaclamol) of DA receptors in the caudate nucleus and putamen are decreased by over 50%($P<.05$). Parallel decreases in choline acetyltransferase activity in these areas suggests: 1) a loss of cholinergic interneurons in the CS, and 2) that at least some of the DA receptors are postsynaptic on the cholinergic interneuron cell bodies.Substantial decreases in DA receptors were also found in the globus pallidus(-53%), frontal cortex(-72%), occipital cortex(-72%) and amygdala(-66%). Data on DA receptors in the SN of HD are too preliminary to draw any conclusions.

To further examine the DA receptors in the CS and SN we have used kainic acid lesions which are thought to selectively destroy neuronal cell bodies. Kainate injection in the CS induces biochemical changes in that area that resemble those seen in HD and suggest that kainate lesion of the CS may serve as a useful animal model for HD. Lesions of the CS and SN may also yield information bearing on the location and function of the DA receptors in the SN. Supported in part by grants from the NIMH(MH-27257) and the Committee to Combat Huntington's Disease and from an RSDA (MH-00095) ot HIY and a USPHS Postdoctoral Fellowship (MH-05248-01) to JZF.

1003 PARTIAL REVERSAL BY THAM OF THE EFFECTS OF HYPOXIA ON NEUROTRANSMITTER METABOLISM. G.E. Gibson, M. Shimada and J.P. Blass. MRRC, UCLA Medical School, Los Angeles, California 90024.

Previous studies in our laboratory and elsewhere have demonstrated that the synthesis of acetylcholine (ACh) is closely linked to the oxidation of carbohydrates; impairing carbohydrate oxidation in vivo or in vitro leads to proportional impairment of ACh synthesis, even though the flux to ACh is less than 1% of that through oxidation. We recently found that the earliest changes accompanying mild anemic hypoxia (induced with $NaNO_2$) are a decrease in the incorporation of [U-^{14}C]glucose into ACh and an increase in cyclic GMP with no change in cyclic AMP. These changes preceded the change in whole brain lactate.

The purpose of the present investigations was to determine if prior treatment with THAM (trihydroxyaminomethane, 10 mmol/kg) at an alkaline pH (10.3) would ameliorate certain gross behavioral and biochemical changes accompanying hypoxia induced with $NaNO_2$ (1.1 mmol/kg). Alkaline THAM significantly delayed the time until loss of righting reflex (from 21±1 to 27±2 min) and until death (from 24±1 to 32±2 min). Values are mean ± SEM; n=25 for controls and 12 for THAM treated; $P < 0.01$ for both measurements. Animals treated with an equivalent amount of THAM at an acid pH (4.5) were indistinguishable from controls.

Alkaline THAM also ameliorated some biochemical effects of hypoxia induced with $NaNO_2$ (1.1 mmol/kg). In these experiments, mice were injected with 3 nCi/kg of [U-^{14}C]glucose and 20 µmol/kg of [$^{2}H_4$]choline 19 min after the injection of $NaNO_2$ and 1 min before sacrifice by microwave irradiation. THAM ameliorated several effects of hypoxia (values are means ± SEM per mg brain protein; numbers of animals are in parentheses):

	[$^{2}H_4$]-ACh pmol	[U-^{14}C]-ACh DPM	Total ACh pmol	cGMP pmol	Lactate nmol	Total Choline pmol
Control (9)	5.1±0.7	31±3	166± 9	0.5±0.1	14±1	230±17
$NaNO_2$ alone (9)	0.7±0.1	4±1	117±16	1.3±0.3	59±3	675±85
$NaNO_2$-THAM (9)	2.1±0.3	8±2	161±17	0.7±0.2	41±6	355±22

Hypoxia increased the amount of [$^{2}H_4$]choline in the brain (19±3 to 50±7 pmol/mg prot) and THAM partially reversed the change (to 33±4). cAMP did not change under the conditions of these experiments.

These studies demonstrate that THAM at an alkaline but not an acid pH can partially reverse the effects of hypoxia. The mechanism of action of THAM is not yet known but seems to involve its potential action as a buffer. (This research was supported in part by NICHD grant HD-06576, Public Health Service Grant RR-05756-03 from the NIMH, and grant 17691 from MH.)

1004 ISOLATION OF NERVE GROWTH FACTOR FROM HUMAN PLACENTAL TISSUE. L. D. Goldstein*, C. P. Reynolds* and J. R. Perez-Polo (SPON: J. R. Perez-Polo). Dept. Human Biological Chem. & Gen., Univ. of Tex. Med. Br., Galveston, TX 77550, U.S.A.

Nerve growth factor (NGF) is a multimeric protein having an essential role in the development and maintenance of vertebrate sensory and sympathetic neurons as well as being necessary for axonal sprouting in adrenergic structures of the central nervous system under certain experimental conditions. Mouse submaxillary gland and snake venom NGF are the only two molecular species of NGF which have been well characterized. The protein complex isolated from these sources contains up to three non-identical subunits (α, β, and γ) which are of similar molecular weight but display different isoelectric points. The NGF activity resides strictly with the basic β-NGF subunit. Although levels of NGF activity have been detected in human tissues by the chicken dorsal root ganglion assay and by the radioimmunoassay using antibodies directed against mouse β-NGF, no successful isolation of human NGF has ever been reported. Human placental tissue has been investigated as a suitable source from which NGF may be isolated. Biological activity employing the chicken embryo dorsal root ganglion assay was determined for the amnion, cord serum, fetal, maternal and mixed bloods, and placental cotyledonary tissues. Only the amnion and placental cotyledons showed significant levels of NGF activity. Applying techniques standardized for mouse NGF purification, a fraction rich in NGF activity (20 BU/mg) was isolated at neutral pH from placental cotyledons. Analysis by thin layer isoelectric focusing in polyacrylamide gel (TLIEF) revealed a basic protein species which when eluted from the gel demonstrated NGF activity. NGF activity was not detected in any other part of the pH gradient. Fractionation of the complex isolated at neutral pH by preparative sucrose gradient isoelectric focusing also yielded a basic protein which demonstrated NGF activity (1-3 nanograms/BU). A basic protein species having NGF activity was also isolated from a preparation of human amnion tissue by preparative isoelectric focusing on a granulated gel slab. Supported by NINDS grant NS14034, Welch Grant H698, a gift from the Brown & Lupton Foundation to J.R.P. and a McLaughlin Fellowship to L.D.G.

1005 SPECTRAL STUDIES OF CROTOXIN AND ITS SUB-UNITS. Michael R. Hanley.* (SPON. M.Calvin). Lab.Chem.Biodynamics & Dept. Mol.Biol., Univ. of Calif., Berkeley, Ca. 94720 USA.

Crotoxin, a protein neurotoxin from Crotalus durissus terrificus (Brazilian rattlesnake) venom, is a complex of an acidic polypeptide (crotoxin A) and a basic polypeptide (crotoxin B). Lethality of the complex results from synergistic interaction of the two components. Crotoxin A is not toxic. Crotoxin B is weakly toxic and has phospholipase A2 activity. To study how crotoxin A influences the B component, we have investigated the characteristics of their complex by fluorescence and circular dichroism (CD) spectroscopy. The crotoxin complex is dissociated at acid pH. Over the pH range 2 to 4, there was a 70% attenuation in intrinsic fluorescent intensity and a concomitant shift of the emission maximum from 345 nm to 338 nm. Several near-UV CD bands, tentatively assigned to tryptophan residues on crotoxin B, increased in magnitude and shifted to longer wavelengths. These data are consistent with "burying" of crotoxin B tryptophans in the complex. Evidence of larger structural changes with complex formation was obtained from the far-UV spectra. From pH 2 to 4, the proportion of ordered secondary structure increased (28% to 40% α-helix and 18% to 45% β-structure). Computer summation of the individual contributions of the isolated sub-units' CD agreed well at pH 2, but gave a substantial underestimate at pH 4. Complex formation also stabilized against heat and guanidine hydrochloride denaturation. These results suggest that the complex is not only stable, but also conformationally unique at neutral pH. Exposure of toxin to 80% trifluoroethanol (conditions thought to mimic membrane environments) produced dissociation of the complex. Similar treatment of crotoxin A produced a conformational change reducing the proportion of ordered structure. A comparable structural transition in the A sub-unit may be induced by contact with the physiological target membrane, thereby releasing the active B sub-unit. In this way, crotoxin A would act as a delivery vehicle for crotoxin B and increase its relative lethality by more selective targeting. In view of the requirement of both the enzymatic and synaptic-blocking activities for calcium, we have investigated the effects of divalent cations on spectral parameters. A CD signal at 303 nm (assigned to crotoxin B tryptophan) gave a dose-dependent increase to twice control values with increasing calcium concentration at neutral pH. The calcium effect was strongly pH-dependent and was abolished at pH 4. The data are consistent with a calcium-binding site similar to those reported in other phospholipase A2 enzymes. (Supported by Division of Biomedical and Environmental Research of US Energy and Development Administration).

1006 ION-EXCHANGE/FLUOROMETRIC MEASUREMENT OF AMINO ACIDS IN HUMAN CEREBROSPINAL FLUID. T.A. Hare and B.S. Glaeser, Thomas Jefferson University, Philadelphia, PA

Measurement of amino acids and related amines in human cerebrospinal fluid (CSF) has been limited because of the relatively low concentration of most of these components in CSF. Using conventional amino acid analysis with ninhydrin detection, approximately 30 components can be readily measured (Perry et al., J. Neurochem. 24, 587, 1975; Lakke and Teelken, Neurology 26, 489, 1976) although when 10-fold concentrates of CSF have been utilized the number of detectable components is increased to about 40 (Dickinson and Hamilton, J. Neurochem. 13, 1179, 1966). Recently with the introduction of the fluorogenic reagent orthophthalaldehyde (OP) (Roth and Hampai, J. Chromatogr. 83, 353, 1973), it has become possible to increase the sensitivity of amino acid analysis by several orders of magnitude. Human CSF specimens which had been obtained from patients with various neurological disorders and stored at -70°C, were pooled, lyophylized to dryness, and then taken up to 0.07 times the original volume with water. This preparation was deproteinized using 0.4 N perchloric acid. Aliquots of 0.25 ml of the deproteinized solutions (equivalent to 1.7 ml of CSF) were analyzed for their amino acid content. The analytical procedure utilized a 6 mm ID column which contained a 60 cm bed of spherical cation exchange resin. The column was eluted with a 0.15 N lithium citrate buffer pH 2.9 for 475 min followed by a 0.15 N lithium citrate buffer pH 4.00 for 225 min followed by a 1.10 N lithium citrate buffer pH 4.60 for 510 min. Primary amines were detected in the eluate using the fluorogenic OP reagent. When these analyses were carried out at a relatively low sensitivity setting on the fluorometer 45 components were readily distinguishable including peaks corresponding to those previously described in the literature. When the analyses were carried out at a 10-fold higher sensitivity setting, an additional 35 peaks were apparent which had been evident only as trace constituents in the previous run. Chemical and biological characterization of these components may provide valuable new information about the functioning of the central nervous system.

1007 THE EFFECTS OF MAGNESIUM DEFICIENCY ON THE LEVELS OF DOPAMINE, NOREPINEPHRINE, AND SEROTONIN IN THE RAT BRAIN AND HEART. Mary Daniel Healy*, Jose A. Perez*, Audelio Rivera*, David Limon* and Dolores Chacon* (SPON: A. T. Modak). Incarnate Word College of The United Colleges of San Antonio, San Antonio TX 78209.

The neuromuscular involvement in the magnesium deficiency (MGD) syndrome in rats has been well documented in the literature. The animals exhibit signs of neuromuscular hyperirritability, often culminating in generalized seizures and death. The biogenic amines--dopamine, norepinephrine, and serotonin--play an important role in the nervous system as neurotransmitters. Although the exact functions of these biogenic amines have not been elucidated, their levels have been shown to correlate with changes in a rat's susceptibility to seizures. In this study, the effect of a MGD diet on the levels of dopamine, norepinephrine, and serotonin in the rat brain and heart was investigated. Groups of male albino rats weighing 90-110g at the beginning of the experiment were placed on MGD and control diets. The biogenic amines of the brain and heart in experimental and control animals were analyzed spectrophotofluorometrically at 5 day intervals for 20 days.

The concentration of norepinephrine and serotonin were found to be progressively depleted in the brain and heart tissue in dietary magnesium deprivation. The dopamine levels in the brain, however, were higher than the control values on days 5 and 15, and lower on days 10 and 20. This dopamine graph correlated directly with the levels of hyperexcitability as measured in magnesium deficiency.

It is thought that the hyperexcitability of the nervous system in MGD may be due to altered neuronal membrane stability. We have attempted to clarify some of the possible pathogenically important chemical changes underlying the neurologic manifestations of the MGD syndrome in young rats and to obtain data on the quantitative interrelationship between concentration of electrolytes in the brain and heart and the concentrations of the neurotransmitters--dopamine, norepinephrine and serotonin--in these two organs. Support by NIH Grant RR-08077.

1008 EFFECT OF STRESS ON LSD-INDUCED DISAGGREGATION OF BRAIN POLYSOMES. J. Heikkila*, L. Holbrook* and I. Brown* (SPON: C. K. Govind). Dept. of Zoology, Scarborough College, Univ. of Toronto, West Hill, Ontario, Canada M1C 1A4.

Previously we have reported that brain polysomes are disaggregated after intravenous injection of LSD to young rabbits (Holbrook and Brown, J. Neurochem., 27,77,1976). The effect is brain specific and due to a decreased rate of reinitiation of protein synthesis. We now report that LSD produces a stress-like response in that plasma corticosteroids are elevated and that application of physiological stress accentuates the extent of LSD-induced brain polysome disaggregation. One hour after administration of LSD (50-100 ug/kg) plasma corticosteroid levels were increased by 2.5-3.0 fold over saline controls. Three forms of physiological stress were applied in addition to LSD (25 ug/kg): physical restraint (immediately after drug injection), hypoglycemia (previously starved for 24 hr.) or epinephrine bitartrate (25 ug/kg concomitant with LSD). All three forms of stress greatly accentuated the level of LSD-induced disaggregation of brain polysomes and also elevated plasma corticosteroids. Stress treatment without LSD did not effect brain polysomes. Sedation with the general anaesthetics, ethanol (4 gm/kg) or pentobarbital (20 mg/kg) before LSD (100 ug/kg) resulted in a near total inhibition of polysome disaggregation. Animals placed in an unfamiliar environment after LSD injection showed a greater disaggregation of brain polysomes than rabbits returned to their home cages. These results suggest that elements of physiological stress, arousal and environment influence the degree to which brain protein synthesis is affected.

(Supported by the Medical Research Council of Canada)

1009 ROLE OF THE CHOROID PLEXUS IN ENHANCING THE CEREBROSPINAL FLUID SINK EFFECT DURING UREMIA. Mark A. Hise* and Conrad E. Johanson* (SPON: J. W. Woodbury). Dept. Pharmacology Univ. of Utah Col. Med., Salt Lake City, Ut. 84132

The uremic state is associated with a progressive change in the concentration of electrolytes, urea and metabolic toxins in the blood. Such an alteration in blood composition is a potential threat to the finely-regulated composition of the extracellular fluid (ECF) of the C.N.S. An enhanced cerebrospinal fluid (CSF) sink action (due to an increase in CSF secretion) on substances leaking into the brain could serve to protect the brain ECF during uremia.

To test the hypothesis that there is an enhanced CSF sink effect during uremia, the following experiments were done to ascertain the activity of the Na-K pump (Na-K-ATPase) system in the choroid plexus (CP). Uremia was induced in adult male rats by bilateral ligation of the renal pedicles for periods of 1,8,16, 24,32 or 48 hr. At the termination of the experiment, lateral ventricular CP, blood and cisternal CSF were sampled and analysed for Na and K. Values given below are in mEq/kg wet, expressed as the ratio of Na/K.

Uremic state for:	Plasma	CP	CSF
1 hr	143/4.5	52.1/101	152/2.86
8 hr	143/6.4	54.4/100	154/3.13
16 hr	141/7.0	55.8/106	155/3.21
24 hr	139/7.5	59.7/106	155/-

The trend of a progressive increase in both Na and K in CP as well as in CSF continues at 32 hr and 48 hr post nephrectomy; similarly, the trend in plasma Na and K noted for the initial 24 hr continues for the subsequent 24-hr-period.

The changes in CP electrolytes are apparently a reflection of an enhanced activity of the Na-K-ATPase in this secretory tissue. Since an augmentation of Na-K-ATPase activity in the CP is generally associated with a concomitant increase in CSF secretion, it is tempting to conclude that there is an increased CSF sink action during uremia due to a greater bulk flow of CSF through the ventricular system. The mechanism of Na-K pump stimulation is presumably due to a build-up in CSF K during uremia. (Supported by NIH Grant-GM00153.)

1010 DOPAMINERGIC FUNCTION AFTER ETHANOL WITHDRAWAL Paula L. Hoffman * and Boris Tabakoff. Department of Physiology, School of Medicine, University of Illinois, Chicago, Illinois 60612

Previous work in our laboratories demonstrated a decreased sensitivity of central dopaminergic (DA) receptors in mice withdrawn from chronic ethanol treatment. Animals were less responsive to the hypothermia induced by several doses of the DA receptor agonist, piribedil, for up to seven days following ethanol withdrawal, and this change was paralleled by a reduced response of dopamine-sensitive adenylate cyclase to stimulation by dopamine in the ethanol-withdrawn animals. The time course of disappearance of these functional alterations in the DA systems followed that of disappearance of tolerance to ethanol. To further elucidate the possible relationship between modifications in dopaminergic function and development of physical dependence on ethanol, the time course of the appearance of changes in DA- sensitive adenylate cyclase activity was studied. At the time of withdrawal, adenylate cyclase was stimulated by DA to an equal degree in both ethanol- treated and control animals; however, by eight hours after withdrawal, when ethanol was eliminated from the animals, sensitivity to dopamine stimulation had decreased significantly. Differences in adenylate cyclase activity were more prominent in brain areas containing the nigro-striatal system compared to the mesolimbic systems. Enzymes from ethanol-treated and control animals were, however, equally stimulated by Na fluoride, indicating no change in total amount of adenylate cyclase activity. To determine whether the decreased sensitivity to dopamine stimulation reflected a decreased density of dopaminergic receptors or changes in coupling between receptor and adenylate cyclase, specific binding of ^{3}H-dopamine to brain regional preparations from both ethanol-treated and control animals was characterized by Scatchard analysis. The results of these studies will be discussed.

This work was supported in part by the NIAAA and the St. of Ill. Dept. of Mental Health. B.T. is a Schweppe Foundation Fellow.

1011 EFFECTS OF OSMOLARITY ON RESPIRATION AND FINE STRUCTURE *IN MITO*CHONDRIA FROM MATURE AND IMMATURE RAT BRAIN. D. Holtzman*, M. M. Herman*, M. Desautel* (SPON: K. A. Kelts). Stanford Univ. Sch. Med., Stanford, CA, 94305

We recently have shown that isolated mature rat brain mitochondria respond to changes in ambient osmolarity very differently than liver mitochondria (submitted for publication). Polarographic study of brain mitochondria in hypo-osmolar media showed inhibited State 3 (ADP-dependent) respiration with a NAD-linked substrate pair, glutamate and malate, and with succinate. In hyperosmolar media there was an increase in State 4 (ADP-independent) respiration and only a transient inhibition of State 3 with the NAD-linked substrates. With succinate as substrate, respiration was not affected by moderate increases in osmolarity. In contrast, liver mitochondria showed increased State 4 respiration in hypo-osmolar media and inhibited State 3 in hyperosmolar media with both substrates. Electron microscopy showed that liver mitochondria were markedly swollen in hypo-osmolar media and very condensed in hyperosmolar media, while brain mitochondria swelled less in hypo-osmolar media and, in hyperosmolar media, half the mitochondria were condensed and half showed no morphologic changes compared to controls.

In hypo-osmolar media, five day old rat brain mitochondria showed respiratory changes similar to those seen in the adult. However, in contrast to the adult, five day old rat brain mitochondria showed persistent inhibition of State 3 respiration with both NAD-linked substrates and succinate in hyperosmolar media. The spontaneous reversal of State 3 inhibition with NAD-linked substrates and the loss of inhibition with succinate in hyperosmolar media appeared progressively with maturation and reached adult levels by 30 days. During this same maturational period, brain mitochondria resistant to changes in fine structure in hyperosmolar media progressively appeared. At five days almost all brain mitochondria were condensed in the hyperosmolar media. By 30 days approximately half the mitochondria showed little or no morphologic change in hyperosmolar media. The age-dependent appearance of this "osmolar resistant" sub-population of brain mitochondria is coincident with astroglial proliferation and may be important in maturation of the brain's resistance to edema-producing insults (e.g., heavy metal encephalopathy and seizures).

1012 PHENYTOIN-INDUCED STIMULATION OF THE Na-K PUMP IN THE CHOROID PLEXUS - CEREBROSPINAL FLUID SYSTEM. Conrad E. Johanson* and Quentin R. Smith* (SPON: S.A.Turkanis) Dept. Pharmacology, Univ. of Utah Col. Med., Salt Lake City, Ut 84132.

Determination of the effects of the anticonvulsant drug, phenytoin (PT), on the distribution of Na and K among various compartments in the C.N.S. is important because of relevance not only to convulsive disorders but also to other electrolyte-related disorders (cerebral edema, hydrocephalus, etc.). The ratio of Na:K in the CSF is 50:1; since PT stimulates Na-K-ATPase activity maximally when Na:K is 50:1, it has been hypothesized that PT enhances the turnover of Na and K across the CSF-facing membrane of the choroid plexus (CP).

On the basis that a change in the rate of transport of ions across a cell membrane is reflected by a change in the cell concentration of those ions, we have tested the above mentioned hypothesis as follows: Adult rats were injected i.p. with PT at a dose of either 10 or 40 mg/kg (or appropriate vehicle) and sacrificed 1 hr later for analysis of tissue electrolytes. In response to the 40 mg/kg treatment, the [K] in CP (lateral ventricle) increased by 11% to 101 mEq/kg while [Na] decreased by 6% to 47 mEq/kg. At the 10 mg/kg dose, there was also a statistically significant rise in CP [K] and a fall in [Na] but neither change was as great as that in the 40 mg/kg animals. CSF [K] varied more-or-less inversely with dose of PT; however, PT did not significantly alter CSF [Na]. In both cerebral cortex and cerebellum there was a slight rise in [K] and a similarly small reduction in tissue [Na]; however, such changes in electrolytes in these regions of the brain were not significantly different. Since PT did not alter plasma [K], and because the [K] in erythrocytes decreased following PT administration, the rise in CP [K] after PT treatment cannot be accounted for by a change in the electrolytes in residual blood of the sampled tissue; a similar conclusion can be drawn about the decrease in CP [Na]. The extracellular fluid volume in the CP, as measured by the distribution of tritiated-inulin, increased progressively with dosage of PT.

Thus, the electrolyte and the radioinulin space data for the CP, together with the observed changes in CSF [K], constitute evidence in support of the hypothesis that PT stimulates a Na-K pump in the CP.

1013 HISTOCHEMICAL DISTRIBUTION OF HEXOKINASE IN THE NORMAL AND ISCHEMIC GERBIL BRAIN. S. Kakari*, K. Nishimoto*, J. Walker* and M. Spatz. (SPON: M. Nirenberg) NIH, Bethesda, MD 20014.

Hexokinase (HK) catalyzes phosphorylation of glucose to glucose-6-phosphate - a control step in glycolysis. A histochemical evaluation of the brain HK in gerbils, both normal and those subjected to unilateral common carotid artery occlusion and release, has been undertaken in order to obtain additional information about the ischemic sequelae of carbohydrate metabolism.

In the normal gerbil, HK-reaction is distributed in increasing order: cerebral cortex, hippocampus, basal ganglia in both hemispheres symmetrically. Activity appears strong in the gray but weak in the white matter. In gray matter, HK is variable strong in both neuronal perikarya and the neuropil. The most intense HK-reaction is seen in ependyma and choroid plexus, while capillaries show a moderate activity.

In unilateral cerebral ischemia HK diminishes first in hippocampus followed by the basal ganglia and cortex, proportional to the duration of the post-ischemic period (1-20 hrs) following one hour occlusion. The loss of HK in basal ganglia, first seen at 3 hours progressively extends to encompass almost the whole region by 20 hours post-release. By contrast, enhanced HK may also be seen in various structures including (a) pyramidal cells in the H3 sector of hippocampus at 5 hours and (b) axonal swellings and reactive glia in the white matter adjacent to hippocampus 20 hours post-release.

The regional and cellular changes in hexokinase activity demonstrated by these studies may add another dimension in the evaluation of changes in the regional cerebral glucose consumption seen in the ischemic gerbil brain (Kakari et al., J. Neuropath. Exp. Neurol. 36:680, 1977).

1014 DOPAMINE SYNTHESIS IN SYNAPTOSOMES: EFFECT OF CALCIUM REMOVAL WITH EGTA. Gregory Kapatos* and Michael J. Zigmond. (SPON: B. Dixit). Dept. of Life Sciences, University of Pittsburgh, Pittsburgh, PA 15260.

Exogenous Ca^{++} has been reported to inhibit, stimulate, or have no effect on soluble preparations of striatal tyrosine hydroxylase (TH). Ca^{++} has also been shown to inhibit dopamine (DA) synthesis by striatal tissue slices. These inconsistant findings prompted us to examine the effect of Ca^{++} on DA synthesis by striatal synaptosomes, a system which offers a natural physical state and pterin cofactor for TH but does not retain the intact neural circuitry of the tissue slice. Synaptosome-rich P2 fractions were incubated in the presence of L-(1-^{14}C) tyrosine (TYR) in a Kreb's-Ringer phosphate buffer at a final pH of 6.2 (optimal) or 7.2 which contained either 0.87 mM Ca^{++} (control medium), no Ca^{++}, or no Ca^{++} with 0.5 mM EGTA. DA synthesis was determined by collecting $^{14}CO_2$. The removal of Ca^{++} without chelation produced a small decline in DA synthesis (11%), when determined in the presence of 8 µM medium TYR. The removal of Ca^{++} and the addition of EGTA produced an elevation in synthesis under these conditions which was greater at pH 7.2 than at 6.2 (40 vs. 18%). By varying medium TYR concentration we determined that this stimulation of synthesis was due entirely to an increase in Vmax without an alteration in Km TYR regardless of medium pH. (Under control conditions Vmax decline as pH was increased but again no change in Km TYR was observed). Although the stimulation of synaptosomal DA synthesis by Ca^{++} displays characteristics which appear identical to the effect of db-cAMP, we have determined that these treatments do not act by a similar process. In contrast to stimulation by db-cAMP, stimulation by Ca^{++} removal did not alter the ability of exogenous DA (1 µM) to inhibit synthesis. Moreover, Ca^{++} removal antagonized the stimulation of synthesis by db-cAMP (1 mM) and also partially reversed the ability of db-cAMP to overcome synthesis inhibition by DA. Soluble TH prepared from synaptosomes which were stimulated by Ca^{++} removal was not in an activated state, although less TH was found associated with synaptosomal membranes. These data suggest that Ca^{++} plays some role in the activation of TH by db-cAMP but that the removal of Ca^{++} does not in itself alter the characteristics of TH in striatal synaptosomes. Supported in part by a grant from the USPHS (MH-20620).

1015 DISTRIBUTION OF ANGIOTENSINOGEN IN RAT BRAIN. John A. Lewicki*, James H. Fallon, and Morton P. Printz*. (SPON: Arnold Miller). Depts. of Med. and Neurosci., Univ. of Calif., San Diego, La Jolla, Calif. 92093.

Recent evidence has accumulated for the existence of an independent central renin-angiotensin system. However, the mechanisms and sites of angiotensin generation within the CNS are not yet understood. One approach toward answering this question is to examine the properties of angiotensinogen, the specific prohormone of angiotensin I, within the brain. We have recently demonstrated that angiotensinogen is present in whole brain homogenates in significant concentrations and that it is physicochemically similar to plasma angiotensinogen (Fed Proc. 35:770, 1976). The purpose of the present study was to investigate the regional distribution of this prohormone throughout the brain. Sprague-Dawley rats were perfused with saline to remove all blood from the central compartment and the brains extracted and sectioned in a Minotome. A punch technique was used to isolate 32 specific brain regions. The tissues were then homogenized and incubated with excess kidney renin (37°, pH 6.0) to generate angiotensin I which was measured by radioimmunoassay. The highest angiotensinogen levels were localized to the area postrema, periventricular hypothalamus, and organum vasculosum lamina terminalis. Further studies, however, indicated that these areas appeared erroneously high due to the relative deficiency of a proteolytic enzyme activity (angiotensinase) which degraded the angiotensin I generated at the incubation pH. This angiotensinase activity was not inhibited by EDTA, phenylmercuric acetate, phenylmethylsulfonylfluoride, or any combination thereof. However, the angiotensinase was separated from angiotensinogen by micro-precipitation of the latter with 2.3M ammonium sulfate. Reassay of the extracted angiotensinogen disclosed a more uniform distribution of the prohormone throughout the brain. Only the pituitary, parietal cortex, and cerebellum were relatively deficient in the prohormone, while the periventricular hypothalamus and several other midline structures were slightly elevated over the remainder of the areas. Further characterization of the prohormone in the various regions is currently underway. We conclude that angiotensinogen is not restricted to only a few sites in the CNS, but rather is widely distributed. Based on these findings, the function of angiotensinogen within the brain remains unclear. (Supported by NIH HL 15808).

1016 EFFECT OF SMALL INCREASES IN EXTRACELLULAR [K^+] ON PROTEIN SYNTHESIS IN THE HIPPOCAMPUS: LOCALIZATION AND MECHANISM. Peter Lipton* and Catherine J. Heimbach*, (SPON: D.D. Gilboe). Dept. of Physiology, Sch. Med., Madison, WI 53706

Small increases in extracellular [K^+] ([K^+])$_{e.c.}$) increase the rate of protein synthesis in the guinea pig hippocampus maintained in vitro (Lipton & Heimbach, J. Neurochem., in press). We have postulated that this effect may be one way by which cerebral electrical activity increases protein synthesis in situ and thus may be related to biochemical plasticity. Here we report further characterizations of the effect.

A. LOCALIZATION OF THE EFFECT. 1. Tissue Specificity. Increasing [K^+]$_{e.c.}$ from 3.0 to 6.4mM increases [^{14}C]-lysine incorporation into protein of cerebral cortex to the same extent as into the hippocampus (29%); however it has no effect upon incorporation into kidney cortex, liver or heart slices. 2. Cell Specificity. We measured the effect of increasing [K^+]$_{e.c.}$ on [^{14}C]-lysine incorporation into sub-cortical white matter. Basal rates of incorporation into this tissue were similar to those of hippocampus but [K^+]$_{e.c.}$ had no effect upon incorporation suggesting that [K^+]$_{e.c.}$ affects protein synthesis in nerve cells and not in glia or capillary endothelial cells. 3. Intracellular Localization. Effects of [K^+]$_{e.c.}$ on incorporation into crude subcellular fractions was assessed. Incorporation into the soluble (105,000g supernatant) protein was unaffected by [K+]$_{e.c.}$. The greatest effect upon incorporation was in the crude mitochondrial and nuclear fractions. (% increases in synthesis: Homogenate 20±5; Nuclear 27±12; Mitochondrial 29±6; Cytosol 3±5, n=8 experiments.

B. MECHANISM OF THE EFFECT. 1. Transcription or post-transcription. Increasing [K^+]$_{e.c.}$ from 3.0 to 6.4mM increased [^{3}H]-uridine incorporation into RNA by 14%, suggesting that its effect upon protein synthesis might be mediated by an effect on transcription of RNA. However, when tested in the presence of a combination of α-amanitin and actinomycin D at concentrations which decreased [^{3}H]-uridine incorporation into RNA by 97% [K^+]$_{e.c.}$ exerted its normal effect upon protein synthesis. This strongly suggests that the effect is exerted post-transcriptionally. 2. We measured the effect of increasing [K^+]$_{e.c.}$ upon intracellular [K^+]. Increasing [K^+]$_{e.c.}$ from 3.0 to 6.4 increased intracellular [K^+] by 7±3%. This small increase suggests that increased cell [K^+] is not the basis for the increase in protein synthesis. [K^+]$_{e.c.}$ thus appears to exert a tissue specific effect, in vitro, upon cerebral protein synthesis - apparently increasing synthesis of (some of) the non-soluble neuronal proteins. The effect appears to be exerted post-transcriptionally and not to be mediated by increased intracellular [K^+]. Supported by NSF.

1017 PARTIAL CHARACTERIZATION OF RADIOLABELED α-BUNGAROTOXIN SPECIES AND THEIR INTERACTION WITH MEMBRANE-BOUND ACETYLCHOLINE RECEPTORS. Ronald J. Lukasiewicz*, Michael R. Hanley* and Edward L. Bennett. Lab. Chem. Biodynamics, Univ. of Calif., Berkeley, CA, USA 94720.

Toward preparation of a suitable toxin-label for the nicotinic acetylcholine receptor in brain, studies concerning structural and functional properties of radiolabeled α-bungarotoxin derivatives were undertaken. ^{125}I is incorporated into a single tyrosine residue of α-bungarotoxin (α-Bgt) at ca. 85% yield, using a non-enzymatic iodination procedure. Mono-iodinated ([I_1]α-Bgt) and di-iodinated([I_2]α-Bgt) derivatives are purified and separated from native toxin on Whatman CM-52, 5mM $NaPO_4$, pH 6.5 with gradient elution (0.02-0.1M NaCl). Catalytic reduction of [I_1]α-Bgt in the presence of tritium gas yields tritiated α-Bgt ([^{3}H]α-Bgt) at ca. 90% recovery which is chromatographically and spectrally indistinguishable from native toxin. Mono-iodinated α-Bgt may be differentiated from native and [^{3}H] α-Bgt species on the basis of ultraviolet absorption (UV) and circular dichroism (CD) spectra. UV and CD spectra of [I_2]α-Bgt are markedly altered relative to native α-Bgt, exhibiting strong positively dichroic UV absorbtion at 320nm and little or no dichroism at 230nm. These differences in chromatographic and UV and CD spectral properties are suggestive of a small conformational change accompanying iodine incorporation, and a larger change in three dimensional structure of α-Bgt on introduction of a second iodine atom into an exposed tyrosine residue.

That these structural changes are manifest as differences in toxin binding characteristics is shown in preliminary experiments using membrane-bound nicotinic acetylcholine receptor (nAChR) derived from Torpedo electroplax, and rat brain crude mitochondrial fractions (CMF). As determined from log probit analyses, native α-Bgt is 3-6 times more effective than cold [I_1] -Bgt and [I_2]α-Bgt towards competing for [$^{125}I_1$]α-Bgt and [$^{125}I_2$]α-Bgt binding sites in rat brain CMF. Rank order of α-Bgt derivative inhibition effectiveness is preserved for binding to electroplax nAChR, but differences in absolute effectiveness are reduced relative to that for CMF α-Bgt binding sites. Values of K_d determined from saturation binding assays are ca. 10nM for electroplax nAChR, independent of the form of radiolabeled α-Bgt, while K_d for specific binding to rat brain CMF is ca. 0.8nM for[^{3}H]$_d$α-Bgt, 1.0nM for[$^{125}I_1$] α-Bgt, and 3.0nM for [$^{125}I_2$] -Bgt. These results suggest that there might be differences in the toxin binding active site for nAChR derived from peripheral and central sources, in addition to the established differences in radiolabeled α-Bgt derivatives. Supported by Div. of Biomed. and Environ. Research of ERDA. RJL is a postdoctoral fellow of NINCDS.

1018 QUANTITATION OF CELLULAR PROTEINS BY COMPUTER ANALYZED TWO DIMENSIONAL POLYACRYLAMIDE GEL ELECTROPHORESIS (PAGE). W.A. Lutin*, W.W. Carley*, and J.A. Freeman. Dept. Biochem. and Anat., Sch. Med., Vanderbilt Univ., Nashville, TN. 37232.

Previous work has shown (Freeman, Nature, 1977, in press) that chronic binding of cholinergic receptor protein in the optic tectum of the toad B. marinus with α-bungarotoxin is associated with plastic modifications of retinotectal synapses. In order to study the dynamics of receptor protein and other cell surface proteins during synaptogenesis, we have developed a method for quantitating cell proteins separated by 2-dimensional PAGE, using a modification of O'Farrell's method (JBC 250: 4007, 1975). Cellular proteins from tectum and retina homogenates were extracted with phenol, dialyzed, and run on 2-dimensional PAGE. Tectal gels contained over 400 clearly separated protein components, ranging in molecular wt. from 2000 to 500,000 daltons, and in pI from 4 to 8 pH units. Gel proteins were detected either by autoradiography following incorporation of ^{14}C-amino acids, or with Coomassie blue. Autoradiograms or photographs were scanned with a digital densitometer. The resulting 1000x1000 point image was analyzed with a Sigma-7 computer. Image details were displayed as a 2-D reconstruction, a 3-D perspective display revealing relative concentration of protein peaks, or as iso-density contour maps. The numbers, positions, and concentrations of individual proteins were determined by a spatial convolution technique. Individual protein spots were characterized by a 2-dimensional Gaussian least squares best fit. Using orthopthalaldehyde labeled protein standards, we have been able to estimate concentration, isoelectric pH and molecular weight for essentially all of the proteins resolved by the 2-D gel separation. To compare the protein spectra of two or more gels, their Gaussian parameterized representations were first normalized with respect to electrophoretic mobility and concentration, and then differenced. The resulting residual surfaces clearly revealed differences in protein expression. This method is being used to quantitate changes in different proteins during degeneration and regeneration of retinotectal synapses.

1019 ^{3}H - CHOLINE UPTAKE IN ABDOMINAL GANGLIA OF LIMULUS POLYPHEMUS. M.A. Maleque* and James G. Townsel, Department of Physiology, Meharry Medical College, Nashville, Tennessee 37208.

Nervous tissue is unable to synthesize choline (Ch) (Ansell and Spanner, 1971, Biochem. J. 110: 201, Schwartz et al., 1975, J. Gen. Physiol. 65: 255) an immediate precursor of acetylcholine (ACh). Thus, the supply of Ch for ACh synthesis is functionally important. A high affinity (HA) sodium dependent transport system presumably localized in cholinergic nerve terminals has been described. Moreover, this Na^+ dependent HA transport system is closely associated with the synthesis of releasable ACh.

ACh has been implicated as a neurotransmitter in Limulus polyphemus (Garry, 1942, Am. J. Physiol. 136: 182; Stephens and Greenberg, 1973, Histochem. Cytochem. 21: 923; Townsel et al., 1976, Neurosci. Abs. 2: 618). Choline acetyltransferase activity has been demonstrated in the brain as well as the abdominal ganglia of Limulus (Emson et al., 1974, J. Neurochem. 22: 1089; Malthe-Sorenson and Emson, 1976, J. Neurochem. 27: 341). The current study was undertaken to determine the kinetics and nature of choline uptake in Limulus abdominal ganglia.

The results indicate dual uptake systems for Ch within the abdominal ganglia of Limulus. One, a HA system with K_m 4 x 10^{-6} M and V_{max} 7.5 pmole/10 min./mg of tissue in the concentration range of 1 x 10^{-7} - 1 x 10^{-6}M and another a low affinity (LA) system with K_m 3.3 x 10^{-4} and V_{max} 38.64 pmole/10 min./mg of tissue in the concentration range of 1 x 10^{-6} - 1 x 10^{-4}M. In the HA system Ch uptake was decreased by 78% in the absence of Na^+. Maximal Ch uptake was achieved at a concentration of 0.44 M Na^+ which is the Na^+ concentration in Limulus physiological saline (Chao, 1933, Biol. Bull 64: 358). The replacement of K^+ and Ca^{2+} resulted in nominal inhibition of Ch transport (i.e. 17% and 18% inhibition respectively in the HA system and 3% and 19% inhibition within the LA system). The addition of 2.5 mM glucose did not enhance uptake. The pharmacological sensitivities of these uptake systems will be presented. The presence of a Na^+ dependent HA system within the abdominal ganglia of Limulus suggests the presence of cholinergic neurons within this structure.

1020 HETEROGENEITY OF BRAIN TUBULIN SUBUNITS AND CHARACTERIZATION OF LOW MOLECULAR WEIGHT ASSOCIATED PROTEINS. Charles A. Marotta, Jamie L. Harris,* Aesta A. Manschreck,* and Jeffrey M. Gilbert. Harvard Med. Sch. and Mailman Res. Center, McLean Hospital, Belmont, Ma. 02138

Microtubular protein was isolated from rat forebrain by biochemical purification (ammonium sulfate precipitation followed by DEAE cellulose chromatography) or by two cycles of aggregation - disaggregation. The protein subunit structure was examined on two-dimensional electrophoretograms: first dimension, urea isoelectric focusing gel; second dimension, sodium dodecyl sulphate exponential acrylamide slab gel. Two forms of α tubulin were separated in the second dimension on the basis of different rates of migration (α_1 and α_2). Each of these species were further differentiated into at least two subunits with distinct isoelectric points. β Tubulin was separated into a major species (β_1) and a minor species (β_2). The same results were obtained using protein from either purification method. Molecular weights were determined: the α_1 and α_2 groups of proteins have approximate sizes of 58,000 d. and 57,000 d. respectively. β_1 migrated slightly ahead of β_2 (53,300 d. and 54,600 d., respectively) We have consistently observed the presence of low molecular weight proteins that co-purify with tubulin. These consist of a single species of 70,000 d. and four proteins in the size range of 34,000-36,000 d. Artefactual results were ruled out by detection of the multiple forms of α and β tubulin as well as the associated proteins in a two-dimensional electrophoretogram of total supernatant proteins from rat brain; on this gel we observed that the single major soluble protein of rat brain is the β_1 subunit of tubulin. In summary, the subunit structure of brain α and β tubulin is more complex than previously reported; low molecular weight tubulin associated proteins co-purify with the major α and β proteins. Separation and visualization of multiple forms of α and β tubulin on two-dimensional electrophoretograms is consistent with reports that provide evidence for post-translational modification of these proteins. The gel system described should make feasible the isolation of individual species for chemical analysis. (This work was supported in parts by USPHS Grant MHI6674, a Mellon Faculty Award to C.A.M., and NIMH Research Scientist Development Award 3K01 MH-70713 to J.M.G.)

1021 PURIFICATION AND CHARACTERIZATION OF THY-1 ALLOANTIGEN FROM MOUSE BRAIN. Larry D. McClain and Ronald T. Acton. Diabetes Research and Training CTR., UAB, Birmingham, Alabama 35294.

The fractionation of mouse brain plasma membranes by zonal centrifugation techniques has yielded a preparation high in the expression of Thy-1 alloantigen. Enzyme marker assays reveal this membrane fraction to be rich in Na^+, K^+ dependent, ATPase activity although distinct from fractions expressing 2', 3'-cyclic nucleotide 3'-phosphohydrolase, a putative marker for myelin and glial plasma membranes. This suggests that Thy-1 in brain is localized on membranes of neuronal origin. Immunoferritin labeling of isolated synaptosome preparations substantiates the suggestion that this cell surface antigen may represent a specific marker for synaptic plasma membranes. Thy-1 has been purified from C57Bl/6J mouse brain and physico-chemically characterized. Acetone precipitation of membrane protein is followed by extraction with deoxycholate. Purification is accomplished utilizing a Lens culinaris lentil lectil affinity chromatography column followed by gel filtration on Ultrogel AcA 44. SDS gel electrophoresis of the eluted peak of Thy-1 activity reveals a single band of 25,000 molecular weight. Amino acid and carbohydrate compositions of Thy 1.2 purified in this way are compared with the values for rat Thy 1.1 and mouse lymphoblastoid cell Thy 1.1 and Thy 1.2.

1022 ACTIVATION OF TYROSINE HYDROXYLASE IN INTACT, ISOLATED ADRENAL CHROMAFFIN CELLS. *John A. Meligeni*, John W. Haycock and Jack C. Waymire*. Department of Psychobiology, University of California at Irvine, CA 92717 and Department of Psychology, University of California at Riverside, CA 92502.*

Tyrosine hydroxylation was investigated in 3-7 day old cultures of intact chromaffin cells isolated from bovine adrenal medulla. Activity was monitored by measuring $^{14}CO_2$ evolution from cells incubated (15', 37°C) in a calcium-deficient HEPES buffer system (pH7.2) containing 10^{-5}M 1-^{14}C-tyrosine. Under these conditions the basal level of hydroxylation was 5-10 pmole tyrosine/15 min/10^6 cells.

Addition of 2.5 mM $CaCl_2$ to the medium resulted in a 100-200% increase in hydroxylation. Although without effect in a calcium-deficient medium, both 10^{-5}M acetylcholine (ACh) and 50 mM KCl increased the effect of calcium. In addition, 8-bromo-3',5'-adenosine monophosphate potentiated the effects of either ACh plus $CaCl_2$ or KCl plus $CaCl_2$ but not the effect of $CaCl_2$ alone.

Similar studies were conducted on a partially purified fraction of tyrosine hydroxylase from bovine adrenal medulla. In the presence of pteridine cofactor and DOPA decarboxylase (to release $^{14}CO_2$),none of the above agents increased hydroxylation.

These studies suggest that in the physiological situation both calcium and cyclic AMP may play roles in regulating tyrosine hydroxylase activity. However, the mechanisms by which these agents modify tyrosine hydroxylase appears to be disparate and of an indirect nature. The relationship of such alterations in tyrosine hydroxylase activity to stimulus-secretion coupling processes is currently being investigated.

1023 A NOVEL POTENTIOMETRIC ESTIMATION OF MONOAMINE OXIDASE ACTIVITY USING AN AMMONIA SELECTIVE ELECTRODE. L.R.Meyerson, K.D. McMurtrey*, B.L. Pashkoff* and V.E. Davis. V.A. Hospital and Baylor College of Medicine, Houston, Tx 77211.

A sensitive and convenient method for the estimation of monoamine oxidase (MAO) activity in rat brain homogenate and mitochondrial preparations based on measurement of ammonia produced by oxidative deamination of amine substrates by an ammonia selective electrode has been developed. The electrode (Orion Res. Model 95-10) employs a hydrophobic membrane which is permeable to gas and separates the solution measured from the electrode filling solution. The ammonia in the sample diffuses through the membrane until NH_3-N partial pressures are at equilibrium and the resulting potential (mV) is recorded with a mV/pH meter (Orion Res. Model 701-A). Assay mixtures consist of 0.05 M sodium pyrophosphate (pH 8.1), tissue preparations containing 0.3 - 5.0 mg protein, 1.0 mM freshly prepared substrate and triple distilled deionized water in a total volume of 2.0 ml. After incubation at 37.5°C for 30 min., the reactions are terminated by the addition of 4 ml of pH 12.0 Titrisol buffer (E.M. Labs). The electrode is then immersed in the stirred reaction mixtures and the mV potentials are recorded. The amount of ammonia generated enzymatically is obtained by calculating the difference in ammonia concentration in control (substrate added after incubation) and test mixtures. Ammonium chloride is used as the reference standard for preparation of calibration curves. The sensitivity of this method is comparable to radiometric, fluorometric and polarographic techniques. Thirty nmoles of ammonia formed from a substrate in the assay mixture could be measured accurately. This response is obtained with 0.3 mg mitochondrial or 0.5 mg homogenate protein. The Δ mV potential corresponding to ammonia formed from substrate by MAO in brain homogenate and mitochondrial preparations is linear to enzyme protein concentration and to time during the 30 min. incubation period. The stoichiometric relationship between the amounts of ammonia production and amine depletion, measured by high pressure liquid chromatography (Anal. Biochem. 72: 566, 1976), is evidenced by the equal amounts of ammonia formed and substrate deaminated. The assay technique offers diverse utility. Numerous primary amine substrates can be employed with this method. The procedure is also useful for enzyme kinetic analyses, comparison of substrate specificity and the study of enzyme inhibitor interactions. Compared to many other assay procedures, the method outlined offers the advantages of sensitivity, simplicity, accuracy and rapidity. (Supported by USPHS Grant AA 00226 and the Veterans Administration).

1024 THE EFFECT OF CEREBRAL ISCHEMIA AND POSTISCHEMIA ON MONOAMINE OXIDASE ACTIVITY. Dejan Micic*, Igor Klatzo and Maria Spatz (SPON: B. B. Mrsulja). Lab. Neuropath. & Neuroanat. Sci, NIH, Bethesda, MD 20014.

In our previous experiments, we had described the cerebral ischemic and postischemic reduction of biogenic amines and the accumulaton of its metabolites being due to (1) increased synthesis and (2) possible outtransport inhibition but not due to altered monoamino oxidase (MAO) activity in the brain (Acta neuropath. 36, 1, 1976 and Brain Res. 98, 388, 1975). In order to elucidate further the metabolic fate of these substances we investigated the cerebral MAO activity itself during ischemia and postischemia of Mongolian gerbils.

Several groups of anesthetized animals (pentobarbital 20 mg/kg i.p.) were subjected to unilateral carotid artery occlusion for 1 hour and various periods of release or to continuous occlusion fr 1-5 hours. The mitochondrial MAO activity was assayed by microfluorimetric method (Bioch. Pharmacol. 14, 1686, 1965).

The activity of MAO was significantly reduced in the hemisphere ipsilateral to 1 hour occlusion and release for 20 and 72 hours and 1 week as compared to the contralateral, to the one from control and sham operated animals (ischemic = 16.05 + 1.35 (7), 12.99 $\pm$ 1.59 (7), 13.23 $\pm$ .76 (6) nmoles 4HOQ/mg P/hr, respectively; control = 21.91 $\pm$ .79 (12) nmoles 4HOQ/mg P/hr). Normal levels of the enzyme were found 4 weeks after the release of 1 hour occlusion. In the continuously ischemic gerbils the MAO activity was found to be only reduced at 5 hours (15.79 + 1.0 (7) nmoles 4HOQ/mg P/hr).

These results substantiate our previous postulate that the MAO activity couldn't be responsible for the decreased levels of biogenic amines and/or increased accumulation of its metabolites in ischemic and postischemic brains.

1025 ELECTRICAL ACTIVITY AND ENERGY METABOLISM IN THE ISOLATED TOAD BRAIN - ROLES OF GLYCOLYSIS AND OXIDATIVE METABOLISM. D. F. Moffett* and J. C. LaManna. Department of Physiol. Pharmacol., Duke Univ. Med. Cntr. Durham, N.C. 27710.

Isolated toad brains provided with pyruvate respond to electrical stimulation with an initial decrease in fluorescence intensity corresponding to a net oxidation of reduced nicotinamide adenine dinucleotide ($NADH_2$). The period of net oxidation lasts about 30 sec. and is followed by return to or overshoot of the resting fluorescence baseline. The reductive overshoot is exaggerated and prolonged if glucose is substituted for pyruvate. If pyruvate is the exogenous substrate, addition of the glycolysis inhibitor iodoacetate abolishes the reductive overshoot while sparing the initial oxidative response. If glucose is the substrate provided, iodoacetate abolishes fluorescence transients immediately and initiates a transition to an increased steady-state fluorescence. Replacement of pyruvate by succinate also abolishes the oxidative transient. After change to succinate, each train of pulses is followed by a transition to an increased fluorescence level until after several trains a new steady-state level is attained. Return to pyruvate results in a decrease in steady-state fluorescence and recovery of the oxidative transient. These results are interpreted as follows: The initial oxidative transient reflects the response of terminal oxidative metabolism, while the later increase in fluorescence is due to activation of glycolysis. The increased fluorescence in the presence of glucose + iodoacetate is not readily explained but might be due to diversion of glucose metabolism into the pentose phosphate pathway, with consequent reduction of nicotinamide adenine dinucleotide phosphate (NADPH). The abolition of oxidative transients of $NADH_2$ by succinate is attributable to monopolization of electron flow through phosphorylation site I of the respiratory chain by succinate with possible reverse electron flow adding to the increase in $NADH_2$.

In the absence of electrical stimulation, pyruvate-glucose, pyruvate-lactate and pyruvate-succinate changes fail to evoke changes in the steady-state level of fluorescence, suggesting that during rest access of exogenous substrate to the reactions of intermediary energy metabolism is restricted.

1026 HYPERTHERMIA IN INFANT RATS: EFFECTS ON BRAIN POLYSOMES AND AMINO ACID LEVELS IN BRAIN AND BLOOD. L.L. Murdock* and F.L. Siegel. Depts of Pediatrics and Physiological Chemistry, Center for Health Sciences, University of Wisconsin, Madison, WI 53706.

Brain polysomes prepared from infant rats (7-days old) exposed to elevated ambient temperature (39.5°C for 45 min) are highly disaggregated. Disaggregation is evident 15 min after the animals have entered the hot environment and is nearly maximal after 25 min. Substantial recovery of polysomes is seen 20 min after hyperthermic rats are transferred from 39.5°C to 33°C ambient temperature. After 45 min exposure to 39.5°C ambient temperature the levels of certain amino acids, particularly essential amino acids, rise markedly in brain. Amino acids whose levels rise under these conditions are: phenylalanine (388%), valine (387%), leucine (340%), arginine (320%), isoleucine (262%), lysine (181%), histidine (136%), methionine (110%), threonine (84%), tyrosine (61%), serine (47%), glycine (43%), glutamic acid (17%). The levels of glutamine, aspartic acid, taurine, γ-aminobutyric acid and citrulline did not change under these conditions. These increases in brain amino acid levels were reversed within an hour after the rats were transferred from the hot environment to 33°C ambient temperature. The levels of amino acids in blood plasma also rise during hyperthermia; these rises are smaller than those in brain and are less selective but are likewise reversed by returning the animals to 33°C ambient temperature. Although the mechanism of the rises in blood and brain amino acid levels and their relationship to polysome disaggregation remain to be elucidated, it seems likely that the rises may have significant consequences for a) the functional status of protein synthesis in brain; b) the levels of neurotransmitter substances which are derived from amino acid precursors in brain; and c) intermediary metabolism in brain. (Supported by PHS grant HD 09045).

1027 THE EFFECT OF ACUTE SPINAL CORD INJURY ON AMINO ACIDS IN THE THORACIC CORD OF THE CAT. JL Osterholm, TA Hare, BS Glaeser, JD Irvin, JL Alderman. Depts. of Neurosurgery and Pharmacology, Thomas Jefferson Med. Coll., Phila. Pa. 19107.

The levels of amino acids (AA) including the putative inhibitory AA neurotransmitters glycine (Gly) and GABA and excitatory transmitters aspartate (Asp) and glutamate (Glu) were determined in the spinal cord of the cat one hr following 500g/cm injury to the thoracic region (T-8). A 2 cm cord sample containing the injury site and immediately adjacent regions was subdivided into 2mm sections and AA were measured on an AA analyzer after conversion to a fluorescent derivative of O-phthaldehyde.

Neither Gly nor GABA were altered in either the site or adjacent regions. There was a decrease in both Asp and Glu at the site although this was not statistically significant. Alanine, Isoluecine and leucine were elevated 330, 320 and 280% (all $p < .05$) respectively at the site and returned to control values 3mm remote to the injury. Phenylalanine, Tyrosine and several basic AA were also elevated above normal levels within the site proper. These data suggest that neurons containing the inhibitory AA transmitters are relatively unaffected by severe cord trauma one hr post-injury. In contrast, profound and highly site restricted aberrations in behavior occur in those AA generally considered as part of the metabolic pool.

1028 INCREASED PERMEABILITY OF PERIVENTRICULAR TISSUES IN LEAD POISONING. L.A.O'Tuama, C.S.Kim*, J.D.Mann* and J.T.Gatzy*. Univ. N. Carol. Sch. Med., Chapel Hill, N.C. 27514

IV administered pulses of ^{210}Pb accumulate selectively in neural barrier tissues (O'Tuama et al. Toxicol Appl Pharmacol, 35, 1-9, 1976) and the accumulation of tyrosine by choroid plexus is inhibited by the addition of lead nitrate in vitro (Kim et al. Environ Health Perspectives, in press, 1977). These results suggest that the barrier tissues may be a "target organ" for neural effects of lead. The present study was designed to define further the interaction of inorganic lead with the neural barrier tissues. Adult mongrel cats were assigned to control or poisoned groups. The poisoned group was pretreated with lead carbonate 600mg qd for 5 days. On the sixth day the animals were anesthetized and subjected to ventriculocisternal perfusion with mock CSF containing inulin with or without added ^{210}Pb (approx.600cpm/ml). Blood lead concentrations (means ± SD) averaged 91.5 ± 72μg/100ml in the pretreated group and only 3.65 ± 2.76μg/100ml in controls. However tissue lead levels between control and poisoned differed only for the paraventricular tissues (.18 ± .02 vs. .42 ± .18μg/gram) ($P<.05$). CSF formation did not differ in controls and treated animals (.021 ± .006 vs. .026 ± .002ml/min). The net clearance (k_o) of ^{210}Pb from the perfused ventricle was strikingly greater in the pretreated group (ml/min: controls .022 ± .005; poisoned 3.24 ± 1.55) ($P<.01$). Whereas % of ^{210}Pb recovered in the cisternal collection of control animals exceeded by 4-fold that in the poisoned group ($P<.05$). The increased clearance of ^{210}Pb from CSF in the pretreated group may have influenced the deposition of the metal within neural tissue since whole brain recovery of ^{210}Pb in pretreated cats was only 1/2 that found in control animals. The question arises whether the increased removal of the tracer from the ventricle in the poisoned group is due to an increase in overall permeability of the paraventricular tissues or to occupation of tissue binding sites by endogenous lead with resultant changes in complexing of the metal by the tissues. Preliminary results suggest that an increased ventricular clearance of ^{14}C labeled urea accompanies the high extraction of ^{210}Pb in the pretreated group, suggesting that these animals show a generalized increase in permeability of the periventricular tissues. These studies support our hypothesis that the neural barrier tissues may be a target site for inorganic lead. Furthermore, this interaction occurs in a species showing minimal behavioral reaction to lead and before detectable elevation of neural tissue levels. Lead-induced barrier dysfunction may offer a model for the mechanisms of neurotoxicity associated with "low level" lead exposure (David et al. Lancet 3:900-903, 1972.) Supported by grant from NIEHS #5 R01 ES01151.

1029 CHARACTERIZATION OF A PEPTIDE DERIVED FROM THE SERUM OF PSYCHIATRIC PATIENTS. R. M. Palmour*, F. R. Ervin, H. Wagemaker*, and R. Cade*. Dept. Genetics, U California, Berkeley, CA 94720; NPI, UCLA, Los Angeles, CA 90024; Dept. Psychiatry, U Louisville, Louisville KY 40202; Dept. Medicine, U Miami, Miami, FL 33124.

Wagemaker and Cade (Amer. J. Psych., 1977, in press) have reported that hemodialysis leads to clinical improvement in a group of drug-resistant psychiatric patients. Dialysate #1 (from a series of sixteen weekly dialyses) contains greater than 100-fold concentrations of a particular peptide as compared to dialysate #16. We have isolated the oligopeptide (MW approximately 3000) from the dialysate of several different patients, and have quantitated its disappearance in dialysate #1, #8, and #16. Furthermore, the quantity of peptide present in serum before and after dialysis has been determined for several patients. The quantity of peptide in a patient who showed clinical deterioration following cessation of dialysis was determined, as was the quantity of peptide present in dialysate #16 of a patient whose clinical improvement was ambiguous. Amino acid composition and amino acid sequences have been determined for the specific peptide derived from the serum and/or dialysate of each patient. The potential utility of this peptide as a marker for a sub-category of psychiatric disease, and as a predictor for a specific therapeutic regimen, will be discussed.

1030 PHOSPHORYLATION OF PROTEINS IN THE SQUID GIANT AXON
Harish C. Pant* and Tohru Yoshioka* (SPON. Y.P. Loh). Lab of Neurobiology, National Institute of Mental Health, Bethesda, Maryland 20014

Proteins in the squid giant axon were labeled with ^{32}p by (1) incubation of intact axons in artificial sea water containing [γ-^{32}P]-ATP or $^{32}PO_4$; (2) intracellular infusion of the axons with the radioactive ATP or PO_4; and (3) by in vitro incubation of isolated axoplasm with radioactive ATP or PO_4. When the intact axon was incubated with extracellular [γ-^{32}P]-ATP, twice as much ^{32}P-labeled protein appeared in the axoplasm than in the sheath as was determined using the extrusion technique. The two major phosphorylated peaks in axoplasm had molecular weights of 400 x 10^3 and 200 x 10^3, whereas in the sheath the major phosphorylated protein was 12 x 10^3 daltons. The phosphorylation of the 200 x 10^3 dalton protein in axoplasm was decreased when cAMP was added to the axoplasm and [γ-^{32}P]-ATP in vitro; or in situ, when the axon was subjected to repetitive electrical stimulation in the presence of [γ-^{32}P]-ATP. The 12 x 10^3 dalton protein increased in phosphorylation, both in axoplasm and sheath, during repetitive electrical stimulation. The significance of these results will be discussed.

1031 FATTY ACID COMPOSITION OF SUBCELLULAR FRACTIONS DERIVED FROM A VITAMIN B_{12}-DEFICIENT BRAIN.
Robert B. Ramsey and Naren L. Banik*. Dept. of Neurology, St. Louis University School of Medicine, St. Louis, MO 63104 and Dept. of Neurology, Medical Univ.of South Carolina, Charleston, SC 29401.

Subcellular fractionation and subsequent lipid isolation has been carried out on brain from a patient who suffered a cellular deficiency of the 5-deoxyadenosylcobamin and methylcobalamin co-enzyme forms of vitamin B_{12}. Adenosylcobalamin is required for the enzyme methylmalonyl-CoA mutase. Reduced activity of this enzyme results in an accumulation of methylmalonyl-CoA and propionyl-CoA, potential precursors for branched-chain and odd-chain fatty acids, respectively. Examination of the fatty acid composition of choline and ethanolamine glycophospholipids indicated a relative enrichment of odd-chain fatty acids which were identified by gas-liquid chromatography-mass spectroscopy as C_{15}, $C_{15:1}$, C_{17}, and $C_{17:1}$. A mixture of methyl branched C_{17} fatty acids was also identified. These odd-chain fatty acids were found in all the subcellular fractions examined. Soluble, microsomal and mitochondrial fractions were isolated from both gray (GM) and white (WM) matter, and myelin which was only isolated from white matter. The affected brain phospholipids generally had a lower unsaturated fatty acid content than the control brain phospholipids. Odd-chain fatty acids accounted for 8.5-13.2% of the total fatty acid in choline phospholipid compared to control values up to 1.2%.

Phosphatidyl Choline Odd-Chain Fatty Acid Content (% Total Fatty Acids)

	Soluble	Microsomes	Mitochondria	Myelin
Control				
WM	1.2	Trace	Trace	Trace
GM	1.1	0.8	0.5	---
Patient				
WM	10.2	12.0	11.5	9.8
GM	13.2	9.7	8.5	---

Examination of the myelin sphingolipids, sphingomyelin, cerebroside and sulfatide, yielded abnormal fatty acid profiles. The sphingomyelin contained only small amounts of $C_{24:1}$ fatty acid. Both normal and hydroxy fatty acid-containing cerebroside and sulfatide had reduced levels of C_{24} fatty acid. Determination of the relative hydroxy and normal fatty acid content of these galactolipids indicated an abnormally high hydroxy fatty acid level. If the abnormal sphingolipid fatty acid profiles are characteristic of vitamin B_{12} deficiency is unknown. Further cases will need to be analyzed to establish this fact.

1032 OXIDO-REDUCTION OF NICOTINAMIDE ADENINE DINUCLEOTIDE IN NEURONS FOLLOWING EXCITATION DURING CARBON DIOXIDE PARTIAL PRESSURE CHANGES.
Carlos Rodríguez-Estrada. Cátedra de Fisiología, I.M.E. Facultad de Medicina, Universidad Central de Venezuela, Caracas, Venezuela.

It has been reported (Rodríguez-Estrada, Am J Physiol 228:996, 1975) that reduced nicotinamide adenine dinucleotide (NADH) level of dorsal root ganglion neurons change after a short period of peripheral nerve stimulation in aerobic conditions, the changes observed were an initial decrease (oxidation) followed by an increase of NADH level (reduction). In this work it was expected that NADH rate of oxido-reduction of dorsal root ganglion neurons should changed after rising or lowering the intracellular pH due to change of oxido-reduction potential of NADH/NAD couple of pyridine-linked dehydrogenases. Fluorometric NADH determinations were done on in vitro preparations of dorsal root ganglion neurons of frogs (Rana palmipes spix). In vitro preparation was placed in a moist chamber at a constant temperature of 25°C. This chamber was provided with an outlet and inlets for gases. The peripheral nerve was stimulated with square pulses (0.2 ms duration, 20 p/s, 5 sec stim). The pH changes were induced by circulating moistened micture of carbon dioxide in oxygen. NADH level of the preparation increased after oxygen was replaced with a CO_2/O_2 mixture (CO_2= 2.5%, O_2= 97.5%), afterwards replacing the gas mixture with oxygen, the NADH level returned to that level observed before. The transient changes observed on the preparation following peripheral nerve stimulation were blocked after lowering the pH by replacing the oxygen with CO_2/O_2 mixture. Afterwards, changing the CO_2/O_2 mixture with oxygen, the transient changes on the NADH level of the preparation were observed again. The transient changes were blocked, first, NADH reduction and later on NADH oxidation, and they returned again in the same order. The increase of NADH after a decrease of pH was attributed to a decrease of the rate of oxido-reduction of the mitochondrial respiratory chain, and this decrease of oxido-reduction rate was also observed in the transient changes induced during neuron excitation. Decrease in the rate of respiration will decrease the energy supply of the neuron.

1033 A RAPID ASSAY FOR FEMTOMOLE QUANTITIES OF DOPAMINE, NOREPINEPHRINE, AND EPINEPHRINE IN BIOLOGICAL SAMPLES.
Charles F. Saller* and Michael J. Zigmond. Dept. of Life Sciences, Univ. of Pittsburgh, Pittsburgh, PA 15260.

We have developed a method for the analysis of the catecholamines (CAs), dopamine, norepinephrine, and epinephrine, based upon a procedure originally described by Engelman et al. (Amer. J. Med. Sci. 255:259, 1968), and later modified by Coyle and Henry (J. Neurochem. 21:61, 1973) and Cuello et al. (J. Neurochem. 21:1337, 1973). The CAs are converted to their O-methylated derivatives, 3-methoxytyramine (3-MT), normetanephrine (NMN), and metanephrine (MN), by the enzyme catechol-O-methyltransferase (COMT; EC 2.1.1.6) with ^{3}H-S-adenosylmethionine serving as the methyl donor. Samples are deproteinized in 0.1N $HClO_4$ and the supernatants containing up to 1 ng of total CA are incubated for 10 min at 37°C with 10 mM $MgCl_2$, 6 mM EGTA, 11 mM dithiothreitol, 0.3 mg COMT [purified according to Nikodejevic et al. (J. Pharmacol. Exp. Ther. 174:83, 1970) through the ammonium sulfate precipitation steps and freeze dried], 0.5 µc S-adenosylmethionine (100 nM) and 0.5 M Tris acetate buffer, pH 9.1, in a final volume of 30 µl. The incubation is stopped by placing tubes on ice, adding 2 µl of 2.5 M $CaCl_2$ to inhibit COMT and 10 µl 20% phosphotungstinic acid in 2N HCl (2:3) to precipitate unreacted S-adenosylmethionine. (Blanks receive $CaCl_2$ prior to incubation.) Precipitates are sedimented by brief centrifugation and the supernatants are spotted on the absorbent layer of silica chromatography plates (LQ6DF, Kontes) followed by 5 µl of a carrier solution containing 5 µg 3-MT, 2.5 µg NMN, and 2.5 µg MN in 0.2N acetic acid. The plates are developed in the dark for 90 min using chloroform:methanol:ethylamine (16:3:2) (De Prada and Zürcher, Life Sciences 19:1161, 1976). The spots, corresponding to 3-MT (Rf = 0.83), NMN (0.45), and MN (0.64), are visualized under UV light and scraped into scintillation vials. The silica is eluted overnight with 10 ml Econofluor scintillation cocktail (New England Nuclear) containing 2.5% di-(2-ethylhexyl) phosphoric acid, to which is added 400 µl 0.5 M borate buffer, pH 10.5. This assay offers a number of advantages over the original procedures: First, it permits the simultaneous determination of all three CAs, with little or no cross contamination or interference by CA precursors, metabolites, or a variety of drugs including amphetamine, 6-hydroxydopamine, and α-methyltyrosine. Second, it is highly sensitive, yielding 20-30,000 CPM/ng for each CA with a blank of <500 CPM, and thus can quantify 300 fmols (50 pg) or less of these compounds. Third, it is extremely simple and rapid and can be used to analyze 100 tubes or more in a few hours. Supported in part by a grant from the USPHS (MH20620).

1034 DEVELOPMENTAL CHANGES IN REGIONAL DISTRIBUTION OF CENTRAL NERVOUS SYSTEM CARBONIC ANHYDRASES. Victor S. Sapirstein*, Michael C. Trachtenberg and Marjorie B. Lees. E.K. Shriver Ctr., Waltham, MA 02154 and Boston VA Hosp., Boston, MA 02130.

Brain carbonic anhydrase (CA) is a predominantly glial enzyme whose major function concerns fluid and ion movements. The concentration of CA is known to vary with species, age and brain region. The present study was undertaken to further define the regional distribution of CA and to differentiate the developmental patterns of the soluble, membrane-bound and myelin forms of the enzyme.

Long-Evans rats were perfused rapidly with heparinized saline and the brain and spinal cord dissected at 4°. Total, soluble, membrane and myelin fractions were prepared by standard procedures. Assay for lactic dehydrogenase showed no contamination of the myelin by the soluble fraction.

In adult animals (90 days), the total CA activity per gm fresh tissue showed an antero-caudal progression with upper brain stem 2250 units, lower brain stem 1600, cerebellum 1080 and spinal cord 375. Activity in the upper brain stem was therefore more than 5 times higher than in spinal cord. A similar pattern was observed in 75, 37 and 16 day old animals but the upper brain stem values decreased with age; upper brain stem/ spinal cord ratios were 5, 3 and 1, respectively. The ratio of lower brain stem/ spinal cord similarly decreased from 4 at 90 days to slightly more than 1 at 16 days. This pattern reflects the delayed development of anterior regions as compared with spinal cord. The soluble and membrane-bound forms of the enzyme each showed a developmental pattern similar to that of the total enzyme. Furthermore, the relative contribution of soluble and membrane-bound CA remained constant at the ages studied. Analyses of discrete anatomical regions reinforce the relative invariance in the percentage of membrane-bound CA. White matter regions exhibited significantly higher activity than did gray matter regions, while maintaining a similar neuraxial progression. These observations suggest that CA plays an important role in white matter fluid dynamics.

The specific activity (units/mg protein) of the myelin obtained from different regions of the CNS also showed an rostro-caudal progression: upper brain stem 12, lower brain stem 6, cerebellum 5 and spinal cord 2. However, in contrast to the other fractions, the specific activity of the myelin remained constant between 16 and 90 days. The myelin CA thus appears to be under separate developmental control and probably represents a distinct form of the enzyme.

Supported by NIH grant NS 13649 and VA project 8519-01.

1035 DISTRIBUTION OF TYROSINE HYDROXYLASE, CHOLINE ACETYLTRANSFERASE, AND GLUTAMIC ACID DECARBOXYLASE IN THE RAT STRIATUM. Michael C. Scally,* Ismail H. Ulus,* and Richard J. Wurtman. Laboratory of Neuroendocrine Regulation, MIT, Cambridge, MA 02139.

Recent reports describe the distribution of dopaminergic innervation and receptors within various parts of the striatum. In the present study, we mapped the rostral-to-caudal distribution of the neurotransmitter-synthesizing enzymes tyrosine hydroxylase (TOH), choline acetyltransferase (CAT), and glutamic acid decarboxylase (GAD) in striatum. Coronal sections of caudate-putamen of 400 µm width were taken beginning with the most rostral part (9700 µm, according to Konig and Klippel) of the striatum and extending to the most caudal part (6100 µm). The distribution of these enzymes varies markedly within the striatum. TOH and CAT were present primarily in the rostral part of the striatum (2.50 vs. 1.06 nmoles $^{14}CO_2$ formed per mg protein per hour for TOH, and 52.7 vs. 33.8 nmoles ^{14}acetylcholine formed per mg protein per hour for CAT at 9300 and 6500 µm, respectively), while most of the GAD activity was present caudally (117.4 vs. 198.6 nmoles $^{14}CO_2$ formed per mg protein per hour at 9300 and 6500 µm, respectively). The relative activities of TOH and CAT paralleled each other throughout the length of the striatum. These data provide further evidence for reciprocal innervations by cholinergic and dopaminergic neurons in the striatum (Ulus, I.H. and Wurtman, R.J., Science 194:1060, 1976). (These studies were supported in part by a grant from ADAMHA, MH-28783.)

1036 EFFECT OF FLUPHENAZINE ON HIGH AFFINITY CHOLINE UPTAKE IN VITRO AND ON ACETYLCHOLINE AND CHOLINE LEVELS IN STRIATUM AND CORTEX. Kathleen A. Sherman*, Israel Hanin, and Michael J. Zigmond (SPON: R. J. Ertel). Depts. Psychol., Psychiat. (WPIC), and Life Sci., Univ. Pittsburgh, Pittsburgh, PA 15261

Striatal acetylcholine (ACh) interneurons appear to be inhibited by nigrostriatal dopamine (DA) neurons. Administration of neuroleptic drugs, which block DA receptors, should result in increased ACh activity. In fact, increased striatal ACh turnover has been reported following such drugs. Both decreases in ACh levels and increases in high affinity choline (Ch) uptake have been proposed as indices of increased ACh turnover. Following neuroleptics, Ch uptake has been reported to increase (Atweh et al., Life Sci. 17:1535, 1975), while conflicting reports exist for changes in ACh levels (e.g., Trabucchi et al., Nature 249: 664, 1974; Coyle & Campochiaro, J. Neurochem. 27:673, 1976). In the present study, both Ch uptake and ACh and Ch levels were examined after treatment with the neuroleptic, fluphenazine (FLU) (2.5 mg/kg, s.c.), or saline (SAL) at pH 4.8. Male albino rats were killed by microwave irradiation, and striatum and cortex analyzed by gas chromatography. FLU decreased ACh in striatum within 15 min. The effect was maximal (-37%) by 30 min (SAL: 63.4 nmol/g; FLU: 39.9), and persisted up to 24 h. Striatal Ch levels were unchanged (SAL: 24.6; FLU: 24.2), as were cortical ACh (SAL: 14.4; FLU: 15.6) and Ch levels (SAL: 18.4; FLU: 17.8). Next, rats were decapitated 30 min after FLU or SAL, and synaptosome-rich P_2 fractions of striata prepared. Using 1 µM Ch and 37°C, no significant increase was observed in either active Ch uptake (SAL: 56.7 pmol/mg protein/2 min; FLU: 60.6) or Na^+-dependent Ch uptake (SAL: 50.1; FLU: 54.2). A coupling of high affinity Ch uptake to the rate of cholinergic nerve impulse activity has been proposed on the basis of experiments examining other brain regions. The present findings, however, suggest that, at least in the striatum, uptake of Ch is not coupled to utilization of ACh and that synthesis is not sufficiently stimulated by FLU to maintain steady-state concentrations of ACh. [Supported by NIMH grants #MH26320 (IH) and MH20620 (MJZ).]

1037 CHOLINE IN BLOOD AS A POSSIBLE INDEX OF BRAIN ACETYLCHOLINE METABOLISM IN VIVO. Tsung-Ming Shih, Ursula Kopp* and Israel Hanin. Dept. of Psychiat., Univ. of Pittsburgh Sch. of Med., Western Psychiatric Institute & Clinic, Pittsburgh, PA. 15261.

The aim of these studies has been to determine whether the rate of incorporation of deuterium-labeled choline (Ch) administered to mice in their diet may be used as an index of brain Ch and acetylcholine (ACh) metabolism. Mice were fed with Ch-[methyl-D_9]bromide (D_9-Ch) administered in drinking water as a supplement to the basic diet. Experiments with different concentrations of Ch have shown that 0.5 mg/ml will not affect normal steady-state levels of plasma Ch or brain Ch and ACh. This concentration was, therefore, used in our subsequent experiments. Fourteen days after exposure to this diet, D_9Ch was omitted from the drinking water and mice were fed with normal diets and tap water for an additional 21 days. These animals were sacrificed by microwave irradiation on days 7 and 14 during D_9Ch exposure and on days 2 and 7 following discontinuation of D_9Ch. Blood was drawn from the periorbital sinus of each mouse prior to killing. Plasma Ch and brain Ch and ACh were determined by chemical ionization gas chromatography-mass spectrometry. The data obtained are summarized in the following table:

	Days of Feeding		Days After Discontinuation of Feeding	
	7	14	2	7
Plasma Ch	3.8±0.43(12)	6.8±0.41(12)	4.2±0.13(9)	2.9±0.33(9)
Brain Ch	4.2±0.33(17)	6.2±0.35(17)	4.1±0.38(15)	2.9±0.32(16)
Brain ACh	3.8±0.27(17)	4.8±0.39(17)	3.0±0.27(15)	2.3±0.32(16)

Data are presented as mean percent ratio ± SE for the number of mice shown in parentheses. Percent ratio is calculated as the ratio of the concentration of deuterated Ch or ACh to that of the entire pool of Ch or ACh, multiplied by 100. There is an excellent correlation between plasma D_9Ch and whole brain D_9Ch and D_9ACh percent ratio during the tracer build-up stage, and the subsequent decrease in D_9Ch and D_9ACh from 0 up to 7 days following discontinuation of feeding the animals with the deuterium-labeled Ch. These findings provide further evidence that Ch pools in plasma and brain, as well as the ACh pool in brain exist in a dynamic equilibrium in vivo. The data also suggest that analyses of the metabolism and disposition of brain cholinergic components may be feasible utilizing measurements of D_9Ch mole ratios in blood of animals fed with deuterium-labeled Ch. (Supported by NIMH Grant #MH26320.)

1038 LOCAL CEREBRAL GLUCOSE UTILIZATION DURING CORTICAL SPREADING DEPRESSION IN RATS. Mami Shinohara*, Jane Jehle*, Beth Dollinger* and Louis Sokoloff. (SPON: J. Fenstermacher). Laboratory of Cerebral Metabolism, NIMH, Bethesda, Md. 20014.

Local cerebral glucose utilization (LCGU) was measured during cortical spreading depression (CSD) by the autoradiographic 2-[^{14}C]deoxyglucose technique in rats. CSD was elicited by the application of KCl crystals or filter papers soaked in 25% (w/v)KCl to the dura overlying the surface of the parietal cortex of one hemisphere (experimental side). On the opposite side (control side), filter papers soaked in normal saline were applied. LCGU studies were carried out 10 to 30 min after the first KCl application. On the experimental side, LCGU was increased in cortex to the level of 180 μmoles/100g of tissue/min, which is a higher rate of glucose consumption than in any other structures in 5 control animals while no change was produced in corresponding regions and in any other regions on the control side. The areas where LCGU was highly elevated were different in each experiment depending upon the location of trephine openings. Cortex surrounding the opening showed a very high rate of glucose consumption and deeper layers of cortex were more affected. In basal ganglia and diencephalic structures, except for hypothalamus, mamillary body, and dentate gyrus, marked decreases of LCGU were observed on the experimental side. In structures in the posterior part of the brain (vestibular nucleus, cochlear nucleus, superior olive, lateral lemniscus, inferior colliculus, superior colliculus, and cerebellum) LCGU was not changed significantly. In several studies local cerebral blood flow was measured with the iodoantipyrine method during CSD and showed high rates of blood flow in cortical regions in which glucose consumption was increased.

1039 LEAD & SEIZURES: ROLE OF γ-AMINOBUTYRIC ACID (GABA). E.K. Silbergeld, L.P. Miller*, S. Kennedy*, N. Eng* (SPON: T.N. CHASE), NIH, NINCDS, Bethesda, MD 20014

Chronic exposure of rodents to lead (Pb) from birth has been reported to alter CNS cholinergic and monoaminergic neurotransmission. These effects have been associated with hypermotility and learning disorders in animals (Neuropharm. (1975) 14, 431; Science (1975) 187, 359; Biochem. Pharm. (1975) 26, 397). Because seizures have been described in the latter stages of lead intoxication in both animals and humans, we investigated the effects of chronic Pb exposure on several aspects of the GABA system. Rats were exposed from birth to Pb acetate, 5 and 10 mg/ml in drinking water, and examined at 40-60 days of age. In four brain regions (caudate, substantia nigra, cerebellum, and parietal cortex) the following neurochemical indices were studied: GABA transaminase (GABA-T) activity, glutamic acid decarboxylase (GAD) activity, GABA levels, apparent rate of GABA synthesis (as measured by aminooxyacetic acid-induced accumulation), and synaptosomal GABA uptake and release. The results indicate that Pb exposure is associated with an increase in the apparent rate of GABA synthesis, increased GAD activity, decreased GABA-T activity, and decreased GABA levels. These changes, however, were not osberved consistently in all regions studied. The results could represent either increased GABA-mediated neurotransmission or compensatory response to an antagonism by Pb of GABA interaction at its postsynaptic receptor. This was explored pharmacologically by challenging Pb-treated rats with known convulsants. For picrotoxin and isoniazid, Pb-exposed rats had significantly lowered seizure threshholds. For pentylenetetrazole (PTZ) and strychnine, however, no differences were observed when compared to controls. These results are consistent with earlier studies on Pb-exposed mice, which showed no change in sensitivity to electroconvulsive shock, PTZ, or hyperbaric oxygen exposure. This combined neurochemical and pharmacological study suggests that the observed alterations in the GABA system represent a decrease in GABA-mediated neurotransmission which is associated with changes in the response to convulsants. Thus, decreased GABAergic function may be involved in the incidence of seizures in clinical Pb poisoning.

1040 MECHANISMS REGULATING 6-PHOSPHOGLUCONATE DEHYDROGENASE ACTIVITY IN AXOTOMIZED SUPERIOR CERVICAL GANGLIA OF THE RAT. Dominick V. Sinicropi* and Frederick C. Kauffman and Tong H. Joh. Dept. Pharmacology and Expt. Ther., School of Medicine, Univ. of Maryland, Baltimore, Md. 21201 and Lab. Neurobiol., Dept. Neurol., Cornell Univ. Med. Coll., New York 10021.

Transection of major postganglionic nerve trunks of the superior cervical ganglion elicits a reversible increase in neuronal activities of 6-phosphogluconate dehydrogenase and glucose-6-phosphate dehydrogenase (Härkönen, M. and Kauffman, F.C., Brain Res. 65:141, 1974). Elevation of these activities may be of critical importance to regeneration of injured axons since precursors used in lipid and RNA biosynthesis are formed from hexose metabolized via the oxidative pentose phosphate pathway. To study molecular mechanisms mediating the increased activity of 6-phosphogluconate dehydrogenase in axotomized superior cervical ganglia, an immunochemical assay for this enzyme was developed. The enzyme was purified approximately 1500-fold from rat brain by conventional salt precipitation, ion exchange and affinity chromatography. Two forms of 6-phosphogluconate dehydrogenase in the purified fraction were resolved by polyacrylamide electrophoresis and gel filtration; these forms are a tetramer of molecular weight $\geq$ 100,000 and a larger aggregate of identical charge:mass ratio. Separate antisera to each form of the enzyme were prepared and a microimmunochemical technique for the titration of 6-phosphogluconate dehydrogenase molecules in homogenates of single superior cervical ganglia or lyophilized sections of neural tissue weighing between 0.5 and 5 μg was developed. Antisera against each form of the enzyme cross-reacted with the other. Immunochemical titrations of axotomized and contralateral unoperated control ganglia indicated that the increase in activity produced by axotomy is due, in part, to an increase in the absolute amount of enzyme protein. Since available data suggest that immunotitration curves from the two groups are not parallel, additional mechanisms such as a change in the tetramer-polymer equilibrium or conversion of an inactive pro-enzyme to an active form may contribute to the increased activity produced by nerve transection. (Supported in part by funds from the Pangborn Foundation, University of Maryland)

1041 CALCIUM ACTIONS AND CALCIUM-BINDING PROTEIN IN ELECTROPLAX. Ari Sitaramayya*, James A. Campbell, and Frank L. Siegel. (SPON: H.A. Kubinski). Departments of Pediatrics and Physiological Chemistry, University of Wisconsin Center for Health Sciences, Madison, WI 53705.

Calcium is known to regulate several aspects of neural function, including the release of neurotransmitters from vesicular stores and the synthesis and metabolism of cyclic nucleotides, which may mediate the post-synaptic actions of some neurotransmitters. Evidence from several laboratories has shown that the calcium activation of brain cyclic nucleotide phosphodiesterase and adenylate cyclase is mediated by a calcium-dependent regulator protein (CDR). This protein is found in electroplax of Electrophorus electricus at much higher levels than in mammalian brain, the second richest source, and we have investigated its actions in this cholinergic tissue. Electroplax PDE is not inhibited by EGTA under conditions where the brain enzyme is inhibited by 50%, indicating that the major activity of PDE in electroplax is not activated by calcium and CDR. Electroplax PDE was separated into two fractions of approximately equal activity by sucrose gradient centrifugation. The first PDE activity is a cyclic AMP-specific PDE, while peak II displays activity directed against both cyclic AMP and cyclic GMP. Neither activity is inhibited by the addition of EDTA, or activated by the addition of exogenous calcium and CDR. These data indicate that CDR, the major soluble protein of electroplax, has different functions in this tissue than in mammalian brain. The actions of calcium on cyclic nucleotide synthesis and protein phosphorylation have been compared in electroplax with a high CDR content (Electrophorus) and electroplax with a lower CDR content (Torpedo). Adenylate cyclase in electroplax was stimulated 370% by 100 μM calcium. Protein phosphorylation in electroplax from Electrophorus was activated by calcium to a greater extent than that of Torpedo. Phosphorylation in Electrophorus was calcium-activated at all concentrations of ATP tested, whereas in Torpedo calcium inhibited phosphorylation at high ATP concentrations and activated phosphorylation at ATP concentrations below 100 μM. In the absence of calcium, proteins of Electrophorus electroplax incorporated ^{32}P from ^{32}P-γATP at a rate of 1 nmole/min/mg protein, while the corresponding value in Torpedo proteins is 0.2 nmole/min/mg protein; calcium exaggerates this difference. Polyacrylamide gradient gel electrophoresis reveals major differences in the membrane protein composition of the two electroplax membranes, and suggests caution in generalizing the results found in any single electroplax preparation as reflecting events at cholinergic synapses. (Supported by PHS Grant NS 11652).

1042 SIMULTANEOUS DETERMINATION OF SEROTONIN, NOREPINEPHRINE AND DOPAMINE TURNOVER IN THE TELENCEPHALON, DIENCEPHALON, MESENCEPHALON AND PONS-MEDULLA OBLONGATA OF RAT BRAIN. J.E. Smith, C. Co* and J.D. Lane*. Dept. Psychiat. and Pharmacol., Sch. Med. LSU, Shreveport, LA 71130.

Two different general approaches have been used to assess the rate of synthesis of brain biogenic amines. One method involves the use of pharmacological agents that block the synthesis of one or more of these neurotransmitters with a resulting decrease in brain content which is used to compute turnover. This method cannot be used to measure turnover in behaving animals because of the debilitating behavioral effects of the blocking agents themselves. The second general approach is to administer radioactive precursors and determine the specific activities of the biogenic amines. The intravenous administration of such precursors usually involves stressful conditions or anesthesia which can result in changes from normal in vivo synthesis rates. We report a method for measuring the concurrent turnover of serotonin (5-HT), norepinephrine (NE) and dopamine (DA) in small brain regions using a procedure for intravenous injection of radioactive precursors that can be used in awake-behaving animals without disrupting stimulus or schedule control. Six rats were implanted with chronic jugular catheters. One week later 100 µl intravenous injections of heparinized saline containing 0.5 mCi of ^{3}H-L-tryptophan and 0.5 mCi of ^{3}H-L-tyrosine were given through the jugular catheters. Sixty and 90 min later the rats were sacrificed by near-freezing in liquid nitrogen and the brains removed and dissected at -4°C into telencephalon (TEL), diencephalon (DIEN), mesencephalon (MES) and pons-medulla oblongata (P-M). The brain parts were individually pulverized in liquid nitrogen and the biogenic amines extracted into 1N formic acid-acetone (v/v-15:85). DA, NE and 5-HT were extracted using a cation exchange resin and assayed fluorometrically with compound specific micro assays that have been previously described (Smith et al., Anal. Biochem. 64, 149, 1975). A fraction of the extract was passed through an alumina column which absorbed the NE and DA but not the 5-HT. The NE and DA were eluted with acid, dried down and separated by TLC. The separate 5-HT, NE and DA fractions were assayed for radioactivity and specific activity and turnover rates determined. The highest turnover rate for 5-HT was seen in the MES (2.8 nmoles/g-hr) and the lowest in the DIEN (0.6 nmoles/g-hr). NE turnover was highest in the P-M (2.5 nmoles/g-hr) and lowest in the DIEN (0.7 nmoles/g-hr). DA turnover rate was highest in the TEL (3.3 nmoles/g-hr and lowest in the P-M (0.36 nmoles/g-hr). (This project was supported in part by USPHS Grant DA-01519-01).

1043 EFFECT OF ANOXIA ON ^{3}H 2-DEOXY-D-(^{3}H) GLUCOSE UPTAKE IN ISOLATED CEREBRAL CAPILLARIES. M. Spatz, D. Micic* and I. Klatzo. Lab. Neuropath. & Neuroanat. Sci., NIH, Bethesda, MD 20014.

A decreased 2-deoxy-D-(^{3}H)-glucose ([^{3}H] 2-DG) cerebral capillary uptake was observed in the capillary fraction isolated from brains of gerbils subjected to bilateral cerebral ischemia (Brain Res. 120, 141, 1977). In order to clarify some aspects of the pathophysiological mechanism responsible for this phenomenon, we investigated the effect of O_2 deprivation and the [^{3}H] 2-DG uptake in the cerebral capillary fraction separated from the nonvascular normal brain tissue.

The procedures for the capillary isolated and [^{3}H] 2-DG uptake studies were the same as the ones described previously (Brain Res. 110, 361, 1976) except for the different incubation solutions used in the atmosphere of various gas mixtures.

A markedly reduced (75%) specific [^{3}H] 2-DG uptake was found in the capillaries incubated in nitrogen atmosphere as compared with the one exposed to normal, or 100% oxygen or 95% N_2 5% O_2. The decreased capillary [^{3}H] 2-DG uptake was recoverable by substituting the atmosphere with normal air or oxygen after 7.5 - 15 minutes exposure to the N_2 gas. The anoxic inhibition of [^{3}H] 2-DG uptake couldn't be restored by addition of either energy phosphate metabolites or mono-, bivalent ions or various free fatty acids to the incubation buffer. Only the addition of essentially fatty acid free serum albumin in 1% concentration to the incubation mixture prevented the reduction of [^{3}H] 2-DG capillary uptake under anaerobic conditions. This process was partly abolished by the incubation mixture containing the same type of albumin with (one or more) free fatty acids.

These results suggest that the oxygen dependent [^{3}H] 2-DG uptake of cerebral capillaries may be closely related to the metabolism of fatty acids.

1044 THE BIPHASIC RESPONSE OF SYNAPTOSOMAL ($Na^+ + K^+$)-ATPase TO ETHANOL. Albert Y. Sun* and Sally L. Seaman. Sinclair Comparative Medicine Research Farm, University of Missouri, Columbia, MO 65201.

We have previously demonstrated that many membrane transport processes in the brain were altered due to the hydrophobic interaction of alcohol with membranes. High concentrations (1-5%) of ethanol inhibit synaptosomal ($Na^+ + K^+$)-activated ATPase. The inhibitory potencies of different molecular size of alcohols correlated well with their lipid solubility properties. Results of recent investigations further showed that at low concentrations of ethanol (0.1-0.5%), the ($Na^+ + K^+$)-ATPase activity of synaptic plasma membranes was enhanced. This biphasic response of enzymic activity to increasing concentrations of ethanol was also observed with other membrane transport systems such as Ca^{2+}-transport and catecholamine-uptake. The enhancement of the biochemical activities in the presence of low concentrations of ethanol is probably due to an increase in membrane fluidity. However, higher concentrations of ethanol may disturb the fine arrangements of membrane macromolecules as a result of the hydrophobic alcohol-membrane interaction. The biphasic phenomenon may explain some of the behavioral responses observed after different doses of alcohol administered. (Supported in part by USPHS Grant #AA02054).

1045 EFFECT OF CALCIUM IONOPHORES ON THE UPTAKE AND RELEASE OF CHOLINE AND ACETYLCHOLINE IN RAT STRIATAL SYNAPTOSOMES. John R. Tencati* and Roger N. Rosenberg (SPON: C.E. Spooner). Dept. of Chem., Univ. of Calif., San Diego, La Jolla, Ca. 92093.

The calcium ionophores A23187 and X537A have been used to study the effects of calcium ions and metabolic inhibitors on the high-affinity uptake of choline and the release of retained labelled choline and acetylcholine (ACh) in rat striatal synaptosomes. The sodium-dependent uptake of (^{3}H)choline was decreased in a concentration-dependent manner as the ionophore concentrations were varied from 0.10 to 5.0µM. Kinetic analysis revealed a decreased initial velocity of choline uptake and a decreased V_{max}, while the K_t was unaffected. Both ionophores were also capable of releasing choline and ACh from synaptosomes which had been preloaded with (^{3}H)choline at concentrations where high-affinity uptake prevailed (0.50µM). Release was a function of ionophore concentration, media calcium concentration, and synaptosomal calcium content. However, release alone was not sufficient to account for the low level of choline accumulated when an ionophore was present during the 30 minute synaptosome loading step.

Release of retained labelled choline and ACh from synaptosomes by A23187 was: a) partially antagonized by media calcium if the (^{3}H)choline loading step had been performed in calcium-containing media (1.5mM), b) partially dependent on media calcium if the loading step was carried out in the presence of 1.0mM EGTA, and c) absolutely dependent on media calcium if the synaptosomes had been depleted of intracellular calcium stores by treatment with carbonyl cyanide m-chlorophenyl hydrazone (1.0µM) and EGTA (1.0mM) prior to (^{3}H)choline loading. In contrast, release by X537A, which has a less specific cation selectivity than A23187 (Pressman, Ann. Rev. Biochem. 45:501, 1976), or by 60mM KCl did not require media calcium in untreated or calcium-depleted preparations. Release of labelled choline and ACh by both ionophores was greatly augmented by pretreatment with the metabolic inhibitors iodoacetic acid (1.0mM) or potassium cyanide (1.0mM). However, larger increases were seen with X537A than with A23187.

These results suggest that the calcium-dependent release of labelled choline and ACh can occur using either free-external or stored-internal calcium pools, and that release by some agents (i.e. KCl, X537A) may occur independent of calcium ion movements or because of a more efficient release of stored calcium. These studies also demonstrate that the effects of media calcium, calcium ionophores, and metabolic inhibitors on choline uptake and release in synaptosomes can be understood in terms of synaptosomal energy requirements and the mechanisms operating to regulate free cytoplasmic calcium concentrations.

1046 A HIGHLY PURIFIED PROTEIN FACTOR (α-LATROTOXIN) FROM BLACK WIDOW SPIDER VENOM EVOKED RELEASE OF NEUROTRANSMITTERS FROM DIFFERENT TYPES OF NEURONS IN MOUSE BRAIN. Mu-Chin Tzeng* and Philip Siekevitz (SPON: C.M. Connelly). Dept. Cell Biol., Rockefeller Univ. New York, N.Y. 10021.

Black widow spider venom has a wide spectrum of activity, and at least three toxic components can be separated from the venom. The major protein component (α-latrotoxin), which was purified to homogeneity (formerly referred to as fraction B_5, Frontali et al., J. Cell Biol. 68, 462 (1976)) and used in this study, is a monomeric protein with MW 130,000 and has no phospholipase activity. It causes both a marked increase in mEPP frequency and ultimate depletion of synaptic vesicles at both frog and mouse cholinergic neuromuscular junctions, but has no effect on those invertebrate systems examined. In this study, the effect of α-latrotoxin on the release of neurotransmitters from mouse brain was investigated. Mouse cerebral cortex slices were preincubated with radioactive choline, NE or GABA in oxygenated medium, and after washing with fresh medium, radioactive transmitters released into the medium were measured. Eserine, pargyline, and (aminooxy)-acetic acid were present throughout to prevent the metabolic conversion of ACh, NE and GABA, respectively. ^{3}H-ACh was determined by use of choline kinase. Since ^{3}H-NE and ^{3}H-GABA were presumably only slightly metabolized, the radioactivity in the medium, assumed to represent unmetabolized transmitters, was directly determined in both cases. In all three cases studied, α-latrotoxin markedly increased the efflux of transmitters with a latency shorter than 5 min, reaching maximum at about 10 min, and lasting for at least 30 min. At the end of the experiment, 88% of the total ^{3}H-ACh was found in the medium, and this accounted for 23% of the radioactivity originally present in the tissue. The released ^{3}H-NE and ^{3}H-GABA each accounted for ∿ 30% of that originally in the tissue. The maximal increase in magnitude of release above the base-line release was ten-fold for ACh and three-fold for NE and GABA. These effects were also observed in a Ca^{++}-free solution containing EGTA. This finding is in contrast to the transmitter-releasing β-bungarotoxin which requires Ca^{++} and has phospholipase activity. Summarizing all existing data, α-latrotoxin appears to show no selectivity towards different neuronal types of the same animal, and seems to act only on vertebrates. The effect of α-latrotoxin is probably not due to membrane depolarization, for agents such as K^+ and veratridine, which depolarize the membrane, require Ca^{++} for their effect in enhancing transmitter release. However, preliminary work (A. Gorio, M.-C Tzeng, W.P. Hurlbut, P. Siekevitz) using ^{125}I-α-latrotoxin, indicates that the toxin acts at the pre-synaptic plasma membrane.

1047 TWO MECHANISMS OF SPREADING DEPRESSION IN THE CHICKEN RETINA. A. Van Harreveld. California Institute of Technology, Pasadena, California 91125.

Two mechanisms underlying spreading depression (SD) have been proposed, a release of K (Grafstein, J. Neurophysiol. 19, 154, 1956) or a release of glutamate (Van Harreveld, J. Neurochem. 3, 300, 1959) from the intracellular compartment. Both K and glutamate cause a change in the transparency of the isolated chicken retina, with threshold concentrations of 5 mM and 0.2 mM respectively. The glutamate reaction is prevented by Mg 10-15 m equiv), the K response is not affected (Van Harreveld and Fifkova, J. Neurobiol. 4, 375, 1973). SD in the chicken retina is characterized by a change in tissue transparency and is prevented by Mg. It was therefore postulated that glutamate is involved in the mechanism of SD. However, Mg prevents SD only at relatively elevated temperatures (above 23°) At 22° or lower Mg loses its protective action. At these low temperatures the metabolism may not be sufficient to maintain the normal ion distribution of the tissue, resulting in a leakage of K ions into the extracellular space. It seems possible that under these conditions K ions are involved in SD. This is supported by the observation that ouabain (0.05 mM), which inhibits the ion pump maintaining the normal ion distribution, causes SD at elevated temperatures (32°) in the presence of Mg Also the inhibition of glycolysis, which seems to be the main energy source of the isolated retina, by iodoacetate or lack of glucose in the medium results in SD at elevated temperatures in the presence of Mg. It would seem that SD can be caused by two mechanisms, one based on a release of glutamate from the intracellular compartment, the other on a K release. There are slight differences between these forms of SD. At 22° the glutamate based SD moved at a mean velocity of 2.3 mM/min over the retina, the K based SD at 1.3 mM. The slow potential change accompanying the glutamate based SD was about twice as large as that of the K based SD. These differences were statistically significant.

The two forms of SD can be identified by the effect of Mg which prevents the glutamate based SD but not the K based one. Since the SD in the rat cerebral cortex is inhibited by Mg (Bureš, Physiologia Bohemoslov. 9, 202, 1960) it can be surmised to be a glutamate based SD. It is possible that in other tissues and under other circumstances K is involved in the propagation of SD.

1048 EFFECTS OF d- AND l-AMPHETAMINE ON LOCAL CEREBRAL GLUCOSE UTILIZATION IN THE RAT. Lawrence R. Wechsler*, Helen Savaki*, Charles Kennedy, and Louis Sokoloff. National Institute of Mental Health, Bethesda, Md. 20014.

The actions of the potent sympathomimetic amine, amphetamine, in the central nervous system are generally attributed to its stimulation of catecholaminergic synaptic function resulting from its known influences on the release and uptake of catecholamine neurotransmitters, particularly dopamine. The [^{14}C]deoxyglucose technique provides a means to determine simultaneously the rates of glucose utilization in all the macroscopic structural components of the brain. Because of the close correlation between functional activity and energy metabolism, the method serves also to map regions of altered functional activity in the central nervous system. The [^{14}C]deoxyglucose technique has, therefore, been employed to examine the effects of d- and l-amphetamine in 40 gray and white structures of the brain of normal conscious rats. Local cerebral glucose utilization was measured during a 45-minute period beginning 15 min after the intravenous administration of 5 mg/kg of d- or l-amphetamine. d-Amphetamine caused local increases in glucose utilization in many structures of the extrapyramidal motor system as well as other structures known to contain dopamine-producing or dopamine-receptive cells. The greatest increases produced by d-amphetamine occurred in the subthalamic nucleus and the zona reticulata of the substantia nigra. l-Amphetamine causes increases in some but not all of these same structures. Decreases of cerebral glucose utilization following administration of either d- or l-amphetamine were found in the habenula and suprachiasmatic nucleus of the hypothalamus. These results indicate that amphetamine may influence behavior through effects on specific regions of the brain. Only some of these regions have been previously considered as possible sites of action of amphetamine.

1049 ATROPINE INDUCED ALTERATIONS IN CHOLINE AND ACETYLCHOLINE IN DISCRETE REGIONS OF RAT BRAIN. Lynn Wecker and Wolf-D. Dettbarn. Dept. Pharmacology, Vanderbilt Univ. Sch. Med , Nashville, TN. 37232.

Administration of atropine to rats produced dose and time dependent alterations in levels of choline (Ch) and acetylcholine (ACh) in discrete areas of rat brain. For dose-response studies, animals were injected with 2.0-40 mg/kg atropine sulfate (ip) and sacrificed 15 minutes after drug administration by focal microwave irradiation. ACh and Ch were determined in the caudate nucleus and hypothalamus by pyrolysis gas chromatography. In the caudate, ACh levels decreased from 73 to 45 nmoles/g tissue (62% control) with 20 mg/kg atropine. Higher doses of atropine had no further effect. In contrast, ACh levels in the hypothalamus were unaltered at all doses of atropine studied Concurrent with the induced ACh decrease in the caudate, atropine(10 mg/kg) produced a maximal increase in Ch levels from 20 to 40 nmoles/g tissue. Although atropine did not affect ACh levels in the hypothalamus, Ch levels increased from 17 to 26 nmoles/g tissue (153% control) with 10 mg/kg atropine. When plotted semi-logarithmically, the atropine dose-response curves were sigmoidal, with the Ch curve exhibiting marked inhibition behavior at increased doses.

The time dependency of these alterations was determined in animals treated with 5 mg/kg atropine and sacrificed 15 to 60 minutes after drug administration. In both the caudate and hypothalamus, ACh levels decreased to 75% and 77% control, respectively, by 30 minutes and values returned to control levels 45 minutes after drug administration. In contrast, Ch levels increased 15 minutes after atropine administration to 165% control in the caudate and 130% control in the hypothalamus, and values remained at this level for the following 45 minutes.

Administration of atropine has been reported to decrease total levels of ACh in brain through presynaptic mechanisms including increased ACh synthesis, turnover and release. Furthermore, results from our laboratory have shown that atropine decreases only the bound fraction of ACh. The present data indicate that a) atropine has a differential action on ACh and Ch levels in discrete brain regions and b) Ch levels are altered by doses of atropine that do not affect total ACh levels. Therefore, alterations in Ch levels induced by atropine may be intimately related to the vesicular fraction of ACh and may possibly reflect actions on Ch uptake systems or phopholipid metabolism.

(Supported in part by NIH Grant # NS-12438)

1050 CNS TERATOLOGY OF HALOTHANE, R.C. Wiggins, J.M. Rogers,* J.M. Astrello,* G.N. Fuller,* and B.M. Rigor.* Depts. of Neurobiol. & Anat. and Anesthes., Univ. of Texas Med. Sch. Houston, TX 77025.

Pregnant Sprague-Dawley rats were exposed to 0.4% halothane gas delivered in air to enclosed cages. In the first experiment each exposure lasted 30 min. 3 times daily beginning 2 days before birth and continuing postnatally until sacrifice at 20 days of age. In the second experiment, exposures of 3x1 hour, began 11 days prior to birth and were terminated at 7 days of age. These rats were sacrificed at 23 days. On the day of sacrifice, we applied a double isotope method designed to detect altered synthesis of brain subcellular fractions during metabolic perturbation (Wiggins et al. 1976 Brain Res. 107:257). In both studies 3 experimental rats received 50 uCi of 3H-leucine (IP) and three controls, born on the same day, received 50 uCi of 14C-leucine. After 3 hrs., animals were sacrificed, a 3H-labeled and a 14C-labeled brain paired, homogenized together, and the whole brain particulate subcellular fractions prepared by ultracentrifugation. Radioactivities were measured by two channel liquid scintillation counting and data were reported as ratios of 3H and 14C disentigrations (dpm). In the first experiment isotope ratio values (3H/14C= experimental/control) were: nuclear (1.7-11.5), myelin (0.72-1.0), synaptosomal (0.88-1.1), mitochondrial (1.1-1.3), and microsomal (0.79-0.90). In this experiment, the nuclear fraction had a unique high value when compared with other subfractions which had similar values. In the second experiment ratios were: nuclear (0.80-0.85), myelin (0.63-0.66), synaptosomal (0.75-0.86), mitochondrial (0.87-0.96), and microsomal (0.83-0.92). In this case a unique low value was obtained for myelin. Brain weights of 20 halothane exposed as well as 20 control rats, including weights of dissected regions (cerebellum,cerebral cortex, hypothalamus, hippocampus, midbrain, medulla oblongata, and striatum) were statistically indistinguishable. In the absence of growth stunting, the apparent high rate of nuclear membrane synthesis in exp. #1 may result from a delay in the time of maximum cellular multiplication, so that declining synthesis in controls preceeds that in halothane exposed rats. On the basis of previous experience with altered metabolic states during development, the more straight forward interpretation - atypical hyperplasia- appears less likely. In experiment #2, the myelin data are consistent with a decline and/or delay in myelinogenesis and these results are comparable to myelin effects observed in other investigations. Furthermore hypomyelination would not result in substantial weight deficits. In each experiment, altered metabolic states were observed in the absence of gross pathology. By the design of the experiment, deviation from the characteristic isotope ratio for a given paired brain homogenate indicates metabolic inequality between experimental and control rats .

1051 INTERACTION OF β-ENDORPHIN WITH RECEPTORS OF ^{3}H-DIHYDROMORPHINE, ^{3}H-NALOXONE, and ^{3}H-MET-ENKEPHALIN IN MEMBRANE OF RAT BRAIN CORPUS STRIATUM. David T. Wong* and Jong S. Horng* (SPON: L. Lemberger). The Lilly Research Labs., Indianapolis, Ind. 46206.

The binding of three radiolabeled ligands (^{3}H-dihydromorphine, ^{3}H-naloxone and ^{3}H-met-enkephalin) to membranes from rat corpus striatum could be resolved kinetically into two components, one with a low dissociation constant (high-affinity binding) and one with a high dissociation constant (low-affinity binding). Values for these dissociation constants (K_D) were estimated from Scatchard plots. The K_D values for the high affinity binding of all three ligands were increased by β-endorphin, an analgesic peptide, present at 20 nM (see Table). The K_D value for the low-affinity binding of dihydromorphine was similarly increased by β-endorphin, whereas the low-affinity binding of met-enkephalin was less affected and the low-affinity binding of naloxone was not affected by β-endorphin. The total numbers of receptor sites for dihydromorphine, naloxone and met-enkephalin, in fmoles/mg protein were 324, 410 and 1800, respectively. The number of binding sites was not affected by β-endorphin in any case. Thus β-endorphin was a competitive inhibitor of both the high- and the low-affinity binding of dihydromorphine and of the high-affinity binding of naloxone and met-enkephalin. The β-endorphin sensitive binding sites may represent opiate agonist sites, and the β-endorphin insensitive sites that bound naloxone may represent opiate antagonist sites. Approximately 75% of the met-enkephalin receptors belonged to the low-affinity binding component which were insensitive to β-endorphin; these receptors may mediate other physiologic functions besides analgesia in the central nervous system.

Radiolabeled Ligand	*K_D Values (nM)* *Control*	*+β-Endorphin*
High-affinity binding component:		
^{3}H-Dihydromorphine	1.5	3.4
^{3}H-Naloxone	1.8	3.7
^{3}H-Met-enkephalin	5.2	15.2
Low-affinity binding component:		
^{3}H-Dihydromorphine	10.4	35.5
^{3}H-Naloxone	16.8	17.9
^{3}H-Met-enkephalin	56.3	67.4

1052 REGULATION OF CSF COMPOSITION BY THE ARACHNOID MEMBRANE. Ernest M. Wright. Dept. Physiol., Sch. Med., UCLA, Los Angeles, CA 90024.

The arachnoid membrane together with the choroid plexus forms the anatomical barrier between the blood and cerebrospinal fluid (CSF). Little is known about the relative contributions of these two membranes in the regulation of the CSF composition. Using isolated membranes from the frog brain I have measured the role of the arachnoid and the choroid plexus in the transport of amino acids, anions, organic acids, and organic bases between the CSF and blood. In vivo experiments have already established that these solutes are actively eliminated from the CSF. There was net transport of anions iodide (thiocyanate, pertechnetate and bromide) and organic acids (p-aminohippuric acid) across the plexus from CSF to blood, and this was blocked by ouabain and competitive inhibitors. Even though amino acids (e.g. glycine) and organic bases (e.g. choline) were actively accumulated within the choroidal epithelium from the CSF, there was no net transport of these solutes from CSF to blood. However, choline and glycine were actively transported out of the CSF across the arachnoid membrane, and at least for glycine the kinetics of the transport process were identical to values reported for in vivo experiments. Anions (e.g. iodide) and p-aminohippuric acid were neither accumulated in the arachnoid nor actively transported across this membrane.

It is concluded that i)the arachnoid plays an important role in the regulation of amino acid and organic bases in the CSF, ii)the choroid plexus is largely responsible for the clearance of anions and weak organic acids from the CSF, and iii)the accumulation of solutes within the isolated choroid plexuses provides little information about the importance of this epithelium in the transport of solutes between CSF and blood.

1053 CHEMICAL CHANGES IN RABBIT SCIATIC NERVE DURING WALLERIAN DEGENERATION. Allan J. Yates and Diann K. Thompson*. Div. Neuropath., Coll. Med., Ohio State University, Columbus, Ohio, 43210, U.S.A.

Gangliosides are sialic acid containing glycosphingolipids which are present in high concentrations in cerebral cortex. They are membrane-bound and their carbohydrate moieties protrude from the cell surface where they could play a role in cell surface activities such as cell-cell interaction. Data from previous studies on rabbit sciatic nerve are consistent with the bulk of them being located in the axolemma of myelinated but not unmyelinated axons. The present study was done to investigate further their cellular localization in peripheral nerve. The left sciatic nerves of 25 adult rabbits were transected and animals killed in groups of 5 at time intervals of 3, 7, 14, 21 and 28 days following surgery. The left nerves of each group were pooled as experimental and the right nerves as the controls. Lipids were extracted by the method of Suzuki (1) and gangliosides purified and analyzed by that of MacMillan and Wherrett (2). Total ganglioside sialic acid fell from the mean control value of 91.3 micrograms per gram fresh weight to 77.2 at 3 days, and 66.6 at 7 days; then it increased to the maximum value of 118.9 at 21 days and fell slightly to 111.1 at 28 days. The total ganglioside sialic acid per nerve also increased from the mean control value of 19.6 micrograms to 32.1 and 27.5 mcg. at 21 and 28 days respectively. These are in contrast to those for total cholesterol and phospholipids which steadily decreased to 66% and 35% of their respective control values by 28 days. As a per-cent of total ganglioside sialic acid G-1 and G-2 steadily decreased from their control values of 25.0% and 17.2% to 7.3% and 3.3% respectively at 28 days. In contrast, G-5 and G-6 increased from 4.4% and 1.4% to 17.8% and 17.3% respectively in the same time period. There were no changes in G-3 or G-4. Correlating these chemical changes with known histological events in Wallerian degeneration, it is suggested that most of G-1 and G-2 are in the axon while G-5 and G-6 may be in the Schwann cell. Possible cellular locations of G-3 and G-4 are not indicated from these results.

1054 EXTENT OF 2-DIMETHYLAMINOETHANOL (DEANOL) BIOTRANSFORMATION TO CHOLINE (Ch) AND ACETYLCHOLINE (ACh) IN BLOOD AND BRAIN: A GAS CHROMATOGRAPH/MASS SPECTROMETRIC (GC/MS) ANALYSIS.

N.R. Zahniser*, T.-M. Shih, U. Kopp* and I Hanin. Dept. of Pharmacol., Sch. Pharm., and Dept. Psychiat., Sch. Med., Western Psychiatric Institute & Clinic, Univ. of Pittsburgh, Pittsburgh, PA 15261.

The ability of acutely administered deanol to serve as a precursor of brain ACh *in vivo* is still unresolved. Utilizing GC/MS we, therefore, measured the extent of biotransformation in mice of acutely administered deanol to Ch in blood and Ch and ACh in brain. These compounds were administered as their deuterium-labeled analogs: deanol-[1,2-D_4]as the p-acetamidobenzoic acid salt (D_4-deanol) and Ch-[D_9-methyl]-Br (D_9-Ch). Brain, plasma and RBC levels of the nonlabeled and deuterium-labeled deanol, Ch and ACh were measured by GC/MS according to an extension of the procedure of Zahniser *et al*. (J.P.E.T. 200:545, 1977). When mice were injected intravenously with equimolar (20μmol/kg) doses of D_4-deanol or D_9-Ch, no label from the D_4-deanol, in contrast with that of the D_9-Ch treatment, was incorporated into either Ch or ACh stores in the brain up to 8 minutes post injection. Following a longer pretreatment time (30 min.) with a much larger dose of D_4-deanol (1.1mmol/kg;i.p.), plasma Ch increased with respect to control from 26.5 to 90.3 nmol/ml, while RBC Ch increased from 45.2 to 95.7 nmol/ml. The increased Ch in the plasma and RBCs was totally accounted for by D_4-Ch. Despite the elevated levels of Ch in the blood, whole brain Ch and ACh levels did not differ from those of control animals (control: ACh 24.7±0.7 nmol/gm, Ch 28.4±1.4; treated: ACh 26.1±0.6, Ch 24.2±4.1). Furthermore, while the brain concentration of D_4-deanol (87.4±8.6 nmol/gm) was extremely high, there was little evidence of any significant conversion of D_4-deanol to either D_4-Ch (2.8±4.5) or D_4-ACh (0.0). The results of these studies demonstrate that: (1) Exogenously administered deanol rapidly elevates plasma and RBC Ch levels. This effect is presumably due to conversion of deanol to Ch in the liver. (2) Increased levels of Ch in blood after deanol treatment did not induce corresponding increases in brain Ch or ACh. The D_4-Ch measured in the blood might be in an acid-soluble form (released during extraction) which does not penetrate the blood/brain barrier *in vivo*. (3) Our data do not support a direct precursor role for deanol in the synthesis of brain Ch and ACh at short times after deanol administration. They do not preclude, however, the possibility that deanol administered chronically may be a precursor of brain ACh *in vivo*.

NEUROCYTOLOGY

1055 GEOMETRICAL CHARACTERISTICS OF THE SCHWANN CELL LAYER ENCLOSING THE SQUID GIANT AXON. W. J. Adelman, Jr., J. Moses* and R. V. Rice*. Laboratory of Biophysics, NINCDS, NIH, Woods Hole, MA 02543, Department of Biological Sciences, Mellon Institute, Carnegie-Mellon University, Pittsburgh, PA 15213, and Marine Biological Laboratory, Woods Hole, MA 02543.

To correlate series resistance, R_S, with Schwann cell layer anatomy, giant axons of *Loligo pealei* were fixed and stained. Cross and longitudinal sections were examined by transmission electron microscopy. Montage micrographs were assembled and measurements were made of the width and frequency of mesaxonal clefts at the periaxonal space and at the basilar lamina. The average mesaxonal cleft width = 10.5 nm. One cm^2 of the giant axon surface is enclosed by a single cell layer containing about 120,000 Schwann cells. One cm^2 of axon surface has a sheath mesaxonal area of 0.001 cm^2 at the periaxonal surface and 0.016 cm^2 at the basement membrane, the mesaxons branching frequently as they cross the sheath. A model was used to predict R_S. Assuming the mesaxonal clefts contain seawater, and can be lumped into a truncated cone with the narrower radius at the inner surface, then (normalized for 1 cm^2 of axon surface) $R = (\rho h)/(\pi r_1 r_2)$, where ρ = specific resistance (25Ωcm), h = width of Schwann cell layer (0.93 μm), r_1 = inner diameter of the cone (0.018 cm) and r_2 = outer diameter (0.071 cm). Thus, R_S = 0.58Ωcm^2. For an axon having 1 cm^2 of surface the volume of the Schwann cell layer = 9.55 x 10^{-5} cm^3, and the volume of the mesaxonal (extracellular) space = 6.33 x $10^{-7}cm^3$. The value of the Schwann cell membrane capacity was estimated to be approximately 0.7 μF/cm^2.

1056 GLYCOGEN AGGREGATIONS IN CENTRAL NEURONS OF INSECTS. Vincent Argiro*, Peter Pelikan*, Malcolm Wood* and Melvin J. Cohen. Dept. Biol., Yale Univ., New Haven, Conn. 06520.

In the central neurons of the cockroach Periplaneta americana, large aggregates of glycogen appear in the soma cytoplasm following prolonged exposure to CO_2 or nitrogen and also after axotomy. The large glycogen masses (1-3μm) are tightly surrounded by mitochondria and are made up of individual glycogen particles 25-50nm in diameter.

Normal thoracic ganglion neurons examined in the electron microscope show a fine scattering of individual glycogen particles in the soma. Fresh frozen 10μm cryostat sections stained with the aqueous periodic acid-Schiff procedure (PAS) show a barely discernable distribution of stained particles scattered in the peripheral cytoplasm of some large motor neurons. In approximately 5% of the large motor neurons in the normal animal stained with PAS, there is a scattering of larger stained particles in the peripheral cytoplasm.

Animals placed in a CO_2 atmosphere for 15 minutes and examined 18 hours to 5 days later show massive aggregates of PAS stained material in the peripheral cytoplasm of thoracic motor neurons. The reaction is primarily confined to the large motor nerve cell bodies. Exposure to an atmosphere of nitrogen for 10 minutes causes a similar glycogen response. The polysaccharide nature of these aggregates was confirmed by the absence of PAS staining after incubating the sections in 0.5% aqueous α-amylase.

Axotomy by amputation of a limb at the trochantor-femoral joint without anaesthesia also results in aggregates of PAS stained material on the side ipsilateral to the operation. Exposing a thoracic ganglion and cutting the nerve trunks on one side results in some cells on both sides showing the PAS positive response, with a preponderance on the operated side. The use of CO_2 was avoided in these experiments by immobilizing the animals with cold at 6°C for 5 minutes. One μm plastic sections of the axotomized preparations stained with toluidine blue shows densely stained material distributed in a pattern similar to the PAS positive material. Sections of the same cells examined in the electron microscope indicate that the aggregates stained with toluidine blue consist of 1-5μm masses of glycogen particles tightly surrounded by mitochondria.

The induction of the large glycogen aggregates by either CO_2 or nitrogen suggest that this response is caused by a lack of oxygen. Axotomy and, to a lesser extent, other procedures such as exposure of the ganglion also cause an aggregation of glycogen. The magnitude and rapidity of this glycogen response in identified insect neurons may provide a useful model for investigating factors controlling carbohydrate metabolism in central neurons.

1057 IMMUNOLOGICAL AND BIOCHEMICAL ANALYSES OF SOME OF THE MAJOR PROTEIN COMPONENTS OF POST-SYNAPTIC DENSITIES. K. Berzins*, R.S. Cohen*, D. Grab*, and P. Siekevitz. Dept. of Cell Biol., Rockefeller University, New York, N.Y. 10021.

Post-synaptic densities (PSDs) isolated from dog cerebral cortex have been found to contain some ten major and twenty minor proteins. Actin was identified biochemically and immunologically to be one of the major proteins, though myosin was not found (Cohen et al., J. Cell Biol. 1977, in press). Some of the other major proteins have now been characterized and tentatively identified. The major component of PSDs (51,000 MW) was shown in immunodiffusion to be immunologically identical to axonal neurofilament protein. Antiserum either against purified axonal neurofilament protein or against the 51,000 MW region of PSDs separated in SDS-PAGE both precipitated one and the same component from a crude axonal neurofilament preparation and from an extract of PSDs. Yen et al. (Neurosciences Abstr. 1976) reported a similar reaction of antiserum to axonal neurofilament protein with a PSD extract. The 51,000 MW band of PSDs occasionally appeared as two closely-spaced bands in SDS-PAGE, the upper band of which co-migrated with the axonal neurofilament protein. The 18,000 MW protein of PSDs showed several similarities to the Ca^{++}-binding muscle troponin C. It co-migrated exactly in SDS-PAGE with one component of the skeletal muscle troponin complex and with the purified troponin C-like cAMP-phosphodiesterase modulator protein from bovine brain (Watterson et al., J. Biol. Chem. 251, 4501 (1976)). In addition, the 18,000 MW region of the PSD gel bound radioactive Ca^{++}. Ca^{++} seemed to be essential for the binding of the 18,000 MW protein to the PSD, as the protein is readily extracted from the structure by means of EGTA, and could be re-bound, after removal of the EGTA, by the addition of 50 mM Ca^{++}, Mg^{++} being ineffective. By means of an antiserum to purified chicken skeletal muscle tropomyosin (Jorgensen et al., Am. J. Anat. 142, 519 (1975)) we were able to precipitate one component from a PSD extract, indicating the presence of a tropomyosin-like protein in the PSD. Furthermore, this protein may be the 31,000 MW PSD protein, since the latter co-migrated in SDS-PAGE with a purified preparation of dog skeletal muscle tropomyosin. Amino acid analyses and immunological experiments are in progress to confirm the identities of both the PSD 18,000 and 31,000 MW proteins. Experiments are being performed to ascertain whether all the major proteins of myofibrils, except for myosin, are present in PSDs.

1058 BINDING OF CATIONIZED FERRITIN AND COLLOIDAL IRON TO SYNAPTIC ELEMENTS IN DISPERSED CELL CULTURES OF RAT CEREBELLUM. Richard W. Burry and John G. Wood. Dept. of Anat., University of Tennessee Center for the Health Sciences, Memphis, Tennessee, 38163

Electron microscopic studies have shown that negatively charged groups on cell surfaces bind to either cationized ferritin (CF) or positively charged colloidal iron (CI). CF has been shown to bind exposed surfaces of cultured neurons and also to aggregate into patches with increased incubation time (Wessells et al., Proc. Natl. Acad. Sci., U.S.A. 73:4100, 1976). We have investigated the mobility of negatively charged groups on both the appositional cell membranes of adjacent neurons and membranes of synaptic contacts. Dispersed cell cultures of 2 day old rat cerebellums, prepared as described by Lasher (Brain Res., 69:235, 1974), were used at 7 days in vitro.

The distribution of the CI over the plasma membranes of fixed neurons was uniform but sparse, with little or no CI binding found in the synaptic cleft. With cultures incubated in CF after fixation, very heavy globular labeling of exposed surfaces was found with almost no penetration of the CF between cells. Use of 0.1M NH_3Cl after fixation reduced the amount of binding to exposed surfaces and increased slightly the penetration of CF between cells. Incubation of unfixed cultures with CF showed scant but patchy binding to exposed surfaces and uniform heavy binding to appositional membranes, even those at some distance from the exposed surfaces. We interpret this pattern in the unfixed membranes to indicate lateral movement of the CF binding receptor from exposed surfaces to areas of apposition.

Binding of CF in fixed cultures to synaptic elements was only to exposed surfaces and not seen in the synaptic cleft. In cultures exposed to CF 10 sec. before fixation, label was seen around the synaptic contact but not in the cleft. Incubation for 1, 5, or 8 min. showed an increasing percent of synapses with CF penetrating into the synaptic cleft. Thus, synaptic junctions served as a brief barrier to the movement of negatively bound membrane groups. The number of synapses seen decreased to none after a 60 min. chase with media, and apparently, once a synapse was penetrated with CF bound groups it did not remain intact.

In summary, the mobility of CF particles indicates that negatively charged groups in developing neuronal membranes were mobile in the plane of the membrane with the exception of the synaptic junction where the mobility was partially restricted. In addition, the penetration of CF bound groups into the synaptic cleft appears to cause a reduction in the number of synapses.

1059 SUPRAEPENDYMAL ELEMENTS ON THE VENTRICULAR SURFACE OF THE HAMSTER MEDIAN EMINENCE AND ORGANUM VASCULOSUM OF THE LAMINA TERMINALIS. J.P. Card* and J.A. Mitchell. Department of Anatomy, Wayne State University School of Medicine, Detroit, Michigan 48201.

Due to the similarity in structure of both the median eminence (ME) and organum vasculosum of the lamina terminalis (OVLT) as well as the hypothesized neuroendocrine role of ependyma in both of these regions, this study was undertaken to compare and characterize at the scanning (SEM) and transmission (TEM) electron microscopic levels the numerous supraependymal elements found in each of these regions. Brains from 25 adult hamsters were removed following intracardiac perfusion with Karnovsky's aldehyde fixative and processed for SEM or TEM. Following SEM examination, some specimens were prepared for correlative TEM. A single supraependymal cluster of neuronal cells and processes was consistently found on the floor of the ME, just anterior to the infundibular recess. Each cluster is remarkably consistent not only in size and location, but also in its surface morphology, intrinsic organization and distribution of associated processes. Neurons averaging 11u in diameter are characteristically found on the surface of the cluster and enclose a core of loosely arranged axons and dendrites. Dendrites are routinely observed arising from the peripheral neurons and passing into the core. The origin of axons within the core is less certain, but their vesicle filled endings are often seen forming synaptic contacts with the soma of the neuronal elements as well as numerous other processes within the core. A large number or processes associated with the base of the cluster contribute to an extensive network of neuronal processes on the floor and ventralmost aspects of the ventricular wall. The supraependymal elements on the surface of the OVLT exhibit a number of characteristics similar to those of the ME. Extensive networks of branching processes traverse the entire extent of the nonciliated ependymal surface covering the OVLT. However, the processes of this region rarely extend from a single structure as highly organized as that seen in the ME. In contrast, these processes accumulate at multiple foci in extensive entangled networks. Many times one or more supraependymal cells are present on the network surface, however these cells are much smaller (2-4μ vs. 11μ) than the neurons found on the ME. Other supraependymal cells (7μ) are visible on the OVLT which give rise to a number of the processes traversing the ventricular surface. While preliminary findings indicate these processes to be neuronal, extensive investigation at the TEM level is presently being conducted to determine conclusively the nature of the OVLT supraependymal elements. (Supported by NIH Grant No. RR-05387-13.)

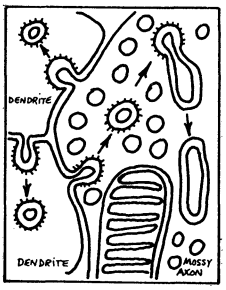
1060 PEROXIDASE UPTAKE BY PHOTORECEPTOR TERMINALS IN THE CHICK RETINA DURING DIFFERENT PHYSIOLOGICAL CONDITIONS. Nigel G.F. Cooper* and Barbara J. McLaughlin. Dept. of Anat., Univ. of Tenn. Center for the Health Sciences, Memphis, TN 38163.

Electron microscopy of in situ eyecup preparations from 1 wk. old White Leghorn chicks was used to correlate changes in photoreceptor synapses during different physiological states. Chick retinal photoreceptors are organized into three layers: an outer layer of rods and cones and two inner layers of cones (Morris and Shorey, J. Comp. Neurol., 129:313, 1967). We have used uptake of the extracellular tracer, horseradish peroxidase (HRP) and changes in the degree of dendritic invagination into the receptor terminals during light and dark adaptation as indicators of photoreceptor activity (Schacher et al., J. Cell Biol., 70:178, 1976; Schaeffer and Raviola, Symp. Quant. Biol., 40:521, 1976). In addition, magnesium (20mMg++) was added to some eyecup preparations to determine its effect on receptor synaptic activity (Ripps et al., J. Cell Biol., 70:86, 1976). When the retina is illuminated in the presence of HRP for 15-30 minutes, HRP is found in all three layers of cone terminals, in the coated vesicles, synaptic vesicles and smooth ER cisternae. The rods, filled predominantly with dense core vesicles, do not take up the tracer and coated vesicles are rarely seen. In addition,the dendrites synapsing with rod terminals are much less deeply invaginated than those synapsing with cone terminals. During similar periods of darkness, both rods and cones take up tracer, with labeled coated vesicles, ER cisternae and synaptic vesicles seen in the rods and cones. Unlabelled tubular ER becomes abundant in the cone terminals. The postsynaptic dendrites of rod terminals become much more deeply invaginated in the dark than in the light. Mg++ in the dark-adapted retina blocks the uptake of tracer in the second layer cones and their dendritic invaginations become flattened as seen in the light-adapted rods. Coated vesicles in these terminals are sparse. The other two receptor layers are unaffected by Mg++ and are similar in appearance to the normal dark-adapted state. Some tracer uptake is evident in the Mg++ treated, light-adapted retina and in all receptor terminals there is a significant reduction in the number of synaptic vesicles that is suggestive of an increased stimulation of synaptic vesicle release. In these terminals no tubular ER is present, as is found in the normal dark-adapted state, but there is an increase in the number of ER cisternae, some of which contain tracer. In summary, we have described certain anatomical changes in the photoreceptor terminals of the chick retina during light and dark adaptation and treatment with Mg++, which may indicate differences in synaptic activity between the various receptor types. Supported by USPHS Grant GM-00202 and Fight for Sight, Inc. New York City.

1061 FORMATION OF DOUBLE-WALLED COATED VESICLES IN THE DEVELOPING MOUSE CEREBELLUM: A POSSIBLE MECHANISM FOR GLOMERULAR REMODELING. Maryellen F. Eckenhoff* and J.J. Pysh. Department of Anatomy, Northwestern Univ. McGaw Medical Center, Chicago, Ill. 60611.

Double-walled coated vesicles (DWCV), consisting of an outer coated wall of invaginated mossy terminal plasma membrane and an inner wall of evaginated granule cell dendritic membrane, attached or free in the cytoplasm, were first described in electron micrographs by Andres (Z.Z.M.A. 64:63, 1964) who interpreted these structures as being components of the cyto-machinery associated with synaptic transmission. Subsequently, these structures have been interpreted in other ways.

We have noted large numbers of double-walled structures in electron micrographs of immature cerebellar mossy rosettes. DWCV's,100nm in diameter, consisted of 1) a coated invagination of mossy terminal plasma membrane enclosing an evagination of dendritic membrane or 2) coated invaginations of dendritic membrane enclosing evaginations of either mossy terminal or granule cell dendritic membrane. In the mossy terminal, these invaginations arise from either flat apposed membranes or the tips of long dendritic protrusions. Also, we have observed free DWCV's in the cytoplasm, coalescing DWCV's, and presumptive double-walled vacuoles. Cerebellar glomeruli of 16, 20, 37 and 70-day old mice were examined. All of these double-walled membranous structures were more frequent in mossy terminal cytoplasm in 16, 20 and 35-day old animals than in adults. Twenty-day old animals had the largest numbers of these structures, some 30-60 times more than adults. A serial section analysis was carried out in an attempt to elucidate the origin and fate of these structures. The results indicate that plasma membranes of adjacent cell processes are internalized and become free DWCV's that coalesce and possibly form double-walled vacuoles. However, it is unclear whether the DWCV's or vacuoles are transported retrogradely to the cell body or are disposed of in the processes. The fact that these structures are present in greatest numbers in 20-day old mossy fibers suggests they are not related to synaptogenesis, formation of desmoid junctions or synaptic transmission. We suggest that the DWCV's may be a mechanism for remodeling of the surface membranes of the cerebellar glomerulus during late development. (Supported by NIH Research Grant NS10657.)



1062 A GOLGI ANALYSIS OF THE OPOSSUM INTRALAMINAR AREA. James C. Hazlett. Dept. Anat., Sch. Med., Wayne State Univ., Detroit, MI 48201.

Previous Nissl studies of the opossum thalamus have reported three nuclei which probably constitute the entire intralaminar system in this form. From anterior to posterior they include the nucleus paracentralis (PC), the nucleus parafascicularis (PF) and the nucleus parafascicularis posterolateralis (PFP). In our Golgi preparations we have identified well impregnated long axon neurons in each of these three nuclei. Although all three cell groups contain isodendritic neurons, subtle differences in somatic size and shape, the presence of somatic spines, the dendritic arborization patterns and the relative numbers and distribution of dendritic spines permit a certain recognition of separate nuclei. However, as a consequence of dendritic overlapping, discrete boundaries between adjacent intralaminar nuclei are not always apparent. In addition, dendritic overlapping is also observed between the intralaminar nuclei and the surrounding specific thalamic cell groups. The present study, a composite reconstruction of the intralaminar area, is an attempt to demonstrate the extent and boundaries of the individual nuclei. The purposes of this approach are to (1) establish the three dimensional organization of the opossum intralaminar system and (2) to demonstrate the precise neuronal morphology necessary for the identification of separate nuclear groups. (Supported by USPHS Grant No. RR 05384-15.)

1063 OBSERVATIONS OF CELLS WHICH ENSHEATHE AXONS IN NERVE GRAFTED SPINAL CORDS. C. C. Kao* (SPON: H. E. Booker). Dept. Surgery, Sch. Med., University of Wisconsin, Madison, WI 53706.

In a transected and reanastomosed peripheral nerve, cells proliferate and form the "union scar" which unites the proximal and the distal cut ends of the nerve (J. Neurosurg. 1:400, 1944). Bared axons sprouting from the proximal cut ends of the nerve are initially ensheathed by the cells in the union scar which then become myelinated (Z. Zellforsch. 124:165, 1972).

We are reporting, in the spinal cord, structures similar to the union scar in the peripheral nerve anastomosis. The spinal cords were transected and small segments of autogenous peripheral nerve were transplanted into the spinal cord gap, oriented end-to-end with the spinal cord stumps. Within one to three weeks, cells proliferated and bridged the spinal cord-nerve graft junction.

Further electron microscopic study revealed presence of abundant bared axons at the spinal cord-nerve graft junction. These axons were swollen and contained abundant axoplasmic organelles.

Four cell types were identified in the nerve grafted spinal cord and all of the four types of cells were capable of ensheathing the axons. The cell types were (1) Schwann cells, (2) oligodendrocytes, (3) reactive glial cells, and (4) macrophages.

At a later stage, axons bridged the spinal cord-nerve graft junction and became myelinated. On the spinal cord side, the axon was myelinated by an oligodendrocyte, whereas across the junctional node of Ranvier, the same axon was myelinated by a Schwann cell.

The present observation suggests that cellular proliferation plays an important role in axonal regeneration in the nerve grafted spinal cords.

1064 ACTIN- AND MYOSIN-LIKE FILAMENTS IN BRAIN PERICYTES. Yvi J. LeBeux and Joan Willemot*. Departments of Anatomy and Biochemistry, Laval University School of Medicine, Québec, Québec, Canada G1K 7P4.

The question whether pericytes do or do not contain contractile filaments has been debated for decades. To help clarify this issue, we have investigated, using heavy meromyosin (HMM) labeling the possible actin-like nature of the 6-nm microfilaments which we observed forming bundles in the cytoplasm of brain pericytes. Pieces from rat brain were incubated in glycerol solutions of decreasing concentrations at 4° and then transferred into standard phosphate buffer (6 mM Na^+ phosphate buffer containing 100 mM KCl and 5 mM $MgCl_2$, pH 7.0) 1) with HMM, 2) without HMM, 3) with HMM+2.5 mM Na^+ pyrophosphate, and 4) with HMM+5 mM ATP. Bundles of smooth-surfaced microfilaments were seen within the pericytes of HMM-untreated nervous tissue. These filaments appeared to branch and anastomose, and to anchor on the plasma membrane. After reaction with HMM, the microfilaments were strikingly increased in number and in width to 18-20 nm, and intertwined in tightly-woven networks occupying larger areas of cytoplasm than in the pericytes from unreacted tissue. At higher magnification, their surfaces were seen to be heavily coated by short, thick side-arms cross-bridging the space between adjacent filaments at more or less regular intervals. The dense material thus observed was so tightly packed that it appeared as an irregular meshwork, where the polarity and the periodicity of the HMM-reacted filaments were distinguished with difficulty. In a few cases, typical arrowhead configurations were seen as periodic arrays of polarized elements along the surfaces of short segments of the filaments, depending upon their longitudinal orientation, or more often as single elements along the course of the filaments, interrupting the fuzzy appearance of their surfaces. When cross-sectioned, the microfilaments were seen as dense dots from which a material of lesser electron density radiated. After incubation in HMM solutions containing ATP or Na^+ pyrophosphate, they were no longer coated with thick side-arms. The microfilaments are thus of actin-like nature. In addition, after incubation in solutions containing both ATP and Mg^{++}, a drastic change occurred in pericyte cytoplasm. The smooth, 6 nm-wide microfilaments were now intermingled with, and converged onto the surfaces of, numerous, thick, tapered filaments, which we tentatively identified as being of myosin-like nature. It thus appears that certain of the major elements necessary for contraction are present in brain pericytes.

1065 MACROPHAGES ON THE EPENDYMAL SURFACE OF THE FELINE AREA POSTREMA. R. A. Leslie and D. G. Gwyn. Dept. Anat., Dalhousie Univ. Med. Sch., Halifax, N.S., Canada B3H 4H7.

The floor of the fourth ventricle of the cat brain has been investigated with the scanning (SEM) and transmission (TEM) electron microscope. In particular, attention was directed towards supra-ependymal (SE) cells of the surface of the bilateral area postrema (AP). These cells invariably occur on the surface of the feline AP and are generally found with greater frequency on the caudal region of the organ. The surface characteristics of AP ependymal cells vary along the rostro-caudal axis of the organ, but not along the lateral-medial axis. At the rostral extreme the apical surfaces of ependymal cells of the AP are relatively smooth and flat, displaying polygonal outlines with no cilia and few microvilli. Bulbous or short filiform microvilli, generally occuring singly, are visible in this region. In contrast, the microvillus complement is more numerous and complex nearer the caudal extreme of the AP. Large tufts of microvilli, often highly-branched, are regularly seen. The tufts often occur close together and may provide a dense covering of the AP surface in the mid-to-caudal regions. SE cells interspersed with the microvillus tufts have a typical appearance suggestive of macrophages. Under the SEM they were seen to possess numerous pseudopodia-like processes. TEM revealed many large membrane-bound vacuoles distributed through out the cytoplasm of these cells. In a test for possible phagocytic activity of these cells, animals were injected intrathecally with an exogenous protein (horseradish peroxidase - HRP). Cells were later examined for the presence of HRP with the TEM after being incubated in the Graham and Karnovsky medium which produced an electron-opaque reaction product. SE cells proved to have ingested considerable quantities of HRP, most of which was contained in phagosomes. Morphologically there is great similarity between the SE cells of the feline AP and cells described as occuring regularly in the subarachnoid space of other mammals (Malloy & Low, J. Comp. Neur. 167: 257, 1976). Our findings, therefore, are strongly suggestive that macrophages regularly occur on the surface of the AP of the cat, and are generally disbursed in moderate numbers mainly on the caudal aspect of the surface of the organ.

1066 IMMUNOCYTOCHEMICAL LOCALIZATION OF GLYCEROL-3-PHOSPHATE DEHYDROGENASE IN RAT BRAIN: ARE OLIGODENDROCYTES TARGET CELLS FOR GLUCOCORTICOIDS? Paula J. Leveille*, Jean de Vellis and David S. Maxwell. Dept. Anat., Sch. Med., UCLA, Los Angeles, CA 90024.

Immunoperoxidase methods, adapted for combined light and electron microscopy, were employed to investigate the cellular localization of glycerol-3-phosphate dehydrogenase (EC 1.1.1.8; GPDH) in adult rat central nervous tissue. The use of rabbit monospecific antibodies generated against purified rat GPDH resulted in the differential staining of one glial cell population. GPDH-positive cells in perineuronal, perivascular, and interfascicular positions were identified as oligodendrocytes by classic morphological criteria.

Direct correlation of histological and ultrastructural visualization of GPDH established the cytoplasmic localization of specific reaction product within this cell type. The specificity of GPDH antigen-antibody reaction was determined by 1) Ouchterlony diffusion, 2) quantitative immunoprecipitation tests, and 3) immunocytochemical controls for both methodologic and immunologic sources of non-specific reaction product.

The illustrative data from this study defines oligodendrocytes as the structural correlate for GPDH activity in rat central nervous tissue. Quantitative evidence which demonstrates that the maximum concentration of rat brain GPDH is selectively regulated by glucocorticoids and the localization of GPDH in one cell population warrant the interpretation that oligodendrocytes are target cells for glucocorticoid activity. (Supported by USPHS Grant HD-05615 and by ERDA Contract EY-76-C-03-0012)

1067 FREEZE-FRACTURE STUDY OF SYNAPTOGENESIS IN THE CHICK OPTIC TECTUM. Catherine F. McGraw, Barbara J. McLaughlin, and Lou K. Boykins*. Dept. Anat., Univ. of Tenn. Ctr. for the Hlth. Sci., Memphis, TN. 38163.

The superficial layers of the rostral pole of the optic tectum of chicks from embryonic days (E) 6-16 and in the hatchling have been studied by freeze-fracture in order to investigate changes in the membrane structure during retinotectal synaptogenesis. Freeze-fracture analysis of early embryonic stages reveals sparsely distributed intramembrane particles on the cytoplasmic (P-face) and external (E-face) membrane leaflets of neuronal and glial plasmalemmas. Throughout development small aggregates of small-sized particles are seen on the E-faces of plasmalemmas resembling those aggregates described in freeze-fracture studies as puncta adhaerentia (Landis and Reese, J. Comp. Neur. 155: 93, 1974). By E-7, areas of loosely-arranged clusters of medium-sized particles are observed on the P-faces of presumed neurite plasmalemmas. These clusters may represent early stages of intramembrane organization at presynaptic active sites. When the underlying cytoplasm in these regions is cross-fractured, a few synaptic-like vesicles are seen which may identify the particle clusters as belonging to developing synaptic terminals. At later stages presumed vesicle fusion sites are seen interspersed with the particle clusters and complementary intramembrane specializations are observed on the E-face presynaptic membranes. Other particle aggregates are seen at early embryonic stages on the E-faces of presumed neurite plasmalemmas. They exist as solitary aggregates of large-sized particles that are closely packed. As development progresses these E-face aggregates increase in size and packing density and occupy large oval domains in the membrane. These particle aggregates are similar to the intramembrane specializations described for postsynaptic sites at excitatory synapses (Landis and Reese, J. Comp. Neur. 155: 67, 93, 1974). By E-14, there are many particle-free zones on the P-faces of cell bodies and neurites bordered by ridges of particles which appear to delineate the boundaries of neurite appositions. Many large, oval-shaped aggregates of medium-sized particles are circumscribed by these particle-free zones. Some of these P-face aggregates are seen apposed to E-faces of presynaptic regions and may represent regions complementary to the previously described postsynaptic E-face specializations or they may correspond to a second type of postsynaptic organization. In summary, intramembrane organization of particles into aggregates begins by E-7 corresponding to the time the first synapses are observed in thin sections. As development progresses these aggregates become more complex and well-defined as either pre- or postsynaptic regions. (USPHS Grants 5T01-GM00202 and RR-05423, and Fight for Sight, Inc. N.Y.C.)

1068 CLUSTERS OF BAR SHAPED PARTICLES ON INTERNODAL AXOLEMMA Rodman G. Miller, The Salk Institute for Biological Studies San Diego, Ca. 92112

Freeze fracture of the rat sciatic nerve fixed with glutaraldehyde and impregnated with 20% glycerin reveals numerous intermembranous particles on the fracture faces of internodal myelin (PNAS 72:4046). Most of these particles are small (3-7nm apparent size). Large (13nm apparent size) particles have been found on the A face of the periaxonal Schwann membrane. Many of these are arranged into hexagonal rosettes and occasionally these rosettes join sharing a pair of particles, indicating a three-fold symmetry of the particles. The adjacent, axolemmal B face, demonstrates clusters of irregularly shaped particles. Occasionally,the particle clusters are similar to the rosettes, but, more often, the irregularity of the particles obscures any symmetry that might be present (see Miller and Pinto da Silva, Brain Res., in press).

When sciatic nerve is freshly frozen (e.g., unfixed and unimpregnated with glycerin) the particles on the axolemmal B face are bar shaped. The orientation of the individual particles seems to be random with respect to the other particles in the cluster, and the length of the particles is variable and can be as long as 40nm. The morphology of the particle rosettes seen on the periaxonal Schwann A face is the same with fresh freezing and the standard fixation and impregnation procedure.

Incubation of the tissue in high calcium concentrations prior to freezing reduces the length of the bar shaped particles to that seen in fixed and impregnated tissue.

These results are consistent with a model in which the rosettes and particle clusters are connected into a single unit and the bar shaped particles are, in vivo, extended into the axoplasm. Upon facture after fresh freezing, the bar shaped particles are pulled through the inner leaflet of the axolemma and are seen upon the surface of the B face of the axon.

1069 THE PRESENCE OF SUPRAEPENDYMAL NEURONS IN THE 3rd VENTRICLE OF THE GUINEA PIG. J.A. Mitchell, D.R. Garris[1]* and J.P. Card*. Department of Anatomy, Wayne State University School of Medicine, Detroit, Michigan 48201.

Scanning (SEM) and transmission (TEM) electron microscopic studies in our laboratory have established the presence of supraependymal neurons residing within the 3rd ventricle of the hamster, rat and guinea pig. In the present study the frequency, distribution and morphology of supraependymal neurons within the 3rd ventricle of the guinea pig were investigated. Adult guinea pigs were perfused with Karnovsky's fixative and the walls and floor of the 3rd ventricle prepared for examination by correlative SEM and TEM.

Neuronal perikarya were only observed on the densely ciliated aspects of the lateral ventricular walls and were not present in all specimens examined. Considerable morphological diversity was apparent: neurons occurred singly or in densely packed clusters. Cell bodies ranged from 25-50μ in width; cell surfaces exhibited numerous protrusions and were covered by a rich meshwork of crisscrossing, varicosed fibers. Cells gave rise to multiple processes of varying diameters and lengths; processes extended for as far as 325μ over the ventricular surface. Processes either terminated on or penetrated the ependyma, or made contact with the cell bodies or processes of adjacent supraependymal neurons. Occasionally, numerous processes ran in parallel and formed large fasciculated bundles. As such bundles coursed over the ependymal surface, individual processes branched off and penetrated the subjacent ependyma. Correlative transmission electron microscopic observations indicate that both the cell bodies and processes of such supraependymal cells possess ultrastructural features characteristic of neurons. (Supported by NIH Grant No. RR-05387-13, [1]Charles B. DeVlieg Fellow.)

1070 GROWTH PROCESSES OF MATURE CORTICAL NEURONS IN FELINE GANGLIOSIDOSIS. Dominick P. Purpura,George D. Pappas and Henry J. Baker*. Dept. Neurosci. Albert Einstein Coll. Med., Bronx, N.Y. and Dept. Comp. Med., Univ. Ala., Birmingham, Ala.

Massive spine-bearing structures (meganeurites) develop at aberrant sites between the cell body and initial portion of the axon in cortical pyramidal neurons in several human ganglioside storage diseases (Purpura and Suzuki, Brain Res. 116: 1(1976). Meganeurites with extensive secondary neuritic outgrowths are also found in cortical neurons in a feline mutant with β-galactosidase deficiency and G_{M1}-ganglioside accumulation (Purpura and Baker, Nature 266:553(1977). Electron microscope studies of cortical neurons in this feline mutant indicate that outgrowths of meganeurites have morphological features of large growth processes. These features include the presence of smooth endoplasmic reticulum, occasional large,clear as well as dense core vesicles, mitochondria and vacuoles. In many instances growth processes are postsynaptic to presynaptic terminals packed with round vesicles. Apposing membranes exhibit asymmetrical densities. Growth processes arising from meganeurites may have expanded terminal heads that contain vesicles, whereas the connecting stalks have tubules and linear arrays of smooth cisternae. These growth processes are clearly distinguishable from meganeurite spine synapses. Proximal portions of meganeurites adjacent to the soma do not show surface membrane undercoating. Distal regions that merge with the axon exhibit a dense granular layer beneath the axolemma. This is suggestive evidence that the initial axonal segment is displaced distally by the formation of the meganeurite near the region of the axon hillock. The demonstration of neurites and growth processes with presynaptic endings in mature cortical neurons in ganglioside storage disease calls attention to the possible role of gangliosides in neuronal differentiation and synapse induction during cortical ontogenesis.

1071 EFFECT OF AY9944, A CHOLESTEROL BIOSYNTHESIS INHIBITOR, ON MYELIN: A COMPARATIVE STUDY BETWEEN TWO DIFFERENT PERIODS OF BRAIN DEVELOPMENT. F.A. Rawlins, F. Proverbio* and C. López-Jiménez*, Dept. Biophysics, I.V.I.C., Apartado 1827, Caracas 101, Venezuela.

The use of AY9944 [trans-1,4 bis (2-chlorobenzylaminomethyl) cyclohexane dihydrochloride], or other cholesterol biosynthesis inhibitors, opens up the opportunity to study the relative importance of the endogenous and exogenous sources of cholesterol for myelin formation and maintenance. So far, all the studies related with the effect of AY9944, a Δ^7-reductase inhibitor, on the nervous system (NS) have been carried out during the period of major brain growth spurt which is the highest vulnerable period during brain development. Therefore, the possibility exists that various of the morphological changes found in NS of animals treated within that period might be due to focal cytoplasmic degradation which is a common response of cells to various unrelated noxious stimuli. In order to clarify this point, in the present work we have carried out a comparative study of the effect of AY9944 on central NS myelin ultrastructure and chemical composition in rats treated: a) during brain growth spurt, i.e., from 1 to 21 days of age (group 1); and b) after brain growth spurt, i.e., from 30 to 70 days of age (group 2). The drug was administered every other day by intraperitoneal injection (30 mg/Kg/injection). Electron microscope (EM) analysis of group 1 revealed focal splitting and vacuolation in a large number of myelin sheaths in the optic nerves from AY9944-treated rats. Vacuolation was so pronounced that in certain areas myelin vacuoles became large electron-lucent edemas limited by 3 or 4 myelin lamellae with no continuity with any myelin sheaths. Myelin isolated from the brain of these rats was 1/3 of that from controls and 51% of its cholesterol was substituted for 7-dehydrocholesterol. The activity of $(Na^+ + K^+)$-stimulated ATPase was higher than in control myelin. EM analysis of group 2 showed no morphological difference between the optic nerve from control and AY9944-treated rats. However, isolated myelin was substituted for 7-dehydrocholesterol. Activity of $(Na^+ + K^+)$-stimulated ATPase was also higher than in control myelin. The results indicate that treatment of rats with AY9944 after the period of brain growth spurt results in the incorporation of 7-dehydrocholesterol into myelin without further changes in its ultrastructure. However, 7-dehydrocholesterol is not as efficient as cholesterol causing a slower deposition of newly formed myelin lammellae. Increment in the $(Na^+ + K^+)$-stimulated ATPase activity indicates that a functional chante is also taking place in myelin membranes of AY9944-treated rats.

1072 ABSENCE OF NODAL AND PARANODAL AXONAL MEMBRANE SPECIALIZATIONS IN FREEZE-FRACTURE REPLICAS OF JIMPY MOUSE BRAIN AND SPINAL CORD. Jack Rosenbluth. Departments of Physiology and Rehabilitation Medicine, New York University School of Medicine, New York, N.Y.

Previous freeze-fracture studies of myelinated axons in the central nervous system have revealed characteristic structures in fracture faces of the nodal and paranodal axolemma. The most distinctive of these are 1. Nearly transverse ridges on the inner leaflet of the paranodal axolemma and corresponding grooves in the outer leaflet which sometimes contain lines of particles. These ridges and grooves represent the non-junctional portion of the paranodal axolemma, which faces the helically disposed interspace between successive turns of the ensheathing glial cell. 2. An oblique pattern visible in the outer leaflet of the paranodal axolemma in the axo-glial junctional region between successive grooves. This pattern corresponds to the oblique particle rows in the inner leaflet of the glial cell membrane adjoining the paranodal axon and may also correspond to the "transverse bands" between the respective membranes. 3. Accumulations of large particles in a concentration of ~1200 per μ^2 in the outer leaflet of the nodal axolemma. It has been proposed that these correspond to the ionophores involved in the generation of the action potential at the node. In order to determine whether these characteristic nodal and paranodal features are intrinsic to the axon alone or are dependent on the presence of a surrounding myelin sheath, axons were examined from the central nervous system of Jimpy mice, which lack CNS myelin almost completely but bear normal myelin on the peripheral segments of their axons. Extensive examination of freeze-fracture replicas of the medulla and spinal cord of these animals reveals typical axons whose membrane exhibits numerous particles on the inner leaflet but very few on the outer leaflet. No examples have been found of ridges, grooves, or oblique patterns representing paranodal membrane specializations, nor have any regional accumulations of particles been seen in the outer leaflet of the axolemma corresponding to the nodal particle accumulations described previously. It is concluded on the basis of this negative evidence that the outer leaflet specialization of the axolemma at the node of Ranvier and the inner and outer leaflet specializations of the paranodal axolemma do not appear in central nervous system axons that have never been myelinated.

1073 CORRELATIVE SCANNING/TRANSMISSION ELECTRON MICROSCOPIC ANALYSIS OF THE CEREBRAL VENTRICULAR WALLS OF PERINATAL RODENT CIRCUMVENTRICULAR ORGANS. D. E. Scott, T. H. McNeill, G. Krobisch Dudley* and W. K. Paull.* Depts. Anatomy, Univ. Rochester, Rochester, N.Y. and the Medical College of Georgia, Augusta, Ge.

The ultra-architectural organization of the developing ventricular wall of the 6 day old perinatal rat was examined with combined SEM/TEM analysis of the same tissue specimen. Tissues were prepared following the techniques of Wickham and Worthen (1973). As observed with SEM, the surface morphology of the dorsal thalamic wall was characterized by a profuse nap of microvilli and thick aggregations of knob-tipped cilia. In contrast to this typical ultrastructural appearance of the cerebral ventricular wall the surface morphology of adjacent circumventricular walls differed remarkably and in such regions as the infundibular recess and the area postrema, the dominant membranous modification of the apical surfaces of tanycytes were microvilli. Numerous supraependymal cells were noted upon the ependymal substratum. These were especially abundant in such circumventricular regions as the infundibular recess (dorsum of the median eminence) and the area postrema. Two apparent types of supraependymal cells were noted and were remarkably different in their surface organizations. One type exhibited flattened palmate processes with fluted edges and delicate filapodia. The second type of supraependymal cell possessed long primary processes that were observed to course horizontally for long distances over the ventricular surface. Subsequent analysis of previously scanned tissue with light and transmission electron microscopy revealed that ependyma which constitute the apical surface of non-circumventricular areas (such as the dorsal thalamic wall) are essentially ciliated cuboidal cells which do not penetrate the underlying parenchyma for significant distances. However, in contrast tanycytic ependyma of circumventricular organs extended processes throughout all underlying zones to terminate upon fenestrated capillaries. The ultrastructural organization of the neonatal cerebral ventricular wall is remarkably diverse and serves to suggest early functional differences from region to region in the perinatal state. The presence of two apparent classes of supraependymal cells is discussed with respect to potential histiocytic and /or neuroendocrine receptor roles that have been hypothesized in other adult mammalian species.

(Supported by NIH Grant NS11642-04)

1074 ORGANIZATION OF THE TEGMENTAL RETICULAR NUCLEUS IN THE ALBINO RAT. Jack C. Sipe, Joseph N. Riley and Robert Y. Moore. Dept. of Neurosciences, UCSD Sch. Med. and Veterans Administration Hospital, San Diego, CA 92037.

The tegmental reticular nucleus of von Bechterew (TRN, nucleus papilliformis) has been recognized as a prominent component of the pontine reticular formation for many years. Nevertheless, little is known of its connections or function and no previous studies of its ultrastructure have been reported. In the present investigation, the organization and synaptology of the TRN has been analyzed in material prepared for light microscopy by the Nissl and Golgi methods and by electron microscopy. Light microscopic analysis of Nissl and Golgi-stained material indicates that this nucleus, situated in a ventral paramedian position in the pontine reticular formation, is composed principally of two types of neurons. Large multipolar neurons (40-80 μ diameter) contain abundant Nissl substance and extend 4-7 sparsely branching primary dendrites up to 500 μ in length. Medium sized fusiform neurons (20-40 μ diameter) have less Nissl substance and a more closely ramifying 120-160 μ dendritic field radius. The primary dendrites of both neuronal types are usually oriented perpendicular to the long axis of the brainstem. In adult animals, very few spines are evident in the dendritic arborization of large neurons while medium sized neurons exhibit a slightly greater spine density. Ultrastructural analysis of the TRN confirms the presence of large and medium sized neurons which are compactly organized, together with numerous large dendritic trunks, between bundles of myelinated axons coursing in the rostrocaudal and transverse planes. This distinctive arrangement produces the appearance of "grey islands" between myelinated axon bundles. Within these areas a rich network of synaptic terminals virtually covers completely the available surfaces of dendrites and their perikarya. Two types of synaptic terminals are encountered in approximately equal distribution. S synapses contain 400-600 Å diameter lucent spherical vesicles and form axosomatic and axodendritic terminals with asymmetrical postsynaptic densities. F synapses are composed of flattened lucent vesicles and are distributed similar to S synapses. A variant of S and F synapses contains one or more 1000-1200 Å diameter dense granular vesicles and accounts for no more than 10% of the terminal population. Like many other sites of chemical synapse in mammalian brain, terminal boutons and boutons en passant form the majority of synaptic specializations.

(Supported by USPHS Grant NS-12080, and by the Veterans Administration)

1075 EARLY STAGES OF UPTAKE AND TRANSPORT OF HORSERADISH-PEROXIDASE BY CORTICAL STRUCTURES, AND ITS USE FOR THE STUDY OF LOCAL NEURONS AND THEIR PROCESSES. H. Vanegas, H. Holländer and Hj. Distel. Max-Planck-Institut für Psychiatrie, 8000 München 40, BRD.

Horseradish-peroxidase (HRP) was injected (0.05 µl of 30% aqueous solution) into the visual cortex of adult cats, and the stages of its spread, uptake by neural structures, and retrograde descent towards the dorsal lateral geniculate nucleus (LGNd) were studied. Particular attention was given to post-injection times of 10 min to 8 hours, but animals with up to 5 days' survival were analyzed. Brains were usually processed according to Jacobson and Trojanowski (Brain Res. 74: 149; 1974).

It was found that the brown spot produced by the injection (primary diffusion) of HRP remains constant in size for about 2 hours, and then spreads out (secondary diffusion) to invade neighboring cortical areas. This invasion, however, does not result in further retrograde labelling of LGNd neurons. Local neural structures labelled during primary diffusion include a large number of infracortical axons, many of which show bifurcations directed towards the cortex, as postulated by Garey and Powell (Proc. Roy. Soc. (B) 169: 107; 1967) and Stone and Dreher (J. Neurophysiol. 36: 551; 1973). As HRP descends within these axons, fewer and deeper bifurcations appear labelled as though, after initial uptake, HRP were no longer taken up by their terminals at the cortex. Possible reasons for the lack of further HRP uptake after primary diffusion include observed local inflammatory reactions, which might also be the cause for the secondary diffusion.

Labelled neural structures include neuron somata and processes located near, but not adjacent, to the injection track. At short survival times, these are diffusely labelled with HRP and resemble Golgi-impregnated structures. At 8 hours' survival, intracellular brown granules begin to appear,and increase in number thereafter. Particularly before secondary HRP diffusion, these structures show fine details such as dendritic spine necks, terminal bouton stalks, synaptic contacts, and a remarkable degree of axonal preterminal and terminal branching. Several of these labelled structures appear alone and can be followed up with the electron-microscope. Here HRP labelling is transparent enough to allow for the characterization of, e.g., pre- and postsynaptic specializations. Labelled axons show deposits of reaction product adhering to the inner surface of the axolemma and to the neurotubuli. Diffusely labelled neurons show granular deposits in the soma and the dendrites. Labelled terminals show HRP positive deposits adhering to the synaptic vesicles and the mitochondria.

NEUROENDOCRINOLOGY

1076 EFFECT OF DENERVATION ON THE FINE STRUCTURE AND INDOLE METABOLISM OF THE RAT AND HAMSTER PINEAL GLAND. Alan Armer. Dept. Anat., Univ. Roch., Roch., NY 14642

The influence of the pineal gland over the reproductive system is most vividly demonstrated in the golden hamster. Melatonin (MEL), an indole synthesized by the pineal of rats and hamsters, has been proposed as a mediator for this antigonadotropic effect. Whereas the control of N-acetyltransferase (NAT) activity by NE is well established in the rat, it may well be that the control of indole metabolism in the hamster is significantly different.

Animals were sacrificed 3 wks after pineal denervation by bilateral SCGx and processed for EM or utilized in organ culture (OC) studies. Denervated rat pineals display atrophic pinealocytes characterized by abundant synaptic ribbons, microtubular sheaths and lipid droplets. Dense-core (DCV) vesicles were rarely seen. Hamster pinealocytes were also atrophic. Large numbers of DCV, dense bodies and lysosomes and a sparsity of agranular reticulum were the most pronounced features of these cells.

Glands from SCGx rats and hamsters were maintained in OC in BGJb Fitton-Jackson media. 3H-5HT (48uci/um, 0.2mM) was added and a media sample obtained 24hr later. Labeled indoles were separated and quantified by TLC. During the fourth day in culture glands from SCGx rats released 13pmoles N-acetylserotonin (NAS) and 5 pmoles MEL. Similar glands stimulated with 10^{-5}M NE synthesized 180pmoles NAS and 30pmoles MEL. Under identical conditions hamster pineals released pmole amounts of NAS and MEL barely detectable by the chromatographic system. After NE there was only a slight increase in the production of NAS (6.5pmole) and MEL (6.0pmole). These data indicate that the in vitro indole metabolism of the denervated hamster pineal is significantly lower than that of the rat and is remarkably less responsive to NE stimulation.

Despite these findings, the dramatic influence which the hamster pineal exerts on the reproductive axis is abolished if its innervation is eliminated by SCGx. It may be that NE in the hamster may only partially mediate pineal NAT activity. Neural input to the hamster pineal may be more directly involved in the synthesis/secretion of a non-indolic secretory product. Such a product may be associated with the DCV found within the pineal gland of the hamster.
(Supported by NINCDS NS-11642).

1077 SEQUENTIAL POSTCASTRATIONAL CHANGES IN LUTEINIZING HORMONE-RELEASING HORMONE (LH-RH), LUTEINIZING HORMONE (LH) AND FOLLICLE STIMULATING HORMONE (FSH). Thomas M. Badger* and Theodore J. Cicero. Dept. Psychiatry. Wash. U. Sch. Med., St. Louis, MO 63110

Castration has been used to examine certain functional aspects of the hypothalamic-pituitary-gonadal axis, particularly with respect to the regulatory role of gonadal steroids. In the course of several studies in which we attempted to use castration as a means of disinhibiting the hypothalamic-pituitary axis, we found that the level of activity in the axis was markedly influenced by the post-castration interval employed. Many investigators have examined the effects of castration on the concentrations of LH-RH and LH and FSH at selected time intervals after gonadectomy, but there have been very few studies in which changes in these hormones have been concomitantly examined at regular intervals after castration. In the present studies, we have conducted such assessments at sequential intervals from 1 to 60 days after castration. It appears that the post-castrational changes in LH-RH and LH can be divided into 2 phases. Phase 1 is characterized by an immediate 15-fold rise in serum LH levels in castrates relative to controls within 24 hours. During this phase, which lasted until day 7, there were no significant differences in pituitary LH content nor in serum or hypothalamic LH-RH levels. At about the 7th day, phase 2 began and was characterized by a marked rise in serum LH levels to a level three times the phase 1 levels by the 14th day post-castration. Coincident with this increase in LH levels, pituitary LH increased by three fold and hypothalamic LH-RH dropped to less than 50% of controls. In vitro studies indicated that the response of the pituitary to LH-RH also could be divided into two phases following castration. There were no differences in the responsiveness of the pituitary to LH-RH during phase 1, whereas during phase 2 pituitaries from castrates were more sensitive to LH-RH than were those obtained from shams. A plausible explanation for the two phases of post-castrational changes in LH-RH and LH levels may be that during the first phase changes in the levels of the releasing factor and LH reflect a release of negative feedback control, whereas during the second phase some cellular adaptations occur. Serum concentrations of FSH also increased markedly following castration, reaching a level of 3 times that of controls. Similar to LH levels, serum FSH concentrations were significantly greater in castrates than shams by 24 hours post-castration. Unlike LH, however, FSH levels continued to rise steadily until plateauing 30 days after castration. There were no significant alterations in pituitary FSH content. 1078 SUB-SYNAPTOSOMAL LOCALIZATION OF TRH, α-MSH, AND LHRH IN RAT HYPOTHALAMIC TISSUE. A. Barnea, G. Cho, and J. C. Porter. Cecil H. & Ida Green Ctr. for Reprod. Biol. Sci., Depts. of Ob/Gyn and Physiol., Univ. of Texas Health Sci. Ctr. at Dallas, Southwestern Med. Sch., Dallas, TX 75235.

A 10% homogenate of male rat hypothalami, prepared in 0.32 M sucrose-10 μM $CaCl_2$, was diluted either with one volume of 0.32 M sucrose-10 μM $CaCl_2$ (iso-osmotic) or with 10 μM $CaCl_2$ (hypo-osmotic). A 900 x g supernatant fluid (0.9K-S) was prepared from the diluted homogenates and fractionated on sucrose density gradients under non-equilibrium and equilibrium conditions. In the iso-osmotic 0.9K-S, TRH, α-MSH, and LHRH were each found to be sequestered in two populations of synaptosome-like particles which differed in size but were similar in density. In the hypo-osmotic 0.9K-S, the large synaptosomes containing TRH, α-MSH, and LHRH were not demonstrable; but each peptide was found to be sequestered in a single population of particles. In their sedimentation properties, the hypo-osmotically resistant particles and the small particles present in the iso-osmotic 0.9K-S were identical: (1) The banding densities of these two sets of particles under conditions of non-equilibrium sucrose gradient centrifugation (100,000 x g for 30 min) were 0.58 M for TRH and α-MSH and 0.76 M for LHRH. Under conditions of equilibrium centrifugation (150,000 x g for 180 min), the densities of the particles were 1.15 M for TRH and α-MSH and 1.25 M for LHRH. (2) The small particles present in the iso-osmotic 0.9K-S and the particles present in the hypo-osmotic 0.9K-S pelleted when centrifuged at 20,000 x g (30 min) but remained in suspension when centrifuged at 2,200 x g (30 min) (2.2K-S). If one takes as 100% the amount of peptide contained in the small particles present in the iso- or hypo-osmotic 0.9K-S, the small particles recovered from the iso- or hypo-osmotic 2.2K-S contained 80% of the TRH, 73% of the α-MSH, and 93% of the LHRH. The iso-osmotic 2.2K-S contained the small particles, but this fraction was essentially devoid of the large synaptosomes containing α-MSH and LHRH. When the iso-osmotic 2.2K-S was made hypo-osmotic by dilution with 1 vol of 10 μM $CaCl_2$ and then fractionated on the gradients, the hypo-osmotic 2.2K-S small particles were found to contain 106 ± 15.7% (mean ± SE) of the α-MSH and 56 ± 7.9% of the LHRH present in the iso-osmotic 2.2K-S small particles. If one takes as 100% the total amount of particle-bound peptides recovered after gradient centrifugation of the iso-osmotic 0.9K-S, the amount of TRH, α-MSH, and LHRH recovered in the small particles was 39 ± 1.3%, 50 ± 3.9%, and 39 ± 1.4%, respectively; the amount recovered in the hypo-osmotically resistant particles was 42 ± 1.8%, 68 ± 2.1%, and 66 ± 4.9%, respectively. It is concluded that a sub-synaptosomal pool of hypo-osmotically resistant particles containing α-MSH or LHRH is present within the large synaptosomes. This pool accounts for 36% of the α-MSH and 70% of the LHRH present in the large synaptosomes. The size of the sub-synaptosomal pool of hypo-osmotically resistant particles containing TRH is not clear.

1079 CHANGES IN BRAIN MONOAMINES ASSOCIATED WITH GROWTH ACCELERATION IN SEPTAL-LESIONED HAMSTERS. Katarina T. Borer, Michael E. Trulson and Roy A. Wise. Neuroscience Laboratory and Dept. of Psychology, University of Michigan, Ann Arbor, MI 48109, Dept. of Psychology, Princeton University, Princeton, NJ 08540, USA, and Dept. of Psychology, Concordia University, Montreal, Quebec, Canada.

Rostral septum restrains somatic growth in adult hamsters through an inhibitory influence over growth hormone (GH) and insulin release. Unilateral electrolytic destruction of rostral septum accelerates somatic growth and elevates the serum concentrations of GH and insulin (Borer, K.T. et al., Neuroend., 1977, in press).

In this study we have examined the possible involvement of monoamine neurons in the neuroendocrine control of hamster growth with two methods. First, we have measured the concentrations of serotonin (5-HT), noradrenaline (NE), and dopamine (DA) in four brain regions: hippocampus (HIP), cerebral cortex (CC), corpus striatum (ST), and diencephalon (D) in unilaterally septal-lesioned (n=6) and control (n=8) female hamsters by the method of Jacobowitz (Res. Comm. chem. Path. Pharm., 1974, 9, 29). Second, we have examined coronal and sagittal brain sections from unilaterally septal-lesioned (n=5) and control (n=4) female hamsters for evidence of NE and DA fluorescence by the glyoxylic acid method of Battenberg and Bloom (Psychopharm. Comm., 1975, 1, 3).

Eight to ten days after lesioning, during the maximal acceleration of somatic growth, there was a significant reduction in the concentrations of 5-HT in HIP (27%, $p < .001$) and CC (9%, $p < .01$) and of NE in HIP (27%, $p < .05$). Fluorescence was seen in ST (DA), locus coeruleus (NE), and septum (DA). Septal fluorescence was abolished by the lesions.

We conclude that the 5-HT projections to HIP and CC, the dorsal NE projection to HIP, and the mesolimbic DA projection to septum may be responsible for the suppression of somatic growth in adult hamsters.

1080 EFFECT OF COMPLETE AND SELECTIVE AMYGDALOID ABLATION ON TWENTY-FOUR HOUR RESTING LEVELS OF PLASMA CORTICOSTERONE, GROWTH HORMONE, PROLACTIN, TESTOSTERONE AND HYPOTHALAMIC LHRH IN MALE RATS. Gregory M. Brown, John Chambers* and Jo A. Seggie. Neuroendocrine Research Section, Clarke Institute of Psychiatry, 250 College Street, Toronto, Ontario M5T 1R8.

It has been hypothesized that the amygdala plays a role in regulating the diurnal adrenal cortico-steroid rhythm. The present study involved an examination of corticosterone and other hormonal rhythms following destructive lesions of the amygdala or of its components. Adult male rats were housed in individual cages in 3 rooms having lighting cycles of 12 hours light and 12 hours dark. Great care was taken to avoid undue disturbances to ensure that at the time of sacrifice animals were indeed in a resting state. Separate groups of rats were removed for prompt decapitation from each of the rooms to provide trunk blood samples and hypothalami at 4 hour intervals throughout the 24-hour light/dark cycle. Three separate experiments were performed involving normal controls, sham-operated controls and rats that had bilateral electrolytic lesions of the amygdala. In the first experiment, the entire amygdala complex was destroyed. In the second experiment, the cortico-medial amygdala was destroyed while in the third experiment the baso-lateral amygdala was destroyed. Destruction of the entire amygdala had no effect on normal resting levels or on the 24-hour variation of plasma corticosterone, growth hormone or prolactin. Cortico-medial amygdala destruction had no effect on normal resting levels or on the 24-hour variation of plasma corticosterone or prolactin. Destruction of the baso-lateral amygdala had no effect on normal resting levels or on the 24-hour variation of plasma corticosterone, growth hormone, prolactin or testosterone. However, preliminary data from a portion of the samples in this study suggest that the baso-lateral amygdala lesion may obliterate the normal 24-hour rhythm of hypothalamic LHRH in resting animals. Data from other studies indicate that the baso-lateral amygdala lesions also influence the adrenal stress response. On the basis of the present data, it would appear that the amygdala and its cortico-medial and baso-lateral components play no significant role in the regulation of the normal resting 24-hour hormone rhythms studied. It is suggested, however, that the baso-lateral amygdala may have a role in reproductive function and/or the ability of an animal to respond to stress.

1081 PREOPTIC-HYPOTHALAMIC PERIVENTRICULAR ABLATION ALTERS ADH RELEASE AND ATTENUATES PRESSOR RESPONSES TO INTRACEREBROVENTRICULAR INJECTIONS OF ANGIOTENSIN AND HYPEROSMOTIC SOLUTIONS. James Buggy, William E. Hoffman* and A. Kim Johnson. Cardiovascular Center, Univ. of Iowa, Iowa City, IA 52242.

Blood pressure and antidiuretic hormone (ADH) release are increased after angiotensin II(AII), hyperosmotic NaCl, or hyperosmotic sucrose solution injections into the anteroventral third ventricle of rats. Ablation of the preoptic-anterior hypothalamic periventricular tissue surrounding this region results in transient adipsia, hypernatremia, and persisting thirst deficits to systemic AII and hyperosmotic NaCl dipsogenic challenges. The following experiments on animals with this periventricular ablation examined ADH release and pressor responses to intracerebral injections of AII and hyperosmotic solutions. After electrolytic lesions aimed at the periventricular region, hydration was maintained during 1-9 days of adipsia. Lateral ventricular cannula and arterial, venous and bladder catheters were placed in sham lesioned and lesioned rats after recovery of ad lib. drinking when animals appeared in good health. Blood pressure and urine flow and conductivity were monitored in awake, unrestrained rats. An iv hydrating infusion was administered to produce a diuresis. Changes in urine conductance resulting from iv ADH injections were used to generate standard curves in each rat for estimation of ADH release. Blood pressure and urine conductance changes were then recorded after lateral ventricular injections of AII (50 and 500 ng), hyperosmotic artificial cerebrospinal fluid (10 ul of 0.5 osmol), and phenylephrine (50 ug). Blood pressure increases elicited by phenylephrine did not differ between groups whereas the pressor responses to AII and hyperosmotic stimulation were virtually abolished in lesioned rats. Analysis of ADH release to central stimulation was complicated since about 60% of lesioned rats failed to show a typical diuresis (ie., stable, low conductivity) during the hydrating infusion. In these animals, iv injection of ADH antibody lowered urine conductance suggesting incomplete ADH inhibition to the hydrating infusion. Antidiuretic responses to central stimulation were attenuated but highly variable due to the unstable baseline. The unique finding that hydrating infusions do not elicit a typical diuresis in most lesioned rats suggests inappropriate ADH release in the face of a hypotonic stimulus which normally inhibits ADH release. The data also suggest a critical role for the periventricular region in mediation of pressor responses to AII and osmotic stimuli.

1082 EFFECT OF MATERNAL DEPRIVATION ON PREWEANLING RAT SERUM GROWTH HORMONE LEVELS. S. R. Butler,* C. M. Kuhn,* and S. M. Schanberg. Dept. of Physiol. & Pharmacol., Duke Univ. Med. Center, Durham, N. C., 27710.

Our laboratory previously has reported that removal of preweanling rat pups from the mother for as little as 1 hour produces an approximately 50% reduction in brain and heart ornithine decarboxylase (ODC) activity, the first and probably rate-limiting step in polyamine biosynthesis; the decline is rapidly reversed by return to the mother (Butler and Schanberg, Trans. Am. Soc. Neurochem. 8: 259, 1977). This decrease in ODC activity is not caused by alterations in body temperature or nutritional intake, but instead appears to be due to the interruption of some mother-pup behavioral interaction. Clinically, reduced levels of serum growth hormone (GH) have been reported in maternally deprived babies and young children (D,Ercole et al., J. Pediatr. 90: 375-81, 1976). As GH given either centrally or peripherally stimulates brain ODC activity (Roger et al., Endocrinology 95: 904-11, 1974), we examined the effect of maternal deprivation on preweanling rat serum GH levels. Removal from the mother for 1, 2 or 6 hours resulted in a 40-50% reduction in pup serum GH, while return to the mother rapidly reversed this effect. GH rose to 150% of control after 15 minutes of return, and declined to baseline by 1 hour of return. These data suggest that the maternal deprivation-induced changes in preweanling rat brain ODC activity may be mediated through alterations in serum GH levels. Further, they suggest that preweanling rat maternal deprivation may be a model for the human maternal deprivation syndrome. 1083 LUTEINIZING HORMONE RELEASING HORMONE (LHRH) CONCENTRATION IN PITUITARY PORTAL PLASMA OF RAT: EFFECT OF CASTRATION AND SEX STEROID REPLACEMENT. Melvin Ching. Dept. Anat., Univ. Rochester Sch. Med., Rochester, NY 14642.

Sprague Dawley and Long Evans female and male rats weighing 350-450g and 450-550g respectively were left intact, castrated, or castrated and injected sc (nuchal) with 1mg testosterone proprionate (TP)/day or with 20ug estradiol benzoate (EB) 24 hours before the collection of pituitary stalk blood. Normal and castrate controls were injected with the diluent of Mazola corn oil (volume of 0.25ml). After 4 to 5 weeks the rats were anesthetized with an ip injection of 43mg α chloralose + 425mg urethane/kg BW and pituitary portal blood collected using a parapharyngeal surgical approach (Acta Endocr. 83:449, 1976). Animals were decapitated immediately following the collection of portal blood. Aliquots (100-200ul) of portal plasma and trunk plasma and whole hypothalami were extracted in 100% methanol, centrifuged, and the supernatants evaporated under N2 gas at 37°C. The residues were dissolved in Krebs ringer bicarbonate buffer, pH 7.4, for radioimmunoassay of LHRH (Neuroendocrinology 17:274, 1975). Luteinizing hormone (LH) was quantified in peripheral plasma to monitor the effect of gonadectomy and sex steroid replacement.

In both male and female castrates, plasma LH concentrations increased 14 to 16 times over normal ($p < 0.01$). Chronic TP replacement prevented the rise in plasma LH. The single injection of EB to ovariectomized rats reduced the plasma titer of LH 50% but the level of this gonadotropin remained elevated (8-fold) over normal (diestrus) ($p < 0.02$). Castration resulted in a 50% reduction in hypothalamic content of LHRH in both sexes ($p < 0.01$). Testosterone therapy elevated hypothalamic stores of LHRH to normal whereas acute EB replacement further reduced LHRH stores ($p < 0.01$). The concentration of LHRH in portal plasma did not differ from normal following ovariectomy, orchidectomy or replacement therapy (females: 172±25SE - 240±70pg/ml; males: 244±41SE - 368±80pg/ml) but was 2 to 4 times the systemic levels ($p < 0.02$ - > 0.05, 4-7 determinations/group).

The results show that castration in both male and female rats reduced hypothalamic stores of LHRH and plasma titers of LH commensurate with the magnitude of feedback by gonadal hormones without altering hypothalamic secretion rates of LHRH. Thus it appears that synthesis rather than release of LHRH is under gonadal regulation and favors the view that androgens and estrogens modulate the LHRH-induced release of LH directly at the pituitary level.

1084 α-MSH AND MIF-I EFFECTS ON GUANOSINE-3', 5'-CYCLIC MONOPHOSPHATE (cGMP) LEVELS IN VARIOUS RAT BRAIN AREA. C.W. Christensen*, M.A. Spirtes, C.T. Harston* and A.J. Kastin. Veterans Administration Hospital and Tulane University School of Medicine, New Orleans, LA 70146.

Alpha-melanocyte stimulating hormone (α-MSH) and a hypothalamic peptide which may inhibit the release of this hormone from the pituitary (MIF-I) exert direct effects on the brain which are expressed as changes in animal behavior. It has been suggested that these peptides may affect the cyclic nucleotides adenosine -3',5'-cyclic monophosphate (cAMP) or guanosine -3',5'-cyclic monophosphate (cGMP). Previous findings reported from our laboratory indicated that α-MSH (80 μg/kg) significantly elevated cAMP levels in the occipital cortex of both normal unoperated and hypophysectomized (hypoxed) rats (Christensen, et al., Pharm. Biochem. Behav. 5, Suppl. 1: 117-120, 1976). We now report our findings after treatment of rats with α-MSH and MIF-I followed by measurements of cyclic GMP in a number of brain areas from the same rats. Normal and hypoxed rats were administered α-MSH (80 μg/kg, daily x3) or MIF-I (1 or 10 mg/kg daily x3) in 0.9% NaCl-0.1% ascorbic acid i.p. Controls received an equivalent amount of solvent. The animals were sacrificed 30 min after the last injection in a focused microwave oven (1.5 kw; 2-3 sec). Seven different cortical and subcortical brain areas were then removed using the method of Glowinski, et al. (1966) and assayed for cyclic-GMP by the radioimmunoassay method of Steiner, et al. (1972). Administration of α-MSH did not statistically alter the cyclic-GMP level of any area of the brain in which it was measured except in the thalamus of hypoxed rats. Here it was 31% higher ($p < 0.05$) than in the controls. A smaller (17%) statistically nonsignificant rise occurred in the same area of normal rats. The lack of effect of α-MSH on cGMP levels in the occipital cortex gives added significance to our previously reported results of α-MSH elevating cAMP in this same area and its correlation with increased visual attention. Treatment with MIF-I also raised the level of cyclic-GMP in the thalamus in a statistically significant manner for both normal and hypoxed animals (21% and 63% respectively). The fact that cyclic nucleotide changes were found in both unoperated and hypoxed animals after administration of MIF-I suggests that the measured effects occurred directly in the brain without the influence of pituitary hormones. It is of interest that the "Yin-Yang" hypothesis has not been confirmed for either the occipital or the thalamic areas in these experiments. These findings are the first to indicate a direct effect of a hypothalamic peptide (MIF-I) on cGMP levels in the brain and this effect occurred in both normal and hypoxed animals. (Supported by the Medical Research Service of the Veterans Administration and NIH grant number NS 07664).

1085 EFFECT OF GLUTAMATE LESIONS OF THE ARCUATE NUCLEUS ON THE NEUROENDOCRINE SYSTEM IN RATS. James A. Clemens, Michael E. Roush* and Carl J. Shaar*. Lilly Research Labs., Indianapolis, Indiana 46206.

Lesions of the arcuate nucleus were produced by i.p. administration of 4 g/kg of monosodium glutamate to rats on days 2, 4, 6, 8 and 10 after birth, and all experimental work was performed at about 3-4 months of age. In agreement with earlier studies we noted a striking reduction in the number of cell bodies in the arcuate nucleus, a marked degeneration of the visual system and smaller anterior pituitaries, ovaries, testes and seminal vesicles in adult rats that had been treated with glutamate during the neonatal period. A 60 percent reduction in the concentration of dopamine was observed for the medial-basal hypothalamus. In glutamate-treated rats estrous cycles were irregular with several extra days of estrus, and serum levels of LH and FSH were usually lower than in control rats while prolactin levels remained unchanged. Administration of 30 mg/kg of quipazine (a serotonin agonist) or 2.5 mg/kg of chlorpromazine resulted in elevated serum prolactin levels of a magnitude similar to those seen in control animals after drug treatment. This indicates that the ability of the pituitary gland to release prolactin is not impaired after glutamate treatment. Hypothalamic content of LH-RH was found to be unchanged after glutamate treatment while PIF activity of hypothalamic extracts was slightly reduced. After ovariectomy serum LH levels were much lower in glutamate-treated rats than in control rats. In another experiment ovariectomized glutamate-treated and control rats were given 1 μg of estradiol benzoate daily for 9 days and serum levels of LH and prolactin were measured at 0800 h and 1600 h on the 10th day. Large elevations in serum LH and prolactin were observed in the control rats at 1600 h, whereas only very small elevations of prolactin and LH were found in glutamate-treated rats. In contrast, a much larger increase in serum prolactin was seen after L5-hydroxytryptophan (30 mg/kg) administration in glutamate-treated male and female rats than in control rats. These results suggest that glutamate-induced lesions of the arcuate nucleus result in an impaired release mechanism for LH and prolactin under conditions where estrogen is the "inducer", but produce a condition where serotonergic stimuli are much more effective in releasing prolactin.

1086 NOISE DETECTION AND REDUCTION BY CROSS-CORRELATION IN MULTIPLE UNIT RECORDING SYSTEMS. Donald K. Clifton*, Jamshid Rabii*, and Charles H. Sawyer. Dept. Anat. and Brain Res. Inst., Sch. Med., UCLA, Los Angeles, CA 90024

Although lacking the specificity of single unit methods, multiple unit (MU) recording techniques have the advantage of long-term stability and provide a much better indicator of local activity than the EEG. One problem with MU recording is that the signal is very small (usually < 50 μV) making the recording susceptible to noise. Electrical noise is generated within the MU system at the input stage of the amplifier and at the tissue to electrode interface, which characteristically has a high impedance.

A multiple unit recording system has been designed which eliminates amplifier and electrode noise. An electrode made of two 64 μM insulated stainless steel wires fastened together with epoxylite is placed in the area from which recordings are to be made. Each wire is attached to a standard MU preamplifier so that there are two separate MU channels measuring activity in the same area. Noise generated within the two channels will be stochastically independent; however, there is a component of the MU signal that is common to both channels. The outputs of the preamplifiers are filtered to remove the EEG and fed into an analog multiplier which, along with a low pass filter, act as a zero phase shift cross-correlator. The output of the correlator is proportional to the mean square MU activity common to both electrodes; all uncorrelated noise (i.e. electrode and amplifier noise) is cancelled out. Although biological artifacts (such as chewing) are not eliminated by this system, their presence is easily detected. This is done by correlating the signal from one wire of the MU electrode with the signal from a distant electrode. This separation precludes the possibility of there being any common MU signal, and any correlated activity would be attributable to artifact.

Construction of the system is simple and relatively inexpensive. It has been tested in rats using both acute and chronic preparations. Examples of several such tests will be presented. (Supported by grants from Eli Lilly, NIH and the Ford Foundation.)

1087 DEVELOPMENT OF THE RHESUS MONKEY THIRD VENTRICLE: SCANNING ELECTRON MICROSCOPY (SEM). P.W. Coates. Dept. Biological Structure, Univ. Wash. Sch. Med. Seattle, WA 98195.

The development of the third ventricle in a series of 5 normal fetal, neonatal and young M. mulatta monkeys was investigated with SEM. Three regions were compared: the dorsolateral wall (DW), the ventrolateral wall-floor (VF), and the choroid plexus (CP). At 132 days gestation (G132), the DW was ciliated while the VF was not. Cilia appeared shorter and more clustered compared to later ages. Surface modifications on ependymal cells of the VF, many of which are considered tanycytes, consisted of minute rounded microvilli among which were scattered longer protuberances, presumed budding cilia. Widespread polygonal surface patterns resulting from microvilli outlining cell borders, characteristic for this region in mature monkeys, were not discernible. Surfaces of the CP were relatively flat; individual ependymal cells were indistinct and covered with stubby microvilli interspersed with clusters of short cilia. By 149 days gestation (G149) the DW had prominent ridges and furrows. Cilia looked longer and less tightly clustered, obscuring underlying surfaces. Microvilli on the VF were more irregular in shape than at G132. Individual cilia and miniblebs were present. Patterning of the VF was not conspicuous. Individual ependymal cells of the CP were more distinct and possessed longer microvilli and cilia than at G132. At 12 hr post partum, although individual cells were larger, surface features resembled G149. 44 days after birth, microvilli of variable shapes covered ependymal cells on the VF, along with somewhat larger miniblebs and occasional cilia. A few unit patterns on the VF were present. Apical surfaces of ependymal CP were large and rounded. By 13 months 20 days after birth, ependyma of the VF possessed all basic surface features of the adult: microvilli, miniblebs and cilia, but did not exhibit the rich variety of detail nor extensive cell surface unit patterns. Supraependymal cells and presumed nerve processes were evident by G132 and G149, respectively, and at later ages. SEM data reveal distinct regional differences in fetal and young Rhesus monkey third ventricle. The CP and DW preceded the VF in attaining many mature characteristics shortly before and after birth. More than a year after birth, surface features and patterning of the VF, although present, were not yet elaborated to their full extent. Significant differences between males and females were not apparent. (Supported by USPHS Grant HD-10010 and by Initiative 171 Funds from the Grad. Sch., Univ. Wash.)

1088 PLASMA CORTICOSTERONE AND INSTRUMENTAL LEARNING AS MEASURES OF CLASSICALLY CONDITIONED FEAR, AND THE EFFECTS OF DEXAMETHASONE. Gary D. Coover, Betty R. Sutton*, Stephen L. Welle* and Robert P. Hart*. Dept. Psychol., Northern Illinois U., DeKalb, IL 60115.

Glucocorticoid hormones were examined as an emotional response measure and as a modulator of learning and performance. Male Long-Evans rats were first habituated to a small Plexiglas chamber with a grid floor, and then conditioned with 30 CS-US (light-footshock) pairings during a single session. On the following day they were tested in the same chamber under one of two conditions: either they were confined and presented with only the CS at 2-min intervals, or they were trained to escape the conditioned fear stimuli by jumping a hurdle into another dark chamber with a solid floor for 25 or 30 trials.

In Experiment 1 the corticosterone response to CS presentations was found to be positively related in magnitude to the intensity of footshock (.3 or 1.3 ma) used on the previous day of classical conditioning. Both footshock intensities produced larger corticosterone conditioned responses than placement in the chamber without CS or US presentations. This indicates that with this paradigm corticosterone can provide a sensitive quantitative measure of the intensity of acquired fear.

In Experiment 2, injections of the synthetic glucocorticoid dexamethasone were given 90 min prior to the classical conditioning session and again 24 hr later prior to a session of instrumental learning to escape conditioned fear stimuli. The dexamethasone caused the expected effects of decreasing the magnitude of the corticosterone response and the hurdle-jump speeds on the later blocks of trials. The effect on hurdle-jump speeds is that expected from many previous findings of a glucocorticoid facilitation of extinction of avoidance responding.

In Experiment 3, dexamethasone injections were given only prior to, or immediately following (control group), the classical conditioning sessions. Dexamethasone prior to conditioning resulted in slower hurdle-jump speeds on the early blocks of trials in hurdle-jump acquisition. However, this cannot be interpreted as an effect of deficient classical conditioning of fear, since the experimental animals attained hurdle-jump speeds equivalent to control values on the later blocks, and their corticosterone responses were not smaller during instrumental acquisition or CS presentation sessions. Two explanations for the results are that dexamethasone facilitated acquisition of a response such as freezing that competed with hurdle-jump acquisition, or that state-dependent effects were involved such that fear was not experienced on the test day until endogenous glucocorticoids were elevated.

1089 GONADAL HORMONE-CATECHOLAMINE INTERACTIONS IN DISCRETE REGIONS OF THE CENTRAL NERVOUS SYSTEM. W. R. Crowley*, T.L. O'Donohue* and D. M. Jacobowitz (SPON: Larry Ng). Lab. Clin. Sci., NIMH, Bethesda, MD 20014.

Norepinephrine (NE) and dopamine (DA) were measured in 20 discrete brain nuclei, using the punch microdissection technique and a sensitive radioenzymatic assay, and were found to vary over the estrous cycle. NE levels in the medial preoptic and paraventricular nuclei were lower on proestrus and estrus than on metestrus or diestrus. NE levels were elevated in the lateral septum and mesencephalic central gray on metestrus. Caudate DA decreased from proestrus to estrus and rose on diestrus. DA levels were elevated in the lateral septum on diestrus and in the nucleus of the diagonal band on metestrus. Median eminence DA increased from proestrus to estrus. These preliminary findings suggest that cyclic changes in catecholamines may be related to fluctuations of gonadotropins and ovarian hormones to influence ovulation and mating behavior.

In a second experiment, sex differences were found to exist in catecholamine levels in discrete brain regions in adult, intact male and female rats. Males contained more NE than females in the median eminence and in the paraventricular, periventricular, arcuate and preoptic-suprachiasmatic nuclei as adults, and more DA than females in the median eminence and caudate, arcuate and diagonal band nuclei.

Castration of males at 1 day of age tended to lower NE in the arcuate and preoptic-suprachiasmatic nuclei and significantly lowered DA in the arcuate and diagonal band nuclei to levels similar to the female. Administration of 1.25 mg testosterone propionate to females of 4 days of age significantly elevated DA in the arcuate nucleus and tended to elevate DA in the diagonal band nucleus and NE in the arcuate and preoptic-suprachiasmatic nuclei to levels similar to males. These results suggest that the catecholamine innervation of the above-cited areas is altered during sexual differentiation.

1090 BEHAVIORAL SPECIFICITY OF THE INHIBITORY EFFECT OF PROGESTERONE IN THE HAMSTER. Joseph F. DeBold*, Julie L. Morris*, and Lynwood G. Clemens* (SPON: K. L. Lovell). Dept. Zoology, Michigan State Univ., E. Lansing, MI 48823.

In addition to its well-known facilitative action, progesterone can inhibit estrogen-induced sexual receptivity. We have recently demonstrated that the female hamster is particularly sensitive to this inhibitory action of progesterone. However, the behavioral, sexual and steroidal specificity of this effect has not previously been examined. In a series of 3 experiments the possible effects of progesterone (P) were assessed on testosterone propionate (TP) and estradiol-benzoate (EB) induced male copulatory behavior in males and TP and EB induced sexual receptivity in both male and female hamsters.

Immediately following castration, male hamsters were given daily replacement therapy with 150 ug TP, 150 ug TP + 500 ug P, 5 ug EB, 5 ug EB + 500 ug P, 50 ug EB, 50 ug EB + 500 ug P, 500 ug P or the oil vehicle. In weekly tests for male copulatory behavior TP treated males performed at precastration levels, while animals receiving EB stopped ejaculating. Treatment with P did not alter the response to TP or EB, nor did P have any apparent activity when given alone. In subsequent weeks the dose of P was increased to 2.5 mg without effect. In order to maximize any possible effect of P, male hamsters were castrated, but replacement did not begin for 8 weeks. Animals receiving 150 ug TP + 2.5 mg P returned toward precastration levels at a slightly slower rate than the group receiving 150 ug TP alone. In the final experiment, male and female hamsters were gonadectomized and then 2 weeks later began daily treatment with 5 ug EB, 5 ug EB + 500 ug P, 50 ug EB, 50 ug EB + 500 ug P, 150 ug TP, 150 ug TP + 500 ug P, 500 ug TP or 500 ug TP + 500 ug P. In weekly tests for sexual receptivity, both males and females receiving chronic P exhibited greatly reduced lordosis duration. Although TP was much less effective for inducing receptivity than EB, P inhibited the response to either steroid.

Our experiments demonstrate that chronic P administration is virtually without effect on androgen or estrogen induced male copulatory behavior. However, P is capable of reducing androgen or estrogen-induced receptivity in both male and female hamsters. Thus, P appears to be behaviorally specific but not sex or steroid specific.

1091 A SYSTEM OF GAP JUNCTIONS AND SOME UNUSUAL GLIAL-NEURONAL CONTACTS IN THE ARCUATE NUCLEUS OF ALBINO RATS. Manuel del Cerro and Karl M. Knigge. Ctr. Brain Res. and Dept. Anat., Sch. Med., U. of Roch., Rochester, N.Y. 14642.

During the course of a study on the ontogenesis of the arcuate region of the ventromedial hypothalamus we have observed numerous instances of cell-to-cell contact between glial cells and/or glial cells and neurons. These contacts may be important for the neuroendocrine functions of this site. Albino rats, aged from 20 to 60 postnatal days, were perfused with aldehydes and their hypothalami post-fixed with OsO_4 and treated in block with uranyl acetate. The latter chemical increases the electron density of the tissue and also prevents the formation of spurious cellular appositions (Brightman and Rees, 69). The material was studied simultaneously by optical and electron microscopy. An extensive system of gap junctions was observed along the somas of the tanycytes (radial glia) which line the ventricular wall and extend at great distances within the neuropil of the arcuate nucleus. Numerous gap junctions, or nexi, occur at the level of the head and neck of the tanycytes, joining them with the bodies of adjacent tanycytes or their side projections. Some of these nexi are unusually extended, sometimes surrounding the entire circumference of a tanycytic process, or involving three or more participant cells. By optical microscopy it is possible to observe frequent contacts en passant between tails of tanycytes and neuronal somas; electron microscopically it has been possible to observe gap junctions in some of those contacts. A noteworthy form of cell-to-cell contact within the arcuate nucleus is the presence of a unique synaptoid contact between the neck of tanycytes and large dendrites; these formations involve the presence of paramembranous densities, with accumulation of vesicles on the glial side. From the functional point of view these observations indicate that physical channels communicate tanycytes with each other and with neurons. The significance of the synaptoid contacts between tanycytes and dendrites requires further study.

1092 COMPARISON OF THE EFFECT OF MEDIAL FOREBRAIN BUNDLE, RAPHE OR SUPRACHIASMATIC NUCLEAR ABLATION ON THE 24-HR PERIODICITY IN PLASMA CORTICOSTERONE LEVELS. J. D. Dunn, A. J. Castro and J. A. McNulty*. Dept. Anat., Loyola Univ. of Chicago, Stritch Sch. Med., Maywood, Ill. 60153.

Monoaminergic systems have been implicated in rhythmic neuroendocrine activity and associated behavior but information regarding specific nuclei and/or pathways is still lacking. Thus the present study was undertaken to determine whether the circadian periodicity characteristic of pituitary-adrenal function is abolished after ablation of the raphe nuclei (RN), medial forebrain bundle (MFB) or suprachiasmatic nuclei (SCN). Additionally, the daily variation in body temperature was evaluated. Non-stress plasma corticosterone levels were assessed fluorometrically in blood samples obtained from a tail vein of individual adult female rats at 4 hr intervals during 24-hr and 36-hr periods, 3 mo. and 6 mo. after surgery, respectively. Body temperature was recorded every 4 hr during a 48-hr period (4 mo. post-surgery) using a tele-thermometer and rectal probe.

The highest corticosterone levels for most intact, MFB and RN animals were obtained in samples collected just prior to the period of light-dark transition. The amplitude of the rhythm in MFB but not RN rats was similar to that noted for controls; RN rats presented a "flattened" rhythm. Individual SCN rats demonstrated steroid excursions of normal amplitude but they were asynchronous and devoid of circadian rhythmicity. All groups showed circadian periodicity in body temperature; the amplitude did not vary among the groups and the highest temperatures were recorded during the latter half of the dark period.

The data indicate that neither the rhythmicity in plasma corticosterone levels nor body temperature is abolished after ablation of the ascending monoaminergic systems and that ablation of the SCN abolishes the periodicity in pituitary-adrenal function but not body temperature.

1093 EFFECTS OF HIPPOCAMPAL LESION ON BLOOD PRESSURE, PLASMA CORTICOSTERONE AND SOCIAL BEHAVIOR IN DIFFERENT ENVIRONMENTAL CONDITIONS. Daniel L. Ely, Ernest G. Greene and James P. Henry.* Dept. Biology, Univ. Akron, Akron, OH 44325, Dept. Psychol. and Dept. Physiol., Univ. So Calif., Los Angeles, CA 90007.

The aim of the present study was to investigate the role of the hippocampus upon autonomic nervous system function and social behavior in competitive and non-competitive conditions.

Hippocampal-lesioned (HL) male CBA mice competing for territory and social position for 81 days in a population cage developed systolic hypertension (160 mmHg, $P < .01$) as compared to unoperated controls (UC, 131 mmHg) or cortical lesioned controls (CLC, 134 mmHg). However, HL animals living in a non-competitive environmental condition (standard laboratory living conditions for mice) did not develop hypertension (137 mmHg) nor did they significantly differ in blood pressure from the UC (126 mmHg) or CLC (136 mmHg) groups in the same environmental conditions. Similarly, the HL animals in the competitive condition showed significantly elevated plasma corticosterone (21 ug%, $p < .05$) as compared to UC (14 ug%) or CLC (14 ug%). Whereas, the HL animals living in the non-competitive situation exhibited no significant difference in corticosterone (9 ug%) from the other control groups under the same conditions (UC-11 ug% and CLC-10 ug%).

Computer based behavioral measurements showed that the HL animals failed to develop a social hierarchy with dominant and subordinate individuals and they displayed hyperactivity with disorganized behavior patterns as compared to control groups. The HL groups in the competitive situation also failed to show aggressive responses to an intruder animal. When the roles were reversed and they were now the intruder in another colony they showed abnormal escape behavior and received 3 times more attacks than did controls.

As an alternative to unitary constructs of hippocampal function the hippocampus may have several different functions including modulation of social behavior and secondary effects on the autonomic and endocrine systems. (Research supported by NIH grants MH19441, MH17706, and MH26155).

1094 THE EFFECTS OF NEONATAL ADMINISTRATION OF LOW DOSES OF ESTRADIOL BENZOATE UPON THE DIFFERENTIATION OF SEXUAL BEHAVIOR IN THE FEMALE HAMSTER. Anne M. Etgen* and Richard E. Whalen. Dept. of Psychobiology, University of California, Irvine, CA 92717.

Several lines of research suggest that androgens may exert their effects on sexual differentiation only after they have been enzymatically converted to estrogens. This aromatization hypothesis is supported by the demonstration that estrogens, but not non-aromatizable androgens, can effect behavioral differentiation in rodents. The normal adult female hamster is behaviorally unresponsive to androgen stimulation. However, female hamsters can be masculinized by the injection of as little as 1.0 ug of testosterone propionate (TP) at birth. This observation suggested that perhaps sexual differentiation of the hamster is mediated by androgens since somewhat less than 1 percent of testosterone is aromatized to estrogen. To test this hypothesis, the effects of very low doses of estradiol benzoate (EB) administered at birth upon the expression of sexual behavior in the adult female hamster were investigated.

Female hamsters were injected subcutaneously within 24 hours of birth with oil vehicle, 1.0 ug TP (a dose which has been shown to masculinize but not defeminize the female hamster), or with 0.05, 0.10, 0.50, 1.0, or 2.0 ug EB. All animals were ovariectomized between 55-65 days of age and tested for the occurrence of both male and female sex behavior in response to appropriate hormonal stimulation. Male behavior was measured as the average number of (a) mounts without pelvic thrusting (M) and (b) mounts accompanied by pelvic thrusting (M+T) in each of 3 weekly 10 minute tests with a receptive female. Female behavior was measured as the average total lordosis duration (TLD) in 3 weekly 10 minute tests with sexually experienced males.

All doses of EB elicited more male sexual behavior than oil vehicle, and a one-way analysis of variance indicated that 0.5 ug EB elicited significantly more Ms ($F=7.87$; $df=1,26$; $p<.01$) and M+Ts ($F=14.16$; $df=1,26$; $p<.01$) than 1.0 ug TP, and that 0.05 ug EB induced as many M+Ts as 1.0 ug TP. In addition, EB decreased the average TLD in a dose-dependent fashion when compared to vehicle-injected controls while TP had no effect on lordosis.

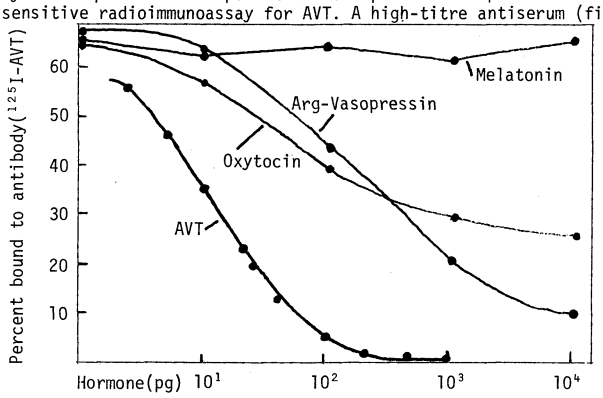
The fact that low doses of neonatally administered estrogen can both masculinize and defeminize the behavioral responses of adult female hamsters much more effectively than androgens provides additional evidence that the differentiation of rodent sexual behavior may indeed be mediated by the action of estrogens during a critical period of development. Further examination of this possibility is being conducted by determining the effects of extremely low doses of RU-2858, a potent synthetic estrogen, upon behavioral differentiation in the female hamster.

1095 THE EFFECT OF DIFFERENTIAL FORNIX ABLATIONS ON THE CIRCADIAN RHYTHMICITY OF ADRENAL CORTICOSTEROIDS. Christine Fischette*, B.R. Komisaruk, H. Edinger, H. Feder‡ A. Siegel. Depts. of Physiology and Neurosciences, College of Medicine and Dentistry of New Jersey, Newark, New Jersey 07103, and Institute of Animal Behavior, Rutgers University, Newark, New Jersey 07102.

Meibach and Siegel (Brain Res 124: 197, 1977) found that fibers from the dorsal hippocampal formation travel in the medial part of the fornix, while fibers from the ventral hippocampal formation travel in the lateral part of the fornix. The medial corticohypothalamic tract, whose cell bodies lie in the anteroventral subiculum, travels in the most lateral part of the fornix and fimbria and terminates in the basal hypothalamus from the level of the suprachiasmatic to the arcuate nucleus. Thus, lateral or medial fornix ablations were performed on adult male rats in order to selectively ablate the medial corticohypothalamic tract. The circadian rhythmicity of corticosterone secretion was assessed 1-2 weeks postoperatively. Analysis of corticosterone was determined by the competitive protein binding method or by radioimmunoassay. On the basis of preliminary data, interruption of the lateral fornix disrupted the cyclicity of corticosterone secretion that is normally synchronized with the light-dark cycle, whereas medial fornix ablated animals or cortical controls showed no such disruption. Group mean levels of corticosterone in the lateral fornix ablated rats were intermediate between peak and nadir levels in the controls. An individual analysis of lateral fornix ablated animals, however, reveals that circadian peaks of corticosterone occurred, but were not synchronized with the light-dark zeitgeber. We speculate that the anteroventral subiculum modulates the timing of the normally-occurring circadian peak of corticosterone via the medial corticohypothalamic tract. (Supported by NINCDS Grant # NS 07941-08).

1096 DEVELOPMENT OF A NEW RADIOIMMUNOASSAY FOR ARGININE-VASOTOCIN[AVT] Laurel A. Fisher*, Bernadette M. Cusack*, and John D. Fernstrom, Laboratory of Brain and Metabolism, M.I.T., Cambridge, MA 02139.

The measurement of arginine-vasotocin, a nine amino acid peptide, in animal tissues and blood, has been limited to date to a complicated, inferrential bioassay, save for a brief period recently when an indirect radioimmunoassay method was available. The ability to study the potential biologic significance of this peptide has thus been encumbered by the unavailability of a standard assay technique. We now report the development of a specific and sensitive radioimmunoassay for AVT. A high-titre antiserum (final



dilution in assay 1:240,000) was generated in New Zealand white rabbits using a bovine thyroglobulin conjugate of AVT (Skowsky and Fisher, J.Lab.Clin.Med.80:134,1972)[synthetic AVT, 95% pure, was kindly provided by Dr. R. Hirschman, Merck, Sharp, and Dohme, Rahway, NJ]. The assay is basically a modification of the method of Skowsky et al.,J.Clin.Endocr.Metab.38:278,1974, using Norit-A to separate antibody-bound and free AVT. The sensitivity and specificity are indicated in the above figure; melatonin, oxytocin, and vasopressin levels in blood and pineal are not great enough to interfere with the quantitation of AVT in these tissues. Studies are currently in progress using this assay to determine the presence of AVT in pineal, blood, and brain, and hopefully to assess its physiologic significance.

1097 EFFECTS OF IN VIVO STIMULATION OF POSTERIOR PITUITARY ON PROTEIN CARBOXYMETHYLASE AND ITS SUBSTRATE. Claude Gagnon , and Julius Axelrod. Lab. Clin. Sci., N.I.M.H., Bethesda, Md. 20014

Protein carboxymethylase (PCM) activity has been shown to be high in brain and endocrine tissues. Diliberto et al. (Proc. Natl. Acad. Sci. USA 73: 4050-4054, 1976) demonstrated the presence of substrate for this enzyme on the membrane of chromaffin granules from adrenal medulla and suggested a possible role of this enzyme in exocytotic secretion. To investigate this possibility, rats were given 2% NaCl in their drinking water. Under these conditions the posterior pituitary is strongly stimulated and vasopressin is released by exocytosis. Posterior pituitary PCM activity and its substrate, the methyl acceptor proteins (MAP) were measured. The MAP dropped rapidly to 80, 40 and 20% of the control levels after 1, 2 and 4 days of treatment and remained at the 20% level up to 28 days. On the other hand, the PCM activity was not affected in the first week. After a lag of 2 weeks there was a significant increase in the enzyme activity. PCM activity rose 62% above control level after 4 weeks. This is the first demonstration of an enhancement of PCM activity following strong stimulation of a gland. This finding supports a role for PCM in neurosecretion.

1098 POSTERIOR MEDIAL HYPOTHALAMIC MEDIATION OF FEMALE COURTSHIP BEHAVIOR IN THE RING DOVE. Marie J. Gibson* and Mei-Fang Cheng* (SPON: K. L. Keim) Inst. of Animal Behavior, Rutgers, Newark, NJ 07102

When a female ring dove is exposed to a courting male, gonadal development occurs which has been correlated with an increase in courtship behaviors and rising titers of estrogen and progesterone (Cheng,J. Endocr. 63:43, 1974). Estrogen, which plays a role in regulating sexual crouching and nestcooing, is shown by autoradiography (Martinez-Vargas, Stumpf and Sar, J. Comp. Neur. 167: 83, 1976) to be taken up in the preoptic (POA) and posterior medial hypothalamic (PMH) regions. The purpose of this study is to examine the role of the hypothalamus in mediating estrogen dependent behaviors in the female ring dove.

In the first experiment laparotomies and behavioral tests were conducted to determine the effects of electrolytic lesions in intact females. Neither gonadal development nor courtship behavior was affected by lesions in the anterior hypothalamus or through the anterior portion of the PMH. However, lesions just rostral to the POA caused gonadal atrophy. No nestcooing and a gradual decline in sexual crouching were observed. Of lesions in the posterior region of the PMH only 1 of 4 caused gonadal atrophy, yet all courtship behaviors were abolished in 3 and greatly reduced in the 4th female.

In the second experiment, exogenous estrogen failed to restore courtship behaviors in intact females with lesions in the posterior portion of the PMH.

Third, ovariectomized females were tested daily with a male while receiving daily injections of estrogen. Behavior was compared under this regimen for a period before and after sham or electrolytic lesions. Sham lesions or those beyond the posterior PMH caused no interruption of estrogen induced sexual crouching or nestcooing, while posterior PMH lesions virtually abolished the behavioral effect of estrogen treatment.

These results suggest that the effects on courtship behavior found with anterior POA lesions are associated with interruption of gonadotropin release. However, the posterior PMH is apparently involved in the mediation of estrogen dependent courtship behaviors independent of its possible role in regulation of gonadotropins.

1099 THE EFFECTS OF ESTROGEN ON THE SINGLE UNIT ACTIVITY OF THE HYPOTHALAMUS AND PREOPTIC AREA IN ESTROGEN-PRIMED AND NON-PRIMED OVARIECTOMIZED FEMALE RAT. D. P. Gilman,* J. C. Hitt and N. R. Remley. Dept. of Psych., TCU, Ft. Worth, TX 76129

Estrogen has been reported to have both depressive and facilitatory effects upon luteinizing hormone (LH) release in ovariectomized rats depending upon the prior estrogen treatment (Caligaris et al., Endo. 88:810, 1971). Similar biphasic effects of estrogen on unit activity in the hypothalamus and preoptic area have not been clearly established. The present study was undertaken to investigate the effects of estrogen upon spontaneous hypothalamic and preoptic unit activity in estrogen-primed and non-primed ovariectomized rats. Extracellular potentials were recorded from paralyzed Sprague Dawley and Wistar Female rats with points of contact and incisions locally anesthetized with procaine.

In the medial preoptic area (MPOA) and anterior hypothalamic area (AHA) single unit activity was generally found to be depressed following a single estrogen administration (30 ug/kg estradiol benzoate in oil i.m.) compared to unit activity in the non-primed ovariectomized preparation. A substantial decrease in the number of units with response rates greater than one pulse per second was noted following a single estrogen administration. In the estrogen-primed rat, unit activity in the MPOA and AHA following a second estrogen administration was significantly elevated, with the majority of units recorded demonstrating firing rates greater than one pulse per second. These preliminary results suggest estrogen can have both depressive and facilitative effects upon hypothalamic and preoptic unit activity depending upon prior estrogen treatment.

1100 SEXUAL DIMORPHISM IN DENDRITIC PATTERN IN BASAL FOREBRAIN REGIONS OF INTACT ADULT HAMSTERS. W. T. Greenough, C. S. Carter, T. Ackerman*, R. Reeder*, J. Mateer*, T. Reeder*, E. Lyerla*, M. Bohnsak*, P. McCabe*, C. Suits*, and T. DeVoogd. Depts. Psychol. and Ethol., Ecol., and Evol. and Program in Neural and Behavioral Biology, Univ. Illinois, Champaign, IL 61820.

Prior work by our group and others indicates sexual dimorphism in connectivity patterns in rodent dorsomedial preoptic area (dmPOA). Our prior study (Greenough et al., Brain Res., 1977, 126: 63-72) indicated that dendrites of dmPOA neurons in male hamsters were more centrally concentrated than those in females. That study used animals gonadectomized in infancy or adulthood. We have now studied two-dimensional reconstructions of dendritic patterns of Golgi-Cox stained neurons from dmPOA and suprachiasmatic nucleus (SCN) in intact male and female hamsters. Dendritic distribution around each neuron was quantified in terms of the number of intersections between dendrites and an overlying grid of 20 micron equivalent squares. Dendritic distribution of groups of cells was reconstructed by adding grid intersection coordinates to cell body location coordinates (to 100 micron accuracy; ref. above). For dmPOA, the distribution paralleled prior work: males showed a central concentration while females showed a more widely distributed pattern of dendrites. This was true whether or not dendritic values were averaged relative to underlying cell body locations. Non-averaged distributions for males and females differed significantly at $p < .001$ ($\chi^2 = 1757.5$, df = 155). This suggests that our previously reported sex differences are not seriously affected by adult hormonal differences. In SCN, only dorsal and lateral neurons were analyzed due to sizeable sex differences in the number of neurons staining in ventromedial areas. The highest concentration of female dendrites was aligned along a ventromedial to dorsolateral axis, whereas male dendrites were, again, more centrally concentrated. This was emphasized by one-dimensional projection of the intersections to an oblique line orthogonal to this axis (slope = 0.5 mediolateral units per dorsoventral unit). Distributions along this axis differed at $p < .001$ ($\chi^2 = 37.4$; df = 7). In addition, analysis of the location around individual cell bodies where dendrites terminated revealed a sex by location effect within SCN, such that dendrites of male neurons tended to project toward the center of SCN, regardless of cell body position, whereas female dendrites were more evenly distributed or tended toward the above-noted oblique axis. Studies of the development of these differences and of possible dimorphism in anterior hypothalamus are in progress.

1101 CHANGES IN POLYAMINE SYNTHESIS IN THE BRAIN AND THE LIVER OF THE RAT FOLLOWING ABLATION OF THE PITUITARY, ADRENAL OR THYROID GLANDS. Sami I. Harik. Dept. of Neurology, University of Miami School of Medicine, Miami, Fl. 33152.

Liver ornithine decarboxylase (ODC) activity and putrescine and spermidine levels in the liver and the brain were studied in hypophysectomized, adrenalectomized and thyroidectomized rats and in normal controls. Spermidine levels were decreased in the liver of all the endocrinopathic groups of rats while ODC activity and putrescine levels were not significantly altered. In the brain where ODC activity is not usually detectable, the levels of putrescine, which is the immediate product of the reaction catalyzed by ODC, was significantly increased in hypophysectomized and thyroidectomized rats. Brain spermidine was generally higher in all groups of endocrinopathic rats, but this increase did not reach statistical significance except in the thyroidectomized rats.

The chronic deficiency of hormones secreted by the pituitary, adrenal and thyroid glands does not seem to decrease the activity of ODC, which is the rate-limiting enzyme in polyamine synthesis.

Because of the intimate relationship between polyamine biosynthesis on one hand and nucleic acid and protein synthesis on the other, these results may help elucidate some aspects of growth and development under the effects of chronic hormone deprivation.

1102 BURSTING ACTIVITY IN RAT HYPOTHALAMIC NEUROSECRETORY CELLS IN VITRO IN RESPONSE TO OSMOTIC STIMULATION. Glenn I. Hatton, William A. Gregory, and William E. Armstrong. Dept. Psych., Mich. St. Univ., E. Lansing, MI 48824.

Extracellular potentials were recorded from rat hypothalamic cells in brain slices, using 2M NaCl-filled glass micropipettes. Rats were killed by decapitation, brains were rapidly removed, the hypothalamus was blocked with a razor blade and chopped into 500 μm thick slices on a tissue chopper. Usually 6 slices were placed in a temperature controlled chamber, supplied with a humidified 95% O_2/5% CO_2 mixture, and bathed in 2 ml of media (Yamamoto, Exp. Brain Res. 1972, 14, 423) of osmolality ≈ 300 mOsm/kg. An infusion-withdrawal pump was used to exchange the media bathing the tissue for media of either the same or higher osmolality. A total of 69 such preparations yielded recordings from 252 cells, of which 116 were paraventricular (PV) and 128 were nucleus circularis (NC) cells. The eight remaining units were recorded from the pituitary stalk, the nucleus of the diagonal band, the anterior hypothalamic area and the arcuate nucleus. Median basal firing rates for PV and NC cells were 5/sec and 7/sec, respectively. Exchanging the media without change in osmolality resulted in either no change or decreases in firing rates. Exchanges with media of 310 mOsm produced patterns of phasic activity similar to those seen in neurosecretory cells in vivo in response to osmotic stimulation. At this time, most of our data during media changes have been obtained from NC cells. Bursting activity (rapid, phasically occurring increases in firing rate) was seen in 6% of NC cells prior to osmotic stimulation, whereas 55% of cells recorded after stimulation were classified as bursters. Rates within bursts commonly reached 15/sec with some as high as 20/sec. Some cells in both nuclei were monitored before, during and after osmotic stimulation, and were observed to alter their firing patterns from random spiking to bursting activity. Such activity was not seen in any cells from other brain areas. These results suggest that bursting activity may be an intrinsic property of mammalian hypothalamic neurosecretory cells and that it can be evoked by osmotic stimulation.

1103 NEURAL TRIGGERS FOR THE RELEASE OF VASOPRESSIN IN THE MONKEY. James N. Hayward and Kanok Pavasuthipaisit*. Dept. Neurology & Neurobiology Program, The University of North Carolina, Chapel Hill, N.C. 27514.

The behavioral state of the monkey is a major determinant for the release of vasopressin (VP) from the neurohypophysis. In the chronically prepared, chamber-isolated rhesus monkey we recorded EEG, EOG and body movement and obtained blood samples from an indwelling cardiac cannula for measurement of plasma VP by RIA (Endocrinology 98: 965, 1976). The sitting rhesus exhibits a circadian rhythm of VP with peaks at midnight during sleep and lows at noon during waking. With dehydration mean levels of VP rise in parallel with dehydration even as the day-night difference remains constant. A nocturnal, sleep-related, non-osmotic neural trigger may produce these nocturnal peaks of VP. During a 3-min simulated capture in the naive sitting rhesus, plasma VP rises rapidly to 10-20 fold above control values. Several factors, including the duration of simulated capture, conditioning of the animal and the intensity of capture, determine the magnitude of VP elevation. The neural pathways involved in this release of VP during simulated capture are unknown. In order to evaluate the possible role of the amygdala in the neural control of VP release we applied electrical stimuli to the temporal lobe, the hypothalamus and the pituitary gland. In the amygdala-stimulated monkeys, the plasma VP which rose rapidly to peak values (50-100 times basal) at the end of stimulation fell abruptly to control levels in 30 min. In monkeys stimulated electrically along the final neuroendocrine pathway (hypothalamus and pituitary gland) there was a temporal pattern of VP rise and fall identical to that seen following amygdala stimulation and simulated capture. Blood sampling timed precisely to the onset and end of these neural stimuli was an important factor in our ability to detect the rise and fall in plasma VP. We suggest that in the conscious monkey, the neural stimuli associated with sleep, simulated capture and electrical stimulation of the amygdala can trigger the release of VP. (Supported, in part, by NIH Grant NS-13411 and a Sloan Foundation Grant to the Neurobiology Program).

1104 RESISTANCE OF THE PITUITARY-ADRENAL SYSTEM OF THE MOUSE TO HABITUATION. Michael B. Hennessy* and Seymour Levine. Dept. Psychiatry & Behav. Sci., Stanford Sch. Med., Stanford, CA 94305.

The pituitary-adrenal system of the mouse is known to be sensitive to a variety of stimuli including exposure to a novel testing apparatus. Since responsiveness to the apparatus may mask responsiveness to stimuli presented within it, animals are often repeatedly exposed to the testing situation prior to testing in order to habituate responsiveness to the apparatus. Experiments in our laboratory suggest that these procedures often do not result in habituation.

In Experiment 1, blood samples were collected from adult male mice after they had been either: removed rapidly from their home cage (basal level control condition), placed in an apparatus once for 30 min (novelty condition), or had experienced one of three procedures involving prolonged exposures to the apparatus (habituation conditions). Assay of blood for plasma corticosterone showed that no habituation had occurred in any of the habituation conditions. One habituation condition produced sensitization, increasing rather than decreasing responsiveness. The elevated corticoid levels did not appear to be a result of novelty since animals in the habituation conditions had extensive time to become familiar with the apparatus.

Experiment 2 attempted to determine if the elevated corticoid levels could be accounted for in terms of the handling involved in placing animals into the apparatus. One vs. repeated exposures (of the sequence which produced sensitization in Experiment 1) was factorially combined with handling only vs. handling plus apparatus-exposure. Animals were found to not respond to handling alone, whether handling occurred once or repeatedly. That is, sensitization, and responsiveness in general, did not occur unless animals experienced apparatus-exposure.

Experiment 3 varied the familiarity of the apparatus to the home cage. Plasma corticosterone levels showed a clear discrimination of three apparatuses in terms of their familiarity. Thus, while response to novelty does not seem sufficient to explain the elevated corticoid levels, responsiveness does seem to depend upon the degree of discrepancy between home cage and apparatus.

These experiments demonstrate: the difficulty of habituating pituitary-adrenal responsiveness in the mouse; that repeated exposures to an apparatus can result in increased rather than decreased corticoid levels; that the elevated corticoid levels are not a response to handling; and that while novelty does not appear to account for the elevated corticoids, increasing the discrepancy between the home cage and the apparatus increases responsiveness to the apparatus.

1105 MODULATION OF PAIN SENSITIVITY IN THE RAT BY ADRENOCORTICAL HORMONES. John P. Heybach* and Joan Vernikos-Danellis*. (SPON: W. R. Mehler). NASA, Ames Research Center, Moffett Field, Ca. 94035.

Adrenocortical insufficiency in humans has been reported to lead to increases in sensitivity (ie. decreases in detection thresholds) to taste and to olfactory stimuli which were reversed via treatment with prednisolone (1). Similarly, an increased sensitivity to olfactory stimuli, which was reversed by corticosterone treatment, has been reported in the rat (2). The present study was conducted to determine whether adrenal hormones may also modulate cutaneous sensitivity to a painful thermal stimulus. Adrenalectomy and the circadian variation of adrenal function were the test conditions used to determine the effect of endogenous physiological changes in circulating adrenocortical hormone levels on pain sensitivity. Adrenalectomized adult male rats showed markedly decreased latencies in the display of a paw-lick, and subsequently a jump response, when placed on a grid at 55°C. Although sham adrenalectomized rats displayed some degree of adaptation or tolerance to this stimulus, as evidenced by increasing response latencies across days, adrenalectomized rats did not show a similar increase with repeated exposures. Adrenal demedullation had no effect on either paw-lick or jump latencies. The data suggest that adrenocortical hormones are involved in mediating pain sensitivity and the development of tolerance to pain. They further suggest that the rat is a useful model for studying the mechanisms of involvement of adrenocortical hormones in sensory processes.

1106 IMMUNOCYTOCHEMICAL EVIDENCE OF A STRUCTURAL SIMILARITY BETWEEN PINEAL ANTI-GONADOTROPHIC SUBSTANCE AND LUTEINIZING HORMONE RELEASING HORMONE (LHRH). G. E. Hoffman, K. M. Knigge*, and S. A. Joseph*. Dept. Anatomy, Sch. Med., Univ. Roch., Roch., N.Y. 14642.

The rat pineal gland in culture produces nanograms per day of substances with chemical characteristics (heat stability, extractability in methanol and acetic acid, proteolytic enzyme inactivation, and chromatographic mobility) suggestive of a small peptide similar to LHRH. Bioassay of this pineal substance by incubation with dispersed cultured rat anterior pituitary cells revealed no release of LH or inhibition of LHRH stimulated LH release. When melatonin was separated from the media, or its synthesis prevented by 100 µgram/ml p-chlorophenylalanine (PCPA), the pineal substance inhibited LHRH stimulated LH and FSH release. Immunocytochemical reaction of brain LHRH antigen-antibody reaction, using the unlabeled antibody peroxidase method of Sternberger, was inhibited when pineal media was present during incubation of antisera with tissue or when the antisera was pre-incubated with the pineal media. No inhibition of staining was seen when antisera was pre-incubated with melatonin or PCPA media incubated in the absence of pineals. Pineal substance was capable of displacing I^{125} LHRH from binding to anti-LHRH in the radioimmunoassay. The behavior of this pineal hormone with respect to LHRH antibodies and its chemical properties thus suggest this small peptide has as its primary structure, amino acid sequences which provide antigenic determinants similar to LHRH. (Supported by NIH fellowship HD 1 F22 00640).

1107 EFFECT OF CENTRAL CATECHOLAMINE DEPLETION ON CENTRALLY MEDIATED CARDIOVASCULAR RESPONSES. W.E. Hoffman*, J. Buggy, P.G. Schmid. Cardiovascular Division, Dept. of Internal Medicine, U. of Iowa, Iowa City, IA 52242.

Angiotensin II (A II), when delivered intraventricularly (IVT) produces an increase in blood pressure and release of antidiuretic hormone (ADH). In experiments reported here we have investigated the role of central catecholamines in these responses. Blood pressure was measured in chronic unanesthetized rats. ADH was determined by an on-line bioassay. After central 6-hydroxydopamine (6-OHDA) treatment IVT A II was less effective in producing a blood pressure increase of ADH release. Similar responses to IVT carbachol were also inhibited. Pressor responses to phenylephrine were not significantly changed after 6-OHDA treatment although ADH release was decreased. In further analysis, both a dopamine blocker, haloperidol, and phentolamine, an α-adrenergic blocker inhibited the pressor response but not ADH release to IVT A II. Both effects may be explained by α-adrenergic blockade. Dopamine IVT alone was ineffective in producing either ADH release or a blood pressure increase and phenylephrine produced both effects in a dose dependent manner. We conclude that noradrenergic mechanisms may be important as a common mediator of central sympathetic outflow. The ADH release produced by A II and carbachol may be by direct action on periventricular receptors which can be damaged non-specifically by 6-OHDA.

1108 THYROTROPIN RELEASING HORMONE - A PHYSIOLOGICAL β ENDORPHIN ANTAGONIST? John W. Holaday*, Choh Hao Li*, and Horace H. Loh* (SPON: Harry C. Holloway). Dept. Pharmacology, UCSF, San Francisco, CA 94143.

β Endorphin (BE) has been shown to be a potent hypothermic agent when injected intraventricularly (i.v.). Conversely, Thyrotropin Releasing Hormone (TRH) results in hyperthermia when administered i.v. We were interested in ascertaining whether or not TRH would antagonize the thermoregulatory as well as cataleptic, sialogogic, and antinociceptive effects of BE and to assess these effects in hypophysectomized rats.

Male Long-Evans rats, weighing 190 ± 10 (SD) grams, were hypophysectomized (hypox) or sham operated 10 days before testing. BE (30 µg in 20 µl saline) was injected i.v. through a guide cannula into the lateral ventricle. Pharmacological measures, accomplished in the 26.5°C room where housed, were continued until drug effects ceased.

This dose of BE had no significant effect on rectal temperatures of sham animals, whereas hypox rats experienced a 4°C decrease in temperature 3 h after injection - returning to normal at 5 h. Naloxone (4 mg/Kg) completely reversed this hypothermia when given 30 min after BE. TRH (20 µg in 20µl saline i.v.), injected 30 min after BE, also blocked the BE induced hypothermia in hypox rats, yet produced mild hypothermia in BE pretreated sham animals. Hypox rats, treated with TRH alone, become more hyperthermic than sham controls. Thus, hypox sensitizes to the thermoregulatory effects of both BE and TRH.

We have shown that BE (i.v.) initially results in wet-dog shakes followed by copious salivation, occasionally accompanied by a clonic seizure-like state in rats (manuscript in preparation). These behaviors were related to an altered thermoregulatory set-point. BE induced salivation in sham animals is decreased by TRH but potentiated by TRH in hypox rats. TRH alone causes wet-shakes in hypox rats to a greater extent than in sham controls. Conversely, BE alone causes more wet-shakes in sham animals than in hypox rats. These findings are consistent with the known BE hypothermic effects and the TRH hyperthermic effects.

Catalepsy induced by BE in both hypox and sham rats is antagonized by subsequent TRH injection. This is similar to previous reports of TRH antagonism of neuroleptic-induced catalepsy (Kruse, J. Pharmacol. (Paris) 6, 249, 1975). However, BE induced antinociception as measured by tail-flick is unaltered by TRH. Furthermore, TRH alone is without effect on tail-flick latencies.

Collectively, these studies support the hypothesis that a physiological interplay between TRH and endorphins may serve to modulate body temperature and other behaviors. Supported in part by Walter Reed Army Inst. Rsch., NIH, and NIDA grants.

1109 EFFECTS OF PRENATAL PROGESTERONE ON BEHAVIOR OF RATS. Elaine M. Hull, Jonathan Franz*, and Abigail Snyder*. Dept. Psychol., S.U.N.Y., Buffalo, N. Y. 14226.

Recent reports that administration of progesterone to women during pregnancy results in higher than average IQ among offspring or in increased "independence" measured on personality tests have raised a question concerning the potential mode of action of prenatally administered progesterone on the brain. At present no animal model of these effects has been demonstrated. Coyle, et al. (1977) have reported no statistically significant differences on numerous anatomical, physiological, and behavioral measures, though prenatal progesterone-treated rats did exhibit more rearing behavior and a greater amount of DNA in brain assays.

In the present experiment low (4mg), medium (8mg), and high (12mg) doses of progesterone were embedded in a Silastic pellet which was implanted subcutaneously in female rats on the sixth day of pregnancy. Control animals received plain Silastic pellets. 120 offspring of 12 females were tested on one-way active avoidance on Day 14 and on open field activity, Lashley III maze acquisition, one-way active avoidance, and passive avoidance beginning at 90 days of age. Animals born to medium-dose and control females performed best on the adult active avoidance task, compared to those born to low- and high-dose mothers. Significantly more medium-dose offspring than any other group obtained mean scores of 60 sec or faster on their last 5 Lashely III maze trials. While medium-dose animals obtained somewhat faster scores on the infant active avoidance task, the differences were not statistically significant. There were no Progesterone-related differences on open field activity, passive avoidance or weight at weaning. In summary low and high doses of prenatal progesterone impaired performance on two tasks, while the medium dose animals performed as well as controls on one task and better than all other groups on another.

1110 ACTIVITY OF ARYLAMIDASES IN THE RAT BRAIN INACTIVATING GONADOTROPIN RELEASING HORMONE AND THE EFFECT OF NEONATAL ANDROGENIZATION OF FEMALE RATS. I. A. Kamberi*, R. V. Wenn* and J. de Vellis (SPON: R. A. Gorski). UCLA, Sch. Med., Los Angeles, CA 90024.

Arylamidase activities towards specific substrates, the 4-nitroanilides of L-alanine, L-leucine, L-phenylalanine, L-tyrosine, L-cystine, L-glutamic acid, and L-glycine, have been investigated in different regions of the hypothalamus of normal male and female rats and neonatally androgenized female rats (1 mg testosterone propionate on day 3 after birth). In all hypothalamic regions examined (anterior, median eminence, posterior, lateral), it was found that the arylamidase activities with respect to these substrates decreased in the order listed above. The arylamidase activity towards L-alanine-4-nitroanilide and L-cystine-bis(4-nitroanilide) was elevated in all hypothalamic tissues as compared to the cerebral cortex. However, the relative distribution of the activity towards these two substrates varied in different regions with more pronounced activity in the anterior hypothalamus. The arylamidase activity was considerably higher in neonatally androgenized female than in normal diestrus female rats. There was no significant difference between activity in male rats and androgenized female rats. Hypothalamic gonadotropin releasing hormone (Gn-RH) was decreased in androgenized females as compared to normal diestrus females. Hypothalamic concentration of Gn-RH and serum levels of luteinizing hormone (LH) were not significantly different in neonatally androgenized female and normal male, but were much lower than in diestrus female rats. These results suggest that androgen treatment produces masculinization through activation of a mechanism responsible for Gn-RH inactivation in the hypothalamus. This in turn is reflected in changes in the gonadotropin secretion in neonatally androgenized female rats. (Supported by ERDA Contract EY-76-C-03-0012 and USPHS Grant HD-05615)

1111 ESTRADIOL-INDUCED ACTIVITY IN THE FEMALE RAT: EFFECTS OF LIMBIC AND DIENCEPHALIC LESIONS. James M. King. Dept. Psychol., University of Texas at Arlington, Arlington, TX 76019*

Female albino rats were given daily access to activity wheels for 1 hr during the dark portion of a reversed light-dark cycle. Following a 15 day baseline period, all subjects were ovariectomized and given sham lesions or bilateral lesions of one of the following sites: medial preoptic area (MP), anterior hypothalamic nucleus (AH), or corticomedial anygdala (CM). After surgery, subjects were given either daily subcutaneous injections of 3.0 micrograms of estradiol benzoate (EB) in sesame oil or the oil alone. After a 15 day recovery period, 15 additional days of activity data were collected. The EB enhancement of activity was sharply attenuated following MP lesions, and was entirely eliminated following AH lesions. CM lesions had no effect on EB-induced activity. A second study revealed that neither MP nor AH lesions interfered with the induction of activity by food deprivation, suggesting that the observed deficit is specific to EB-induced activity.

*(Present address: Neuropsychology Branch, Biomedical Laboratory CSL, APG, MD 21010).

1112 ECDYSONE TITERS IN NATURALLY AND BRAIN EXTRACT-INDUCED MOLTING MANDUCA SEXTA. Timothy G. Kingan* and R.W. Newburgh*. (SPON: Dorothy H. Paul). Dept of Biochem. & Biophys., Oregon State Univ., Corvallis, OR 97331.

The titer of the insect molting hormone, ecdysone, has been measured by radioimmunoassay (RIA) in the hemolymph of Manduca sexta larvae undergoing an L_4-L_5 molt. Evidence of hormone release is seen within three hours after "lights off" in larvae staged to initiate molting with prothoracicotropic hormone (PTTH) release on the day of selection. Ecdysone RIA activity increases six-fold within 18 hours of "lights off". Hemolymph ecdysone titers in similarly staged neck-ligated larvae were examined in response to injections of extracts of wandering stage larval brains. A significant increase ($P<.05$) in ecdysone titer occurs within one hour after injection when compared both to time = 0 and to control (2% NaCl injected) animals. The finding that the presumed primary endocrine response to PTTH release can be measured by ecdysone RIA may facilitate the characterization of PTTH. (Supported in part by NIH grant NS-09161-20.)

1113 EFFECTS OF GAMMA-BUTYROLACTONE AND OTHER ANESTHETICS ON GONADOTROPIN AND LUTEINIZING HORMONE-RELEASING HORMONE (LH-RH) LEVELS IN THE OVARIECTOMIZED ESTROGEN-PROGESTERONE PRIMED FEMALE RAT. John H. Kitchen* (SPON: K. M. Knigge). Dept. Anatomy, Univ. of Rochester Sch. Med., Rochester, N.Y. 14642

Gamma-hydroxybutyrate (GHB) is a naturally occurring product of gamma-aminobutyric acid (GABA) metabolism within the central nervous system. Clinically, GHB has been used to produce a type of anesthesia described as resembling 'natural' sleep or an epileptiform-like stupor. Gamma-butyrolactone (GBL) is converted by a blood lactonase to GHB, the active substance in inducing the unconscious state.

Ovariectomized, estradiol benzoate primed (EB, 10 μg s.c.) female rats were intraperitoneally injected, on the morning of progesterone administration (P, 1.5 mg s.c.) with GBL, urethane or pentobarbitol, using doses sufficient to produce surgical anesthesia. Animals were sacrificed by decapitation at various times after the injection of the anesthetics. Appropriate control animals were also sacrificed. Gonadotropin (sera, pituitaries) and LH-RH (brain punches) were determined by radioimmunoassay.

GBL did not block the afternoon rise in sera gonadotropin levels, in contrast to the results of urethane and barbituate anesthesia. LH-RH content, measured in the anterior preoptic and median eminence arcuate regions, did not significantly differ ($p < 0.05$) in any of the groups tested. Preliminary results suggest GBL does not alter blood pressure. The effects of GBL on central catecholamine content in discreet anatomically defined areas is currently being investigated using a radioenzymatic assay.

GBL, used alone or as an anesthetic adjuvant, may prove beneficial in experiments requiring a long-term anesthetic (electrophysiological recording, hypophyseal portal blood collection) which does not exert adverse or blocking actions on the reproductive neuroendocrine circuits.

1114 RHYTHM IN PINEAL MELATONIN EXCRETION IN HUMANS: DISRUPTION FOLLOWING CERVICAL SPINAL CORD LESIONS. *L.W. Kneisley[1,2], M.A. Moskowitz[2,3], H.J. Lynch[3], *H.R. Tyler[2], *A.B. Rossier[2]. From the Research and Spinal Cord Injury Services, West Roxbury Veterans Administration Hospital, Boston, Mass.[1], Section of Neurology, Peter Bent Brigham Hospital, Harvard Medical School[2], and Department of Nutrition and Food Science, Massachusetts Institute of Technology, Cambridge, Mass.[3].

In order to determine the extent to which disrupting the nervous innervation of the pineal organ alters the biosynthesis and secretion of melatonin in man, levels of this hormone were measured in the urines of subjects with traumatic spinal cord lesions. Urine samples were collected every four hours for twenty-four hours from 3 young male subjects with clinical evidence of complete cord transection above the C8 level. Melatonin excretion was determined for each interval by radioimmunoassay. Sleep was monitored by electroencephalography and serum samples were drawn from an indwelling catheter for additional neuroendocrine studies. The levels of melatonin in the urine during the waking state ranged from 0.3-1.5 ng/hr; those during sleep and darkness ranged from 0.3-1.5 ng/hr. In contrast to previously reported data from neurologically healthy adults, the pattern of excretion among patients with quadriplegia due to cervical cord lesions did not exhibit diurnal variations. One explanation for this failure to display a daily rhythm relates to the disruption of descending spinal sympathetic fibers that innervate the pineal organ via the intermediolateral horn of the spinal cord and superior cervical ganglia. Relative immobility and inactivity of these patients secondary to motor paralysis may also be a contributing factor. These findings suggest that in man as well as other animals, an intact spinal cord is necessary for generating a daily rhythm in melatonin biosynthesis.

1115 CONVERSION OF ANDROGENS TO ESTROGENS (AROMATIZATION) IN DISCRETE REGIONS OF THE RAT BRAIN: SEXUAL DIFFERENCES AND EFFECTS OF CASTRATION. Ronald M. Kobayashi and Ken C. Reed*. VA Hosp., San Diego, Dept. Neurosci. UCSD, La Jolla, CA 92097 and Dept. Biol. City of Hope, Duarte, CA 91010*.

Conversion of androgens to estrogens by aromatization of the A ring has been demonstrated in different brain regions. We report the localization of aromatase activity to discrete regions of the rat brain using a specific radioisotopic assay based on the release of ^3H_2O from [1β-^{3}H]-androstenedione. High sensitivity permitted measurement in tissue removed from individual animals by the microdissection technique of Palkovits.

Aromatase activity was distributed unevenly throughout the preoptic, hypothalamic and limbic regions. Highest activity in the male rat was measured in the n. preopticus medialis (npm), n. preopticus periventricularis (npp) and n. amygdaloideus medialis (nam). In the female, aromatization was highest in the nam. Activity in the median eminence, n. arcuatus and n. ventromedialis (nvm) was low to intermediate in both sexes. Discrete localization was striking, with activity in the npm 10-13x higher than in the adjacent n. preopticus lateralis and nam activity was 11-20x greater than in the adjacent n. amygdaloideus corticalis (nac).

Sexual differences were significant in 5 regions (npm, npp, n. preopticus suprachiasmatis (npsc), n. hypothal. ant. and nac). Activity in the male was 2-4x higher than in the female. Castration significantly reduced aromatase activity in the npm, npsc, nac and nvm, with decrease to levels resembling the intact female. No sexual difference in aromatase was present in the nam.

These results indicate that aromatase activity in the adult rat brain is discretely localized especially to the medial preoptic and medial amygdaloid regions, sexual differences are present and castration reduced activity in some regions. Aromatization in these loci may be relevant to sexual differentiation and regulation of sexual behavior. (Supported by VA Clinical Investigator Award and NIMH 26072 to RMK and USPHS-Australian National University Fellowships to KCR).

1116 GONADOTROPHIN SURGES INDUCED BY ADRENAL AND OVARIAN STEROIDS IN THE IMMATURE RAT. Ilze Kraulis*, K.B. Ruf, D. Lee* and F. Naftolin*. Dept. OB/GYN, Royal Victoria Hospital, McGill Univ., Montreal, P.Q. H3A 1A1, Canada.

Sexually immature female rats "primed" with estrogen release large amounts of LH and FSH in response to progesterone (Caligaris et al., J. Endocr. 55: 97, 1972; ibid. 58: 547, 1973); the resulting gonadotrophin surge resembles the one underlying spontaneous pubertal ovulation in this species. We have used this model to investigate the possible role of aromatizable androgens (known to be secreted by the adrenal) in estrogen-priming and of other adrenal steroids in the triggering of the preovulatory surge. Sprague-Dawley rats (23 d old) were injected with various androgens (0.6 mg or 6.0 mg/100 g b.w., s.c. for 3 days) and challenged with progesterone (1 mg) on day 26 (1200 h). Plasma was collected 5 h later and LH and FSH concentrations were measured by radioimmunoassay. Uterine weights, determined at the same time, served as cumulative index of prior exposure to estrogen. Rats primed with the higher dose of dehydroepiandrosterone or Δ^4-androstenedione exhibited peaks of similar magnitude (5 - 20x baseline) as animals primed with a single injection of 10 ug estradiol benzoate (EB) on day 23. The degree of uterine hypertrophy was also comparable in all groups. In the lower dose, the above androgens were ineffective, but massive gonadotrophin peaks were found after priming with 0.6 mg testosterone. 5α-Dihydrotestosterone and 3β,17β-androstanediol proved ineffective in either dose. A single injection of an antiserum raised against estradiol-17β in sheep abolished or greatly reduced the priming efficiency of EB and of the aromatizable androgens. In EB-primed rats, massive gonadotrophin surges could also be elicited by the administration of $ACTH^{1-24}$ (0.1 mg) or DOCA (1.5 mg). It is concluded that sexually immature rats are able to convert androgens in sufficient quantities to replace estrogen in sensitizing the hypothalamo-pituitary axis to the gonadotrophin-releasing effect of progesterone. Moreover, the data indicate that adrenal steroids other than progesterone might participate in triggering the pubertal preovulatory gonadotrophin surge in suitably primed animals. The adrenal is thus capable of contributing substantially to both components of the surge system.

1117 SUBCELLULAR LOCALIZATION OF ANTERIOR PITUITARY AND HYPOTHALAMIC 5α-DIHYDROPROGESTERONE 3α-HYDROXYSTEROID DEHYDROGENASE ACTIVITY. James E. Krause* and Harry J. Karavolas. Dept. of Physiol. Chem., Univ. of Wis., Madison, WI 53706.

Progesterone is metabolized by the anterior pituitary and hypothalamus to 5α-pregnane-3,20-dione (5α-dihydroprogesterone) and 3α-hydroxy-5α-pregnan-20-one. 5α-dihydroprogesterone has been proposed as a mediator of progesterone's neuroendocrine effects on gonadotropin regulation. The second enzyme in this metabolism of progesterone, the 3α-hydroxysteroid dehydrogense (3α-HSD), catalyzes the conversion of 5α-dihydroprogesterone to 3α-hydroxy-5α-pregnan-20-one. Thus, establishing the intracellular location of the enzyme involved in the metabolism of 5α-dihydroprogesterone may help to define the locus of 5α-dihydroprogesterone action.

The subcellular distributon of female rat anterior pituitary and hypothalamic 3α-HSD activity was investigated utilizing ^{3}H-5α-dihydroprogesterone as substrate and a reverse isotopic dilution assay system. Both NADPH and NADH stimulated 3α-HSD activity in whole homogenates, although stimulation by NADPH was greater. The NADPH and the NADH enzymatic activities could be separated and localized into distinct intracellular compartments using subcellular fractionation by differential centrifugation. Hypothalamic NADH dependent 3α-HSD activity was localized in a cell debris-membranes fraction derived from the 1000 x g pellet. 3α-HSD activity was absent in purified nuclei. Hypothalamic NADPH dependent 3α-HSD activity was present in the 105,000 x g supernatant. In contrast to the hypothalamic activity, anterior pituitary NADH dependent 3α-HSD activity was present in the 17,000 x g pellet and was localized further to a fraction containing tropic hormone secretory granules. As in the hypothalamus, anterior pituitary NADPH dependent 3α-HSD activity was present in the 105,000 x g supernatant. (Supported by grants from NIH and the Ford Foundation.)

1118 AXONAL PROJECTIONS FROM THE VENTROMEDIAL NUCLEUS OF THE HYPOTHALAMUS IN THE RAT. Monica S. Krieger*, Lily C. A. Conrad* and Donald W. Pfaff. The Rockefeller University, New York, New York 10021.

Previous work from this laboratory has demonstrated that estrogen-concentrating cells exist in the ventromedial nucleus of the hypothalamus (VMH) in a number of vertebrate species. Other researchers have implicated the VMH in the control of gonadotropin secretion and reproductive behavior. A way to help elucidate the roles of estrogen-concentrating cells and other VMH cells in controlling gonadotropin secretion and reproductive behavior is to describe VMH efferent connections. We have done this using tritiated amino acid autoradiography.

Injections of 10 nl of a concentrated solution of ^{3}H-leucine (200 μCi/μl) were made into the VMH using stereotaxic procedures. Forty-eight hours after injection into VMH, rats were perfused with formalin. The brains were removed, embedded in paraffin, sectioned and mounted on slides. These slides were dipped in Kodak NTB-3 nuclear emulsion, exposed for 30 or 45 days and then developed. Projections from VMH neurons were charted systematically, using light and dark field microscopy to analyze the autoradiograms.

Fibers ascending from VMH passed through the preoptic area and the diagonal bands of Broca. Diffuse silver grains were seen in the bed nucleus of the stria terminalis and the lateral septal nucleus. Fibers going dorsally ran toward the periventricular thalamus, or entered the stria terminalis and projected to the amygdala. Some descending fibers coursed medially through the premammillary region and swept dorsally in the posterior hypothalamus through the periventricular system into the mesencephalic central gray. Other descending fibers coursed laterally. These included labelled fibers in a strong, bilateral projection in the ventral supraoptic commissure, some fibers of which entered the amygdala. Terminations were found in the medial, cortical, lateral nuclei and in the area surrounding the central nucleus of the amygdala. Other supraoptic commissure fibers cut through the cerebral peduncle and more caudally they swept through the thalamic reticular nucleus and over the dorsal thalamus toward central gray. There was also a lateral descending projection through the zona incerta which continued into the lateral mesencephalic reticular formation. Although in most cases it is difficult to interpret intrahypothalamic connections there appeared to be a projection from VMH to the median eminence.

(Supported by NIH grant HD-05751 and PHS training grant GM 01789.)

1119 THE FACTITIOUS ROLE OF SEROTONIN ANTAGONISTS ON PROLACTIN SECRETION. S. W. J. Lamberts* and R. M. MacLeod*. (SPON: J. I. Kitay). Dept. of Medicine, Univ. of Virginia, Sch. Med., Charlottesville, VA 22901

Normal prolactin (PRL) secretion is under the tonic inhibition of dopamine (DA). We previously showed a direct inhibitory effect of DA on PRL secretion at the pituitary level. In contrast, the serotoninergic system is thought to be stimulatory toward PRL secretion because the administration of 5-HTP stimulates the secretion of the hormone. In this study, we analyzed the action of certain serotonin antagnoists on PRL synthesis and release in vitro by incubating rat pituitary glands with ^{3}H-leucine. The amount of newly synthesized and radioimmunoassayable PRL in the incubation medium and pituitary was determined. Serotonin (0.1-10 μM) in vitro did not effect PRL synthesis or release in the pituitary of male and female rats. The inhibitory effect of dopamine (500 nM) on PRL release in vitro was unchanged in the presence of serotonin (6 μM). A serotonin antagonist, methysergide (3 nM), had no in vitro effect on PRL secretion or synthesis, but it blocked the dopamine-mediated inhibition of PRL release. Another serotonin antagonist, cyproheptadine (60-600 nM), had a significant inhibitory effect on the release of ^{3}H-PRL (35 and 81%, resp.), while the release of radioimmunoassayable PRL was inhibited to a lesser extent (24-55%); the sum total of RIA-PRL in the medium and pituitary together was unchanged by cyproheptadine suggesting that the primary effect of cyproheptadine is on PRL secretion. The effect of cyproheptadine was dose-dependent and the IC_{50} was 0.24 μM (0.4 μg). The addition of 25 ng TRH to control pituitary gland incubations stimulated PRL secretion 40%. Although TRH produced a similar degree of stimulation in the presence of .58 μM cyproheptadine, the peptide did not restore hormone secretion to control levels. In contrast to the effects seen with methysergide the co-incubation of cyproheptadine and DA had an additive inhibitory effect on PRL secretion. We have previously demonstrated that the inhibitory effect of DA and its agonists was blocked by various neuroleptic agents. Contrary to this, the inhibitory effect produced by cyproheptadine was not blocked by haloperidol (50 nM), pimozide (50 nM) and perphenazine (50 nM). It is concluded that the stimulating effect of serotonin on PRL secretion is mediated through some hypothalamic mechanism and not directly on the pituitary. Methysergide has properties of a dopamine agonist and antagonist, depending upon the test system. Cyproheptadine is an inhibitor of PRL secretion, but this effect is not mediated through the dopaminergic system.

1120 CORTICOSTERONE MODIFICATION OF THE SYNTHESIS OF SPECIFIC PROTEINS IN THE CENTRAL NERVOUS SYSTEM. Kevin S. Lee*, Anne M. Etgen*, and G. S. Lynch. (SPON: E. Greene). Dept. Psychobiology, University of California, Irvine, CA 92717.

Corticosterone, the principal glucocorticoid secreted by the rat adrenal cortex, is selectively bound and retained by certain limbic structures, especially the hippocampus. The majority of this hippocampal binding is localized within neuronal nuclei, as demonstrated by autoradiography and subcellular fractionation techniques. Specific, high-affinity cytoplasmic and nuclear receptors for corticosterone have also been isolated from the hippocampus. However, intracellular actions of this steroid hormone on its central nervous system (CNS) targets have not been identified. Since glucocorticoids act as intracellular modulators of gene expression in many peripheral tissues by regulating protein synthesis, the present investigation sought to determine if corticosterone modifies protein synthesis in its primary CNS target, the hippocampus.

Transverse slices of hippocampus prepared from adult male Sprague Dawley rats were maintained at 32-34°C in a balanced salt medium. Protein synthesis was measured by the incorporation of ^{3}H-leucine into protein during a 1-hour incubation with or without 10^{-9}M corticosterone added to the medium. The total protein synthesis rate in control and treated slices was determined by calculating the amount of labeled leucine incorporated into TCA-precipitable protein. The rate of synthesis of specific proteins was evaluated by fractionating proteins from several subcellular fractions on SDS-polyacrylamide gels. In some experiments, slices of cerebral cortex, a tissue which does not bind corticosterone, were coincubated with the hippocampal slices in order to assess the specificity of the hormone's action.

Corticosterone did not alter total protein synthesis in either the hippocampus or the cortex. However, the 1-hour hormone treatment consistently (18/20 experiments) and significantly ($t=4.21$; $df=19$; $p<.001$) increased the synthesis of at least one soluble cytoplasmic protein in the hippocampus by an average of 12 percent over controls. This protein has an apparent molecular weight of approximately 53-55,000 Daltons. Hormone treatment did not affect the synthesis of any cortical proteins.

Corticosterone thus altered the synthesis of specific protein(s) in a central target tissue without effecting any change in total protein synthesis. These results provide the first evidence that steroids can regulate specific protein synthesis in the CNS as well as in peripheral target organs. These observations are discussed in light of the current model of steroid hormone interaction with the genome. The possible mediation of glucocorticoid effects on brain electrical activity and behavior through hormonal regulation of specific protein synthesis is also suggested.

1121 DIFFERING NEUROCHEMICAL AND HORMONAL RESPONSES TO SPECIFIC STRESSORS. R. H. Lenox, J. L. Meyerhoff, G. J. Kant, G. R. Sessions, L. L. Pennington*, and E. H. Mougey*, Depts. of Medical Neurosciences and Microwave Research, Walter Reed Army Inst. Rsch. Washington, DC 20012.

It has been observed that the hormonal response to stress varies depending upon the nature of the specific stressful stimulus (Mason, Psychiat. Res. 8 (1971) 323). In the rat various stressors have been found to increase plasma corticosterone and prolactin and to decrease growth hormone levels. Cold stress in rats has been shown to cause increases in cyclic GMP (cGMP) in several brain regions (Mao, Molec. Pharm. 10 (1974) 736). We have compared the response of several neurochemical and hormonal systems to immobilization or cold exposure.

Male albino rats, WRC strain, weighing between 250-300 gm, were maintained in a light-cycled chamber and habituated to both handling and placement into a plexiglass cylinder twice a day for 1 week. On the day of sacrifice, animals were placed into one of three groups. The first group was placed in the plexiglass holder and immediately sacrificed by a high power microwave irradiation system, modified in our laboratory (Lenox, IEEE Microwave Theory Tech. 24 (1976) 58). The second group was immobilized for 5 minutes in the plexiglass holder, before irradiation. The third group was exposed to cold (4°C, with fur wetted) for 5 minutes and then irradiated. Immediately following exposure to the microwave irradiation, animals were decapitated and blood was collected in heparinized containers.

Levels of cGMP in specific brain regions were significantly elevated only in animals exposed to cold stress. The cGMP increase in cerebellum was approximately 3 fold with significant increases also noted in 9 other regions. Cyclic AMP (cAMP) levels throughout the 16 regions of brain examined showed no significant response to either of the stressors. In the pituitary, the level of cGMP was elevated in animals exposed to cold stress, while the cAMP level tended to increase only in the immobilized group. In the regions noted, the cGMP response to cold exposure was not affected by bilateral lesions of the locus coeruleus. Plasma prolactin levels were elevated over 10 fold in the immobilized group, while only rising 2 fold in the cold stress group. Levels of corticosterone were significantly increased while growth hormone levels tended to decrease in both the immobilized and cold stress groups.

It would appear from our data that regional brain cGMP and plasma prolactin respond differentially to 2 stressors while plasma corticosterone and growth hormone respond less specifically. The specifics of the stressful stimuli may be crucial in determining the nature of the neurochemical and hormonal response to stress in the rat.

1122 RESPONSE PATTERNS ELICITED BY α-MSH IN CENTRAL DOPAMINE NEURONS:ROLE OF ACTIVE SITES,DOSE AND HORMONAL STATE. Walter Lichtensteiger and Florianne Monnet*,Inst. Pharmacol.,Univ.Zürich,CH-8006 Zürich, Switzerland.

In ovariectomized, estrogen-progesterone-pretreated rats, acute systemic administration of α-melanotropin (α-MSH) has been found to affect the functional state of the tubero-infundibular and nigrostriatal dopamine (DA)neuron systems(Lichtensteiger and Lienhart,Nature 266,635, 1977).In both neuron groups,the peptide elicited the same response,an increase in neuronal fluorescence intensity as assessed by microfluorimetry, which indicates neuronal activation.In preliminary experiments,ACTH 4-10 was able to induce a similar reaction. In male rats,the response patterns are more complex and differ in part between the two DA systems. In the nigral group, a dose of α-MSH effective in females remained without effect or tended to reduce neuronal fluorescence(or activity),whereas a lower dose(ineffective in females)provoked a response of the type seen in females. The tuberal DA neurons responded to the whole dose range studied (2-100 μg/kg) by an increase in intensity.Differences between the two DA systems were further noted when their response(30 min) to comparable doses of peptide fragments containing the central and C-terminal active site of the α-MSH molecule, i.e.,ACTH 4-10 and MSH 11-13 (acetyl-Lys Pro Val NH_2),was investigated.In males, ACTH 4-10 exerted some effect on the nigral DA neurons but remained largely ineffective on the tuberal system.In contrast, the tuberal but not the nigral DA neurons exhibited a rise in fluorescence intensity after MSH 11-13.

The results indicate that the hormonal state of the animal strongly influences the response of central DA systems to peptides of the α-MSH type. Moreover, the two active sites of the α-MSH molecule appear to be of unequal importance for the two DA systems. Together with our earlier observations on differences in the neuronal circuitry underlying the peptide effect, this finding suggests that the physiological significance of the reaction differs between the two DA systems. The assessment of a possible involvement of the pituitary in these peptide effects is complicated by marked effects of hypophysectomy itself especially on the tuberal DA neurons. Supported by SNSF grant 3.669-0.75.

1123 HALF-CYLINDER CUTS ANTERO-LATERAL TO THE VENTROMEDIAL NUCLEUS REDUCE SEXUAL RECEPTIVITY IN THE FEMALE HAMSTER.# C.W. Malsbury, D.Strull* and J.Daood*. Western Psychiatric Inst.& Clinic, Dept. Psychiatry, Univ. Pittsburgh Sch. Med.,Pittsburgh, Pa. 15261

Previous data had shown that lesions in the region of the ventromedial nucleus of the hypothalamus (VMN) can disrupt the lordosis response in female golden hamsters (Malsbury, Kow & Pfaff, Physiol. & Behav.,in press). In the present study a Halász-type knife was used to help determine the connections of the medial basal hypothalamus that are critical for this response.

Ovariectomized, estradiol benzoate plus progesterone treated females were given weekly tests for lordosis before and after hypothalamic cuts. The vertical and lateral dimensions of the cuts were approximately 1.5 and 1.2 mm respectively. It was found that complete MBH isolations produced by a 360° rotation of the knife blade can eliminate lordosis. However, when VMN tissue was left outside the cut lateral, or anterior, lordosis could still be elicited. One-half cylinder cuts (180° knife rotation) were made either antero-lateral or postero-lateral to the VMN. Some of the antero-lateral cuts disrupted lordosis as completely as full-cylinder cuts, while postero-lateral cuts had little or no effect. The 360°, and 180° antero-lateral cuts passed through, or posterior to the suprachiasmatic nuclei on the midline, while postero-lateral cuts passed through the mammillary bodies or interpeduncular region. The behavioral data are summarized below. We conclude that neural pathways critical for lordosis pass in or out of the VMN region in an antero-lateral direction.

Lordosis Performance Following Medial Hypothalamic Knife Cuts†

			180° Cuts			
Group (N)	Unop. Control (10)	360° Cut (6)	Antero-Lateral (9)	Postero-Lateral (7)	A-L Sham (5)	P-L Sham (3)
Manual	94(±11)	40*(±20)	50(±16)	93(±7.1)	99(±1.3)	88(±7.2)
Male	105(±7.0)	27*(±21)	23*(±13)	81(±10)	86(±5.8)	77(±5.8)

†The mean (±S.E.M.) post-lesion lordosis performance in each group was calculated as: (mean post-lesion lordosis duration/mean pre-lesion lordosis duration) x 100. Total lordosis duration was measured in response to 5 min. of continuous manual stimulation and 5 min. of exposure to a sexually active male.

* Significant difference from unoperated control group (Mann-Whitney U test, $p < .05$, two-tailed.)

1124 SUBFORNICAL ORGAN: SITE OF PRESSOR AND DRINKING EFFECTS OF ANGIOTENSIN II. Michael L. Mangiapane* and John B. Simpson. Depts. of Psychology and Physiology, Univ. Washington, Seattle, WA 98195

The area postrema, a circumventricular organ, has been implicated as a central site of angiotensin II (A II) pressor action in some species. However, Hoffman and Phillips (Brain Research, 110, 1976) reported that lateral and rostral third ventricular A II injections produced maximal pressor responses in the rat with concurrent water ingestion; the fourth ventricle was insensitive. We now report that the subfornical organ (SFO), a site known to contain receptors for the drinking effect of intracranial A II (Simpson and Routtenberg, Science, 181, 1973), also mediates a pressor response to intracranial A II. In unanesthetized, freely moving rats prepared with intracranial cannulae and chronic aortic catheters, the pressor and drinking effects of A II injection were compared at three loci: SFO, adjacent ventral fornical commissure (VFC), and dorsal third ventricle (III V). At 10 ng, 1 ng, and 0.1 ng of A II (0.2 ul injection volume), SFO injections were clearly the most effective, producing pressor responses of 24, 19, and 9 mm Hg with concurrent drinking of 7.6, 5.8, and 3.8 ml H_2O. Both effects were blocked by the A II antagonist, Saralasin Acetate (Norwich). Saline vehicle injections had neither dipsogenic nor pressor effects. Adjacent to SFO, VFC and III V injections at these doses of A II produced responses less than or equal to half of the SFO drinking and pressor responses. Further, mean SFO pressor latencies (from injection until onset of blood pressure increase) ranged from 4-13 sec; significantly longer latencies were recorded at the other two loci. Injections into SFO invariably produced a significant pressor response which was not secondary to the act of drinking. Smaller A II doses which, in some cases, did not elicit drinking did provoke a pressor response; further, the onset of the pressor effect always preceded the onset of water ingestion. It is important to note that SFO cannulae did not rupture ventricular ependyma at any point, and that ventricular A II injection was less effective than SFO injection of A II. Ventricular access of A II thus seems to be unnecessary for drinking or pressor effects. These results suggest that the neurons of one circumventricular organ, the SFO, may mediate both behavioral and physiological responses to A II, and establish that pressor activity emanates from this structure.

1125 INHIBITION OF LORDOSIS BY INTRACRANIAL IMPLANTS OF PROGESTERONE IN THE FEMALE RAT. B. L. Marrone*, J. F. Rodriguez-Sierra* and H. H. Feder* (SPON: W.B. Quay) Institute of Animal Behavior, Rutgers-The State University, Newark, NJ 07102.

Progesterone implants in the medial-basal hypothalamus (MBH) have been reported to facilitate lordosis in ovariectomized, estrogen-primed rats and guinea pigs. In the present set of experiments we examined the lordosis facilitatory and inhibitory effects of progesterone implants in the MBH of rats.

Ovariectomized rats were implanted with unilateral, double barreled cannulae aimed at regions in and adjacent to the MBH. One week after surgery implants of progesterone or cholesterol were inserted a) 1 hr prior to a priming dose of estradiol benzoate (EB, 5 ug/Kg) followed 44 hr later by 0.5 mg progesterone (concurrent inhibition) or b) 44 hr after a priming dose of EB (facilitation) followed by 0.5 mg of progesterone at 68 hr (sequential inhibition). All animals were allowed 10 mounts by a male rat at 44 hr and 48 hr after EB. Animals tested for sequential inhibition also received tests at 68 hr and 72 hr after EB. Lordosis quotients (lordoses/10 mounts x 100) were computed for each test.

No facilitatory effects of progesterone implants were observed in any site tested. However, both concurrent and sequential inhibition of lordosis were observed when progesterone was implanted in the MBH. Progesterone implants lateral, anterior, or dorsal to this region or cholesterol implants were ineffective.

Results show that the MBH is an area responsive to inhibition, but not facilitation of lordosis by progesterone. In addition, the similarity of sites responsive to concurrent and sequential inhibition suggest that these two inhibitory effects of progesterone on sexual behavior are achieved via the same mechanism.

1126 CORRELATIVE FLUORESCENCE-IMMUNOCYTOCHEMICAL LOCALIZATION OF MONOAMINES AND NEUROPHYSIN, VASOPRESSIN AND GONADOTROPIN-RELEASING HORMONE IN THE RAT AND MONKEY HYPOTHALAMUS. Thomas H. McNeill and John R. Sladek, Jr. Dept. Anat., University of Rochester School of Medicine, Rochester, N.Y. 14642.

A technique has been developed for the correlative localization of monoamines and neurohormones on sections of freeze-dried tissue in the mammalian hypothalamus. Adult male and female rats and monkeys were used for this experiment. Brains were excised after decapitation and the diencephalon was dissected and frozen in freon-22 prechilled in liquid nitrogen. Tissues were freeze-dried in a Sladek-Kontes freeze drier, exposed to paraformaldehyde vapors and embedded in paraffin. Tissues were sectioned at 10μm and mounted on glass slides for fluorescence examination, with adjacent sections mounted for immunocytochemistry. The unlabeled antibody peroxidase anti-peroxidase technique was used for the localization of neurophysin (NP), vasopressin (VP), and gonadotropin-releasing hormone (Gn-RH). The distribution of the immunoreactive precipitates for these neurohormones and the monoamine fluorophors was similar to what has been described previously in the rat and monkey hypothalamus using these two techniques separately. Catecholamine varicosities were seen, for example, within the preoptic area, the supraoptic (SON) and paraventricular (PVN) nuclei, the median eminence and elsewhere. Fluorescent perikarya of the A-12 and A-14 dopamine cell groups also were observed. Despite the absence of fixation prior to freeze-drying, NP, VP, and Gn-RH were localized in perikarya and axonal varicosities within the hypothalamus. Catecholamine varicosities were found adjacent to neuronal perikarya of the SON and PVN. This apparent axosomatic juxtaposition suggests a possible interaction between catecholamine terminals and NP-containing perikarya. NP and VP terminals were seen principally in the zona interna of the median eminence, however, beaded fibers were found in the zona externa next to the portal capillaries. Gn-RH terminals were seen in linear profiles adjacent to fluorescent tanycytes. This combined fluorescence-immunocytochemical technique provides, for the first time, a correlative method for the study of the interaction between neurotransmitters and neuropeptides on adjacent sections, which will allow for the further elucidation of the role of these substances in the regulation of the peripheral endocrine system.

1127 EFFECT OF D- AND L-AMPHETAMINE ON RAT SERUM PROLACTIN LEVELS. H.Y. Meltzer, M. Simonovic, R. Fessler, and V. Fang. Dept. of Psychiatry and Med., U. Chicago Schl. Med., Chicago, IL. 60637.

Secretion of prolactin from the rat pituitary is under tonic inhibition by dopamine (DA) released into the pituitary portal circulation. Thus, drugs which increase dopaminergic activity at the pituitary: e.g. L-DOPA, apomorphine, decrease rat plasma prolactin levels. Amphetamine (AMP) increases the release of DA, blocks reuptake of DA, and prevents its catabolism by inhibiting monoamine oxidase activity. Thus, AMP should decrease plasma PRL levels. However, Lu and Meites (Proc. Soc. Exp. Biol. Med., 137, 480, 1971) reported that D-AMP, 5.0 mg/kg i.p. markedly increased serum prolactin levels in female rats, while decreasing pituitary prolactin levels. However, Horowski and Gröf [Acta Endocr. (Kbh) Suppl., 199, 203, 1975] reported that D-AMP, 10 mg/kg subcutaneously, diminished the increase in serum prolactin produced by reserpine but not reserpine plus alpha-methylparatyrosine (AMPT), an inhibitor of DA synthesis. D-AMP itself had no effect on serum prolactin levels in male rats.

We have studied the effect of D- and L-AMP on male rat plasma prolactin levels to determine the relative potency of each isomer in antagonizing the increase in prolactin produced by RES and AMPT. This would help determine the relative effect of each isomer on dopaminergic mechanisms. D- or L-AMP in doses of 0.5, 1.0, 2.5, 5 and 25 mg/kg was given 3 1/2 hr after RES 5 mg/kg i.p. The increase in PRL was partially antagonized by D-AMP even at the lowest dose and was completely antagonized by all doses greater than 2.5 mg/kg i.p. L-AMP 25 mg/kg completely antagonized the increase in PRL produced by RES. Our results suggest that the effect of D-AMP on increasing DA levels at the pituitary is 5-10 times greater than that of L-AMP.

Neither D- or L-AMP, at doses up to 5 mg/kg i.p. had any effect on the increase in rat plasma prolactin produced by AMPT-methyl-ester 100 mg/kg i.p. given 30 min prior to AMP. On the other hand, apomorphine, 5 mg/kg i.p., and LSD, 0.1 mg/kg i.p., both DA agonists, readily inhibited the AMPT-induced increase in rat plasma prolactin. These results are consistent with other studies indicating D-AMP and L-AMP are indirect DA agonists while apomorphine and LSD are direct DA agonists.

Chronic treatment with D-AMP for 10 days with doses up to 10 mg/kg i.p. did not affect the ability of D-AMP to antagonize the increase in prolactin produced by RES 5 mg/kg i.p. This is in accord with previous results indicating that tolerance does not develop to the effects of D-AMP on DA mechanisms.

1128 EFFECTS OF AN ENDORPHIN ANALOG ON THE HABITUATION OF AN INNATE FEAR RESPONSE IN GOLDFISH. Gary Michell*, Richard D. Olson, Abba J. Kastin, Gayle A. Olson*, Dolores Montalbano*, and David H. Coy*. Dept. of Psychology, Univ. of New Orleans, New Orleans, LA 70122

After an initial adaptation period in a tall, narrow tank, goldfish typically swim up and down at a fairly constant rate. If a loud buzzer is sounded during the ascent, however, the fish will either become immobile and remain near or actively swim to the bottom of the tank. Upon repeated experience with the buzzer, this innate response habituates and the rate of ascent and descent gradually approaches baseline.

Using this paradigm, fish were administered a 5 µl (8µg/kg) IP or ICV injection of the endorphin analog (D-Ala-2-β-endorphin) or the diluent control. Half of each endorphin group was tested without the buzzer as a control for immobilization. Results indicated that while the latencies of ascent increased reliably for all endorphin groups, they were not significantly different from each other. Thus it appeared that the primary effect of endorphin was immobilization. For the fish exposed to the buzzer versus those not exposed to the buzzer, latencies after endorphin were virtually identical when collapsed over trials. In addition to the typical trials effect indicative of habituation, a reliable peptide-by-trials interaction was obtained due to the very long initial latencies and the short terminal latencies. A significant injection-by-trials interaction appeared to be accounted for by an intense effect of the peptide in ICV groups at the start of testing followed by a rapid dissipation over trials. Activity scores obtained during a 15-minute adaptation period showed all endorphin groups to be reliably less active than controls. Furthermore, IP groups were less active than ICV groups. All activity differences disappeared during the subsequent testing period which followed immediately. Finally, total testing time did not differ between groups. These data were consistent with the basic finding that endorphin had an intense immobolizing action, and that IP injections required additional time to manifest the effect.

1129 PINEAL AND GONADAL RESPONSES TO LIGHT IN THE DEVELOPING RAT. Robert Y. Moore, Nicholas A. Vick and Richard L. Rapport. Dept. of Neurosci., Univ. Calif., San Diego, La Jolla, CA 92093.

The pineal gland in the rat exhibits an active metabolism of indolamines which is regulated by central circadian rhythm generating mechanisms, synchronized by the diurnal cycle of light and dark. The product of this metabolism, melatonin, is dependent upon the activity of the pineal enzymes, serotonin N-acetyltransferase (NAT) and hydroxyindole-O-methyltransferase (HIOMT). The NAT rhythm develops early, appearing by 6 days of age and reaching adult values by 21 days of age. In contrast to NAT, pineal HIOMT activity is high in animals maintained in constant darkness (CD) and low in animals maintained in constant light (CL; Wurtman et al, 1963) but shows no significant diurnal fluctuation (Klein, 1974). Pineal HIOMT activity reaches adult levels late in comparison to NAT (Klein and Lines, 1969).

The present study was carried out to determine if a relationship exists between the development of the pineal HIOMT response to light and gonadal function in the rat. Two groups of pups were used; one consisted of animals raised from birth in CD and the other in CL. Each group contained a subgroup of sham operated pups and a group of pinealectomized (PX) pups. The operations were performed on day 6. Both CD and CL control animals show very low levels of pineal HIOMT activity until day 12 when an abrupt increase occurs. HIOMT activity then gradually increases in both CD and CL animals until day 32. At that point, CL animals exhibit pineal HIOMT of about 150 pmoles melatonin formed/gland/hr and this remains constant thereafter. CD animals show increasing pineal HIOMT between days 32 and 36 to approximately twice that of the CL animals. Female rats raised in CD show vaginal opening on day 43.8 ± .4 whereas CL female rats show vaginal opening on day 37.1 ± .1. CD-PX animals show vaginal opening on day 37.6 ± 1.2 co-pared to CL-PX, 36.2 ± .3. Similarly, ovarian weights were nearly identical in all groups, about 35 mg/100 mg body weight except for the CD sham operated group, 23.2 ± 1.2 mg/100 mg body weight. Male rats exhibit similar differences in seminal vesicle weight.

These data suggest that the pineal HIOMT response to light may play a significant role in the control of puberty in the rat. (Supported by USPHS Grant NS-12267)

1130 AUTORADIOGRAPHIC LOCALIZATION OF ^{3}H-ESTRADIOL, ^{3}H-TESTOSTERONE AND ^{3}H-DIHYDROTESTOSTERONE IN THE BRAIN OF THE LIZARD, ANOLIS CAROLINENSIS. Joan I. Morrell, David Crews[1]*, Arleen Ballin* and Donald W. Pfaff. The Rockefeller University, New York, New York; [1] Harvard University, Boston, Massachusetts.

The neuroanatomical pattern of sex steroid concentrating cells in the brain of the lizard, Anolis carolinensis, was demonstrated with the autoradiographic method. Studies in a wide variety of vertebrates (Morrell et al., '75) have shown that brain areas of greatest cellular concentration of sex steroids are frequently involved in neuroendocrine mechanisms of reproduction or sex behavior.

Healthy female and male (weight range 2.3 to 5.1 gms) Anolis were gonadectomized, and one month later the animals were injected with 4µCi/gm body weight of either ^{3}H-estradiol (9 animals), ^{3}H-testosterone (5 animals) or ^{3}H-dihydrotestosterone (4 animals) (S. A. 80-100 Ci/mMole). Two hours later the animals were sacrificed, the brains removed and frozen. Autoradiograms and control sections were prepared using the methods previously published by this laboratory. After five or nine months exposure the autoradiograms were developed, and scanned systematically.

After ^{3}H-estradiol administration many labelled cells were found in specific telencephalic and diencephalic structures. The largest number of labelled cells are seen in the medial and lateral preoptic areas; in the anterior, ventromedial and posterior areas of the hypothalamus; and in the amygdala. The anterior pituitary contains a large number of extremely heavily labelled cells. The medial and lateral septum and a cellular group just dorsal to the lateral forebrain bundle, at the level of the preoptic area contain large populations of labelled cells. Many labelled cells are found in the lateral telencephalic cortex, and in the ventral striatum between the lateral forebrain bundle and the amygdala. Some labelled cells are found in the dorsal and medial telencephalic cortex. The mesencephalon contains a number of labelled cells in the torus semicircularis, some in the tectum and in the tegmentum. The rhombencephalon contains labelled cells in several distinct groups, although the number of cells is small compared to the number in the forebrain.

After ^{3}H-testosterone or ^{3}H-dihydrotestosterone injection, locations of labelled cells are in general similar to those following ^{3}H-estradiol injection, but in most areas the number and/or intensity of labelled cells was clearly less. For all three hormones, no differences in concentration pattern were seen when males and females were compared. The nature of diencephalic and telencephalic sex hormone binding in Anolis reinforces the notion of a vertebrate-wide pattern of sex hormone uptake by neurons (see Morrell, et al., '75; Brain-Endocrine Interaction II, Karger).

1131 NEONATAL SUPRACHIASMATIC NUCLEUS LESIONS IN THE RAT: EFFECTS ON THE DEVELOPMENT OF CIRCADIAN RHYTHMICITY AND THE RETINOHYPOTHALAMIC PROJECTION. Sarah S. Mosko and Robert Y. Moore. Dept. Neurosciences, UCSD, La Jolla, CA 92093.

Bilateral ablation of the suprachiasmatic nucleus (SCN), the terminal nucleus of the retinohypothalamic (RH) projection, in the adult rat results in the loss of a number of circadian rhythms. In the present study, the SCN was destroyed in the neonatal rat to determine whether the developing RH projection would exhibit plasticity and innervate another hypothalamic nucleus and whether the developing CNS can establish circadian rhythms in the absence of the SCN. The SCN was ablated bilaterally in newborn rats prior to the arrival of the RH projection from the eye. When adult, females subjected to neonatal SCN lesions fail to show normal estrous cycles and exhibit long periods of constant vaginal cornification. Both females and males show a loss of circadian rhythmicity in locomotor activity and drinking. Autoradiographic analysis of the developing RH fibers reveals a high degree of specificity of the fibers for their normal target tissue. In the absence of the SCN, no evidence is found for an aberrant projection to other areas, e.g., nearby hypothalamic sites. However, partial SCN ablation often results in hyperinnervation of the surviving SCN fragment(s). In correspondence with the normal topography of innervation, retinal fibers retain a remarkable specificity for the caudal portion of the nucleus and some degree of preference for its ventral and lateral aspects. These findings emphasize the developmental significance of the SCN in circadian rhythm generation and demonstrate, first, a great developmental specificity in the RH projection and, second, that in contrast to other components of the visual system, neither sparing of function nor developmental plasticity occurs after early SCN lesions. (Supported by USPHS Grant NS-12267)

1132 CHEMOSENSITIVITY OF HYPOPHYSIOTROPIC NEURONS TO THE MICROELECTROPHORESIS OF BIOGENIC AMINES. R.L. Moss, M.J. Kelly* and C.A. Dudley*. Dept. Physiol., Univ. of Tx. Hlth. Sci. Cntr., Dallas, TX 75235.

Determination of the catecholaminergic and cholinergic sensitivity of neurons projecting from the medial-preoptic (MPO) and arcuate-ventromedial (ARC-VM) nuclei to the median eminence was undertaken due to the implied involvement of such neurons and putative transmitters in the regulation of anterior pituitary function. The action of norepinephrine (NE), dopamine (DA), serotonin (5-HT), acetylcholine (ACH) and glutamate (Glut) when applied in the immediate vicinity and in minute quantities via microelectrophoresis to single MPO and ARC-VM neurons was studied in the urethane anesthetized, ovariectomized female rat. Multibarrelled glass micropipettes were utilized for extracellular recording and for microelectrophoresis of the putative transmitters.

Four specific neuron types were identified by electrical stimulation of the median eminence, namely, antidromically identified (AI) MPO neurons, uninvaded MPO neurons, AI, ARC-VM neurons and uninvaded ARC-VM neurons. The major findings based on responsive neurons, i.e., those neurons which reacted to the drug application by an increase or decrease in spontaneous activity are reported. Examination of the data revealed that NE had different effects on neurons in the two areas studied. The majority of AI, ARC-VM (72%) and uninvaded ARC-VM (69%) neurons exhibited a marked increase in firing rate to the application of NE. However, responsive AI, MPO neurons were inhibited by NE application [(-)24%; (+)7%] and uninvaded MPO neurons had a similar percentage of excitatory (32%) and inhibitory (27%) responses. The influence of DA was not as clearly defined, although there was a slight trend towards excitation in uninvaded MPO neurons [(+)30%; (-)22%] and inhibition in AI, MPO neurons [(-)25%; (+)16%].

Results based on the testing with 5-HT showed it to have an inhibitory action on uninvaded MPO neurons [(-)43%; (+)13%]. Furthermore, ACH and Glut were shown to have an excitatory action on the majority of responsive neurons tested. The remaining neurons tested with either NE, DA or 5-HT displayed a similar number of excitatory and inhibitory responses. The findings obtained provide positive support for a catecholaminergic and cholinergic regulation of neurons projecting towards the median eminence, which are presumably involved in pituitary function. (Supported by NIH Grant #NS10434)

1133 EFFECT OF LIGHTING ON MATURATION OF NEURAL ELEMENTS CONTROLLING OVULATION IN RATS. Osamu Nakamoto and Nobuyoshi Hagino. Dept. of Anatomy, U.T.H.S.C.S.A., San Antonio, Texas 78284.

In rats (Sprague-Dawley) born in a light-dark schedule (LD), the onset of puberty is 39.4 days of age and regular estrous cycles and spontaneous ovulation are observed. Plasma estrogen is elevated on proestrus prior to ovulation. When 22 day-old rats are transferred to continuous illumination (CI), precocious puberty occurs at 33.7 days and anovulation and persistent estrus occurs as adults. However, when these rats mate under CI, ovulation is induced and pregnancy is possible. Rats from these litters born under CI show normal onset of puberty at 39.9 days and have regular estrous cycles with ovulation even though maintained under CI. These rats exhibit a regular pattern of plasma estrogen similar to that shown by rats maintained under LD. It seems likely that LD is a predominant factor in regulation of the estrous cycle and ovulation when rats are subjected to LD during gestation and through puberty. However, when rats are subjected to CI during these periods, light is no longer a regulatory factor in regard to ovulation and estrous cycles.

Further investigation was made to examine the biorhythm of sleep and wakefulness in rats born and reared in CI. Sleep and waking patterns were assessed by EEG recordings from chronically implanted electrodes in the frontal cortex and dorsal hippocampus, and EMG recordings from neck electromyographic electrodes, together with observation of animal behavior. Recordings proceeded for four consecutive days with one daily interruption to obtain vaginal smears. Rats born and reared in LD exhibit circadian rhythm of EEG slow wave sleep (SWS), alertness (A), and paradoxical sleep (PS). However, when these rats are transferred to CI, circadian rhythm of SWS, A, and PS is annihilated and, indeed, all rhythms disappear. In contrast, rats born and reared under CI demonstrate rhythmatic SWS, A, and PS, but these patterns approach a reversed circadian rhythm.

This evidence indicates that in rats born and reared in LD, the neural elements of the light receptive area effectively modulate the structures controlling either pituitary-ovarian function or circadian rhythm of SWS, A, and PS. Therefore, when the light receptive area becomes refractory by exposure to CI, biorhythm is annihilated.

It may be considered that in rats born and reared in CI, the light receptive area becomes ineffective and other activating systems take over regulation of the estrous cycle, ovulation, and biorhythm of sleep and wakefulness. Furthermore, the activating systems involved in certain control of gonadotrophin secretion, as well as biorhythm of sleep and wakefulness, may be masked by more active participation of the light receptive area in rats born and reared in LD. (Supported by NIH HD 10071).

1134 REDUCED LEVELS OF IMMUNOREACTIVE LHRH IN GENETICALLY OBESE MICE (ob/ob). Charles B. Nemeroff, Garth Bissette*, and John S. Kizer*. Biol. Sci. Res. Ctr., Depts. Pharmacology and Medicine, Univ. North Carolina, Sch. Med., Chapel Hill, NC 27514

The recessively inherited obese-hyperglycemic syndrome in mice is characterized by marked obesity, insulin-resistance, and reproductive dysfunction. Previous studies (Swerdloff et al. Endocrinology 98, 1359, 1976) indicated a disruption in the hypothalamic-pituitary axis as the cause of the sterility and hypogonadism. Our results suggest that ob/ob mice, unlike normal controls (+/+) or heterozygotes (ob/+) have significantly lower levels of immunoreactive LHRH in the hypothalamus. C57 Bl/6J ob/ob, ob/+ and normal controls were purchased from Jackson Laboratories and maintained in an air conditioned, controlled lighting (14 h light, 10 h dark) animal facility and fed laboratory chow and water ad libitum. The animals were sacrificed by decapitation and the hypothalami from representative groups (n=5/group) were rapidly removed, wet weight recorded and assayed for LHRH, TRH, SRIF, DA or NE. The releasing hormones were assayed by radioimmunoassay (RIA) as previously described (Kizer et al., Endocrinology 98, 685, 1976); the catecholamines were assayed by radioenzymatic methods (Coyle and Henry, J. Neurochem. 21, 61, 1973). The results are shown in the table below. Data is expressed as ng/mg wet weight ± SEM.

	Controls	N	ob/ob	N	p
NE	0.79 ± 0.1	5	0.85 ± 0.1	5	ns
DA	0.51 ± 0.1	5	0.48 ± 0.1	5	ns
TRH	0.27 ± 0.04	10	0.25 ± 0.03	10	ns
LHRH	0.07 ± 0.01	10	0.04 ± 0.01	10	<0.01
SRIF	0.24 ± 0.08	5	0.23 ± 0.07	5	ns

In contrast to previous studies (Lordin et al., Brain Res. 96, 390, 1975), we found no statistically significant differences in hypothalamic catecholamine levels between ob/ob and control mice. Immunoreactive levels of TRH and SRIF were also unchanged in ob/ob mice. However ob/ob mice contained almost 50% less hypothalamic LHRH than normal mice. Lean littermate controls (ob/+) did not differ from normal controls (+/+) in any of the parameters measured. These results suggest that diminished LHRH levels in the hypothalamus of the ob/ob mouse may underly the reproductive dysfunction observed in these animals. (Supported by NINCDS NS-05722, NICHD HD-03110 and NIMH MH-28899).

1135 INHIBITION OF RENIN RELEASE BY α-ADRENERGIC STIMULATION. Peter L. Nolan* and Ian A. Reid* (SPON: W.F. Ganong) Dept. of Physiology, U.C.S.F., San Francisco, CA 94143

The antihypertensive drug clonidine suppresses renin secretion by acting within the central nervous system to decrease renal sympathetic nerve activity (I.A. Reid et al., J. Pharmacol. exp. Therap. 192, 713, 1975). It has also been proposed that clonidine inhibits renin secretion by stimulating intrarenal α-adrenergic receptors (W.A. Pettinger et al., Circ. Res. 38, 338, 1976). In the present investigation, the effect on renin secretion of oxymetazoline, a potent α-adrenergic receptor agonist which does not cross the blood brain barrier, was studied. Experiments were performed in pentobarbital-anesthetized dogs in which changes in renal perfusion pressure were prevented by adjusting a suprarenal aortic clamp.

In 13 dogs, oxymetazoline (1 μg/kg i.v.) decreased plasma renin activity (PRA) from 23.7±6.5 to 15.4±5.1, 15.1±5.6 and 15.0±4.6 ng/ml/3h after 15, 30 and 60 min respectively ($P < 0.02$). Mean arterial pressure (MAP) increased transiently but returned to the control value within 15 min. Heart rate (HR) decreased from 131±8 to 119±8 beats/min ($P < 0.02$). In 6 dogs pretreated with the α-adrenergic receptor antagonist phentolamine (0.5 mg/kg i.v. at -45 and -15 min) and then given oxymetazoline (1 μg/kg), PRA decreased transiently from 36.8±9.2 to 29.4±6.0 ng/ml/3h at 15 min but had increased to 34.6±6.5 and 32.2±5.7 ng/ml/3h by 30 and 60 min respectively. MAP and HR did not change significantly.

In a second series of experiments, the effects of clonidine were studied. In 6 dogs, clonidine (30 μg/kg i.v.) decreased PRA from 22.1±7.8 to 13.5±4.8, 8.4±3.4 and 6.9±2.8 ng/ml/3h after 15, 30 and 60 min respectively ($P < 0.05$). MAP increased from 124±8 to 133±7 mm Hg after 15 min but then decreased to 104±4 mm Hg after 60 min ($P < 0.01$). HR decreased from 131±10 to 79±5 beats/min ($P < 0.01$). In 5 dogs pretreated with phentolamine (0.5 mg/kg i.v. at -45 and -15 min), clonidine (30 μg/kg) lowered PRA from 40.8±6.6 to 18.4±3.7, 12.4±2.3 and 8.3±1.6 ng/ml/3h after 15, 30 and 60 min respectively ($P < 0.01$). Phentolamine pretreatment did not antagonize the hypotension or bradycardia produced by clonidine.

These data indicate that stimulation of peripheral α-adrenergic receptors with oxymetazoline inhibits renin secretion. On the other hand the renin-lowering action of clonidine was not reduced by phentolamine and it is therefore unlikely that stimulation of peripheral α-adrenergic receptors contributes significantly to this response.

1136 RADIOIMMUNOASSAY FOR β-ENDORPHIN. Norio Ogawa*, Alberto E. Panerai*, Viktor Havlicek and Henry G. Friesen*. Dept. Physiol., Univ. of Manitoba, Winnipeg, Canada, R3E OW3.

β-endorphin (β-E), corresponding to aminoacid residues 61-91 of β-LPH, binds to the opiate receptor but the physiological significance of this peptide remains to be defined. A sensitive and specific radioimmunoassay (RIA) for β-E has been developed. Synthetic camel β-E (Peninsula Lab.) was conjugated with bovine serum albumin using glutaraldehyde. This complex was emulsified with Freund's complete adjuvant and injected into rabbits to generate antibodies. β-E was iodinated with ^{125}I using lactoperoxidase and H_2O_2 and purified on a carboxymethyl cellulose column using ammonium acetate buffers with a gradient from 0.002 to 0.6 M. Three or four radioactive peaks were eluted, the last peak exhibiting the greatest binding to antiserum. Antisera to β-E bound 55% of ^{125}I-β-E at a final dilution of 1:60,000 by the dextran-coated charcoal method. In the RIA, bound and free ^{125}I-β-E were separated by the double-antibody method. Sensitivity was usually 100 pg/tube. The cross-reactivity of this antiserum is <0.02% with Met^5-enkephalin, <0.01% with Met^5-enkephalin-amide (supplied by Dr. Niall), <0.02% with Leu^5-enkephalin, <0.01% with α-endorphin (supplied by Dr. Guillemin), <0.2% with β-LPH (supplied by Dr. Chrétien), 30% with human β-E and 0% with Naloxone, on a weight basis. Rat anterior plus intermediate and posterior lobes of the pituitary gland were incubated in Krebs Ringer bicarbonate buffer and the β-E concentrations were determined by RIA. The highest concentrations (20 fold greater) of immunoreactive β-E were found in the incubation medium from the posterior pituitary lobe. Immunoreactive β-E was also detected in rat brain using several different extraction methods. The absolute values differed markedly (5-10 fold) depending on the extraction procedure used. Acid extracts of rat pituitary and brain exhibited dose-response curves indistinguishable from that of synthetic β-E. (Supported by MRC, USPHS, and Non-Medical Use of Drugs Directorate, Canada.)

1137 EPILEPTIC DRUGS EFFECT ON ADRENAL CORTEX MATURATION IN THE RAT. Tony D. Okonmah*, Karam F. A. Soliman and Charles A. Walker. School of Pharmacy, Florida A&M University, Tallahassee, Florida 32307.

The effect of CNS stimulation was studied in relation to adrenal maturation. In this investigation, two different weanlings (day 22) Sprague Dawley female rats were placed on 14:10 light-dark cycle at a temperature of 23±1°C. At age 23 and 29 days, pentylenetetrazol (10.00mg/kg) was injected for three days in two groups, while the other groups were left as control. Blood samples were obtained for cortiscosterone determination every 4 hours along the 24 hour period. Result from both age groups indicate that pentylenetetrazol suppressed plasma corticosterone level. The peak level for the corticosterone release occurred during the dark phase in the CNS treated group. While pentylenetetrazol did abolish the corticosterone variation in the 23 day old rats, this was not true in the 29 day old rats. Corticosterone daily changes were correlated to the circadian variation in the ovaries and uteri weights. Peaks for both ovary and uterus occurred at the light phase in the control and the treated animals. In general, ovarian and uterine hypertrophy was observed in the pentylenetetrazol treated animals. The results from this work indicated that CNS stimulation can affect the adrenal corticosteroid diural rhythm and the maturation of adrenal-pituitary axis. Research supported by "NIH" grant, number RR8111.

1138 THE EFFECT OF CORTICOMEDIAL AMYGDALA LESIONS AND STEROID TREATMENT ON SERUM PROLACTIN LEVELS IN MALE AND FEMALE RATS. J.A. Peters* and R.R. Gala* (SPON: R.A. Barraco), Dept. Physiol., Wayne State Univ. Sch. Med., Detroit, MI 48201.

Pituitary prolactin secretion is known to be under inhibitory hypothalamic control, but the neuroendocrine regulation of this hormone by extrahypothalamic brain regions is poorly understood. The effects of bilateral radiofrequency lesions of the corticomedial amygdala (CMN) on serum prolactin (PR) levels were studied in adult male and female Sprague-Dawley rats, 250-350 g, housed under controlled lighting (14 hrs L; 10 hrs D) conditions. In one study adult males were lesioned 1 week after castration and injected either with 1.0 mg of polyestradiol phosphate (PEP), or no steroid 2 weeks later. Two weeks after PEP, castrated males (L_O), castrated PEP treated males (L_e), and similarly treated non-lesioned controls (C_O and C_e) were decapitated at 1100 hrs and 1700 hrs and serum PR levels measured by RIA. PEP significantly elevated PR in castrated males at both time periods. The positive feedback effect of estrogen on PR was significantly greater in L_e than C_e rats decapitated at 1100 hrs. A lesion in the absence of estrogen had no effect on basal PR levels in castrated males. In a second series of experiments, females were lesioned or sham lesioned 1 week after ovariectomy (OVX) and injected 2 weeks later with either 1.0 mg PEP or no steroid. Two weeks later the animals were bled either by decapitation or by aortic catheter at 1100, 1700, and 0400 hrs. PEP treatment elevated PR at all time periods when compared to OVX females, and produced a significant PR elevation at 1700 hrs. CMN lesions had no significant effect on basal or surge PR levels in OVX or OVX-PEP treated females. In another experiment, females were lesioned or sham lesioned 1 week after OVX and 3 weeks later injected with 1.0 mg testosterone propionate (TP) daily for 1 week prior to decapitation at 1100 and 1700 hrs. There was no effect of CMN lesion at either time period. TP induced a significant afternoon PR surge similar to that produced by PEP in OVX females. The 1100 hr PR levels, however, were significantly lower than those of OVX-PEP females and castrated PEP males, and similar to those of castrated males. Finally, neonatally androgenized (NA) females given 1.25 mg TP on day 3 postnatally were investigated as adults. Preliminary data in our lab indicates that bilateral CMN lesions lower the elevated serum PR levels of NA females to the levels seen in males. Our results suggest a role for the CMN amygdala in regulating the estrogen-induced elevation in PR levels in the male and NA female rat. The testosterone induced PR elevation does not appear to involve the CMN. (Supported in part by NSF Research Grant No. 74-17332, and by a WSUSM predoctoral fellowship to J.A. Peters.)

1139 CHANGES IN HYPOTHALAMIC LUTEINIZING HORMONE-RELEASING HORMONE (LH-RH) IN THE MALE GOLDEN HAMSTER IN RESPONSE TO SHORTENED PHOTOPERIODS. Gary E. Pickard. Neuroscience Program, Wis. Reg. Primate Res. Ctr. and Dept. Neurophys., Univ. Wis., Madison, Wis. 53706

Day length and testicular steroids interact to regulate the hypothalamo-adenohypophyseal neuroendocrine system involved in gonadotropin synthesis and secretion in the hamster. Shortened photoperiods (<12.5 hr/day) have been shown to be inhibitory to the reproductive system of the golden hamster (Mesocricetus auratus). This is reflected by the depressed serum gonadotropin levels accompanied by testicular regression. However, the site(s) and mechanism(s) by which non-stimulatory photoperiodic conditions inhibit the hypothalamo-adenohypophyseal neuroendocrine system are largely unknown.

Hypothalamic levels of LH-RH of adult male hamsters housed for 13 weeks either in long day (LD) (14:10) or short day (SD) (6:18) photoperiodic conditions were assessed by both radioimmunoassay (RIA) and immunocytochemical techniques. Specific antiserum to LH-RH was provided by S. Sorrentino, Jr. and the peroxidase-antiperoxidase (PAP) complex was supplied by L.A. Sternberger. Serum LH levels were monitered throughout the experimental period using a rat LH RIA system supplied by NIAMD.

Animals were sacrificed by decapitation and either the arcuate-median eminence (AR-ME) region was dissected out and homogenized in 90% methanol for RIA or the brains were fixed by immersion in Bouin's fixative for subsequent immunocytochemical examination.

After 13 weeks exposure to shortened photoperiods, serum LH and testes weight/100g body weight of SD animals were significantly reduced compared to LD controls. However, the AR-ME tissue of the SD males contained significantly higher concentrations of LH-RH assayable material compared to LD controls. In addition, LD castrates demonstrated decreased AR-ME concentrations of LH-RH compared to LD intact animals, but this decrease in hypothalamic LH-RH was not seen in SD castrates. Immunocytochemical examination of the LH-RH fiber system supported the RIA findings.

Male hamsters housed under non-stimulatory photoperiodic conditions demonstrated depressed serum LH values and testicular regression. The increased hypothalamic levels of LH-RH found in these animals suggest that one possible effect of shortened photoperiods on the neuroendocrine system may be to inhibit the hypothalamic release of LH-RH

1140 SOMATIC, BEHAVIORAL, AND REPRODUCTIVE DISTURBANCES IN MICE FOLLOWING EARLY ADMINISTRATION OF SODIUM L-ASPARTATE.
William J. Pizzi, Josephine M. Tabor* and June E. Barnhart*. Neuropsychology Lab, Northeastern Ill. Univ., Chicago, IL 60625.

Neonatal administration of the dicarboxylic amino acids glutamate and aspartate has been shown to produce both retinal damage and CNS lesions. This report presents data demonstrating that neonatal administration of aspartate can produce adult mice that are obese, have reduced body length, are hypoactive, show reproductive dysfunction and have reduced endocrine organ weights.

96 neonatal mice were given subcutaneous doses of sodium L-aspartate (ASP) or bacteriostatic saline from days 2-11 after birth according to a dose schedule which starts at 2.2 mg/g b.w. and increases to 4.2 mg/g b.w. by the last day of injection. Animals were placed on ad lib food and water until they reached 150 days of age, at which time both male and female ASP-treated animals weighed more than controls (males, C=16, vs. E=26, $p < 0.001$); females, C=25, vs. E=29, $p < 0.001$).

Female reproductive function was assessed by creating mating environments composed of 2 control females, 2 ASP-treated females and 1 control male. Male reproductive function was tested by pairing 1 ASP-treated male with 1 control female. All matings started when the animals reached 150 days of age, and ended at 180 days of age. ASP-treated females failed to become pregnant as often as control females (C=16 of 16 vs. E=2 of 14, $p < 0.005$). ASP-treated males also failed to impregnate control females as readily as did control males (C=8 of 8 vs. E=3 of 11, $p < 0.005$). ASP-treated females showed delayed vaginal canalization indicating a delay in sexual maturation.

Male animals were tested on 2 measures of locomotor and exploratory activity starting between 190 and 195 days of age. ASP-treated males showed significantly decreased activity in both the open field test ($p < 0.025$) and the Boissier Poke Test ($p < 0.01$).

Upon autopsy ASP-treated males had significantly shorter body lengths along with significantly lower weights of pituitary, thyroid and testes. ASP-treated females showed the same pattern with smaller and lighter ovaries. Neither group showed differences in adrenal gland weights when compared with controls. All ASP-treated groups had significantly heavier body weights at the time of autopsy, and showed large accumulations of adipose tissue throughout the body.

These results demonstrate that the neurotoxic properties of aspartate produce the same sequalae of deficits seen in glutamate-treated animals; namely, obesity, decreased body lengths, hypoactivity, reproductive deficits and endocrine dysfunction.

1141 ACUTE ELEVATION OF SERUM LUTEINIZING HORMONE INDUCED BY LOW SYSTEMIC DOSES OF POWERFUL NEUROEXCITATORY ANALOGS OF GLUTAMATE.
M.T. Price, J.W. Olney and T.J. Cicero. Washington University School of Medicine, St. Louis MO 63110.

Glutamate (GLU), a putative excitatory transmitter, destroys neurons in the arcuate nucleus of the hypothalamus (AH) when administered subcutaneously (sc) to infant or adult rats, a brain damaging dose being < 0.5 g/kg in infancy or > 2 g/kg in adulthood. Olney et al. recently reported (Br. Res. 112, 240, 1976) that sc administration of a non-brain damaging dose of GLU (1 g/kg) to adult male rats results in an acute elevation of luteinizing hormone (LH). If, as we postulate, this effect is mediated by the excitatory action of GLU upon AH neurons, it should be possible to reproduce it by sc administration of excitatory analogs of GLU, especially those known to be more powerful excitants than GLU. To test this hypothesis, we administered DL-homocysteate (DLH), N-methyl-DL-aspartate (NMA) and kainate (KA) [listed in order of increasing excitatory potencies] to 25 day-old male Holtzman rats in sc doses from 1 to 100 mg/kg. Nacl-treated control rats were included in each set of experiments. A total of 312 animals were studied, all being sacrificed either for LH serum determination by radioimmunoassay at 7 1/2 min after injection or for histopathological examination of the brain at 3 hours.

Each experimental compound significantly ($p < .001$) increased serum LH levels when compared to controls. The lowest effective doses defined as those doses which produced statistically significant increases in serum LH levels, were 5 mg/kg (KA), 16 mg/kg (NMA) and 50 mg/kg (DLH). At double these doses, NMA and DLH did not damage the 25 day-old rat brain but KA sometimes induced extensive spreading lesions; therefore, NMA and DLH may be useful neuroendocrine probes but KA is probably too toxic.

These findings, together with evidence from microelectrophoretic and ultrastructural studies, suggest that GLU and its analogs interact with excitatory receptors on the dendritic or somal surfaces of AH neurons to stimulate firing of these neurons. Since at least some AH neurons are thought to be dopaminergic, stimulation of these neurons by GLU-mimetic excitants could involve the release of dopamine (DA) from their axon terminals and a dopaminergic mechanism might mediate hypothalamic secretion of luteinizing hormone releasing hormone (LHRH) into the portal vascular system to effect pituitary release of LH. It should be of interest, therefore, to determine whether the LH elevating effects of excitatory amino acids can be suppressed by DA receptor blocking agents. Supported by U.S. Public Health grants NS-09156, DA-00259 and RSD Awards MH-38894 (JWO) and MA-70180 (TJC).

1142 EFFECTS OF INTRACEREBROVENTRICULAR INJECTION OF DOG AND ARTIFICIAL RENIN SUBSTRATES ON DRINKING, BLOOD PRESSURE, VASOPRESSIN AND ACTH SECRETION IN DOGS.
David J. Ramsay*, Ian A. Reid* and Lanny C. Keil* (SPON: J. Korenbrot). Dept. of Physiology, Sch. Med., UCSF, San Francisco, CA 94143 and Ames Research Center, NASA, Moffett Field, CA 94035.

Recent evicence indicates that the enzyme with renin activity in brain is not active at extracellular fluid pH. However, intracerebroventricular (IVT) injection of synthetic tetradecapeptide renin substrate (TDP) has been reported to cause drinking in rats. This has been interpreted as evidence for brain renin activity in vivo. In the present experiments, the effects of IVT injections of TDP and natural dog renin substrate on drinking, blood pressure and the secretion of vasopressin and ACTH were compared.

Injection of TDP into the third ventricle of 7 dogs in doses of 100, 250, 500 and 1,000 ng initiated drinking of 70±24, 253±78, 448±71 and 472±143 ml H_2O respectively in a 30 min period. The latency of the effect was 1-5 min, similar to angiotensin II (AII). The drinking following 500 ng TDP was reduced to 63±22 ml ($P < 0.001$) by IVT injection of 2 µg of the AII antagonist, saralasin, and to 130±83 ml ($P < 0.001$) by IVT injection of 12 µg of the converting enzyme inhibitor, SQ 20881. Administration of the renin inhibitor pepstatin (10 µg IVT), however, did not reduce the drinking to 500 ng TDP (488±152 ml). These results indicate that the dipsogenic action of TDP is mediated via the formation of AII by brain converting enzyme.

Injection of 250, 500 and 1,000 ng of renin substrate prepared from dog CSF did not cause drinking, suggesting that addition of natural substrate to the CSF does not result in AII generation.

In a second series of experiments in 7 pentobarbital anesthetized dogs, the effect of 500 ng TDP and 500 ng natural substrate on CSF AII blood pressure and plasma vasopressin and ACTH concentrations were compared. Hormone levels were measured by radioimmunoassay. Central administration of dog substrate had no effect on arterial blood pressure, plasma vasopressin or ACTH levels. Furthermore, it was not associated with the appearance of AII in CSF. Administration of TDP, however, increased CSF AII concentration to more than 8,000 pg/ml. Blood pressure increased by 18 mm Hg and there were highly significant increases in plasma vasopressin and ACTH concentrations.

These results fail to demonstrate renin activity in dog brain in vivo and indicate that the central effects of TDP are due to formation of AII by converting enzyme.

Supported by USPHS Grant AM 06704 and by the L.J. and Mary C. Skaggs Foundation.

1143 ORGANIZATION OF THE SUPRACHIASMATIC NUCLEUS IN THE ALBINO RAT.
Joseph N. Riley and Robert Y. Moore. Dept. Neurosciences, Univ. Calif., San Diego, La Jolla, Calif. 92093.

A direct projection from the retina to the suprachiasmatic nuclei (SCN) of the hypothalamus has been demonstrated in a number of species. Destruction of the SCN abolishes a number of circadian rhythms, suggesting that the SCN may function as a CNS generator of circadian rhythms. It seemed worthwhile, therefore, to examine the morphological organization of the SCN and the retinohypothalamic projection in detail. The organization of the SCN of Sprague-Dawley rats was examined in Nissl and Golgi-Kopsch material. The retinal projection to the hypothalamus was examined in autoradiographic material prepared after intraocular injections of 3H-proline or 3H-adenosine.

Each nucleus contains approximately 10,000 neurons. The cellular packing density is higher in the ventromedial region. The approximate maximum dimensions of each nucleus are 1.6 mm in length and 0.6 mm in diameter.

Most neurons have 2 or 3 primary dendrites that usually branch only once. Neurons appear to differ in the number of observed dendritic protrusions. The orientation of dendrites differs in various regions: ventral neurons usually have dendrites oriented parallel to the optic chiasm in both saggital and transverse planes; dendrites of dorsally located neurons usually are oriented dorsoventrally. Some evidence has been obtained in Golgi material that neurons located immediately lateral to the nuclei project to the SCN.

The autoradiographic material from intraocular injections of 3H-proline confirms and extends previous autoradiographic studies of the retinal projection to the SCN. The retinal projection is bilateral but heavier contralaterally. In addition to previously described projections to ventral regions, projections to the lateral regions of the SCN were observed. There appears to be no retinal projection to the first 400 µm of the nucleus. The projection is first seen ventrally, then ventrolaterally. The projection extends to the caudal portion of the SCN where numerous silver grains are present in a relatively cell free area surrounding the caudal pole of the nucleus. The lateral projection is denser and appears to extend further caudally on the side contralateral to the injection. The results from a preliminary analysis of 3H-adenosine material are consistent with the observations made on 3H-proline material, suggesting that the cells of the nucleus receiving the innervation are those in the ventrolateral part of the caudal three-fourths of the nucleus.
(Supported by USPHS Grants NS-12267 and NS-07086)

1144 MIDBRAIN CENTRAL GREY: AN EXTRAHYPOTHALAMIC SITE FOR LRH POTENTIATION OF LORDOSIS BEHAVIOR IN FEMALE RATS. Peter Riskind* and Robert L. Moss. Dept. Physiol., Univ. of Tx. Hlth. Sci. Cntr., Dallas, TX 75235.

Previous reports have demonstrated that subcutaneous administration of luteinizing hormone releasing-hormone (LRH) can facilitate lordosis behavior in estrogen-primed ovariectomized (OVX) and ovariectomized-hypophysectomized rats. In addition, microinfusion of 50 ng of LRH into the medial preoptic area (MPOA) or arcuate nucleus, but not into the lateral hypothalamic area or cerebral cortex can potentiate lordosis behavior in OVX estrone-primed rats.

Twelve OVX rats were implanted with 23 guage stainless steel cannulas in the midbrain central grey region under ether anesthesia. Each rat, which had demonstrated consistently high sexual receptivity with estrone-progesterone, was primed with 200 µg estrone sc. Forty-eight hrs later the animals were tested for preinfusion lordosis behavior (PRE) by mating with a sexually vigorous male for 15 mounts. Subsequently the rats were anesthetized with ether and infused with either 50 ng of LRH or 0.9% NaCl through a 30 guage stainless steel infusing cannula. The infusate volume of 0.5 µl was delivered over 60 seconds. One hour and 45 min later each rat was reintroduced into the mating arena and received 15 mounts (POST mating). Of 12 rats, 10 had higher lordosis-to-mount ratios (L/M) following LRH administration than with control. Luteinizing hormone-releasing hormone infusion significantly increased the ΔL/M (POST-PRE) over NaCl infusion alone: ΔL/M LRH-X=.594 SE=.081, ΔL/M NaCl-X=.30 SE=.079, $p < .002$.

Behaviorally active sites to LRH infusion within the hypothalamus correspond to regions of high LRH content. Since midbrain central grey receives afferents from MPOA and contains specific estrogen binding receptors, it may represent an extrahypothalamic locus for LRH potentiation of sexual behavior. These results support such an hypothesis. Further investigation will elucidate the physiologic role of this region in sex behavior, and its relationship to the previously demonstrated hypothalamic loci.

(Supported by NSF Grant #PCM76-10015)

1145 SEROTONIN RECEPTOR ANTAGONISM: SIMILARITIES AND DISSIMILARITIES TO THE ACTIONS OF PROGESTERONE ON THE SEXUAL BEHAVIOR OF THE FEMALE RAT. Jorge F. Rodriguez-Sierra* and Gary A. Davis* (SPON: A. I. Leshner). Wisconsin Regional Primate Research Center, University of Wisconsin, Madison, Wisconsin 53706.

The reduction of serotonergic activity has been postulated as a possible mode of action of progesterone (P) in the facilitation of sexual behavior in estrogen-primed rats (Meyerson, 1964; Acta Physiol. Scand. 248). This initial facilitation is followed by a period of refractoriness to further induction of lordosis by additional P. This "biphasic" effect of P has been attributed by some workers to interference with estrogen priming.

The serotonin receptor antagonist Methysergide (MS) is known to facilitate lordosis. This study tested whether MS also exerts a biphasic action similar to P. Ovariectomized rats pretreated with estradiol benzoate (EB, 10 ug/Kg) were used in all experiments. Ten mounts by a male were allowed to all rats at 44, 48, 68, and 72 hours after EB. Lordosis quotients (LQ, lordoses/mounts x 100) were calculated as a measure of sexual responsiveness.

Treatment with MS 42 hours after EB gave rise to lordotic responding at 2 hr (LQ=60) and 6 hr (LQ=35) later, while vehicle injections had no effect. A second injection of MS at 68 hours was ineffective in MS-pretreated rats, while vehicle controls responded to MS at this time (LQ=66). Studies with P gave results similar to MS.

Despite this similarity, we have found that P facilitates sexual behavior in rats inhibited by MS (LQ=85). Similarly, MS facilitates lordosis in rats inhibited by P (LQ=80).

In order to determine if hypersensitivity of serotonin receptors could account for the "biphasic" action of MS, the response of MS-treated rats to the serotonin receptor agonists Quipazine and 5-Methoxy-O Dimethyltryptamine is being determined.

These results argue against the possibility that the inhibitory action of P (or MS) is due to an interference with estrogen priming. Furthermore, they suggest that the facilitatory action of progesterone involves more than a serotonergic mechanism.

1146 LOCAL CEREBRAL GLUCOSE UTILIZATION FOLLOWING MICROINJECTION OF β-ENDORPHIN INTO THE PERIAQUEDUCTAL GRAY OF THE RAT. Osamu Sakurada*, Yasuko F. Jacquet and Louis Sokoloff. (SPON: G. Maloney). Laboratory of Cerebral Metabolism, NIMH, Bethesda, Md. 20014, and NY State Res. Institute for Neurochem., Ward's Island, NY 10035.

Recent reports have indicated that β-LPH(61-91) (also called β-endorphin, or the C-fragment of β-LPH), when microinjected into rat brain, results in sedation, catatonia and analgesia (Science, 194: 632, 1976). In the present study, we used the recently developed autoradiographic [^{14}C]deoxyglucose method, which measures rates of local cerebral glucose utilization (LCGU), to investigate possible changes in the functional activity of various brain regions which might be correlated with the behavioral state induced by β-endorphin microinjection into the periaqueductal gray (PAG) of the unanesthetized rat. Experimental rats with chronically-implanted cannulae in the PAG were microinjected with 4-8 µg of β-endorphin into bilateral sites of the caudal periaqueductal gray. Control rats with chronically-implanted cannulae in similar sites were injected with an equivalent volume of the vehicle (i.e., physiological saline) alone. The results revealed a tendency for generally reduced rates of local cerebral glucose utilization in the β-endorphin-injected group compared to the saline-control group, but only the medial and lateral geniculate bodies exhibited statistically significant reductions at the $p < 0.05$ level. Other than these structures no regions were found to be specifically affected at the present level of resolution possible with the method.

1147 RADIOFREQUENCY LESIONS IN THE ORGANUM VASCULOSUM LAMINA TERMINALIS (OVLT) BLOCK THE STEROID-INDUCED GONADOTROPIN SURGE. W.K. Samson* and S.M. McCann. Dept. of Physiology, Univ. of Texas Health Science Center at Dallas, Southwestern Med. Sch., Dallas, TX 75235.

Luteinizing Hormone Releasing Hormone (LRH) has been localized in the median eminence (ME) and OVLT of rats. In order to determine the significance of the rostral LRH concentration, radiofrequency lesions were placed in the OVLT of ovariectomized rats. Three days later, the rats received 5µg estradiol benzoate (E) in 50 µl corn oil subcutaneously at 10 a.m., followed two days later by 2mg progesterone (P) in .2ml corn oil subcutaneously at 10 a.m. Blood samples were collected via the jugular vein prior to lesioning, E injection, P injection, and six hours after P injection. Rats were decapitated eight hours after P, trunk bloods and pituitaries collected, and brains removed for histology and assay of LRH content by radioimmunoassay (RIA). Serum values of gonadotropins were determined by RIA. Rats with lesions restricted to the OVLT (n=12) completely lacked the steroid-induced FSH and LH surge seen in controls (n=14), operated controls (n=12), and sham controls (electrode placement but no lesion, n=12) ($p<.001$). Medial septal lesions (n=9) of the same size failed to block the steroid-induced gonadotropin surge. Pituitary content of gonadotropins was significantly greater in the OVLT lesioned rats than in all others. Brains were divided into three portions, anterior (including OVLT), posterior (including ME), and an intermediate zone. In OVLT lesioned rats, the tissue levels of LRH in all three zones were significantly reduced compared to all other groups. These results demonstrate that the rostral LRH containing elements are necessary for the positive feedback effect of gonadal steroids, and that the ME and intermediate zone LRH content is decreased by removal of the OVLT, suggesting the validity of the axonal transport theory for LRH delivery to the ME.

1148 A THYROTROPIN RELEASING HORMONE-LIKE MATERIAL IN THE RAT RETINA: CHANGES DUE TO ENVIRONMENTAL LIGHTING. James M. Schaeffer*, Michael J. Brownstein and Julius Axelrod (SPON: D. Dresher) Lab. Clin. Sci., NIMH, NIMH, Bethesda, Md. 20014

Thyrotropin releasing hormone (TRH) is present in many brain regions in addition to the hypothalamus. We have shown that TRH-like material (measured by radioimmunoassay) is present in the rat retina. Bioassays have confirmed the presence of TSH-releasing activity in retinal extracts. In addition the immunoreactive compound in the retinal extract co-chromatographed with authentic TRH on a Bio-gel P-2 column and was inactivated by pyroglutamate amino peptidase and serum peptidases. The concentration of retinal TRH is high during the daytime (200-300 pg/retina) and low at night (50-100 pg/retina). Rats housed in continuous darkness and killed at 1400 hours had low levels of TRH and conversely, rats housed under continual light and killed during night time had high levels of TRH. This data shows that changes in TRH concentration are dependent upon environmental light rather than an internal rhythm. Injection of rats with cyclohexamide (20 mg/kg) at the time the lights are turned on, prevents the light induced rise in TRH, suggesting that protein synthesis is necessary for the daytime increase. The function of TRH in the visual system is being studied.

1149 PITUITARY CATECHOLAMINES IN THE RAT: EFFECT OF PERIPHERALLY AND CENTRALLY ADMINISTERED 6-HYDROXY-DOPAMINE. W. J. Shoemaker, V. Andersson*, and F. E. Bloom. The Salk Inst., La Jolla, CA 92037.

Although the pituitary gland is known to contain both norepinephrine (NE) and dopamine (DA), only recently has the origin of these substances been investigated. The present experiments sought to determine quantitatively the proportion of each catecholamine (CA) contributed to the pituitary by peripheral sympathetic sources and CNS sources, and to establish the susceptibility of the innervation to 6-hydroxydopamine (6-OHDA). NE and DA determinations were performed by a modification of the radio-enzyme assay on freshly dissected anterior and neuro-intermediate lobes. In some experiments the ocular iris was also assayed; all samples were normalized for protein content. In addition, some animals were processed for fluorescence microscopy using a modified glyoxylic acid perfusion system. Albino male adult rats given either i.p. or intravenous (i.v.) doses of 6-OHDA (100 mg/kg:1 dose/week x 4 weeks) failed to show any loss of NE or DA from either pituitary lobe when compared to either NaBr injected or uninjected controls. The biochemical measurements were confirmed by fluorescence microscopy; 6-OHDA-treated rat pituitaries are indistinquishable from normals. The insensitivity of the pituitary to i.v. 6-OHDA occurs in animals that have iris NE depleted > 80% by the drug. The apparent discrepancy with previous reports (Bjorklund et al., Brain Res. 51: 171, 1973) of denervation of neuro-intermediate lobe blood vessels by surgical sympathectomy has a likely explanation: The loss of NE incurred by destruction of fibers to some blood vessels may be too little to detect by biochemical assay. In an attempt to destroy the CA fibers from CNS sources, rats were given 2 doses (200µg each) of 6-OHDA, 24 hrs. apart, either by the intracisternal route or via permanently implanted cannula in the 3rd ventricle. In both preparations no loss of DA or NE from either lobe could be detected (e.g., DA of neuro-intermediate lobe: cannula 6-OHDA= 18.6; NaBr=15.2; uninjected=22.4 ng/mg prot.). These results are compatible both with our previous demonstration that most diencephalic DA-containing cells are resistant to 6-OHDA, and, with other reports that these same hypothalamic cells are the origin of most pituitary catecholamines.

1150 ANGIOTENSIN INVOLVEMENT IN THE OSMOTIC CONTROL OF VASOPRESSIN RELEASE BY THE ORGAN CULTURED RAT HYPOTHALAMO-NEUROHYPOPHYSEAL SYSTEM. Celia D. Sladek and Robert J. Joynt*. Depts. Neurology and Anatomy, Univ. Rochester School of Medicine, Rochester, N.Y. 14642.

The organ cultured hypothalamo-neurohypophyseal system (HNS) has been used as an in vitro system for studying control of vasopressin (AVP) release. Each of these organotypic explants includes the supraoptic nucleus, median eminence, and neural lobe. The presence of viable supraoptic neurons in HNS explants maintained up to 9 days in culture has been confirmed by evaluating the histological and neurosecretory characteristics of the preparations. The HNS releases AVP at a constant rate in vitro and remains responsive to cholinergic and osmotic stimulation of AVP release. Additionally, angiotensin II is a potent stimulant for AVP release. Addition of angiotensin II to the culture medium at 10^{-6} or 10^{-5}M resulted in 3.8 and 4-fold increases in AVP release respectively ($p<.01$). Addition of saralasin acetate (P113), an angiotensin antagonist, blocked the response to angiotensin without significantly altering the basal rate of AVP release. Saralasin also blocked osmotically induced stimulation of AVP release. Increasing the osmolality of the culture medium from 285 to 300 mosmol/liter by the addition of NaCl resulted in a 3-fold increase in AVP release ($p<.01$). This was not observed when saralasin and NaCl were added concurrently. These data confirm previous observations of angiotensin stimulation of AVP release and suggest that angiotensin may be involved in the osmotic control of AVP release. Further experiments are required to elucidate the nature of this involvement.

1151 MEDIAL PREOPTIC AREA AND STIMULATION OF NEST BUILDING IN MICE. Burton M. Slotnick, Aldair F. Simoes-Fontes*, and Jose C. Simoes Fontes*. Psychology Dept., The American University, Washington, DC 20016.

Individually housed virgin female CF-1 mice were allowed unlimited access to cotton thread nesting material for 21 days prior to experimental manipulations.

Experiment 1 demonstrated that 50-60 mg pellets of subcutaneous progesterone resulted in a 5-10 increase in nest building behavior. This effect could be reversed by removal of the progesterone pellet.

In Experiment 2 progesterone was implanted into various hypothalamic sites in each of 26 mice. The implant consisted of a 29-gauge cannula with the cross sectional opening filled with crystaline progesterone. Four mice showed a dramatic increase in nest building within 4 days after implantation. Histological examination revealed that the implants in each of these mice were located in the medial preoptic area. Mice with implants just lateral or dorsal to the medial preoptic area showed a similar but delayed (5-7 days) increase in nesting. The remaining mice, with implants in the region of the paraventricular nucleus and ventromedial hypothalamus, showed no change in nest building. Implants in the third ventricle were without effect.

In Experiment 3 the effects of subcutaneous progesterone on nest building of mice with medial preoptic lesions were examined. As compared to sham lesioned controls, small lesions confined to the medial portion of the medial preoptic area effectively blocked the increase in nest building by subcutaneous progesterone.

Our results suggest that the medial preoptic area mediates the induction of nest building behavior by progesterone in mice.

1152 CYCLIC NUCLEOTIDES IN NEUROENDOCRINE FUNCTION: THE DOPAMINE AND CHLORPROMAZINE. M. Smyser* and Y. Clement-Cormier*, (SPON: R. Peterson). Dept. Neurobiology and Anatomy, Univ. of Tex. Md. Sch. at Houston, Houston, Tex. 77025.

The distribution of dopamine within the median eminence correlates well with the distribution of some releasing hormones associated with this area. Furthermore, dopamine has long been know capable of facilitating hormone release through an effect that has been localized in the median eminence. This paper reports the occurrence of a dopamine stimulated adenylate cyclase in the median eminence. A half-maximal increase in enzyme activity was observed with 5 μM dopamine. The β-adrenergic agonists l-isoproterenol had no significant effect on adenylate cyclase activity with concentrations as high as 1000 μ M. Apomorphine, known to mimic the pharmacological and physiological effects of dopamine, stimulated adenylate cyclase activity in the median eminence. Several different classes of drugs effective in the treatment of schizophrenia and with well known endocrinological side effects were found to be potent inhibitors of the stimulation by dopamine of the enzyme. The phenothiazine, chlorpromazine was found to be a competitive inhibitor of adenylate cyclase with respect to dopamine. The calculated inhibition constant (Ki) for chlorpromazine was 1×10^{-7} M whereas that for an even more potent phenothiazine fluphenazine was 7.5×10^{-9} M. These studies implicate a role for dopamine-sensitive adenylate cyclase in neuroendocrine function.

These results in the median eminence encouraged us to investigate the action of dopamine and chlorpromazine on adenylate cyclase in the pituitary. Evidence exists showing that certain pharmacologic agents including the phenothiazines can increase prolactin release from the pituitary. In addition, dopamine has been shown to inhibit the action of the phenothiazines on prolactin release. Using homogenates of a cloned pituitary tumor cell line (GH_3/C_{14}) which releases prolactin and growth hormone, dopamine was found to be ineffective in stimulating adenylate cyclase at concentrations up to 3×10^{-4} M. However, chlorpromazine at concentrations as low as 10^{-7} M resulted in significant stimulation of adenylate cyclase. A half-maximal increase in activity of the GH_3/C_{14} adenylate cyclase occurred with 1×10^{-6} M. In addition, the chlorpromazine derivatives 7-methoxychlorpromazine, 7-hydroxychlorpromazine and 8-hydroxychlorpromazine were found to mimic the stimulating action on adenylate cyclase whereas chlorpromazine-5-N, dioxide was virtually ineffective. These results considered with other data suggest that hyperprolactinemia resulting as an effect of phenothiazine treatment may be attributable to a direct action of these drugs to increase adenylate cyclase activity in prolactin containing cells of the anterior pituitary rather than through an action on dopamine-sensitive cyclase in this area. (Supported in part by grants from the Pharmaceutical Manufacturer's Associaton and Upjohn.)

1153 THYROTROPIN RELEASING HORMONE BLOCKS GROWTH HORMONE RELEASE INDUCED BY TRYPTOPHAN IN THE RAT. Eliot Spindel*, Michael Arnold*, Richard Wurtman and John Fernstrom (SPON: Walter A. Rosenblith) Massachusetts Institute of Technology, Cambridge, Massachusetts 02139.

Thyrotropin releasing hormone (TRH) has been shown to block the increases in serum growth hormone (GH) caused by morphine and pentabarbitol (Brown and Vale Endo. 97:1151, 1975). We now report that TRH also blocks the increase caused by the amino acid tryptophan. Injection of tryptophan (200 mg/Kg i.p.) into gentled Wistar rats at a time of day when we observe serum GH levels to be low (11:00 AM) caused a two to five fold elevation in GH concentration after sixty minutes. This increase in GH was completely blocked if TRH was injected (1 μg/Kg s.c.) 30 minutes before sacrifice. In one experiment, TRH alone caused a significant decrease in GH. Since tryptophan administration specifically enhances brain serotonin formation and release, our data provide additional evidence that a serotoninergic synapse influences GH release and suggests that TRH acts to inhibit the secretion of GH induced by activating this serotoninergic synapse. The locus of this inhibitory action of TRH may be within the brain.

1154 INHIBITION BY VENTROMEDIAL HYPOTHALAMIC DEAFFERENTATION OF 2-DEOXYGLUCOSE-AND IMMOBILIZATION-INDUCED RELEASE OF CATECHOLAMINES AND CORTICOSTERONE IN AWAKE RATS. C.L. Sun*, N.B. Thoa* and I.J. Kopin, (SPON: R.W. Colburn). Lab. of Clin. Sci., NIMH, Bethesda MD 20014.

Stressful stimuli evoke release of catecholamines (CA) and corticosterone (CX) by activation of the sympathetic adrenal medullary system and the hypothalamo-pituitary-adrenal axis. The afferent pathways by which they produce this activation seem to depend on the nature of the stimulus. The response to certain stresses depend on the integrity of the neural input into the medial basal hypothalamus whereas others (ether, insulin) do not (Makara et al., J. Endocrinol. 44: 187, 1969; Makara et al., J. Endocrinol. 47: 411, 1970). In the present study, the effects of 2-deoxy-glucose (2DG) were compared with immobilization (IMO) stress. Deafferentation (DX) of ventromedial hypothalamus (VMH) was performed in male Sprague-Dawley rats (450-550 gram). After 5 days, cannulae were implanted in their tail arteries for collection of blood. The next day, blood samples (0.5 ml) were obtained between 9:30-10:00 AM and 2DG (500 mg/kg, I.P.) administered or the animals immobilized and blood samples obtained after 15 and 45 minutes. Plasma norepinephrine (NE) and epinephrine (E) were assayed by a radioenzymatic method and CX by the micro-flurometry. After the experiments, the animals were decapitated and DX confirmed histologically. Plasma levels of CA and CX were similiar in sham and successfully operated undisturbed rats (NE, 350 pg/ml; E, 160 pg/ml; CX, 100 ng/ml). During IMO or after 2DG in sham-operated rats plasma levels of E were similiarly increased (10-fold and 12-fold, respectively) but NE levels were increased to a greater extent after IMO (4-fold) than after 2DG (2-fold). CX levels were similiarly increased with both stresses (4-fold). DX of the VMH resulted in a greater than 50% decrease in the response of plasma E to both IMO and 2DG. The response of NE and CX to IMO were also diminished to about 1/2, but there were no significant increases in plasma NE or CX after 2DG in the operated animals.

These results suggest that the adrenal medullary response to IMO and 2DG, indicated by the increase in plasma E, are partially mediated from sites outside the VMH, but that a significant response is possible when after DX. The effect of DX on the sympathetic (SYM) and adrenal cortical (AC) responses, indicated by plasma levels of NE and CX, vary with the nature of the stress. DX of the VMH almost completely blocks the SYM and AC responses to 2DG, but only partially blocks the responses to IMO. Thus the SYM and AC responses to 2DG appear to be mediated mainly by activation of sites outside the VMH while those of IMO are only partially controlled from such sites.

1155 MEASUREMENT OF SOMATOSTATIN-LIKE IMMUNOREACTIVITY IN BLOOD OF NORMAL RATS. Gloria Shaffer Tannenbaum*, Jacques Epelbaum*, Joseph B. Martin and Paul Brazeau*. Dept. of Neurology, McGill University, Montreal, Quebec H3G 1A4.

Somatostatin (SRIF), a tetradecapeptide originally isolated from the hypothalamus, has subsequently been localized in several peripheral tissues including gastrointestinal tract and pancreas. However, its role in normal physiology remains unclear. Progress in this respect has been limited by the inability to measure SRIF in biological fluids. The aim of the present study was to develop a technique for the measurement of SRIF in blood.

Sequential blood samples were obtained every 15 min for periods of 6h from freely-moving male rats bearing chronic venous cannulae. Each blood sample (0.45 cc) was rapidly withdrawn and added to a centrifuge tube containing Trasylol (400 K.I.U.) to inhibit enzymatic degradation. Following centrifugation, plasma was immediately extracted in an equal volume of 2N acetic acid, and frozen at -20°C until subsequent assay. All samples were assayed within 3 days. Plasma SRIF-immunoreactivity was determined by a sensitive, specific radioimmunoassay (Brain Res. 1977, in press). Plasma growth hormone (GH) levels were simultaneously monitored in all animals.

Preliminary studies revealed that SRIF-deactivated plasma (plasma left at 20°C for 24h and then extracted with acetic acid) exhibited significant displacement of binding (ranging from 21-46%) in our assay system. In order to counteract this non-specific effect of plasma, all subsequent determinations of plasma SRIF levels were obtained from standard curves containing deactivated plasma from each sampled animal. These values are reported as somatostatin-like immunoreactivity (SLI). Recovery of 1000 pg synthetic SRIF added to deactivated rat plasma averaged 85% when analysed in this manner. The half-life of SRIF in blood, determined by i.v. injection of synthetic SRIF, was found to be less than 4 minutes. The 6-h secretory profiles, obtained in 7 rats, were characterized by 3-5 intermittent bursts of SLI rising from undetectable (<96 pg SLI/ml) to peak values of 384-4800 pg SLI/ml. An increased frequency of SLI bursts was observed during trough periods of GH secretion. Administration of urethane (125 mg/100 g b.w. i.p.) to 5 rats, which suppressed GH to undetectable levels, resulted in a significant rise in SLI levels (mean 1.5h post-urethane versus mean 1.5h prior to urethane was 1758 ± 381 vs 721 ± 176 pg SLI/ml, $p < .02$).

These results suggest that SLI can be measured in blood. Precise estimation of SRIF in blood is difficult because of non-specific plasma effects. Urethane anaesthesia appears to suppress GH secretion by release of endogenous SRIF.

1156 PASSIVE IMMUNIZATION WITH ANTISERUM TO SOMATOSTATIN (AS-SS): EFFECTS ON THE DYNAMICS OF GROWTH HORMONE (GH), PROLACTIN (PRL), AND THYROID STIMULATING HORMONE (TSH) SECRETION IN CANNULATED RATS. L.Cass Terry, Jacques Epelbaum*, Paul Brazeau*, and Joseph B. Martin. Dept. Neurology, McGill Univ., Montreal, Quebec.

Somatostatin (SRIF), a tetradecapeptide originally isolated from the hypothalamus, is reported to inhibit the release of GH, TSH, and (in some reports) PRL. Passive immunization with AS-SS has been reported to result in inhibition of stress-induced GH suppression and augmentation of the TSH response to cold or TRF (thyrotropin releasing factor). However, there is little information that describes the effects of AS-SS on the dynamics of GH, PRL and TSH secretion in the undisturbed, basal state.

Chronically cannulated, male Sprague-Dawley rats were kept on a 12:12h light-dark cycle and housed individually in isolation boxes to reduce environmental stimuli. Rats received 1 ml of either AS-SS or normal sheep serum (NSS) iv at 0900h. Blood samples (0.4 ml) were removed every 15 minutes from 1000 to 1600h. Each animal was sampled for a similar period two days before receiving AS-SS or NSS which allowed two sets of controls; NSS and baseline (BL). Plasma GH, PRL, and TSH were measured by radioimmunoassay kits supplied by the NIAMDD.

Mean values of all samples in AS-SS treated rats over the six hour period demonstrated a significant elevation of TSH ($P<.001$), but not of GH or PRL. Analysis of episodic GH secretion revealed no change in the frequency of bursts. There was a significant elevation of GH trough levels ($P<.005$) in AS-SS rats, but no change in peak values. There was no discernible effect on episodic secretion of TSH or PRL. The binding capacity of serum from AS-SS animals was determined at 1000 and 1600h. Both samples exhibited high capacity to bind SRIF but there was a significant reduction in binding capacity at 1600h ($P<.05$) compared to 1000h.

Preliminary evidence indicates that electrical stimulation in the medial forebrain-lateral hypothalamic region of AS-SS treated rats results in GH release and implies the existence of a GH-releasing factor. These results suggest that SRIF exerts a tonic inhibitory effect on basal TSH and GH secretion. Thus, AS-SS elevates baseline levels of GH without affecting its pulsatile nature. The use of AS-SS to suppress SRIF effects may permit unmasking of GRF secretion.

(Supported by the Medical Research Council of Canada).

1157 THE EFFECT OF CASTRATION ON HYPOTHALAMIC SEROTONERGIC NEURONS. L. van de Kar*, Jon Levine*, and L.S. Van Orden III, The Tox. Ctr., Depts. of Pharmacology and Psychiatry, Univ. of Iowa, Iowa City, IA 52242.

Several studies (Ladoski and Noronha 1974, Fuxe, and Hökfelt 1974) have suggested a regulatory role for serotonin in the LH secretory system. This study was conducted to investigate a possible interaction between serotonergic neurons in the hypothalamus and the LH secretory system. Using a radioisotopic assay for serotonin (Saavedra et al., 1973), the steady state level of serotonin in several hypothalamic nuclei of male rats was increased when measured 7 days after castration. This effect was reversed by the administration of testosterone propionate. The increase in serotonin content could be due to increased synthesis, decreased degradation, decreased release of serotonin or any combination of these parameters. In order to elucidate the mechanism of increased serotonin content, male rats were injected with pargyline-HCl (75 mg/kg i.p.), a monoamine oxidase inhibitor, at 10, 20, or 30 minutes before decapitation and the rate of accumulation of serotonin in hypothalamic nuclei was examined. Any accumulation of serotonin would be due to continuing synthesis of neurotransmitter when degradation by MAO is inhibited. The rate of serotonin accumulation was markedly decreased in hypothalamic nuclei from castrated rats and returned to normal in castrated rats which were maintained on testosterone propionate. These results suggest that the increased serotonin content of hypothalamic nuclei after castration may be a result of MAO inhibition and initial MAO levels are important in interpretation of results.

1158 ELEVATED BLOOD PRESSURE AFTER PINEALECTOMY IN THE RAT. G. M. Vaughan*, R. A. Becker* and J. P. Allen. Dept of Medicine, The Univ. of Texas Health Science Center, San Antonio, TX 78284

The pineal gland may be involved in regulation of blood pressure. To test this hypothesis, the effect of pinealectomy on blood pressure was studied in 35 to 123 day old male Sprague-Dawley rats. Systolic blood pressure (BP) and pulse rate were detected by the onset of Korotkoff sounds recorded distally on the tail, and superimposed on the pressure record obtained by slowly deflating a proximally positioned pneumatic cuff.

In the first experiment, pinealectomy (Px) or sham (ShPx) was performed on day 43 and blood pressure measured over the following 20 days. There was no significant difference in mean BP in the Px compared to ShPx groups. Following administration of 1% NaCl as sole fluid source from day 96 to 123, BP was not significantly different in the two groups. However, Px rats drank 65 ± 3.2, whereas ShPx rats ingested 51.7 ± 5.1 mg/day ($p<0.05$), with no difference in body weight. There was no change in pulse rate after the surgical procedures.

In the second experiment, Px or ShPx was performed on day 55 of life. Ten to 20 days after surgery, there was greater rise ($p<0.05$) in the mean BP in the Px group (14.4 ± 2.3 mm Hg) compared to that following ShPx (6.9 ± 2.3 mm Hg). This difference continued into the period when 1% saline was used as sole fluid source (days 96 to 123). During this time 5/6 Px rats averaged a BP $\geq$ 150 mm Hg (range 141 - 171), whereas only 1/7 ShPx rats averaged 150 (range 129 - 150). Mean BP was significantly higher ($P<0.05$) in Px rats compared to ShPx. However, neither saline intake nor pulse was significantly different between the groups. These data confirm that pinealectomy (on day 55) may result in mild hypertension in the rat. Further, this is not primarily due to increased heart rate or saline intake.

1159 EMBRYONIC ESTRADIOL RECEPTORS FROM MOUSE AND RAT BRAIN. Christine C. Vito* and Thomas O. Fox. Dept. of Neuropathology, Harvard Medical School, and Dept. of Neuroscience, Children's Hospital Medical Center, Boston, Mass. 02115.

Sexual differentiation of the brain is influenced by sex steroids. Although the "critical period" of steroid responsiveness is thought to extend from late embryonic to early postnatal ages, the actual existence of sex steroid reception mechanisms in neonatal brain was established only recently.

The first demonstration of typical 4S-5S estradiol-binding macromolecules from neonatal mouse brains was achieved by fractionation with DNA-cellulose(DC) affinity chromatography. We have now developed "affinity-exchange" chromatography which allows us to qualitatively analyze specific estrogen receptors from embryonic brain cytosols free of the high capacity, low affinity estradiol-binding proteins. "Affinity-exchange" chromatography (1) exploits the affinity for DNA of estradiol-bound receptor to separate it from non-adhering macromolecules such as embryonic and neonatal estrogen-binding proteins and (2) permits the selective labeling of specific DC-adhering estrogen receptors with ^{3}H-estradiol via an exchange process at 30 C.

We present biochemical evidence that receptor-like, 4S-5S estradiol-binding macromolecules exist in embryonic hypothalamic-preoptic area(HPOA) and "brain"(whole brain minus HPOA) of both mice and rats. HPOA and "brain" cytosols were prepared from E16 (embryonic day 16) and E18 mouse and rat brains. Following an incubation with 200 nM non-radioactive estradiol, the macromolecular contents of each cytosol were chromatographed on a DC column and washed to remove the non-adhering proteins. Each DC column, containing the DNA-adhering proteins present in each cytosol, was subsequently loaded with ^{3}H-estradiol and incubated for 60 min at 30 C. After this "exchange," the now ^{3}H-labeled contents of each column were eluted and layered on sucrose gradients.

The resultant sedimentation profile obtained from each embryonic cytosol revealed receptor-like macromolecules with 4S-5S sedimentation rates. Other characteristics of these embryonic receptors, such as their apparent affinity for estradiol and DNA adherence, are also typical of cytosol estradiol receptors from neonatal and adult brain. The levels of estradiol receptor per mg of tissue appear to be less in E16 mouse HPOA than in adults. Also, the concentration of estradiol receptor in E16 and E18 mice and rats, as in neonates, appears to be similar in "brain" and HPOA whereas, in adults, the concentration is higher in HPOA.

1160 EFFECT OF ANTERIOR HYPOTHALAMIC CUTS AND ANTIBODY ADSORPTION OF LUTEINIZING HORMONE ON GLUTAMIC ACID DECARBOXYLASE ACTIVITY IN DISCRETE REGIONS OF BRAIN. Cleatus J. Wallis* and William G. Luttge. Dept. of Neuroscience, Sch. Med., Univ. of Florida, Gainesville, FL 32601.

Glutamic acid decarboxylase (GAD) was measured in 14 brain regions of female rats 30 days after either an anterior knife cut (AC) placed just posterior to the suprachiasmatic nuclei or sham surgery (SC). In both intact and ovariectomized AC rats, GAD activity was significantly reduced in the arcuate nucleus ($p<0.01$), anterior hypothalamus ($p<0.05$) and ventromedial hypothalamus ($p<0.05$) as compared to SC controls. While GAD was not reduced in the nucleus interstitialis stria medullaris of ovariectomized AC animals it was reduced in intact AC animals, possibly due to high levels of estrogen as indicated by constant estrus vaginal smears and large uterine weights.

Ovariectomized rats were passively immunized by three daily tail vein injections of rabbit anti-rat LH antibody in a dose adequate to prevent ovulation in proestrus rats. Adsorption of LH resulted in reduction in GAD activity only in the ventromedial hypothalamus ($p<0.01$) and ventral tegmentum ($p<0.05$).

These results suggest that regional GAD activity may be modified by circulating levels of both protein and steroidal hormones.

1161 DISCRETE LESIONS OF SUPRACHIASMATIC PORTION OF PREOPTIC NUCLEUS OR SUPRACHIASMATIC NUCLEUS: INDUCTION OF CONSTANT ESTRUS AND CHANGES IN STEROID CONTROL OF GONADOTROPIN SECRETION. S. J. Wiegand*, E. Terasawa and W. E. Bridson*. Wisconsin Regional Primate Res. Ctr., Univ. Wisconsin, Madison 53706.

Large electrolytic lesions of the medial preoptic-anterior hypothalamic area (MPO-AH) or anterior hypothalamic deafferentation blocks ovulation and induces constant vaginal estrus in female rats. In the present study, the extent to which specific structures within MPO-AH must be damaged to induce this anovulatory syndrome has been established. Adult female Sprague-Dawley rats were housed under 14:10 light-dark cycle (light on 0500-1900) and animals showing regular 4 or 5 day cycles were selected. Small electrolytic lesions were placed in 4 loci within MPO-AH (Fig. 1), and the effect of these lesions on the vaginal estrous cycle observed for 4 weeks postoperatively. Experimental subjects evidencing disruption of normal estrous cyclicity were then ovariectomized, and effects of exogenous estrogen and progesterone on gonadotropin secretion examined. On days 15-19 post-ovariectomy blood samples were obtained daily at 1000 and 1700. Estradiol benzoate (5 µg) injection at 1200 on the second day of blood drawing was followed 48 hrs later by progesterone (1.5 mg). Plasma LH levels were determined by radioimmunoassay. Lesions A, B and C were effective in inducing constant estrus. Lesion D did not induce constant vaginal estrus, however, periods of prolonged diestrus were observed. At 1700, subsequent to progesterone injection, an LH surge was observed in control and sham-operated animals and in animals in lesion groups C (n=2) and D (n=6). The LH surge was not observed in animals with lesion A (n=5) or B (n=7). LH levels after estrogen but prior to progesterone injections were lower in groups A and B compared to controls. Thus, in addition to large lesions of the MPO-AH, small lesions restricted to the POSC or SC are sufficient to induce constant vaginal estrus. However, the destruction of the POSC alone, but not the SC alone, is capable of eliminating the LH surge in response to exogenously administered steroids, demonstrating that disruption of the LH surge and induction of constant estrus can be dissociated

(Supported by NIH Grant RR00167).

1162 ELECTROPHYSIOLOGICAL EFFECTS OF CORTICOSTERONE AND 5α-DIHYDRO-CORTICOSTERONE IN THE PONTINE RETICULAR FORMATION. D.R. Williams, I. Kraulis* and B.O. Dubrovsky. Allan Memorial Institute, McGill University, Montreal.

Intravenous injections of corticosterone (B), (.75mg/.5cc/300gm) consistently increased (30-40% above baseline amplitude; onset lag: 3-5 min.; recovery: 10-15 min.) the amplitude of the sciatic evoked potential (EP) in the pontine reticular formation (RF) of the adrenalectomized rat whereas an identical dose of its reduced metabolite, 5α-dihydro-corticosterone (DB) caused a decrease (17-67% below baseline amplitude; onset lag: 2-8 min.; recovery: 10-15 min.). Control injections of 20% Cremophor-El in saline had no effect. These data show a greater potency and more rapid onset of steroidal action but otherwise confirm our previous observations with intraperitoneal injection (Neurosc. Abs. no.687, 1975; Neurosc. Abs. no.945, 1976) and strengthen the proposition that the responsiveness of the RF may be differentially affected by circulating levels of endogenous steroids. Since CNS excitatory and depressant steroids have long been known to oppose the central effects of one another (Woodbury, J. Pharmacol. 105, 27: 1952) we have looked for a possible interaction of B and DB on central sites. B was injected immediately after a DB induced decrease in EP was evident. The following responses were observed: (i) B caused an immediate increase in EP. (ii) B caused a transient increase in EP, followed by a marked decrease and prolonged recovery. (iii) B prolonged the recovery time of DB without affecting the amplitude of the EP. B was also found to increase EP's or components of EP's which were unresponsive to DB, indicating that the two steroids do not necessarily interact at the same sites. Preliminary studies at the neuronal level with multi-barrelled micropipettes for the electroiontophoretic release of steroids dissolved in ethanol suggest that there are B and DB responsive cells in the pontine RF and that these may be differentially responsive to B or DB. Available data also indicate that neurons in the dorsal regions of the RF (AP post. 6.5-7.5; ML lat. 2.0-2.2; DV H 6.5-7.5)* respond with an increase in their firing rate to electro-iontophoretically applied B while neurons more ventrally located (AP post. 6.5-7.5; ML lat. 2.0-2.2; DV H 7.5-9.0) respond with a decrease and suggest that site specificity in the neuronal response to B may exist in the pontine RF.

Pellegrino and Cushman 1966

1163 AN AUTORADIOGRAPHIC STUDY OF ^{3}H-ANDROGEN RETENTION IN THE BRAIN OF A SONGBIRD (FRINGILLA COELEBS). R.E. Zigmond, R. Detrick*, and D.W. Pfaff. Dept. of Pharmacology, Harvard Medical School, Boston, MA 02115 and Rockefeller University, New York, N.Y. 10021.

Previous workers have shown that there is an overlap between the distribution of androgen concentrating cells in the rat brain and areas of the brain from which implants of testosterone can elicit mating behavior. We studied the distribution of androgen-concentrating cells in the chaffinch (a songbird) to see whether in an animal with a different set of androgen-dependent behavior patterns (and presumably a different neural substrate for such behaviors) a different distribution of androgen-concentrating cells would be found. We previously reported that an area of the midbrain suspected to be involved in the control of vocal behavior contained a large number of androgen-concentrating cells (Zigmond et al., 179: 1005, 1973). We now report our finding of androgen-concentrating cells in other areas of the chaffinch brain suspected to be involved in the control of vocalization and other aspects of mating behavior. Four male birds were castrated and after one to three days they were injected with 0.4 µg of [^{3}H] testosterone (91 c/m mole) intramuscularly. An hour later the birds were killed, their brains quickly removed and frozen, and six micron coronal sections of the brain were cut at -19°C. The sections were placed on slides precoated with emulsion and exposed for about 5 months at 4°C. The autoradiograms were then developed and stained with cresyl violet and the distribution of labelled cells was analyzed quantitatively in over eighty sections. A labelled cell was defined as one which had at least five times the density of reduced silver grains over it as found in areas between cells. (Extensive background counts demonstrated that such a cluster of grains would almost never occur by chance alone.) Labelled cells were particularly concentrated in certain regions of the brain including the magnocellular nucleus of the anterior neostriatum, the caudal nucleus of the hyperstriatum ventralis, the periventricular area of the medial neostriatum, the medial preoptic area, the magnocellular periventricular nucleus of the hypothalamus, the medial posterior hypothalamic nucleus, the lateral septum, the intercollicular nucleus of the midbrain and the hypoglossal nucleus. Grain counting showed that the mean number of grains per cell varied in different brain regions.

The results indicate a substantial overlap between the distribution of androgen-concentrating cells and the distribution of neurons thought to be involved in the control of a number of androgen-dependent behaviors in the chaffinch.

NEUROETHOLOGY

1164 THE NEUROETHOLOGISTS HANDICAP: THE CONCEPTS OF FIXED ACTION PATTERNS AND BEHAVIORAL HIERARCHIES. K. Bellman*(Spons: W. Heiligenberg). Dept Psychology, University of California, San Diego, 92093.

The concept of fixed action pattern (FAP) was developed in order to describe the consistency of an animal's behavior. Though primarily a descriptive term, it possesses strong organizational connotations. These are apparent when the FAP is used as the "minimal unit" of behavior. It is what is being selected, maintained and sequenced with respect to other behaviors. A problem with this view is that when faced with competition between two FAPs, ethologists were forced to adopt the notion of behavioral hierarchies as a way of resolving the conflict. W.Davis (JCP,90:207-243,1974) defines behavioral hierarchies as "the organization of different and unrelated behavioral acts into an explicit priority sequence." Ever since these concepts have been formulated,Lorenz, Tinbergen and others have looked for their neural correlates. In so far as these concepts are inadequate,the neuroethologist's understanding of the neural substrates of behavior will be similarly deficient. The resolution of competition between partially incompatible actions is considered a major problem for a nervous system and a fundamental factor in the design of neural organizations. As a competition-resolving mechanism,the behavioral hierarchy is considered to be inadequate for several reasons. In order to test these criticisms,the competition-resolving capabilities of an animal known for FAPs was tested. Two species of lizards were placed in a series of conflict situations between two highly stereotypic behaviors: aggression and feeding. Results thus far show that both species of lizards when faced with conflict will not choose one behavior over the other as implied by behavioral hierarchies. Rather both species will modify the behavior patterns in several interesting ways. These modifications include timesharing or alternating between patterns and actual blending of postures into ones intermediate to the behaviors. The implication of timesharing and merging capabilities are discussed with respect to neural models of behavior.

1165 BEHAVIORAL ANALYSIS OF RANGE OF OBJECT DETECTION (ELECTROLOCATION) IN THE WEAKLY ELECTRIC FISH, APTERONOTUS ALBIFRONS. Rocco A. Bombardieri[1] and Albert S. Feng[2]. Neurobiol. Unit, Scripps Inst. Oceanography and Dept Neurosci., Sch. Med. UCSD, La Jolla, CA 92093

The 'respiration response', an unconditioned slowing of respiration in response to moving Plexiglas or aluminum rods, mediated by the electrosensory system, was used to measure the object detecting ability of Apteronotus albifrons (Apteronotidae, Gymnotoidei) in order to compare behavioral to physiological responses[3].

Respiration was recorded between an implanted electrode and a second electrode in the aquarium water, adjusted to 2K ohm-cm resistivity. Fish were held in a nylon mesh net in the center of a 27 X 121 X 27cm aquarium. All fish were blinded.

The strength of the respiration response is a function of object distance. The range of object detection is about 6 cm, which is greater than that reported for electroreceptors (2-2.5cm) but appears close to the range shown for cerebellar neurons (4-5cm)[3].

In an experiment in which responses to a 12mm metal rod were compared to those to a 19mm Plexiglas rod the smaller metal rod elicited stronger responses which is similar to results from electroreceptors where metal objects gave stronger responses[3].

In an experiment on object size a 3mm metal rod was compared to a 12mm rod and essentially similar responses were obtained. This may be contrasted to the electroreceptors where larger objects gave larger responses but is similar to the cerebellar neurons[3].

The significance of these data lies in their providing an opportunity to compare an animal's sensory performance from behavioral data to that from physiological recordings at two levels in the nervous system[3].

1166 EVOKED POTENTIALS IN THE BRAIN IN ELASMOBRANCHS AND SILUROIDS TO PHYSIOLOGICAL STIMULATION OF ELECTRORECEPTORS. Theodore H. Bullock. Dept. Neurosc. and Neurobiol. Unit, Scripps Inst. Oceanog., UCSD, La Jolla, CA 92093.

Averaged evoked potentials (AEP's) were recorded by metal semi-microelectrodes either manipulator-held in the exposed brain, or implanted. Quasi-homogeneous electric fields were created by constant current pulses or sine waves.

Sharks (Carcharhinus, Negaprion, Triakis) and the freshwater ray (Potamotrygon) were studied, extending the report of Platt et al., 1974, J. comp. Physiol. 95:323-355. A complex sequence of slow waves and spike bursts (averaged after passing through an inverter) depends for form and latency on brain locus (medulla, mesencephalon, telencephalon), current strength, polarity, orientation, sine wave frequency,and facilitation or antifacilitation from recent responses. Rays (6 genera) typically show longer latencies than sharks (5 genera). Both are typically longer than acoustic, shorter than photic latencies. AEP's show sensitivity down to 0.015 μv/cm in marine species (= 0.8 nA/cm^2). Potamotrygon in 70 Kohm·cm water is sensitive to <50 μv/cm (= 0.7 nA/cm^2). To sinusoidal stimuli the best response by a certain criterion is at 15-30 Hz in Carcharhinus, 5-15 Hz in Potamotrygon, but this depends on the stimulus regime and on the recording site.

Electroreception is now well known in a few catfish but it is not known how general this is among the diverse families of the large group of Siluroidea. I find a good AEP to weak electric stimuli in a species of each of these genera: Sorubim, Pseudoplatystoma, Goeldiella (Pimelodidae), Centrodoras, Oxydoras (Doradidae), Ancistrus (Loricariidae), Callichthys (Callichthyidae). All show responses in the mesencephalon, in the region of the torus semicircularis to electric fields of <2 mv/cm (70 Kohm·cm water) and often down to <0.15 mv/cm (= 2 nA/cm^2). Differences among the families are probable in discrimination of dipole orientation, position, and distance and of frequency of sinusoidal stimuli. 1167 EFFECT OF MIDBRAIN LESIONS ON FEMALE NEST-COO BEHAVIOR DURING THE BREEDING CYCLE. Jeffrey Cohen* and Mei F. Cheng* (SPON: R.L. Thompson). Inst. of Anim. Behav., Rutgers University, Newark, NJ 07102.

Nest-coo is a behavior pattern in which the ring dove assumes an oblique or squat position with its rump end up, flips its wings, and emits a coo-like sound. The performance of this behavior pattern by female ring doves coincides with the drastic growth of the ovarian follicle in response to male courtship, and it is estrogen dependent (Cheng,JCPP 83: 221, 234, 1973). The nucleus intercollicularis (ICo) region has been shown to be involved in the production of male song in a number of passerine species (Nottebohm, Stokes, and Leonard, JCN 165: 457, 1976). In the ring dove, the ICo region has been identified by autoradiographic methods as one that retains estrogen (Martinez-Vargas, Stumpf, and Sar, JCN 167: 83, 1976). Furthermore, local implantation of crystalline estrogen into this region elicits nest-coo behavior in the ovariectomized female ring dove (Cheng, unpub. data). We therefore made lesions in the ICo region to determine their possible effects on nest-coo behavior. Female ring doves of similar ovarian stage received either bilateral electrolytic lesions in the ICo region or sham lesions. Each female was then tested with a sexually active male (two hours, every third day) over an average of 27 days. The occurrence of various reproductive behaviors such as sexual crouch, copulation, and nest-coo were recorded. At the conclusion of testing, females were sacrificed to determine a) site of lesion, b) ovarian weight, oviduct weight, and follicle size. Some females with bilateral lesions of the ICo region failed to show nest-coo behavior. Other ICo lesioned females showed a significant increase in latency to nest-coo, compared to shams. Other reproductive behaviors (sexual crouch) were unaffected. The mean follicle size of ICo lesioned females did not change while that of sham animals showed a significant increase in response to male courtship. These data suggest the following: The ICo region is involved in the elicitation of the nest-coo and appears to exert some effect on the gonadal system. Alternatively the effect of ICo lesions on follicle size may suggest that behavior (nest-coo) itself has a direct effect on the female's own endocrine system.

1168 A ROLE FOR THE LARYNGEAL BRANCH OF CRANIAL NERVE X IN THE RELEASE CALL OF RANA PIPIENS. Carol Diakow and Alan DeFalco* Biology Department, Adelphi University, Garden City, New York 11530.

This study is one of a series on the neurobiology of reproductive behavior of the frog. It was designed to test for a role of the laryngeal nerve in the release call of Rana pipiens. Males and females were each tested 5 times by 30 sec of manual stimulation of the trunk and the number of release calls were recorded. Subjects then were subjected to bilateral or unilateral nerve section, or to sham operations, and retested 5 times. The mean of the mean number of pre operative release calls of the 29 males was 32.7. This was significantly higher than the 21.4 observed for the 26 females; therefore, the data for the males and females were handled separately. Results follow:

Mean ± s.d. Number of Release Calls in 30sec. (FEMALES)

	sham operation n=7	bilateral denervation n=7	right side denervation n=6	left side denervation n=6
PRE OP	21.2 ±10.5	21.0 ±8.4	24.0 ±8.5	21.4 ±12.6
POST OP	14.3 ±10.6	2.0 ±3.9	11.6 ±6.0	13.3 ±13.3

Mean ± s.d. Number of Release Calls in 30sec. (MALES)

	n=7	n=7	n=6	n=9
PRE OP	34.2 ±8.9	30.5 ±7.6	32.5 ±13.5	33.5 ±10.4
POST OP	30.9 ± 11.6	0.0	30.1 ±18.4	26.8 ±11.4

For sham operates, the pre and post op scores did not differ significantly. For each sex, analysis of variance indicates a significant difference among the post op scores, with the reduction in release calling after bilateral denervation being significantly lower than that for sham operates. Release call rate after unilateral denervation was not significantly different than that for sham operates. Based on these data, it is concluded that the laryngeal nerve must be intact, at least unilaterally, for Rana pipiens to maintain a normal rate of release calling.

1169 MERGING OF MODALITIES IN THE OPTIC TECTUM: INFRARED AND VISUAL INTEGRATION IN RATTLESNAKES. Peter H. Hartline, Michael S. Loop, and Leonard Kass. Neural and Behavioral Biology Program and Department of Physiology, University of Illinois, Urbana, IL 61801

In the superficial 500 μm of the optic tectum of Crotalus viridis, neurons are found which have only visual receptive fields (usually contralaterally driven). From 300-1200 μm, neurons driven by the contralateral infrared pit organ and neurons driven by either infrared or visual stimulation are found.

Most visual neurons respond best to introduction or movement of a dark object into a receptive field 5-25° across. Some have inhibitory areas, and some exhibit directional preference. Infrared neurons respond best to introduction or movement of a warm object into an excitatory receptive field 20-70° across the broadest axis. Response to onset of a sustained warm stimulus or removal of a cold one is a transient burst of impulses. Computer-scanned sensitivity contour plots show asymmetry of these fields. Some have inhibitory regions (also asymmetrical). Some infrared neurons exhibit directional motion preference.

Some bimodal neurons respond to either infrared or visual stimulation ("OR" units), and a receptive field could be found for separate stimulation of each modality. Others require concurrent visual and infrared stimulation ("AND" units), such as motion of the hand or a warm object in a lighted room.

Multimodal "OR" neurons have receptive fields whose locations are predictable from the multi-unit spatiotopic maps of the tectum for infrared and visual systems. These maps have similarly oriented axes, but important differences in magnification and in precise detail (Kass, Loop & Hartline, these abstracts). Consider a given tectal locus which receives input from different regions of space in the two sensory systems: a bimodal "OR" neuron at this tectal locus would have similarly disparate visual and infrared receptive fields. Evidently, bimodal neurons do not "correct" the spatial disparity between the infrared and visual maps.

These findings suggest that during development, retinal fibers spread out across the entire tectum to fill available sites, and that infrared neurons (whose composite receptive field is smaller than the composite visual field of an eye) similarly spread out to fill available sites in a different tectal layer. The mapping processes must be similar, but there is evidently no mechanism to bring infrared neurons representing one region of space to the same place where the corresponding visual neurons project or vice versa. Bimodal neurons take their input from a given tectal region, without correcting for the spatial disparity which exists between visual and infrared layers.

1170 ELECTRORECEPTION AND SPECIES RECOGNITION AMONG ELECTRIC FISH. Carl D. Hopkins. Dept. Ecology and Behavioral Biology; Univ. Minnesota; Minneapolis, Minn. 55455.

Gymnotoid and mormyriform electric fish produce and sense electric signals for object detection (electrolocation) and for social communication. Field studies of electric fish in Guyana, in Surinam, and in West Africa, show that the electric organ discharges (EODs) of sympatric species can be highly divergent. Those species with wave-like EODs tend to have divergent frequencies; those with pulse-like EODs tend toward divergent waveforms. Pulse EOD durations from fish within the genus, *Hypopomus* (Gymnotoidei) measure 0.8, 1.5, and 2.5 msec, for three species in Surinam; durations for those in the genus, *Brienomyrus* (Mormyridae) measure 0.3, 0.4, 0.6, 0.8, 1.2, 1.8, 2.5, and 8.0 msec, for the species in Gabon. Pulse durations appear to correlate both with preferred habitat, and with social spacing. Divergence of waveforms probably also occurs because coevolving species have needs for species recognition cues, and for channel privacy. While the species from these genera show a high degree of divergence, species from others are less diverse. Fourier analysis of pulse EODs reveals species-specific differences in the often complex power spectrum that are potentially significant physiologically in recognition.

Electrophysiological studies of electroreceptors among the *Hypopomus* species from Surinam confirm Bastian's findings (J. Comp. Physiol. 1976, 112:165) of two major tuberous electroreceptor types: pulse-marker units (short latency, single spike response to EOD) and burst-duration coders (longer latency, burst of spikes after EOD). Burst-duration coders have varied frequency responses: narrow band units are tuned to the peak frequency of the EOD spectrum; wide band units are tuned lower and more broadly, low pass units cut off at high, but not low frequencies (500 Hz). Pulse-marker units are also tuned to the peak frequency of the EOD spectrum. Each species has all four types, with differing frequency ranges correlating with EOD output.

Pulse-marker units and narrow-band burst-duration coders are thought to play a critical role in identification and recognition of species-specific EODs used in social communication.

1171 TELENCEPHALIC EFFERENT PATHWAYS AND FEEDING BEHAVIOR IN THE PIGEON. R.R. Levine* and H.P. Zeigler. Dept. Psych., Hunter College, CUNY, and Dept.Anim.Behav.,Am.Mus.Nat.Hist., New York, N.Y. 10024.

The present study examined the role of two extratelencephalic efferent pathways in the feeding behavior of the pigeon. The structures chosen for study, the occipitomesencephalic tract (OMT) and the septomesencephalic tract (SMT), arise in the archistriatum and hyperstriatum, respectively, and convey information to brain stem and spinal cord nuclei related to sensory systems (somatomotor and visual) involved in the exteroceptive control of feeding in this species. In addition, both tracts have been homologized with identified components of the mammalian pyramidal system.

Electrolytic lesions were placed in these tracts and their effects upon several measures of ingestive behaviors were examined. While there was no evidence for its direct involvement in drinking, OMT damage resulted in a reduced responsiveness to food which was manifested by periods of aphagia, hypophagia and decreased body weight. Furthermore, OMT birds evidenced a disruption of the consummatory response of pecking which was characterized by impairments in grasping (incomplete opening of the oral aperture) and pecking inaccuracy ("overshoots"). Finally, OMT damage temporarily abolished operant key-pecking reinforced with food. Resumption of key-pecking was marked by significant reductions in feeding and consummatory efficiency, which, in several cases, led to extinction of the key-pecking response. Lengthening the reinforcement intervals, permitting more feeding time, reinstated preoperative levels of key-pecking. However, all other behavioral measures showed persistent impairments. These findings indicate the OMT damage produces both consummatory (somatomotor) and "motivational" (responsiveness) deficits.

SMT lesions resulted in reduced food intake, but did not directly affect water intake. Unlike OMT birds, there were no decreases in responsiveness to food. Furthermore, there were no observable changes in the efficiency or accuracy of their feeding response and only transient reduction in operant responding. SMT birds, however, displayed inappropriate "sorting" behavior which suggests that the lesions may have affected visually controlled preference behavior.

OMT lesions produced feeding behavior deficits similar to those resulting from damage to central trigeminal structures previously implicated in the control of feeding behavior in the pigeon. In view of the anatomical connections between both sets of structures, these findings suggest that the OMT may be part of the pigeon's putative neural feeding system.

1172 EVOLUTION OF SOUND PRODUCTION IN A COCKROACH: STRUCTURAL BASIS AND BEHAVIORAL SIGNIFICANCE. Margaret C. Nelson[1] and Jean Fraser*[2], Dept. Neurobiology[1], Harvard Medical School, Boston, MA 02115, and Dept. Psychology[2], Brandeis Univ., Waltham, MA 02154.

In analyzing the mechanisms of evolutionary changes in behavior it is desirable to define both the role of the behavior in question and the neural/muscular elements involved in its control. We report an evolutionarily "new" behavior that is particularly amenable to such definition. The Madagascar cockroach, Gromphadorhina portentosa, produces audible hisses from a pair of modified abdominal spiracles that have lost their respiratory function. We have established that 4 types of hisses exist and that they serve a communicative purpose. We have also characterized morphological and physiological changes undergone by the modified spiracles during evolution, comparing them to serially homologous spiracles that retain a respiratory function.

The 4 types of hisses occur in differing behavioral contexts and differ in their acoustical characteristics. Adults and older nymphs of both sexes hiss in response to any sudden or disruptive stimulus. Adult males also hiss during courtship, copulation, and aggressive display. These 4 types of hisses (disturbance, courtship, copulatory and aggressive) differ acoustically from one another in absolute amplitude, amplitude envelope, and hiss-train characteristics. Thus, categorizing hisses either by behavioral context or by acoustical characteristics sorts hisses identically. In addition we have observed the effects of placing "muted" males, which are unable to hiss, in courtship or aggressive encounters. Muted males fail to copulate, although their courtship behavior appears normal. Muted males also lose a greater number of fights than predicted from their past performance. Thus several lines of evidence support the hypothesis that hissing serves as communication.

Because the modified spiracle is one in a population of serially homologous structures, one can determine which elements have undergone change and which have remained stable during evolution. Changes in the sound-production apparatus (4th spiracle) have occurred at several points. Morphological differences exist in the trachea, in the opener and closer muscles, and possibly in motoneurons, although the major branching patterns of the latter appear to have been conserved. The rhythmic relationship between ventilatory and spiracular motoneuron outputs also differs in the two classes of spiracles. Thus in this case it may be possible to specify in detail the cellular changes underlying the evolution of an ethologically significant behavior pattern. (Supported in part by NIH grant NS 11010 to Dr. J.G. Hildebrand and by NIH Training Grants NS 05731 and NS 07009.)

1173 TEGMENTAL INFLUENCES ON VOCAL PRODUCTION IN SQUIRREL MONKEYS. J. D. Newman, P. D. MacLean and R. E. Gelhard*. Behavioral Biology Branch, NICHD, NIH and Laboratory of Brain, Evolution and Behavior, NIMH, Bethesda, Md. 20014.

In testing the effects of various brain lesions on the display behavior of squirrel monkeys, abnormal vocalizations were observed following electrocoagulations placed in the diencephalic tegmentum. Spectrographic analysis of the vocalizations of such animals revealed changes ranging from the production of infantile sounds (otherwise found only in the first natal year) to an inability to utter certain elements of the vocal repetoire. The most notable effect was the persistent production of abnormal isolation peeps, including the addition of new harmonic components. The present findings indicate that the diencephalic tegmentum plays an important role in elaborating certain sounds of the squirrel monkey's vocal repetoire.

1174 SINGLE UNIT RECORDING FROM UNRESTRAINED CATS DURING NATURALLY-OCCURRING BITING ATTACK. C. A. Opsahl* (SPON: J. P. Flynn). Dept. Psychiatry, Yale Med. Sch., New Haven, Ct. 06508.

Extracellular recordings were made from 437 cells in five adult cats which spontaneously attacked mice. The cats were fed ad lib and thus did not usually eat the mice. Each cat was fitted with a microdrive assembly that permitted recordings to be made while the cat was unrestrained. The amplitude, duration, and waveform of the single unit activity suggested that the recordings were from cell bodies. Single unit activity was recorded from thalamus, hypothalamus (anterior, posterior, perifornical, far lateral, premammillary), zona incerta, fields of Forel, globus pallidus, amygdala, septum, anterior commissure, superior colliculus, central gray, midbrain reticular formation, and ventral tegmentum. As shown in Table 1, cells were found which increased baseline firing rates only during attack trials. Some cells were correlated with only one component of the behavior (e.g. viewing, pinioning, striking, or biting the mouse) whereas other cells were correlated with several components of the behavior. The specificity of each cell was determined by interspersing a large number of control trials among the trials when the mouse was presented. Sensory controls consisted of the presentation of visual, auditory, tactile, and olfactory stimuli, as well as trials when canned cat food was presented and consumed. Motor controls consisted of lifting the cat, passive and active head movements, leg retraction, and walking. In addition, a sixth cat which did not attack mice was recorded from under identical conditions. Of the 140 cells encountered in this cat, none changed firing rate to the presentation of a mouse. Single units that increased firing rates only during attack trials were found in two regions: the perifornical area of the lateral hypothalamus and the ventrolateral aspect of the midbrain central gray. Cells that increased firing frequency during feeding trials were located in perifornical LH and in the amygdala. It is suggested that these attack-related cells are involved in the integrated, directed behavior of the cat toward the mouse.

Table 1

Responsive only during attack on mouse	15
More Responsive during attack on mouse than during any other condition	13
Responsive only during feeding trials	4
Responsive to moving objects	58
Responsive to tactile stimuli	11
Responsive to auditory stimuli	6

NEUROMUSCULAR JUNCTION

1175 ANAEROBIC MAINTENANCE OF SYNAPTIC TRANSMISSION AT THE CRAYFISH NEUROMUSCULAR JUNCTION. Juan Acosta-Urquidi* and H.L. Atwood. Dept. Zool., Univ. Toronto, Toronto, Ont., Canada.

In the presence of 2,4 dinitrophenol (DNP, 0.4-0.8 mM), an uncoupler of oxidative phosphorylation, stimulation of the single excitor motor axon of the leg-opener muscle in the crayfish, Procambarus clarkii, leads to depression of synaptic transmission, indicating depletion of available transmitter stores. However, depression is generally not complete and considerable recovery can occur. When stimuli are delivered at 10-15 Hz, an initial potentiation of EPSP's occurs, followed after 7-14 min. by progressive depression which follows an exponential time course. The time constant of decay is of the order of 12 min., and varies for different synapse types. Most (95%) DNP rundowns level off at a low steady state of release (ca. 0.5 mv), which can continue for many minutes (up to 20-30) if axonal conduction block does not ensue. After a rest period (1 to 15 min.), another cycle of EPSP potentiation and decay can be evoked by further stimulation. Longer rest periods result in greater recovery, and 3 to 5 successive cycles can be achieved.

Maintained low-level transmission and recovery in DNP suggested that anaerobic production of ATP could be involved in the replenishment of releasable transmitter stores. To test this hypothesis, iodoacetate (IAA) at 10^{-4} to 10^{-3}M, was employed in combination with DNP.

Stimulation in IAA alone produced no depression. When IAA was added to DNP during stimulation, complete depression was achieved after one cycle of stimulation, indicating severe depletion of available transmitter stores. Allowing a rest period and then resuming stimulation led to minimal or no recovery. At most, EPSP's interspersed among failures were recorded over the first 1 to 3 min. of resumed stimulation. These results strongly suggest that maintenance of synaptic transmission during repetitive stimulation requires ATP, and that some of the necessary ATP can be supplied by anaerobic metabolism. 1176 EFFECT OF TETRAETHYLAMMONIUM BROMIDE ON THE ENDPLATE CURRENT OF FROG SARTORIUS MUSCLE. M. Adler, E. X. Albuquerque, M. E. Eldefrawi* and A. T. Eldefrawi.* Dept. Pharmacol. & Exp. Therap., Univ. Maryland, Sch. of Med., Baltimore, MD 21201.

The effect of tetraethylammonium bromide (TEA) was investigated on the endplate region of frog sartorius muscle using a conventional voltage-clamp technique. Endplate currents (EPCs) were recorded from glycerol-treated preparations at 22°C between -180 and +60 mV. Under control conditions, the current-voltage relationship was linear between +60 and -100 mV, and exhibited a small upward curvature with more extreme hyperpolarization. In the presence of TEA ($2x10^{-5}$ to $2x10^{-3}$ M) the current-voltage relationship became markedly nonlinear at hyperpolarized command potentials. With TEA concentrations of $1x10^{-4}$ M or greater, the current-voltage relationship was characterized by an initial linear segment, an intermediate nonlinear segment, and a region of negative conductance. The transition from linearity was dose-dependent; the linear segment extended from +60 to -90 mV at $1x10^{-4}$ M TEA, and from +60 to -40 mV at $1x10^{-3}$ M. Below $1x10^{-4}$ M the current-voltage relationship was still nonlinear, but without a region of negative conductance. The action of TEA was not measurably time-dependent, since similar current-voltage profiles were obtained with command potential durations ranging from 2 sec to 2 msec.

In addition to altering the current-voltage relationship, TEA, in the same concentration range, reduced the dependence of the EPC half-decay time (HDT) on membrane potential. The reduction in the voltage sensitivity of the EPC decay was enhanced with increases in TEA concentration up to $1x10^{-4}$ M, where the HDTs became approximately independent of membrane potential. Higher concentrations of TEA ($2x10^{-4}$ to $2x10^{-3}$ M) reversed the slope of the HDT-membrane potential relationship. The drug-induced alterations in the EPC were found to be independent of the initial holding potential, the interval between steps, and the sequence of potential changes. TEA was without effect on the EPC reversal potential and produced no significant lengthening in the action potential duration even at $2x10^{-3}$ M.

In concomitant biochemical studies, TEA ($4x10^{-4}$ M) inhibited the binding of [^{3}H]perhydrohistrionicotoxin to the acetylcholine receptor enriched microsacs (42% inhibition) and to the solubilized histrionicotoxin binding protein (55% inhibition) from Torpedo electroplax. These results suggest that TEA alters neuromuscular transmission by acting on the ion conductance modulator of the acetylcholine receptor at sites similar to those of the histrionicotoxins. (Supported in part by U.S.P.H.S. Grant NS-12063.)

1177 ACTION OF COLCHICINE, CYTOCHALASIN B, SODIUM THIOPENTAL AND DECANOL ON THE ACETYLCHOLINE RECEPTOR. Roger Anwyl* and Toshio Narahashi. Dept. Physiol. & Pharmacol., Duke Univ. Med. Ctr., Durham, NC 27710 (Present address: Dept. Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611).

The action of colchicine, cytochalasin B, sodium thiopental and decanol was examined on the extrajunctional acetylcholine (ACh) receptor of 5-10 day old denervated rat soleus muscles using intracellular recording techniques. The sensitivity of the muscles to iontophoretically applied ACh was 300-500 mV/nC. Perfusion of colchicine, cytochalasin B, thiopental or decanol all reduced the amplitude and rise time of the ACh potential in a manner dependent on the concentration. A 50% reduction in the amplitude of the potential was caused by 2×10^{-4} colchicine, 8×10^{-5} M cytochalasin B and 5×10^{-5} M thiopental. Decanol is insoluble in water, and a 1:10^4 mixture of decanol to saline caused an 80% decrease in the potential amplitude. Increasing the dose of ACh in the presence of colchicine, cytochalasin B, thiopental or decanol caused a large prolongation of the ACh potential, with the half-decay time increasing by up to 20 times, although little or no increase in the rise time occurred. Further increase in the dose of ACh caused the appearance of a second slow peak in the acetylcholine potential. Increasing the concentration of the perfusing drug also increased the prolongation of the decay phase, with decanol causing the greatest, and cytochalasin B the smallest, prolongation. The action of colchicine, cytochalasin B, thiopental and decanol resembles that found previously for local anesthetics. The site of action of these drugs cannot be determined from the present experiments, for although cytochalasin B and colchicine are widely used to disrupt respectively microfilaments and microtubules, they are also known to bind non-specifically to cell membranes, probably by partitioning to membrane lipids. In view of the similarity of action of the structurally diverse drugs used in the present study, we propose that it is most likely that all these drugs are exerting their effect on the ACh receptor by their non-specific interaction with membrane lipids. (Supported by NIH grant 14145).

1178 KINETICS OF CURARE ACTION AT THE FROG NERVE-MUSCLE SYNAPSE. David Armstrong* and Henry A. Lester, Division of Biology, California Inst. of Technology, Pasadena, CA 91125.

We have measured the time course of curare inhibition of the acetylcholine (ACh) response at the postsynaptic membrane of frog sartorious muscle. Curare and ACh were iontophoresed from twin-barreled micropipettes, and the muscle cell's response was recorded intracellularly with conventional techniques. Typical ACh sensitivities were 0.2-0.5 mV/pC. After a pulse of curare, recovery follows a roughly exponential time course independent of the level of inhibition. The rate constant ($1/\tau_{off}$) equals 0.46 ± 0.14 sec^{-1} at -85 mV and 22°C. After a sudden maintained increase in curare release, inhibition is established with an exponential time course whose rate constant ($1/\tau_{on}$) exceeds $1/\tau_{off}$. When the steady-state ACh response is inhibited to 1/n of its control value, $1/\tau_{on} = n(1/\tau_{off})$.

When we reduced the acetylcholine sensitivity at the endplate with cobra toxin, $1/\tau_{off}$ increased. The effect is quite variable, but on the average a ten-fold reduction in ACh sensitivity produces a four-fold increase in $1/\tau_{off}$. Thus the kinetics of curare inhibition depend on the receptor concentration, [R]. This suggests that the time course of inhibition reflects repeated binding of each curare molecule to several receptors as it diffuses within the cleft, rather than the molecular rate constants of the curare-receptor complex. As more receptors are eliminated with toxin, the measured recovery rate should approach the molecular dissociation rate, k_-, of curare from the receptor. We estimate that k_- exceeds 10 sec^{-1}; since curare's $K_D = k_-/k_+ = 4 \times 10^{-7}$ M, the bimolecular association rate constant must exceed 2.5×10^7 $M^{-1}sec^{-1}$. From equation 7 of Colquhoun et al. (1977 J. Physiol. 266, 388), $[R] = K_D(k_-\tau_{off} - 1)$. Then the receptor concentration in the cleft must exceed 10^{-5} M.

1179 PRESYNAPTIC EFFECTS OF ERYTHROSIN B ON NEUROMUSCULAR TRANSMISSION. George J. Augustine, Jr. and Herbert Levitan. Dept. of Zoology, University of Maryland, College Park, Md. 20742.

The anionic dye Erythrosin B (FD&C Red No. 3), a fluorescein derivative, was previously shown to alter the physiological properties of both the pre- and postsynaptic elements of the frog neuromuscular junction (Neurosci. Abstr. 2: 708, 1976). The frequency and mean amplitude of spontaneous miniature endplate potentials (MEPPs) as well as the mean amplitude of evoked endplate potentials were increased by addition of 20-100 micromolar Red 3. The membrane potential of the postsynaptic muscle fibers was also increased by comparable dye concentrations. Using standard electrophysiological techniques we have attempted to determine the mechanism(s) underlying the presynaptic action of Red 3. The frequency of MEPPs increased approximately exponentially with time after application of the dye. Within 5 minutes of perfusion with frog Ringers containing 10^{-4}M Red 3 the frequency increased 2-10 fold and after 30 minutes was 10-100 times greater than before treatment. The effects of brief exposure to moderate concentrations of the dye were reversible only with extensive washing with normal Ringers. The dye-induced increase in MEPP frequency also occurred when the junction was bathed in calcium-free Ringers to which 2 mM EGTA was added. The increase in frequency after dye addition to calcium-free EGTA medium was not significantly altered by increasing the external potassium concentration from 2.5 mM to 12.5 mM. The higher potassium concentration caused significant increases in MEPP frequency in normal Ringers, presumably by causing a depolarization-induced increase in calcium conductance and subsequent influx of calcium down its concentration gradient. Since the frequency of MEPPs increased even in the absence of external calcium we conclude that the dyes presynaptic action is not due to an increased influx of calcium. The fact that the MEPP frequency did not decrease when higher concentrations of potassium were added to calcium-free EGTA medium containing Red 3 indicates that calcium does not flow out of the terminal when calcium conductance is increased by the presence of high potassium. This suggests that the calcium gradient is not adequate for calcium efflux, either because the internal calcium is not significantly increased or extracellular calcium levels are excessive. The action of Red 3 may therefore be due to the release of subtle amounts of calcium stored in the presynaptic terminal or to some other mechanism which promotes synaptic vesicle-presynaptic membrane fusion. (Supported by NSF grant GB-43141)

1180 RELEASE OF ENDOGENOUS ACETYLCHOLINE FROM THE PERFUSED DIAPHRAGM. George G. Bierkamper* and Alan M. Goldberg, Dept. of Environmental Health Sciences, Division of Environmental Toxicology, The Johns Hopkins Univ., Baltimore, MD 21205.

A model for studying the release of endogenous acetylcholine has been developed using the isolated perfused rat hemidiaphragm. The left hemidiaphragm with intact phrenic nerve is dissected from 300 to 400 g rats and placed in 6mM HEPES buffer (pH 7.4, 23°C) containing (in mM):111 NaCl, 2.5 KCl, 2.0 $CaCl_2$, 1.0 $MgCl_2$ 11 glucose and 0.030 choline bromide. After cannulating the diaphragmatic vein, the preparation is mounted in a closed oxygenated chamber. The muscle is then perfused at the rate of 30-50µl per min. Experiments in which a permeating dye was used revealed that the entire muscle is perfused every 30 sec. at this perfusion rate. Paraoxon, an excellent inhibitor of acetylcholinesterase (AChE), cannot be used in this preparation since early experiments demonstrated that at concentrations sufficient to inhibit AChE it produces rapid degeneration of the muscle. Therefore, in subsequent experiments, Diisopropylfluorosphosphate (DFP, 1.5×10^{-5}M) was added to the perfusion medium for the first 30 min. giving total inhibition of AChE. For the remainder of the experiment physostigmine is maintained in the medium at a concentration of 7×10^{-6}M in order to sustain complete inhibition of AChE. This was verified by direct assay of AChE after homogenization of the muscle and also by complete recovery of radiolabelled ACh after perfusion through the muscle. Following either a condition of rest (spontaneous release) or stimulation (5/sec) of the phrenic nerve, the perfusate is collected and ACh measured by enzymatic radioassay. Preliminary studies indicate that during resting conditions the release of ACh is approximately 1 pmol/min and is increased 6 fold during stimulation. This preparation offers several distinct advantages over other conventional methods. The small volume of perfusion necessary to maintain the preparation facilitates the determination of released endogenous compounds. The ability to perfuse the preparation also allows maximal control for the application and study of xenobiotics. Further, the perfusion system increased the longevity of the preparation so that it is viable for at least 5 to 6 hours. (Supported in part by grants from NIEHS 00454 and 00034.

1181 SOME EFFECTS OF LEAD IONS ON TRANSMITTER RELEASE AT RAT NEUROMUSCULAR JUNCTIONS. Joel C. Bornstein* and Jackson B. Pickett* (SPON: R.A. Fishman). Depts. Physiol. and Neurol., U.C.S.F. San Francisco, CA. 94143.

Little is known about the effects of lead (Pb) on transmission at a mammalian neuromuscular junction (nmj). We have used conventional intracellular recording techniques to examine the effects of Pb on both evoked and spontaneous transmitter release at nmjs in the rat phrenic nerve-diaphragm preparation.

Pb causes a dose dependent reduction in the quantal content of endplate potentials (epps) evoked in a low calcium (Ca)/high magnesium bathing solution by 0.5 Hz suprathreshold stimulation. For example, 0.1mM Pb produces a total block of evoked release, while 5 micro-molar Pb reduces the quantal content by 30%-50%. This effect of Pb is reversed by increasing the extracellular concentrations of Ca ([Ca]) which suggests that the mechanism of action of Pb is similar to that of other divalent cations in antagonising the entry of Ca into the nerve terminal. This hypothesis is supported by the finding that 0.1mM Pb caused a marked shift to the right of the curve relating quantal content to [Ca].

In contrast to the effects of Pb on evoked release, the frequency of spontaneous release is accelerated by concentrations of Pb in excess of 0.05mM although this increase is considerably less than that produced by similar Pb concentrations at frog nmjs (Nature 243:354, 1973). Lead is known to inhibit the uptake of Ca into mitochondria (Brain Res., submitted) and it seems likely that this effect of Pb on spontaneous release is due to an increase in the cytoplasmic concentration of Ca similar to that produced by other inhibitors of mitochondrial Ca uptake (J. Physiol. 248:285, 1975).

Thus, Pb at concentrations equivalent to those seen clinically has significant effects on the properties of transmitter release at mammalian nmjs. However, it remains to be seen whether these acute effects can account for all the symptoms seen in chronic lead poisoning.

1182 CONTRACTILE PROPERTIES OF FAST AND SLOW MUSCLE FOLLOWING GLUCOCORTICOID-INDUCED MYOPATHY. B.R. Botterman*, P.F. Gardiner*, E. Eldred, and V.R. Edgerton. Depts. of Anatomy and Kinesiology, and Brain Res. Inst., UCLA, Los Angeles, CA 90024.

A striking feature found in steroid-induced myopathy is the selective involvement and atrophy of fast-twitch fibers. Since this fiber selectivity might lead to altered contractile properties, histochemical observations and the assessment of several contractile parameters in cat soleus (S) and medial gastrocnemius (MG) muscles were made following two weeks of daily injection (IM) of triamcinolone (4 mg/kg).

Mean muscle weights for S and MG were reduced by 18% and 37% respectively, when compared to control muscles. However, comparisons of muscle/body weight ratios revealed that the S ratio was unchanged, while that of the MG was decreased due to the treatment. In the MG, fast-twitch glycolytic fibers were reduced in cross sectional area to a greater degree (51%) than fast-twitch-oxidative glycolytic fibers (35%), with slow-twitch-oxidative (SO) fibers the least affected (33%). SO fibers in the soleus were reduced in area by 11%. The MG and S of the treated animals showed smaller absolute maximum twitch (P_t) and tetanic (P_o) tensions; however, Po, when expressed per gram of muscle or contractile protein, was not different between the groups for either S or MG.

Speed-related contractile parameters of S and MG were influenced by steroid treatment. Soleus muscles of treated cats had shorter contraction times (72.9 ±2.9 vs. 85.7 ±2.6 ms) and half-relaxation times (73.7 ±3.5 vs. 103.5 ±5.0 ms). However, MG showed longer contraction times(33.8 ±0.9 vs.29.9 ±0.6 ms) and half-relaxation times (26.6 ±1.0 vs. 22.6 ±0.5ms) in the steroid group. No change in either S or MG was seen for the maximum rate of tension development (%P_o/ms). Fusion of S occurred at higher stimulation frequencies while MG fused at lower frequencies compared to control muscles.

As shown by Riker et al. (Arch. Neurol. 32:688, 1975), S post-tetanic potentiation (PTP), which is primarily neurogenic in origin, was enhanced, but might be explained partly by decreased normalized P_t and twitch-tetanus ratios. Conversely, PTP in the MG, which is primarily myogenic, was decreased. Our findings suggest that steroid treatment has direct effects on muscular components of fast- and slow-twitch muscle fibers, as well as influencing neuronal excitability. In addition, the muscle specificity is not solely a function of fiber composition, since SO fibers in S and MG were not equally affected.

1183 NEUROMUSCULAR TRANSMISSION IN HUMAN CONTROL AND PATHOLOGICAL SINGLE MOTOR UNITS. William F. Brown, Hytham A. Kadrie* University Hospital, London, Ont., Canada

In humans, neuromuscular transmission is tested in clinics by measurement of the changes in the maximum compound potential or tensions evoked by presynaptic trains of supramaximal stimuli or, more recently, by measurement of the 'jitter' at individual junctions using the single fiber EMG electrode. Neither method, however, makes it possible to learn if motor units (MU) in human neuromuscular transmission disorders are attacked at random; or if not, the type and proportion of MU most abnormal.

The questions have been investigated by testing single MU by trains of presynaptic stimuli (frequencies 0.1 to 10 per second), ischemia and tetanic stimulation. Because there are established relations of MU surface voltage to tension and conduction velocity, MU low to high in peak-to-peak (p-p)voltage were tested. Control human MU have significants in the p-p voltage linked to reductions in the p-p duration, maximum at 10 per second but present at 1.0 per second; no significant differences in the low-medium or high surface voltage being observed. In neuromuscular diseases, decrements in the p-p voltage of single MU much more striking than in the corresponding maximum compound potentials were observed at stimulus frequencies of 3 and 10 per second. Decrements were clearly most pathological in the low surface voltage MU, units that had the longest latencies (adjusted to a standard distance). The predilection of SMALL MU occurred in myasthenia gravis (proportion of abnormal MU varied from 0 to 90% from patient to patient), motor neurone disease and peripheral nerve diseases having evidence of abnormal neuromuscular transmission.

Though the findings could suggest a neurogenic factor in myasthenia gravis, the universal selection of SMALL MU in all diseases tested to date could be interpreted by a hypothesis that neuromuscular failure occurs first in SMALL MU because even in health the margin for safe neuromuscular transmission is less in SMALL than larger MU, the result being higher risk of synaptic failure in SMALL MU even in diseases that attack MU and junctions at random.

1184 ACUTE EFFECTS OF ACETALDEHYDE ON MOUSE NEUROMUSCULAR JUNCTION- AN ELECTROPHYSIOLOGICAL STUDY. Peter L. Carlen, William A. Corrigall, and Allan L. Staiman. Neurobiology Lab., Dept. of Medicine (Neurology), Addiction Research Foundation, Toronto, Ontario, Canada. M5S 2S1.

Acetaldehyde, the first metabolite of ethanol, has been implicated in acute and chronic effects of alcohol. Effects of acute acetaldehyde were examined in vitro on the phrenic nerve-hemidiaphragm neuromuscular junction of the mouse at 20°C in a superfusion bath. The end-plate potential (EPP) evoked at 1/second stimulation was blocked at acetaldehyde concentrations between 3 - 25mM, and the quantal content (as measured by the failure method) paralleled the reduction in EPP height. During development of the EPP block, the EPP latency was increased. Acetaldehyde concentrations between 3 - 25mM were found to block the compound action potential (CAP) and the nerve terminal spike. Average times for complete reduction of the CAP and the EPP were 29.9 min. and 18.5 min. respectively. Miniature endplate potential (mepp) height and shape were unaltered at these concentrations, suggesting a purely pre-synaptic action. MEPP frequency was observed to 1) decrease only at lower concentrations, 2) decrease initially and then increase at higher concentrations or 3) increase only at high concentrations. The effect of acetaldehyde on mepps is therefore distinct from that of ethanol (in which case there is a monotonic increase in mepp amplitude and frequency with ethanol concentration. Average time of onset of mepp frequency reduction was 3.5 min., if it occurred. Average time for a mepp frequency increase was 14.4 minutes. All effects reported were completely reversible on removal of acetaldehyde. Bath-acetaldehyde concentrations were assayed using gas-liquid chromatography.

(supported by the Non-Medical Use of Drugs Directorate, Health and Welfare Canada / Medical Research Council of Canada.

1185 PROLONGED FACILITATION OF TRANSMITTER RELEASE IN NEUROMUSCULAR JUNCTIONS OF CRAB STOMACH MUSCLES. Milton P. Charlton*, C. K. Govind and H. L. Atwood (SPON: K. Livingston). Zoology Dept., University of Toronto, Toronto, Canada, M5S 1A1.

Facilitation of transmitter release was studied in neuromuscular junctions of the intrinsic stomach muscles (Gm8b) of the Blue Crab (Callinectes sapidus). Seven seconds following a single motor nerve impulse, transmitter released by a second stimulus was increased by as much as 40%. The maximum facilitation immediately following a stimulus was 300%. This facilitation decayed from its initial value along two exponential time courses with time constants of about 100 msec for the intial fast component and 2-5 sec for the secondary slow component. The decay of facilitation was unusually prolonged in these synapses in comparison with synapses in amphibians, squid and arthropods. Moreover, the time constant of decay of the slower component does not appear to be affected by changes in temperature as is the decay of facilitation in squid and toad synapses. The results support the idea that there are several different mechanisms which cause facilitation and its decay.

1186 INFLUENCE OF SUCCINIC ANHYDRIDE ON THE DECAY OF ENDPLATE CURRENTS EVOKED BY HIGH FREQUENCY STIMULATION. Jose del Castillo and Gladys Escalona de Motta*. Lab. of Neurobiol., Sch. Med., UPR, San Juan, P.R. 00901

Saji & del Castillo (J. Neurosc. Res. 1:437, 1975) observed that small organic molecules containing either the ester (-O-CO-) or the carboxylic anhydride (-CO-O-CO-) groups depolarize the endplate membrane of frog muscle. In addition, electro-osmotically applied doses of these compounds, which produce a depolarization of only a few mV, exert a marked potentiating action on the amplitude of iontophoretic acetylcholine (ACh) potentials. Similarly, a potentiation of the effects of bath-applied ACh was observed when these compounds were added to the external solution in concentrations of up to 1 mM. One of them, succinic anhydride (SA) was selected to study further the mechanism of action of this class of compounds.

While confirming all the above effects, we were surprised to find that SA (1 mM) has no significant influence on the average amplitude of the miniature endplate potentials and increases by a factor of only 1.1X the amplitude of the endplate potentials. This is in marked contrast with its potentiating action on the depolarizing effect of bath-applied ACh, (10 uM ACh; 1 mM SA) which increases, on the average, by a factor of 1.5X (range 1.2X to 2X). The conclusion was reached that SA does not act on the ACh-receptors but rather that it accelerates the inward movement of ACh by saturating binding groups located within the diffusional pathways through which ACh must pass on its way from the bath solution to the receptors.

To see whether SA would accelerate also the diffusion of ACh in the opposite direction (i.e. from the synaptic cleft to the bath) we have recorded the decay of the endplate currents (epcs) in frog muscles treated with neostigmine (3 uM). We used sciatic-sartorius preparations electromechanically uncoupled by pretreatment with 1.5 to 2.0 M formamide-Ringer's. From 1 to 4 stimuli, separated by 5 msec intervals, were applied to the nerve while recording the epcs with a two microelectrode voltage clamp system which held the transmembrane potential at -100 mV.

While the half-decay time of the first and second epcs are not changed by SA (1 mM), this compound significantly shortens the half-decay times of the 3rd and 4th epcs. This observation supports the conclusion that SA acts by decreasing the efficacy of a diffusional barrier located away from the ACh-receptors.

This work was supported by Grants Nos. NS-07464, NS-14938 and GM-05567-MRC from the U.S.P.H.S. Contribution No.73 of the Laboratory of Neurobiology.

1187 TEMPERATURE INDUCED ALTERATION OF MUSCLE TWITCH RESPONSE AND CORRELATED ULTRASTRUCTURAL CHANGES OF MOTOR ENDPLATES IN IN VITRO STUDIES. Anna B. Drakontides. Department of Anatomy, New York Medical College, Valhalla, NY 10595.

In vitro preparations are routinely employed for the study of many biological phenomena. Mammalian nerve-muscle preparations are maintained at temperatures ranging from 23-37C. Many investigators, however, have shown that the ambient temperature has a profound effect on the spontaneous release from motor nerve terminals in the frog, and in the frequency of miniature endplate potentials at mammalian neuromuscular junctions. The present in vitro studies show that ambient temperatures of 37C for periods in excess of 4 hours result in the "decay" of the twitch response and that correlated degeneration-like changes are evident at motor nerve terminals. The indirectly evoked isometric muscle contractile response to single supramaximal rectangular pulses of .05 ms duration, at .05 Hz was recorded from phrenic nerve hemidiaphragm preparations of albino rats (150-300 gms). After 4 hours at 37C muscle responses were reduced by 30% and by 8-10 hours by 85-90%. The twitch tension was still within 47% of initial control values after 10 hours in preparations maintained at 30C, while at 23C responses were 90% of initial control following 10-12 hours. A 50% reduction in twitch tension occured after 28 hours at 23C. An electron microscopic study of motor nerve terminals from in vitro diaphragm preparations maintained at 37C revealed structural alterations which were directly related to the degree of twitch tension loss. These changes included a reduction in numbers of vesicles, vesicular clumping, the appearance of membrane-bound clusters of vesicles, an increase in membrane profiles within terminals, mitochondrial swelling, and the presence of numerous vesicular profiles between the secondary junctional folds. All the motor nerve terminals samples from in vitro preparations at 23C sustained for periods as long as 20 hours were normal in structure. Continuous stimulation at .05 Hz was not the cause of changes seen in function and structure at 37C, since preparations maintained in vitro and intermittently monitored exhibited the same changes in twitch loss and morphological alterations. The changes seen at 37C probably reflect increased metabolic activity and energy requirements. In the evaluation of in vitro experiments, therefore, consideration should be given to the alterations that may be induced by the factor of the ambient temperature.

1188 STUDY ON THE MODE OF ACTION OF BLACK WIDOW SPIDER (BWSV) ON VERTEBRATE NEUROMUSCULAR JUNCTION. Alfredo Gorio*, Lee L. Rubin* and Alexander Mauro*. (SPON: F. Brink, Jr.). Rockefeller Univ., New York, NY 10021

Application of BWSV at vertebrate neuromuscular junctions produces, even in the absence of Ca^{++}, a transient increase in mepp frequency and leads eventually to a neuromuscular block and depletion of synaptic vesicles. Since artificial lipid membranes treated with B_5 (the fraction which is active on vertebrate neuromuscular junction) show a great increase in cation conductance, it has been postulated that the entrance into the nerve terminal of Na^+, in the Ca^{++} free medium, releases internal stores of Ca^{++}, thereby secreting neurotransmitter. Since glucosamine is impermeant both to the venom-treated artificial lipid membranes and the postsynaptic membrane of frog muscle, we assumed that it is also impermeant at the nerve terminal. Thus we used glucosamine as a Na^+substitute to test the hypothesis of the ionophore action of B_5. During perfusion in glucosamine Ringer's, of course, no electrical activity can be recorded. The recovery in Ringer's of the response is dependent on the perfusion time and the position of the muscle fiber. In surface fibers, after 30' perfusion in glucosamine Ringer's, mepps reappear in 30"-60" and epps a few seconds later. After 1 hour perfusion, the recovery time is of the order of 3-4 minutes. Ultrastructural analysis of frog cutaneous pectoris muscle fixed after either 30' or 60' in glucosamine Ringer's shows that nerve terminals retained their normal structure. When BWSV is applied in 0 Ca^{++}, glucosamine-Ringer's a good depletion of synaptic vesicles is already noticeable after 15'. After 60' the nerve terminals are depleted of vesicles and the mitochondria appear unchanged in number and structure. On the other hand when Ca^{++} is added to the Na^+ free Ringer's the mitochondria are very swollen. After 15' action of BWSV in glucosamine Ringer's no epps can be recorded and the mepps frequency resembles that at the end of the venom discharge; after 60' treatment only rare mepps can be observed. When muscles are fixed after 1 hour treatment with large doses of BWSV in 0.5 mM Ca^{++}, 4 mM Mg^{++} Ringer's, the nerve endings are greatly swollen and devoid of mitochondria. Most likely swelling and disaggregation of mitochondria are due to an enormous Na^+ entry. From these results we can conclude that BWSV can act in two ways at the nerve terminal: one is to open channels permeable to cations such as Na^+ and Ca^{++} and the other is to stimulate release by a mechanism, yet to be established, which may not involve the ionophore action.

1189 THE ACTION OF CHLORPROMAZINE AND PHENYTOIN ON MUSCLE RIGIDITY DUE TO CEREBELLAR LESIONS. Verne D. Hulce. Department of Pharmacology, Georgetown University, Washington, D.C. 20007

The potentiation of the action of chlorpromazine by phenytoin in reducing the extensor rigidity of decerebration was reported by Anderson and Raines (Neurol. 26:858,1976). Lesions to the anterior cerebellar cortex in cats also produce an extensor rigidity. This rigidity is evoked as a short acting phenomenon after stimulation and lasts up to two-minutes after each stimulation. Lesions were produced in the cerebellum by the aspiration of Larsell's lobules II to V by suction. To test, vestibular stimulation was produced by rotating the whole cat about the rostral-caudal axis or by rapidly lowering the animal. The time course and forces of extensor rigidity were determined from the peak force required to collapse the extended limb measured against a force transducer and recorded on a polygraph. Electromyograms were obtained simultaneously to assist in timing the duration of the evoked extensor rigidity. Chlorpromazine was given as a solution in saline by i.m. injection and phenytoin was administered via the i.p. route suspended in a 0.5% methyl cellulose solution. Both drugs were tested various times after dosing to find a peak effect. The effects of phenytoin and chlorpromazine were found to be distinctly different suggesting different modes of action. Chlorpromazine reduces, in a dose dependent manner, the peak force after vestibular stimulation. Phenytoin, in low doses, reduces the total time of extensor rigidity seen after vestibular stimulation but has no effect on peak force development. As specific examples of these effects, a dose of 40 mg./kg. of phenytoin reduced the time of extensor rigidity from one minute and 56 seconds to less than 5 seconds with no appreciable effect on the peak force. On the other hand, chlorpromazine at a dose of 2 mg./kg. had no effect on the duration of rigidity but reduced the peak force from 3.7 kg. to 1.0 kg. Preliminary studies on the pharmacological interaction of these drugs suggests that their effects are additive but over the two dimensions of force and time. The ability of one drug to potentiate the other in reducing decerebrate rigidity is not seen in the decerebellar rigidity model unless a force-duration product is considered as the dependent variable.

1190 CHARACTERISTICS OF NEUROMUSCULAR JUNCTION AFTER THE COMPLETE RECOVERY FROM DEPRESSION BY SUCCINYLCHOLINE. K. C. Kim. Dept. Anesth. Sch. Med., Indiana Univ., Indpls. Ind. 46202.

This study is to investigate the nature of neuromuscular junction (N.M.J.) after the muscle twitch height completely returned to the control height from the depression by succinylcholine (Scl). METHOD: Twelve mongrel dogs were anesthetized with pentobarbital 35 mg/kg i.v. Achilles tendon was severed and attached to the force transducer for continuous recording of the muscle twitch. The nerve to the gastrocnemis muscle was stimulated with a supramaximum stimulus every two seconds. Scl, edrophonium (Edp) and neostigmine (Nst) were administered in a 0.3 ml volume of saline solution. They were injected into an artery supplied to the gastrocnemis muscle. Edp was given at various intervals after the administration of Scl. RESULTS: When 0.2 mg Scl i.a. was given, the mean total time from the depression to the complete recovery of muscle twitch by Scl was 16 min $\pm$ 6. The muscle twitch was depressed when Edp was given. The depressing effect of Edp lasted for 19 min $\pm$ 11 after the muscle twitch had completely recovered from the Scl depression. The depressing effect of the Edp gradually shifted to the stage where muscle twitch had no response by Edp, then to the muscle twitch augmentation, which lasted for 37 $\pm$ 13 minutes. The augmentation period was determined by the time required to reach the control augmentation height of Edp from the muscle twitch reach to the control height with no response by Edp. The experiment was repeated with neostigmine 0.5 mg given i.a. 10 minutes before Scl administration; the depression, no response, as well as augmenting effect of Edp previously described was significantly prolonged than that of Scl (122% and 178% respectively). The mean total time for recovery of the control state from the neuromuscular blockade with neostigmine 0.5 mg and 0.2 mg Scl was 179 min., which was 2.7 times prolonged by neostigmine than that of Scl.

SUMMARY: This data suggests that this sequence of the characteristic changing of the N.M.J by Edp (depression, no response, and augmentation) after Scl or Nst with Scl could explain the inconsistent response by anticholinesterase to the dual blocks. A test dose of Edp can aid in ascertaining the status of the muscle. This will arrow a method of determining the usefulness of Edp in reversing the relaxation resulting from Scl.

1191 FORMATION OF THE MYOTOMAL NEUROMUSCULAR JUNCTION IN XENOPUS LAEVIS DURING NORMAL DEVELOPMENT: AN ELECTROPHYSIOLOGICAL AND FINE STRUCTURAL STUDY. R.W. Kullberg*, T.L. Lentz and M.W. Cohen. Dept. Physiol., McGill Univ., Montreal, P.Q. and Sect. Cytol., Sch. Med., Yale Univ., New Haven, Conn.

Spontaneous potentials, considered to be MEPPs, were detected by intracellular recording as early as stage 21, and by stage 24 they were observed in every embryo tested. Like MEPPs at later stages they were blocked by curare but not by tetrodotoxin. EPPs, subject to block by tetrodotoxin, were evoked by electrical stimulation of the spinal cord in embryos as young as stage 24 and occurred spontaneously as early as stage 22. The durations of MEPPs and EPPs were initially relatively long. Focal external recordings revealed an eight-fold decrease in duration during the course of development.

Nerve processes emerged from the spinal cord and contacted developing muscle cells as early as stage 21 but junctional specializations were not apparent and vesicles were rare even in stage 24 embryos. During the next 24 hr, between stages 25-36, vesicles increased in number and became localized towards the junctional surface of the nerve ending. Basement lamina developed in the cleft and postjunctional ridges and densities were observed. Individual muscle cells also became contacted by several nerve processes. By stages 48-52 there were fewer contacts on individual muscle cells, and Schwann cell processes partially covered the nerve endings. Gap junctions were observed between muscle cells throughout development but occurred less frequently at the later stages.

It is concluded that by the time they reach the muscle cells, or very shortly thereafter, at least some of the growing nerve processes can release transmitter and some of the muscle cells are sufficiently sensitive to acetylcholine in the region of contact to respond with millivolt depolarizations. These earliest functional contacts are however morphologically undifferentiated.

1192 EVIDENCE THAT β-BUNGAROTOXIN ARRESTS SYNAPTIC VESICLE RECYCLING BY BLOCKING COATED VESICLE FORMATION. N.L. Lassignal* and J.E. Heuser* (SPON: B. Libet). Dept. Physiol., Univ. of Calif., San Francisco, Calif. 94143.

While documenting the phospholipase action of β-bungarotoxin (β-BTX) on the frog neuromuscular junction, we observed that "coated pits" became abundant in some of the nerve terminals that we fixed at about the time transmission was blocked by the toxin (Neurosci. Abst. II: 718, 1976). Later, we noted that coated pits were also abundant in many of Tsai's electron micrographs of β-BTX treated rat diaphragms, especially the ones he obtained from rats that were dying from β-BTX injections (M-C. Tsai, Ph.D. Thesis, Taiwan Univ., 1975). We wondered if this meant that β-BTX enhances this sort of endocytosis, as one of its effects; or whether, on the contrary, β-BTX blocks the formation of coated vesicles and thus produces a "traffic jam" of coated pits.

One indication that the toxin might *block* the coated vesicle formation necessary for recycling of synaptic vesicles was an apparent contradiction in the early β-BTX literature: Chen and Lee first reported that synaptic vesicles had *disappeared* from the diaphragms they removed from rats that were dying from β-BTX injections (Virch. Arch. B Zellpath. 6: 318, 1970). But then they reported that synaptic vesicles were *normally abundant* in diaphragms they bathed in the toxin in vitro and did not stimulate (J. Pharm. Exp. Therap. 184: 339, 1973). Thesleff et al (Neurosci. 1: 175, 1976) observed the same difference while studying the effects of stimulation on the neuromuscular block produced by two other β-toxins closely related to β-BTX, and suggested that these two toxins might exaggerate vesicle disappearance during stimulation by blocking synaptic vesicle reformation.

We here report the results of stimulating frog cutaneous pectoris muscles one hour after they were placed in 2 μg/ml β-BTX in normal Ringer at 22°C. (1) Freeze-fractures of these muscles showed that stimulation led to a great increase in the proportion of nerve terminals that were covered with shallow coated pits -- that is, covered everywhere except at the active zones where exocytosis occurs. (2) Thin sections of these muscles showed that the plasmalemmal pits produced during stimulation in β-BTX were coated with a "basketwork" structurally similar to the "clathrin" that surrounds coated vesicles. (3) Histochemistry of HRP as a marker for endocytosis showed that in spite of all these coated pits, stimulation *did not* produce the usual uptake of HRP into coated vesicles and synaptic vesicles that it does in normal nerves. Such a total block of HRP uptake in β-BTX indicates that the proliferation of coated pits that we see represents *a block of endocytosis*. This further strengthens our idea that coated vesicle formation is the first step in synaptic vesicle recycling.

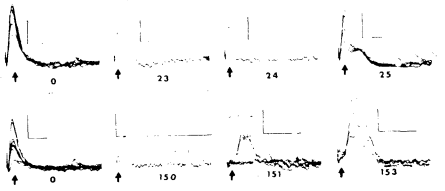
1193 PRESYNAPTIC EFFECTS OF CENTRUROIDES SCULPTURATUS VENOM(CSV) ON FROG NEUROMUSCULAR JUNCTIONS (NMJ). H.E. Longenecker, Jr., J. Bruck* and G.L. Longenecker, Depts. of Physiol./Pharmacol., U. of So. AL, Mobile, AL 36688

Previous investigators demonstrated that CSV contains neurotoxins that alter Na conductance of neurons causing repetitive firing. There are reports on curarized NMJ preparations of CSV induced repetitive firing; however, it was impossible to observe miniature (M) endplate potentials (EPP) or to rule out any post-synpatic venom effects. Thus, we report results from NMJs in which twitch was blocked by reduction of Ca to .5mM with addition of 4mM magnesium (pH =7.4).

In 16 preparations CSV was added to NMJ bathing solution (0.56 to 4.48ug/ml). Repetitive firing of the nerve(NT) was evidenced by post-stimulus repetitive bursts of EPPs. This phenomenon developed gradually and then disappeared. The exact sequence was highly variable (max number of repetitions: 5-50; peak time of max: 5-100 minutes). Occasionally, unstimulated bursts of EPPs were observed.

In several experiments prolonged EPPs were observed (23,25,151,153 min). Since potentials with similar time course have been observed in neurons, we assume that since the nerve would be depolarized for a longer period of time, the release probability is similarly prolonged, thus the elongated EPP. The jagged EPP (t=151,153 min) is the result of superposition of MEPPs on the normal EPP elicited by the prolonged NT potential.



MEPPs were recorded in all preparations. No consistent change in MEPP amplitude was seen. MEPP frequency(F) remained almost unchanged in 4 experiments. However, in 12 experiments MEPPF rose to values of up to 500 per second with subsequent exhaustion of quantum stores. In another set of 8 experiments with Ca free solutions and no indirect neural stimulation, MEPPF rose in all 8 experiments to high values with subsequent depletion. These effects were abruptly blocked by addition of tetrodotoxin (TTX) and never occurred if TTX was added before CSV. Since it has been shown (Longenecker, Neurosci. Abs. 1976) that neural stimulation in Ca free solution leads to high MEPPF, we conclude that CSV induces high frequency repetitive firing of the nerve in Ca free media, and due to Na entry into the NT intracellular Ca is freed and subsequent transmitter release occurs. (NIH #ES01321-01)

1194 CHRONIC STIMULATION OF FROG NEUROMUSCULAR JUNCTIONS IN VITRO. Katy Lynch* (SPON: T. S. Reese). Geo. Wash. Univ. Med. Sch. Washington, DC 20037 and LNNS, NINCDS, NIH, Bethesda, MD 20014.

Matched pairs of sartorius muscles from R. pipiens, with their attached nerves, were maintained in vitro at room temperature for up to 60 hrs. The experimental apparatus permitted each nerve, ligated and cut at the level of the sacral plexus, to be stimulated and the muscle response recorded with a force displacement transducer. Stimulation of the nerves at 120 times/min caused muscle twitches for over 40 hrs. Twitch tension reached a maximal value within 90 sec, then rapidly declined for 15 min to a plateau level 5.4±1.7% of the maximum. In those muscles stimulated continuously for 24 hrs, twitch tension continued to decline very gradually to 0.9±0.7% of the maximal value. Control muscles, rested 24 hrs in vitro and then stimulated at 2Hz for 20 min, developed maximal tensions 5 to 50% less than those achieved in their fresh state. By 6 min, however, their tension recordings were identical to those of fresh muscles. Direct stimulation of curarized muscles yielded a similar though much more regular pattern of response, with equal or greater declines in twitch strength over 24 hrs. This finding, coupled with intracellular recordings, suggests the following: The overall decrement in the twitch tension of indirectly stimulated muscles is primarily due to fatigue of the muscle fibers rather than failure of neurotransmission. The quantal content of the epps, known to decline rapidly at the onset of repeated stimulation (JCB 54:30, 1972), probably hovers near the level required to trigger action potentials. Fluctuations in the number of contracting fibers throughout the long plateau period would explain the unevenness and persistence of the twitch response. Preliminary morphometric analysis of 40 nerve terminal profiles from muscles rested 24 hrs and stimulated 20 min at 2Hz, and of 40 profiles from muscles stimulated at 2Hz for 24 hrs revealed no significant differences in the number of synaptic vesicles, in plasmalemmal area, or in the concentration or size of mitochondria. We conclude that frog motor endplates can utilize local recycling mechanisms or axonal resources to sustain neurotransmitter release for more than 40 hrs. Available axonal resources were reduced by ligating the sartorius nerve at its branch point from the sciatic or by bathing the sciatic in 20mM colchicine or 0.1mM vinblastine. This produced no change in the twitch pattern over 24 hrs, indicating that rapidly transported materials play a negligible role in sustaining synaptic function over this period.

1195 β-BUNGAROTOXIN: RETENTION OF THE PRESYNAPTIC BLOCKING EFFECT FOLLOWING INACTIVATION OF THE PHOSPHOLIPASE. Leona M. Masukawa, Gene S. Tobias*, Mildred A. Donlon* and David R. Livengood. Neurobiology Department, Armed Forces Radiobiology Research Institute, Bethesda, MD. 20014.

β-bungarotoxin (β-BuTX) has been shown to be a specific presynaptic blocking agent at the neuromuscular junction by a number of investigators. Its mode of action has been postulated to be due ultimately to the disruption of transmitter release mechanisms by its phospholipase activity. The phospholipase activity can be removed by boiling the toxin at pH 8.6. After this treatment the toxin (phospholipase-inactive β-BuTX) was still able to block transmission in in vitro neuromuscular preparations of the frog and rat. Blockade of evoked release of acetylcholine was examined by averaging endplate potentials which previously had been partially blocked with 3μg/ml d-tubocurarine. The blockade due to the phospholipase-inactive β-BuTX was complete and irreversible within 20 minutes at high toxin concentrations (.1 to 1 μg/ml) and was not preceded by a transient increase in evoked release as has been shown for the enzymatically active toxin. The degree of blockade was found to be a function of the toxin concentration. The effect was rapid in onset and reached a steady state level. This action is inconsistent with the action of a phospholipase but is characteristic of a direct binding of the toxin to sites important to transmitter release. Miniature endplate potential (MEPP) frequency was measured in the presence of phospholipase-inactive β-BuTX to study further its mode of action. MEPP frequency appeared to increase in the presence of the toxin, and the distribution of miniature amplitudes was shifted to a population of lower amplitude. This decrease in amplitude may be due to a postsynaptic effect; therefore, acetylcholine sensitivity of extrajunctional receptors of denervated muscle was measured in the presence of phospholipase-inactive β-BuTX. We hypothesize that the fully active toxin contains two active sites: one site specific to the presynaptic terminal which can block release of transmitter and another site which has a phospholipase action.

1196 ULTRASTRUCTURAL ANALYSIS OF FUNCTIONAL MOTOR ENDPLATES FORMED IN SCHWANN-CELL-FREE CULTURES OF MOUSE SKELETAL MUSCLE INNERVATED BY VENTRAL CORD EXPLANTS. Edmund B. Masurovsky, Edith R. Peterson*, George D. Pappas and Stanley M. Crain. Dept. of Neuroscience, Albert Einstein Coll. Med., Bronx, N.Y. 10461

Cultures of fetal mouse ventral spinal cord explants and adult skeletal muscle "regenerates", prepared free of Schwann cells, have been maintained for over 3 months in vitro with stable cross-striations, vigorous contractile activity, cholinesterase-positive neuromuscular junctional foci, and other features of mature innervated muscle fibers (Peterson and Crain, Soc. Neurosci.'76, Abstr. p. 1018). Cultures selected for electron microscopy (EM) were first tested electrophysiologically (see below) immediately prior to fixation either in: a) 2.5% glutaraldehyde in Millonigs' buffer; or b) 1% paraformaldehyde, 1% acrolein, 2.5% glutaraldehyde, 2.5% DMSO and 0.005% $CaCl_2$ in cacodylate buffer (pH 7.3) for 1 hr at 4°C., followed by overnight immersion in 2% paraformaldehyde, 5% glutaraldehyde and 0.005% $CaCl_2$. After post-fixation with 1% OsO_4 (50 min at 4°C), standard dehydration, and Epon-embedment, thin sections were cut and stained with 50% ethanolic uranyl acetate and lead citrate for examination in a Philips 300 electron microscope.

By 5 weeks in vitro, EM revealed bare and occasionally partially invested presynaptic nerve terminals situated within postsynaptic endplate formations with prominent primary and secondary infoldings. While most terminals contained agranular ($\sim$ 50 nm) vesicles, some also contained various dense-core ($\gtrsim$ 80 nm) vesicles. Those nerve terminals partially covered by cells with dense-appearing cytoplasm showed no basal lamina typically associated with Schwann cells, although abundant basal lamina was clearly demonstrated along sarcolemma and within clefts. Furthermore, these dense investing cells containing ribosomes and microtubules sometimes projected $\sim$ 11-12 nm period myelin-like loops next to neurites, suggestive of oligodendroglia (Dr. C.S. Raine, pers. comm.) which had migrated from the ventral cord explant with the outgrowing motor nerve fibers. Subsarcolemmal nuclei, typical mitochondria, ordered myofilament lattices, well-developed sarcoplasmic reticulum and triads denoted overall muscle maturity. Prior to EM, vigorous muscle contractions could be repeatedly evoked by electric stimuli to the cord explants and the contractions were selectively blocked by d-tubocurarine (1 μg/ml), as in cultures with organotypic cord-DRG explants.

These correlative data demonstrate that functional motor endplates can develop in longterm co-cultures of mammalian spinal cord and skeletal muscle in the absence of Schwann cells.

1197 HYPERPOLARIZING MINIATURE SYNAPTIC POTENTIALS IN THE MOUSE DIAPHRAGM. Owen B. McManus* and James R. Musick. Dept. of Physiol. U. of Utah, Sch. of Med., Salt Lake City, UT. 84132.

Intracellular recordings were made from muscle fibers of the mouse diaphragm by standard microelectrodes. The high input impedance of these fibers allows recording of miniature endplate potentials (m.e.p.p.s) of ca. 2 mV without using anticholinesterases. M.e.p.p. amplitude frequency distributions are usually normal; occasional cells show multimodal distributions with a less frequent subclass smaller than the mean. Some records show hyperpolarizing miniature synaptic potentials (h.m.s.p.s) as well as m.e.p.p.s. H.m.s.p.s have the following properties: 1. A localized intracellular distribution at the motor endplate since they are recorded when external m.e.p.p.s are seen prior to intracellular penetration. 2. Monophasicity. 3. Rapid rise time with slower exponential decay and shorter total duration than m.e.p.p.s due to rise and decay time reduction. 4. Mean peak amplitude similar to simultaneously recorded m.e.p.p.s. 5. Non-normal amplitude frequency distribution due to positive skewness. 6. Lower average frequency than m.e.p.p.s (ca. 30% reduction). However, some cells show frequency increases during bursts and a greater frequency of h.m.s.p.s than m.e.p.p.s. It is suggested that h.m.s.p.s reflect inward positive ionic current recorded in close proximity to receptor-ionophore complexes activated by quantal acetylcholine release, as predicted by Del Castillo and Katz (1956,J. Physiol. 132: 630).

1198 RELEASE OF LOW MOLECULAR WEIGHT AMINO-COMPOUNDS BY NERVE STIMULATION OF PARALYZED NEUROMUSCULAR PREPARATIONS. James R. Musick. Dept. Physiol., Sch. Med., University of Utah, Salt Lake City, UT 84132.

Nerve stimulation of the R. pipiens sciatic nerve-sartorius preparation, paralyzed by curare, increases the efflux of ninhydrin positive material into the bathing saline solution; average release (± S.E.) was 160 ± 45 pmoles leucine equivalents/mg tissue, n = 13. This response has characteristics similar to the release of Lowry-reactive material (Musick and Hubbard, Nature 327:279, 1972). Simultaneous measurement of ninhydrin and Lowry reactivity of tissue effluents allowed determination of the ninhydrin/Lowry ratio (N/L), in the units moles leucine equivalents/mole BSA equivalent. Under control conditions, the N/L ratio was 282 ± 66 and during stimulation at 5/sec, 1939 ± 409 (mean ± S.E., n = 9, $p < 0.01$ by paired t-Test analysis). These results suggest that nerve stimulation releases amino-compounds with minimal Lowry reactivity. Comparison with N/L ratios of purified test compounds indicate that the released substances may be predominately amino acids or peptides and proteins are a minor component. Preliminary molecular size measurements indicate that the released amino-compounds are $\leq$10,000 molecular weight. These results are consistent with the hypothesis that proteolytic enzymes are secreted together with ACh from motor nerve terminals. The release of low molecular weight amino-compounds may reflect degradation of protein substrates of the synaptic cleft by exopeptidases which liberates amino acids and possibly peptides.

Supported by PHS grant #5 P01 NS07938.

1199 FUNCTIONAL NEUROMUSCULAR CONTACTS FORMED IN VITRO: AN ULTRASTRUCTURAL AND ELECTROPHYSIOLOGICAL STUDY. Yasuko Nakajima, Yoshiaki Kidokoro* and F. G. Klier*. Dept. of Biol. Sci., Purdue Univ., West Lafayette, IN 47907 and Dept. Neurobiol., The Salk Inst., San Diego, CA 92112.

Functional neuromuscular contacts were formed in vitro between rat spinal cord explants and myotubes. At various intervals after the spinal cord explants were added to the myotube-culture (5 hours to 15 days of coculture), the presence of functional neuromuscular contacts was determined by recording miniature endplate potentials (mepps) from myotubes contacted by a few neurites. These myotubes were photographed for identification, and the ultrastructural investigation was conducted only on myotubes having functional neuromuscular transmission.

The presence of mepps was detected as early as 5 hours of co-culture. Although the frequency and amplitude of mepps varied from one myotube to another, a significant increase in the mepp frequency was noticed between junctions formed within 24 hours of co-culture (0.43/sec) and those of 5 to 6 days of co-culture (2.4/sec).

The fine structure of these functional neuromuscular contacts was relatively simple compared to that of adult junctions and showed considerable changes during development. In the earliest stage of functional neuromuscular contacts (7 ~ 8 hour cocultures), a small number of round, clear vesicles and a few dense cored vesicles were already found in the axon endings, but synaptic vesicle aggregation on the prejunctional membrane was found only in a few places. The junctional cleft was narrow, and the junctional membranes did not show specializations except for the occasional presence of coated caveolae in the post-junctional membrane. These results indicate that the presence of synaptic vesicles in the axonal ending is the first noticeable morphological feature for the newly-formed functional contact. A similar structure was also observed in functional contacts formed in 21 ~ 24 hours of coculture, but at this stage some endings accumulated a larger number of vesicles. In the materials of 4 ~ 6 day cocultures, neuromuscular contacts with distinctly more advanced structures were more frequently encountered; number of synaptic vesicles were increased and they were clustered on the prejunctional membrane. These morphological changes are likely to be related to the initial increase in the mepp frequency. However, most of the junctional clefts were still narrow. Only a few contacts had widened clefts with a basal lamina. The neuromuscular contacts formed in 14 day cocultures showed further advanced structures resembling those of adult junctions; the majority had widened clefts with a basal lamina and well-developed postjunctional foldings. (Supported by USPHS grants NS-10457, NS-11918, NS-00102).

1200 THE DIVALENT CATION DEPENDENCE OF SPONTANEOUS QUANTAL SECRETION. R. L. Ornberg* (SPON: H. Gainer). LNNS, NINCDS, NIH, Bethesda, MD 20014.

The effects of black widow spider venom (BWSV), ouabain, 2,4-dinitrophenol, ethanol, and hypertonic saline on the resting miniature endplate potential (mepp) frequency were studied at frog cutaneous pectoris neuromuscular junctions in salines containing varying amounts of Mg^{++} and essentially no Ca^{++}. As previously reported, each of these agents produce a large increase in spontaneous mepps in salines containing little Ca^{++} (10^{-10} M) and millimolar amounts of Mg^{++}. The present study extends these observations to very low Mg^{++} concentrations (10^{-9} M) because it was discovered that tetrodotoxin (2×10^{-6} gm/ml) prevents the adverse postsynaptic effects (spontaneous twitching and membrane depolarization) which ordinarily accompany divalent cation removal.

A number of calcium and magnesium chelators (EGTA, EDTA, CDTA, citrate, and 8-hydroxyquinoline-5 sulfonic acid) were used to buffer Mg^{++} levels in test salines from 3 mM to 10^{-9} M. Ca^{++} was not added to these salines and the calculated free Ca^{++} was 10^{-9} M, assuming a total Ca^{++} concentration of 10^{-6} M due to contamination. In low Mg^{++} saline (10^{-5} M), regardless of the chelator used, the typical rise in mepp frequency produced by BWSV (1 gland/ml), ouabain (0.1 mM) or dinitrophenol (1 mM) is prevented completely. If Mg^{++} or Ca^{++} is added back to the muscle bath at a time corresponding to peak release in normal Mg^{++} (3 mM), an enormous increase in mepps ensues immediately. Preliminary morphological evidence reveals little vesicle depletion before but massive depletion following Mg^{++} addition. In contrast, ethanol and hypertonic saline-induced release are unaffected by low Mg^{++} salines. The rapid onset of high mepp rates following Mg^{++} addition to BWSV, ouabain, and DNP-treated muscles suggests that specific toxic actions involving raised internal Ca^{++} occur even though few quanta are released. Thus, an additional step, involving divalent cations interacting with the surface of the nerve terminal may be required for quantal secretion. Ethanol or hypertonic saline could act on the surface membrane or synaptic vesicles more directly and bypass this step.

1201 ETHANOL AFFECTS THE VOLTAGE-SENSITIVITY AND CALCIUM-DEPENDENCE OF THE RATE OF DESENSITIZATION IN VOLTAGE-CLAMPED EEL ELECTROPLAQUES. Barry S. Pallotta and George D. Webb. Dept. Physiol. & Biophys., Univ. Vermont Col. Med., Burlington, VT 05401.

The effects of calcium, ethanol, and membrane voltage upon activation and desensitization in Electrophorus electricus electroplaques have been studied under voltage-clamp conditions. Cells were equilibrated with 1M ethanol and/or one of several different calcium concentrations for ½h prior to voltage-clamping and bath-application of 0.27 mM carbamylcholine (CCh). The response to CCh is a rapid inward current which peaks and then decays (desensitizes) with a pseudo-first order rate constant k_o.

At -60 mV peak current (I_o) remains constant between 0.5-5 mM Ca^{++} and k_o increases with increasing $[Ca^{++}]$. At 0.1 mM Ca^{++}, however, k_o is fastest, and at 10 mM both I_o and k_o are significantly depressed. Cells treated with ethanol show a reduction in I_o at all $[Ca^{++}]$. Ethanol-treated cells desensitize faster than controls at all $[Ca^{++}]$ except at 0.1 mM, where the effect is a decrease of k_o relative to the control. The ethanol effect is thus $[Ca^{++}]$-dependent.

In physiological saline (2 mM Ca^{++}), k_o is increased 4-fold by increasing membrane polarization over the range of -40 to -90 mV. Ethanol pre-treatment (+2 mM Ca^{++}) causes a doubling of k_o at -40 mV, whereas ethanol increases k_o only slightly at -90 mV. At -40 mV, cells treated with 5 mM Ca^{++} desensitize at the same rate as 2 mM Ca^{++} controls, but at -90 mV I_o is only increased by about 2-fold from the -40 mV rate. In other words, 5 mM Ca^{++} decreases the voltage-sensitivity of k_o so that at -90 mV high calcium inhibits the rate of desensitization.

We have analyzed the interdependence of I_o and k_o in terms of the kinetic model: $A + R \xrightarrow{k_1} AR^* \xleftarrow{k_3}, \xrightarrow{k_4} AD$ where A is agonist, R, receptor, AR* the conducting conformation and AD the desensitized state. This model predicts a decrease in I_o secondary to increases in k_3+k_4 in agreement with our observations. About 15 sec. elapse between the application of CCh and I_o. This time delay is probably due to diffusion of agonist through the 40-80 µm thick layer of gelatinous material covering the electroplaque. Assuming that the apparent k_1 is determined solely by diffusion of agonist, and using equations for diffusion through a plane sheet, we can predict the effects of this unstirred layer on I_o and k_o. As the gel thickness increases, I_o and k_o decrease and time-to-peak current increases. The observed average time-to-peak of 15 sec. predicts a 70 µm thick gel layer, and variations in gel thickness of only ±10 µm may result in variations in I_o and k_o of ±20%. At low agonist concentrations k_1 becomes the rate-determining step and the system becomes insensitive to alterations in the desensitization process (k_3 and k_4). Supported by USPHS ES00885.

1202 MEMBRANE SPECIALIZATIONS IN CULTURED MUSCLE CELLS. H. Benjamin Peng* and Yasuko Nakajima (SPON: Shigehiro Nakajima). Dept. of Biol. Sci., Purdue Univ., W. Lafayette, Ind. 47907.

We have been studying the development of the myotome cells from the Xenopus laevis embryos in tissue culture with the freeze-fracture technique, with special emphasis on the formation of neuromuscular junctions. The muscle cells were isolated from the dorsal mesoderm of stage 21 embryos. After one to two days in culture, cells from the neural tube were added to the culture. Functional neuromuscular junctions were formed one day after the neurons were added as shown by the spontaneous contraction of the muscle cells and MEPPs recorded intracellularly. The preparations were then freeze-fractured with the method demonstrated by Yee et al. (J. Cell Biol. 70: 155a, 1976). Large fracture faces of the plasma membrane, sometimes exposing the whole muscle cell, can be easily obtained.

We have observed the following membrane specializations on the muscle cells. (1) Gap junctions were often observed when two muscle cells make contact with each other. (2) Ruffled membrane patches were frequently observed on the muscle. They appear as a shallow depressions in the plasma membrane with irregular contours and ruffled bottom about 1 µm or longer. Very often a piece of membrane is left on top of such a patch. These results indicate that these patches may be sites of cell-to-cell contact. As many as 30 patches were seen in one cell and they generally lie in a rather localized area. (3) Particle aggregates 0.1 to 0.5 µm wide, consisting of large particles, were often seen on the muscle cell. Their appearance is similar to the peripheral coupling between the plasma membrane and the sarcoplasmic reticulum in some adult muscle. (4) Particle aggregates 1 to 3 µm wide, consisting of tightly packed large particles, were seen on the muscle cell. These large particle patches are often clustered together. The appearance of the particle aggregates resembles post-synaptic particle aggregates observed in adult neuromuscular junctions of various animals. However, these patches seem to exist in a region free of nerve innervation. Therefore, they might represent aggregates of extra-junctional acetylcholine receptors, "hot spots".

1203 INACTIVATION OF ACETYLCHOLINE RECEPTORS BY LOCAL ANESTHETIC AGENTS. P. Pennefather* and D. M. J. Quastel. Dept. of Pharmacology, Faculty of Medicine, The University of British Columbia, Vancouver, B. C., Canada, V6T 1W5.

Tertiary amine local anesthetics split the decay phase of endplate currents at the neuromuscular junction into 2 exponential components. One is faster than the normal decay rate while the other is slower. The model most consistent with our data is that these agents cause a rapid, transient and reversible inactivation of the activated acetylcholine (ACh) receptor-ionophore complex. We have investigated the action of a number of other types of local anesthetics on miniature endplate currents (m.e.p.c.s) recorded at the mouse diaphragm neuromuscular junction. So far all local anesthetics tested have had actions consistent with the above model. Procaine, lidocaine, morphine, naloxone, atropine, scopolamine, quinidine, pentobarbital, diphenylhydantoin, 2-octanol, and menthol all give rise to m.e.p.c.s with a normal height, but with a biphasic decay phase. Streptomycin, an aminoglycoside antibiotic, also had this action. In many cases ethanol was added to the solutions to improve the definition of the m.e.p.c. time course. Ethanol slows the rate of decay of m.e.p.c.s probably by slowing the dissociation of ACh from its receptor. As predicted by the above model, it increased the height of the slow component. Many of the agents decreased the area of the m.e.p.c. without affecting height. Kinetic analysis of the time course of the m.e.p.c. suggests that this represents a slow inactivation process which is dependent on the amount of inactivated receptor produced by fast inactivation. The above model explains how morphine can reduce the size of endplate potentials without affecting the response to iontophonetically applied ACh (Sokoll et al., Prog. Anesthesiol. 1, 169, 1975) and how atropine could appear to act as a non-competitive inhibitor under experimental condition where there was a large receptor reserve (Kirschner and Stone, J. Gen. Physiol. 34, 821, 1951). In the presence of morphine the onset of slow inactivation is about 10 times slower than in the presence of atropine. The rate of onset and offset of fast inactivation also depended on the drug. The action of positively charged agents was voltage-sensitive, while that of negatively charged or neutral agents was not. Studies with varied pH suggest that the positively charged form of morphine is more potent than the uncharged form, while in the case of pentobarbital it is the uncharged form that is more potent.

1204 TENOTOMY DELAYS THE DEVELOPMENT OF SKELETAL MUSCLE MOTOR INNERVATION. Dan A. Riley*. Dept. Anat., Sch. Med., UCSF, San Francisco, CA 94143.

Physiological studies have revealed that the muscle fibers of the rat soleus lose their functional polyneuronal innervation during the second postnatal week and become unineuronally innervated. Furthermore, tenotomy of the soleus prior to the second week slows the normal transition from polyneuronal to unineuronal innervation. The anatomical basis of polyneuronal innervation is multiple axon terminals innervating single muscle fibers; all but one of the multiple terminals per endplate are removed during the second week. The present anatomical study determines whether tenotomy affects the spontaneous elimination of nerve terminals in the soleus muscles of rats and kittens. Soleus muscles of 4-day-old rats were tenotomized and their innervation patterns examined either 9 or 11 days later in silver stained sections. The contralateral soleus muscles and solei from normal rats of the same age served as controls. The tendons had regrown by 9 days, but the muscles were markedly shortened and clearly atrophic. On the average, 36% of the fibers in tenotomized muscles were innervated by multiple terminals, whereas the contralateral and normal muscles both exhibited approximately 30% multiple innervation. By 11 days, the degree of multiple innervation was similar in tenotomized and control muscles. Thus, tenotomy retards the spontaneous elimination of axon terminals from multiply innervated endplates. Other workers have reported that tenotomy of the rat soleus reduces motor neuron activity. In contrast, tenotomy of the cat soleus does not decrease neural activity, although the muscles become shortened and atrophic. If decreased neural activity per se retards neural development, then tenotomy should not delay the process in the kitten. Kitten soleus muscles were tenotomized in 2-wk-old animals prior to the loss of polyneuronal innervation. After 10 days, the tenotomized muscles exhibited 23% multiple innervation while the contralateral control muscles had 16%. Since tenotomy retards neural development in both the kitten and rat, decreased neural activity is unlikely responsible for the delay. In both cases, the tenotomized muscles were smaller than normal and the intramuscular nerve fibers failed to grow in length, as normally occurs in muscles expanding in diameter. Thus, the inhibition of or lack of a stimulus for nerve fiber growth may slow the elimination of excess axon terminals in tenotomized muscles which fail to increase in diameter.

1205 APPEARANCE OF ACETYLCHOLINESTERASE AT CULTURED NEUROMUSCULAR JUNCTIONS. Lee L. Rubin*, Stephen M. Schuetze*, and Gerald D. Fischbach (SPON: U. J. McMahan). Dept. of Pharmacol., Harvard Med. Sch., Boston, MA 02115

Acetylcholine (ACh) receptor clusters and acetylcholinesterase (AChE) are characteristic features of the adult neuromuscular junction. Previous work has demonstrated the appearance of new ACh receptor clusters at sites of transmitter release at embryonic chick nerve-muscle junctions formed in culture. We have now studied the appearance and function of AChE at these newly formed junctions. Synapses between myotubes and motor axons extending from spinal cord explants were located by focal extracellular recording; the spatial resolution of this technique is approximately 5 μm. At each site of transmitter release, the decay phases of extracellularly recorded synaptic potentials were fit by simple exponentials and their mean time constant of decay (τ) was determined. The synapses were grouped into 3 categories based on estimates of τ at 30°C: fast (τ = 1.5 - 2.0 msec), intermediate (τ = 2-3 msec), and slow (τ = 4-6 msec). Cultures were then fixed and stained for AChE by the method of Karnovsky and Roots. Greater than 70% of those synapses at which extracellular potentials showed a fast decay were associated with prominent AChE stain. On the other hand, no reaction product was detected at junctions where τ was greater than 4 msec. Only small faintly stained patches were observed at most synapses exhibiting intermediate rates of decay. These results complement previous studies using AChE inhibitors on adult neuromuscular junctions (Katz and Miledi, J. Physiol. 231: 549, 1973) and directly support the conclusion that hydrolysis of ACh limits the duration of ACh action.

A single myotube may have both AChE-positive and AChE-negative release sites. Thus, the appearance of AChE depends not only on myotube characteristics, but on the properties of particular nerve-muscle contacts. Additionally, at some sites of transmitter release both fast and slowly decaying potentials were recorded. This finding suggests that even within the small field monitored by the extracellular pipette, AChE may have a restricted localization and action.

In contrast to previous studies of nerve-muscle synapses formed by dissociated spinal cord neurons, our data demonstrate the early appearance of AChE at synapses formed by neurites extending from spinal cord explants. AChE was detectable within 24 to 48 hrs after neurite-muscle contact; in older cultures, staining was heavier and more frequent. In these cases, junctions with intermediate decays and light AChE stain may constitute a stage during which AChE is accumulating at particular synaptic contacts. Supported by NS 11160 and the Helen Hay Whitney Foundation.

1206 MODE OF ACTION OF BARIUM IN COUPLING THE NERVE ACTION POTENTIAL TO THE ASYNCHRONOUS DISCHARGE OF ACETYLCHOLINE QUANTA. E. M. Silinsky* (SPONS: R. A. North). Dept. Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611.

It has been observed recently that Ba^{2+} ions are capable of efficiently supporting the quantal release of acetylcholine (ACh) by motor nerve impulses (Silinsky, Brit. J. Pharmac. 59:215 (1977)). In contrast to ACh release in Ca^{2+} solutions, evoked release mediated by Ba^{2+} (i) requires repetitive nerve stimulation at frequencies $\geq$ 1 Hz and (ii) appears as an asynchronous, residual discharge of transmitter quanta that well outlasts the initial stimulation period. This present study was conducted to determine if Ba^{2+} in itself directly couples nerve terminal depolarization to the release of ACh quanta or works indirectly by displacement of Ca^{2+} from internal stores such as mitochondria. The isolated nerve-cutaneous pectoralis preparation of the frog was used in conjunction with conventional intracellular recording techniques. In solutions containing 1.8 mM Ba^{2+} and no added Ca^{2+}, 1 Hz stimulation for < 1 min elevated miniature end-plate potential (min.e.p.p.) frequencies to 5-20 times the control level (seven experiments). As similar results were obtained when a Ca^{2+}-chelating agent was added to the Ba^{2+} solution, it appears that residual extracellular Ca^{2+} is not responsible for mediating evoked release in Ba^{2+} solutions. Ba^{2+} is 2 orders of magnitude more effective than Ca^{2+} in supporting the evoked discharge of min.e.p.p.s - Ca^{2+} in fact is a potent antagonist of the evoked discharge of min.e.p.p.s in Ba^{2+} solutions. This low efficacy of Ca^{2+} appears to render an indirect mechanism whereby Ba^{2+} displaces Ca^{2+} less likely than a direct effect of Ba^{2+} on the release process. The number of ACh quanta released asynchronously by nerve impulses is directly related to the external concentration of Ba^{2+} in a non-linear, possibly exponential, fashion. Mg^{2+} and Co^{2+} both competitively antagonize evoked release in Ba^{2+} solutions. The equilibrium dissociation constant for each ion as an antagonist of asynchronous, Ba^{2+}-dependent release is identical to its respective value as an antagonist of synchronous, Ca^{2+}-mediated release. It thus suggested that Ba^{2+} supports dispersed, quantal ACh release directly by the same release mechanism normally activated by Ca^{2+}. (Supported by NIH grant NS 12782).

1207 SPONTANEOUS AND EVOKED DEPOLARIZATIONS IN PROTRACTOR MUSCLES OF THE OPISTHOBRANCH MOLLUSC, NAVANAX. D. C. Spray, M. Cappell* and M. V. L. Bennett, Dept. of Neuroscience, Albert Einstein Col. Med., Bronx, N. Y. 10461.

Intracellular recordings from muscle fibers that protract the pharynx reveal three depolarizing responses of short duration: (1) spontaneously occurring depolarizations (mPSPs) of one mV or less; (2) PSPs of a few mV evoked by stimulation of the nerve, and (3) action potentials seen during penetration and evoked by depolarization of the fiber. The mPSPs can exhibit amplitude, rise time, and interval distributions similar to those of miniature end plate potentials of vertebrate junctions with localized innervation. The PSPs are about six times the mean amplitude of the mPSPs. In many fibers, amplitude and rise time are not affected by increasing the nerve stimulus strength above threshold; in some fibers both amplitude and rise time increase abruptly as strength of the stimulus is increased. The second case, so far only seen in the dorsal protractor, probably reflects multifiber innervation either of single or of electrotonically coupled fibers. PSP amplitude is depressed by curare and high Mg++ and enhanced by prostigmine and high Ca++. Curare also abolishes the mPSPs. Action potentials are generated in muscle fibers by intracellular depolarizations of 20-30 mV. Protractor muscles of a large specimen may reach a length of 5 cm or so, and action potentials may serve to spread contraction along the muscle. Ventral protractor muscles are innervated by a motoneuron in the ipsilateral buccal ganglion; dorsal protractor muscles are innervated by two motoneurons, one in each buccal ganglion. Stimulation of a protractor motoneuron elicits PSPs in the muscle fibers similar to those evoked by nerve stimulation. We conclude that neuromuscular transmission and postsynaptic responsiveness can be very similar in molluscan, arthropod, and vertebrate muscle.

1208 ETHANOL ON THE CRAYFISH NEUROMUSCULAR JUNCTION. Staiman, A. L. Acosta-Urquidi, J.*, Carlen, P. L. and Corrigall, W. A. Neurobiology Lab, Addiction Research Foundation, Toronto, Ontario, Canada. M5S 2S1

The effects of ethanol on the vertebrate cholinergic neuromuscular junction are well documented. To examine whether ethanol acts in a similar fashion at other neuromuscular synapses we studied the effect on the leg-opener neuromuscular preparation of the crayfish. Selective stimulation of the excitor axon produces an excitatory junctional potential (EJP) mediated by glutamate. Stimulation of the inhibitory axon produces an inhibitory junctional potential (IJP) mediated by GABA. Stimulus frequency used was 5/sec. Ethanol depressed both the EJP and the IJP. At concentrations of 0.2M, 0.4M and 0.6M the EJP was depressed to approximately 80%, 60% and 40% of the control amplitude respectively. Similar results were found with the IJP and therefore there appeared to be no difference in the sensitivity between the EJP and IJP to ethanol. The nerve terminal spike amplitude and latency was unaffected by the former concentrations. Input resistance was measured using two microelectrodes. Depression of the input resistance paralleled the depression of the EJP and IJP. Therefore, the EJP and IJP depression was due to the effect of ethanol on the input resistance. Concentrations of ethanol from 0.2M to 1M caused a small and reversible depression of the resting membrane potential, between 1 to 6mV. At higher concentrations (from 0.8 to 1M) and at approximately 50% reduction of the EJP or IJP hyperexcitability of the nerve terminal was produced. One stimulus to the axon produced from 2 to 10 synchronous EJP's or IJP's. Using a focal extra-cellular electrode it was observed that this effect was due to multiple spiking at the nerve terminal. The effect of ethanol on the spontaneous release of miniature excitatory junction potentials (mejp) was studied. At lower concentrations (0.2M and 0.4M) there was no detectable increase in mejp frequency. At higher concentrations (0.6M to 0.8M) where the input resistance is significantly depressed there also appeared to be no increase in the frequency of mejp's.

1209 EVIDENCE THAT BETA-BUNGAROTOXIN BINDS DIRECTLY TO NERVE TERMINALS: SEPARATION OF BINDING AND ENZYMATIC ACTIVITY. Peter N. Strong, Randall J. von Wedel*, Regis B. Kelly. Dept. Biochem. & Biophys., U. Cal., San Francisco, CA 94143.

ß-Bungarotoxin (ßTX), the presynaptic neurotoxin isolated from the venom of the krait, Bungarus multicinctus, modifies release of acetylcholine at mammalian and amphibian neuromuscular junctions. There is accumulating evidence to suggest that ßTX's physiological effects at the synapse are mediated by the toxin's endogenous phospholipase A_2 activity. The precise cause of the toxin's highly selective action is unknown; ßTX could 1) bind to a specific receptor on nerve terminal plasma membranes and hydrolyze phospholipids in the vicinity, or 2) selectively hydrolyze a unique phospholipid substrate on nerve terminals.

We have sought to distinguish between these two possibilities by looking for evidence of toxin binding under conditions of enzyme inactivation. ßTX phospholipase activity was blocked in two distinct ways. In the first approach we examined the ability of phospholipase inactivated ßTX (chemically modified with *p*-bromophenacyl bromide, BPB-ßTX) to protect a frog neuromuscular preparation against native toxin. 1 µM BPB-ßTX had no effect on indirectly stimulated muscle contraction in Ca^{++} Ringer. After extensive washing, an application of 50 nM native toxin gave no reduction in tetanic tension for 45 min, a time which gave >95% inhibition in control preparations.

In the second approach, we have examined the effects of toxin in Ringer solutions in which Ca^{++} was replaced by Sr^{++}, since Sr^{++} inhibits the phospholipase activity of ßTX. After 30 min in toxin, the preparation was washed extensively for 120 min with Sr^{++} Ringer. Subsequent addition of Ca^{++} Ringer (no toxin) resulted in contraction failure analogous to that seen when native toxin was added to a muscle in normal Ca^{++} Ringer.

These experiments suggest that when the phospholipase activity of ßTX is inactivated either by chemical modification or by Sr^{++} the toxin will still bind to nerve terminals. If inactive derivatives bind, then it is reasonable to assume that a presynaptic ßTX receptor exists. Inactive derivatives, suitably labelled, offer potential as biochemical markers of presynaptic nerve terminals. Supported by NIH grant NS09878. PNS is a Muscular Dystrophy Assn. Postdoctoral Fellow.

1210 EFFECT OF MORPHINE AND NALOXONE IN NEUROMUSCULAR TRANSMISSION. Philip C. Su and Arthur D. Rosen. Neuro. Svs., VA Hosp. Northport, NY and Div. of Neuro., State Univ. of NY at Stony Brook, NY

Morphine has been shown to have both facilitative and depressive effect on neuromuscular transmission. Naloxone auguments the depressive effect of Morphine. We have studied the quantal release produced by Morphine and Naloxone in neuromuscular transmission. Our results indicate that Morphine increases the acetylcholine quantal release in low concentration and reduces the quantal release in high concentration. In addition, we were able to demonstrate that Naloxone specifically antagonizes the facilitative effect of quantal release of Morphine.

Mice phrenic nerve-diaphragm and frog cutaneous pectoris nerve-muscle preparations were used in vitro. Endplate potential (EPP) were recorded in curarized preparations or high magnesium solution. Quantal content was determined by either the ratio of mean amplitude of EPP's and miniature endplate potentials (MEPP) or by the variance method of EPP's. Corrections for nonlinear response of EPP were made by assuming equilibrium potential of 15mV inside negative. At concentration of $1x10^{-6}$ g/ml to $1x10^{-5}$ g/ml Morphine increased the quantal content. This facilitation effect is most noticeable in the first 60 min. after perfusion with Morphine. At concentration of $1x10^{-4}$ g/ml the quantal content was significantly reduced. Morphine has no effect on immediate available store, mobilization rate or probability of release of acetylcholine in the concentration of $1x10^{-6}$ g/ml to $1x10^{-4}$ g/ml. Naloxone at the concentration of $1x10^{-5}$ g/ml completely abolished the facilitative effect of Morphine on quantal content. Naloxone alone ($1x10^{-5}$ g/ml to $1x10^{-6}$ g/ml) had no effect on the quantal content. Morphine at $1x10^{-5}$ g/ml to $1x10^{-4}$ g/ml reduces the amplitude of MEPP in the range of 20% to 80%. Naloxone ($1x10^{-4}$ g/ml) also reduced the amplitude of MEPP about 30%, and did not antagonize the effect of Morphine on the amplitude of MEPP. Both Morphine and Naloxone produced no significant effect on the frequency of MEPP.

We conclude that Morphine and Naloxone in high concentration have significant postsynaptic effect on the neuromuscular junction which is probably nonspecific since Naloxone does not antagonize the effect of Morphine. However, the presynaptic facilitative effect on quantal release produced by Morphine is abolished completely by Naloxone. We believe the neuromuscular junction is a useful simple model for the study of mechanism of action of Morphine at a molecular level.

1211 MECHANISMS REGULATING ACETYLCHOLINE SYNTHESIS AT THE NEUROMUSCULAR JUNCTION. Ken Vaca* and Guillermo Pilar (SPON: M. Wilson). Physiology Section, Biological Sciences Group, Univ. of Connecticut, Storrs, CT 06268.

Electrical stimulation of the chick ciliary nerve causes a frequency-dependent increase in the high affinity uptake of ^{3}H-choline (Ch) and its conversion to acetylcholine (ACh) in the terminals innervating the iris muscle. Conditioning trains of stimuli have little or no effect on uptake or synthesis during subsequent periods of rest, suggesting that after ACh is hydrolyzed in the synaptic cleft, Ch is rapidly and efficiently reaccumulated to replenish ACh stores. If the tissue is depolarized with high K^+ or veratridine during the incubation with ^{3}H-Ch, accumulation is substantially reduced, even in high Mg^{++}, 0 Ca^{++} medium. Thus, energy derived from the membrane potential contributes to the driving force for Na^+-coupled Ch transport. The role of the Na^+ gradient was evaluated in experiments where Na^+, K^+-ATPase was inhibited with either ouabain or K^+-free medium for various lengths of time prior to the uptake of Ch. In both cases, there was a rapid phase of inhibition, which may be due to a direct effect on membrane potential and a prolonged slower phase which could be fit by an exponential curve; presumably reflecting dissipation of the Na^+ gradient. If subsequent to depolarization with high K^+, the tissue is returned to normal medium containing ^{3}H-Ch, the V_{max} for transport is doubled (from 4.9 to 9.8 pmoles/8 min/iris) while the V_{max} for ACh synthesis increases about five-fold (from 1.2 to 6.3 pmoles/8 min/iris) without any significant change in K_m values. The influxes of both Na^+ and Ca^{++} during depolarization are involved in the subsequent activation of uptake. Replacement of Na^+ with either Li^+ or sucrose or addition of tetrodotoxin reduces the extent of activation. Omission of Ca^{++} or antagonism of its influx with D600 or high Mg^{++} has a similar effect. If ouabain is present during Ch uptake following preincubation in high K^+, uptake is not significantly increased; however, ACh synthesis is substantially elevated. It is proposed that activation of Ch uptake is due in part to an electrogenic Na^+ pump. Equations derived using the principles of nonequilibrium thermodynamics allow us to calculate that a 10 mV hyperpolarization will more than double the ability of the terminals to accumulate Ch. In order to account for the differential effects on uptake and synthesis, it is hypothesized that the Ca^{++}-dependent release of ACh from a compartment, presumably vesicular, results in an accelerated translocation of ACh into that compartment from the cytoplasm thus driving ACh synthesis by mass action and allowing further accumulation of Ch.

1212 PERMEABILITY OF FROG END-PLATE MEMBRANES TO ORGANIC AND INORGANIC CATIONS. Shigenori Watanabe* and Toshio Narahashi (SPONS: S.-C. Cheng). Dept. Physiol. & Pharmacol., Duke Univ. Med. Ctr., Durham, NC 27710 (Present address: Dept. Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611).

Permeability of the end-plate membrane of the frog sartorius muscle to a variety of organic and inorganic cations has been studied by iontophoretic applications of acetylcholine (ACh). Recording of the membrane potential was made from the end-plate region by means of an intracellular microelectrode filled with 3 M KCl solution, while ACh or carbachol was iontophoretically applied to the external surface of the end-plate membrane via a microelectrode filled with 1 M ACh or 1 M carbachol. For study of a test cation, sodium in Ringer's solution was replaced by an equimolar concentration of the test cation. Four organic cations caused a sizable increase in ACh potential, with the peak amplitude reaching 150-250% of the control in ammonium-substituted Ringer's solution, 120-160% in formamidine, 120-180% in methylamine, and 150-220% in hydrazine. The resting membrane potential was only negligibly decreased by these cations except for ammonium which caused a 5-20 mV depolarization. Guanidine and lithium decreased the amplitude of ACh potential to 80-90% of the control. Methylguanidine was unique in that it suppressed the ACh potential at low concentrations with an apparent dissociation constant of 0.2 mM. This effect was reversible upon washing with methylguanidine-free medium. Choline has a similar but weaker blocking action on the ACh potential, with 5 mM choline decreasing the potential to 20-30% of the control. It also caused a slight depolarization. The time course of the ACh potential was affected by some of the cations. The time to peak amplitude and the half-decay time were prolonged by methylamine, hydrazine, guanidine and lithium. Since carbachol iontophoretic application yielded the same results as ACh application, and also since physostigmine prolonged the falling phase of ACh potential but did not potentiate the peak amplitude, the observed increase in the peak ACh potential by certain cations is not due to the inhibition of acetylcholinesterase. Thus, ammonium, formamidine, methylamine and hydrazine are more permeant than sodium to the end-plate membrane during the transmitter action. Guanidine and lithium are only slightly less permeant than sodium. The relatively non-selective permeability of the end-plate membrane to these cations is reminiscent of ionic channels of the resting squid axon membrane, but the potent blocking action of methylguanidine and choline is not observed in the squid axon membrane.

1213 POSSIBLES ROLES OF TWO SUBPOPULATIONS OF ANTI-ACETYLCHOLINE RECEPTOR ANTIBODIES IN THE PATHOGENY OF EXPERIMENTAL AUTOIMMUNE MYASTHENIA GRAVIS. Anne D. Zurn* and Bernard W. Fulpius. Dept. Biochem., University of Geneva, Sciences II, Geneva, Switzerland.

Two different subpopulations of anti-acetylcholine receptor (AcChR) antibodies were studied during the evolution of experimental autoimmune myasthenia gravis (EAMG) in a rabbit immunized with Torpedo AcChR.

The antibodies directed against sites other than the bungarotoxin (Bgt)-binding site of the receptor were quantified with a radioimmunoassay. At the onset of paralysis, the titer of these antibodies was 7 nmol ^{125}I-α-Bgt-AcChR complex precipitated per ml serum, a value only 1.4 times higher than the highest level measured before.

The anti-AcChR antibodies directed against the toxin binding site of the AcChR (toxin from Naja naja siamensis) were measured with an assay based on the inhibition of α-toxin binding to the soluble AcChR. At the onset of paralysis, the amount of inhibition was 37% per 0.1 µl serum, a value seven times higher than the highest level measured before paralysis.

When portions of mouse diaphragms were incubated successively with control serum and ^{125}I-α-toxin, the receptors within the region of the nerve terminals were radioactively labelled. With anti-AcChR serum taken at the onset of paralysis, only background radioactivity was detected in this region.

We propose that only one of the two populations of anti-AcChR antibodies, the one which inhibits toxin binding, might be involved in the pathogeny of the neuromuscular blockade observed in EAMG.

NEURONAL CIRCUITS AND PATTERN GENERATION

1214 TRIGGERING OF EXPIRATORY NEURONS IN COUGH. H.L. Batsel and A.J. Lines, Jr. Medical Research Programs VAH Long Beach, Ca 90822.

In lightly pentobarbitalized cats, weak electrical stimulation of the cervical vagus at high frequency (300 Hz) activates about half of the inspiratory neurons located ipsilaterally in ventrolateral nucleus of tractus solitarius (NTS). Under the same conditions about half of the expiratory neurons located ipsilaterally in nucleus retroambigualis (NRA) is inhibited. Slightly stronger stimulation of the vagus is able to increase the number of inhibited expiratory neurons, including a few in contralateral NRA. The effect of such weak stimulation of the vagus on respiratory movements resembles the inflation reflex. Stimulation of the vagus at parameters which cause cough (17 Hz and 5 times the weak stimulus) beginning during expiration results in an initial inhibition of expiratory neurons followed by a long preparatory inspiration, followed in turn by high-frequency bursting discharge of the expiratory neurons which earlier had been inhibited. Stimulation of the vagus at cough parameters causes fixed latency driving of about 80% of the inspiratory in ipsilateral NTS. We conclude that about half of the NTS inspiratory neurons activated by weak high-frequency stimulation of the vagus are interneurons whose function is to promote a shift to inspiration as a preliminary to cough. We assume that the transient parallel inhibition of expiratory neurons must somehow favor the development of the preparatory inspiration.

1215 AUTORADIOGRAPHIC TRACING OF DORSAL CENTRAL GRAY PROJECTIONS IN THE RAT. S. Browder*, D. C. German, M. Mendershausen*, R. T. Brown*, R. S. Kiser, and G. A. Mihailoff (SPON: R. Seaman). Depts. of Physiol., Psychiat., and Cell Biol., U. of Texas Health Sci. Ctr., Dallas, TX, 75235.

The dorsal central gray (DCG) area has been linked with the paleospinothalamic pain system, and electrical stimulation here in animals produces behavioral agitation with frantic running, urination and defecation (Kiser & Lebovitz, Physiol. & Behav., 15 (1975) 47-53). Stimulation of this region in man produces a complex mixture of affective, autonomic, and painlike sensations with emotional responses of fright and feelings of impending death (Nashold et al., J. Neurosurg., 3 (1969) 14-24). In order to study the anatomical projections of this area in the rat, tritiated amino acids (leucine and/or proline, 27-43 uCi/ul) were pressure injected (0.2 µl over 30 min.) or microiontophoresed into the DCG of 10 animals. With the microiontophoretic method, very small injection sites were made within DCG loci where electrical stimulation produces aversive behavioral effects. All projections were primarily ipsilateral to the injection site. Ascending and descending projections were observed running within the central gray. The descending projections travelled to the caudal pons within the lateral reticular formation with label found throughout the brainstem reticular formation. From the injection site, labelled fibers radiated dorsal, lateral and ventral into the tectum in Wisschedels' radiato grisea tegmenti. Ascending axons were followed into the lateral habenular nucleus, parafascicular nucleus of the thalamus, and ventrobasal thalamus. Labelling was also found in the posterior hypothalamic area. These results are consistent with previous autoradiographic studies in the cat, and they will be discussed with respect to silver degeneration studies of DCG projections in the rat.

1216 NEURAL MECHANISMS THAT ENCODE THE INTENSITY AND THE MODALITY OF CUTANEOUS PRESSURE AT THE NEURONS OF THE CAT MEDULLA AND THALAMUS. R. Emmers. Department of Physiology, College of Physicians & Surgeons, Columbia University, New York, N. Y.

When single electrical pulses are substituted for pressure applied to a small peripheral field on the cat's tongue to drive a neuron in the nucleus VPM of the thalamus, the firing pattern of the neuron has two activity peaks. These can be seen best on a post-stimulus histogram. The first has a latency of 6-12 msecs and its height varies with the intensity of stimulation (I peak); the second, with an avg latency of 40 msecs, is characteristic of those neurons that respond to pressure by tonic activity throughout the period of stimulation. This peak, therefore, is the code for a certain sensory modality (M peak). (Brain Res. 21:91, 1970). When dual electrical pulses are applied to the same field, the I-M pattern does not become disorganized but it undergoes certain predictable changes. 1) The 2nd stimulus of the pair is unable to fire the thalamic neuron at interstimulus intervals of 25-30 msecs. Consequently, the pattern originated by the 1st stimulus is disturbed only for as much as the 2nd stimulus interrupts the spontaneous activity of the system by activating inhibitory interneurons at the medullary level. 2) The effectiveness of the 2nd stimulus to fire the thalamic neuron increases progressively as the interstimulus interval is lengthened. With the I peak of the 2nd stimulus (I_2) increasing in height, the M peak of the I_2 also appears (M_2). As a result, the activity peaks interlace at some interstimulus intervals (I_1, I_2, M_1, M_2) but are separate at others (I_1-M_1, I_2-M_2). Interlacing of the activity peaks is controlled by an inhibitory period that occurs at the corresponding pressure relay neurons in the trigeminal nuclear complex soon after the neuron fires for an I peak. The inhibition dissipates slowly within 160 msecs. Consequently, firing of the trigeminal neuron forms only I peaks. In fact, firing of the trigeminal neurons was at its lowest at the time when the thalamic neurons fired for the M peaks. Therefore, it was concluded that the M peaks are formed by re-excitation of the thalamic neurons via circuits that originate on the thalamic level and that the inhibitory period at the trigeminal neurons prevents the modality peaks of multiple stimuli to merge. (Aided by grant NS-03266 from NINCDS)

1217 RHYTHM GENERATION IN NEURONAL NETWORKS WITH RECURRENT CYCLIC INHIBITION. W. Otto Friesen and Gunther S. Stent*, Dept. Mol. Biol., Univ. California, Berkeley 94720.

A network of intra- and intersegmentally connected interneurons gives rise to the swimming rhythm in the medicinal leech (Friesen, W., Poon, M. and Stent, G., PNAS 73, 3734-3738, 1976). The origin of the oscillations in this network can be explained by the mechanism of recurrent cyclic inhibition first proposed by G. Szekely (Acta Physiol. Acad. Sci. Hung. 27, 285-289, 1965). This mechanism applies to any neuron ring consisting of an odd number of cells in which each cell provides inhibitory input to and receives inhibitory input from one other cell, and where all cells are supplied with some tonic source of excitation. Activity progresses around this ring in a sense opposite to the direction of the inhibitory connections. The cycle period of such a network depends on the sum of the times required for each cell to reach impulse threshold following cessation of its inhibition. Further properties of the mechanism of recurrent cyclic inhibition were explored through theoretical considerations and modeling with analog electronic neuronal elements (neuromimes). These neuromimes are "integrate and fire" analog models with provisions for excitatory and inhibitory synaptic inputs, threshold control and impulse outputs. In modeling experiments all neuromimes received externally controlled tonic excitatory inputs from a common source. Experiments showed that in neuromime rings with three or five elements, in which each element inhibits the next with no conduction delay, the cycle period of the oscillations depends almost exclusively on the summed inhibition recovery times of the elements. Since the recovery times vary inversely with the tonic excitation levels, the cycle period of the oscillations also varies inversely with the level of excitation. When a delay was introduced in the impulse conduction between two of the elements in an inhibitory ring, the cycle period was found to display a constant time sector in addition to the variable time sector, in agreement with physiological data from swimming leech preparations. The introduction of the conduction delay, which was designed to mimic the approximately constant time required for an impulse to traverse the distance between segmental ganglia in the leech nerve cord, also provided an adequate phase delay between activity in neuromime elements modeled to be in different ganglia. Finally, the concatenation of two five-membered rings to model the interconnections of three ganglionic oscillators gave rise to an increased cycle period at constant excitation levels and provided for proper phase delays for the modeled activity in a chain of ganglia. (Supported by NIH grants GM 17866 and NS 12818, NSF grant BNS 74-24637 and NIH postdoctoral fellowship NS 05144).

1218 NEURONAL ORGANIZATION OF ESCAPE SWIMMING IN TRITONIA. Peter A. Getting* (SPON: D. H. Perkel). Dept. of Biological Sciences, Stanford Univ., Stanford, CA 94305.

Escape swimming behavior in Tritonia diomedea consists of two major components: an initial reflexive withdrawal followed by a series of alternating ventral and dorsal flexions. The basic mechanism of generating motoneuronal activity "switches" from reflexive to centrally programmed. Three classes of cerebral interneurons and some of their synaptic connections have been identified. Reflexive withdrawal interneurons (RWI) receive direct input from sensory afferents and synapse with motoneurons in the ipsilateral pedal ganglion. This class of interneurons is excited during reflexive withdrawals but is inhibited during swimming. A second class of interneurons termed swim interneurons (SI) also receive excitatory input from sensory afferents and synapse with ipsilateral pedal motoneurons. The SI, however, are excited during both reflexive withdrawals and swimming during which the SI burst in phase with the dorsal flexion motoneurons. The third set of interneurons (C-2) are necessary for the normal initiation and maintenance of the cyclical swim phase. Activity in C-2 neurons appears to retrigger a swim oscillator network cycle-by-cycle. Motoneuronal activity during reflexive withdrawals is determined by the summation of inputs from at least three sets of identified interneurons (RWI, SI, C-2). During swimming, C-2 neurons inhibit the RWI such that the motoneurons are freed to respond primarily to inputs from the SI and C-2 neurons. The switch from reflexive to programmed motor output involves a reordering of central circuitry

1219 MOTOR PROGRAM FOR LOCOMOTION IN APLYSIA DOES NOT REQUIRE PERIPHERAL FEEDBACK. W. Hening, T. Carew and E. Kandel. Div. Neurobiol. & Behav., Dept. Physiol., Columbia P&S, New York, N.Y. 10032.

The locomotor pattern of a number of invertebrates has been shown to result from a central program. In view of the advantages of Aplysia for a cellular analysis of behavior, we have examined the nature of the neural mechanisms underlying pedal locomotion. We now report a preliminary analysis of walking in Aplysia and show that the central neuronal generator for walking produces patterned output without the necessity of afferent feedback.

By videotape analysis of intact animals, we confirmed that walking consists of stereotyped cyclical activity of the foot, parapodia and tail. To find motor neurons participating in this behavior, we recorded from cells in the pedal ganglia of semi-intact preparations. We identified several populations of presumptive motor neurons acting upon the foot, parapodia and tail. Since the semi-intact animal shows walking behavior, we were able to correlate the activity of identified neurons with the phases of walking by simultaneous videotape and intracellular recording. We found that motor neurons are active in those phases of walking during which their target organs exhibit characteristic activity. To determine whether the central generator for walking requires afferent feedback, we conducted two types of experiments. First, while maintaining penetrations of identified cells, we made nerve sections to isolate the ring ganglia (pedals, pleurals and cerebrals). After sectioning, typical cyclical activity persisted in the presumptive motor cells. Second, we recorded from identified presumptive motor neurons in the isolated nervous system. We found that these cells show cyclical activity, both spontaneously and following stimulation of a peripheral nerve, that was indistinguishable from that of walking in the semi-intact preparation. We therefore concluded that the neural generator for walking is located in the ring ganglia and that its patterned output does not require afferent feedback.

We have also examined how parapodial motor neurons contribute to different behaviors. These motor neurons are active both in walking and in respiratory pumping, a complex behavior whose command elements are located in the abdominal ganglion. As in other Aplysia motor systems with graded output, these motor neurons are organized in parallel; they receive both common and unique synaptic input, but form no synaptic interconnections. As a result, different subsets of motor neurons can be selectively activated to produce the varying patterns of activity required for different behavioral sequences.

1220 DEVELOPMENT OF SYNAPTIC CONNECTIONS IN THE HIPPOCAMPUS FOLLOWING REMOVAL OF NORMAL RECIPIENT NEURONS BY NEONATAL X-IRRADIATION. Anders Hjorth-Simonsen* and Søren Laurberg* (SPON: Erik Westergaard). Dept. Anat., Univ. Aarhus, DK-8000 Aarhus C, Denmark.

The brains of new-born rats were exposed to graduated X-irradiation, which arrests further proliferation of neurons while it is relatively harmless to differentiating or mature neurons. The majority of the granule cells, which form a discrete layer in the dentate gyrus, develop after birth in a latero-medial sequence, consequently, in the irradiated animals, only the lateral portion of the granule cell layer is formed. The major sources of afferents to the granule cells, viz., the medial and lateral entorhinal cortices and the regio inferior of Ammon's horn, are generated before birth and, therefore, would be expected to be resistant to the irradiation. The axons from the three different sources normally terminate, with little or no overlap, in specific zones across the granule cell dendrites. These zones are reflected in a distinct chemoarchitectonic stratification seen in Timm-sulfide silver preparations.

In the irradiated rats that were allowed to grow up, an equally distinct stratification was found with the Timm method not only above the surviving granule cells, but also medially where these were lacking. It was found with the Fink-Heimer method that each histochemically defined zone corresponded to one of the three major afferent systems to the dentate gyrus in the normal sequence from the pial surface. These findings indicate that the spatial segregation of the converging pathways has occurred relatively independent of the normal target neurons at the site examined.

Golgi preparations of irradiated brains showed that the basal dendrites of pyramidal cells in the Ammon's horn adjacent to the hilus of the dentate had extended into the terminal zones formed in the absence of granule cells. It is possible that the abnormal dendritic growth has been induced by the afferents deprived of normal target cells.

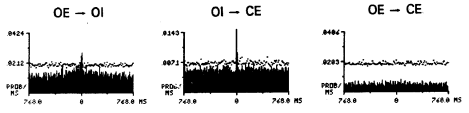
1221 SYNAPTIC CHANGES AND MODIFIED BEHAVIOR IN A CHRONICALLY ISOLATED SEGMENT OF THE MEDICINAL LEECH. William B. Kristan, Jr., Department of Biology, University of California, San Diego, La Jolla, California 92093

Swimming in the medicinal leech is a well-defined behavioral act. After initially flattening, each of the 21 mid-body segments undergoes an alternating dorsal and ventral longitudinal muscle contraction in metachronal synchrony with the other segments. If all the interganglionic connectives to a single segmental ganglion are severed, the neurally isolated segment so produced is at first incapable of swimming movements. However, after 1 to 2 weeks of isolation, the segment acquires the ability to produce swimming movements by itself. In order to find the basis for this behavioral change, properties of neurons known to be involved in swimming were measured in ganglia isolated for 2 to 4 weeks. Three kinds of synaptic connections are found in these ganglia which are never seen in normal segmental ganglia: electrotonic synapses between dorsal and ventral longitudinal muscle excitors; inhibitory connections from excitatory motor neurons onto inhibitory motor neurons; and connections from tactile sensory neurons onto a cell which initiates swimming. The latter synaptic modification is potentially involved in the acquisition of the ability of the isolated segment to swim.

INTERACTIONS AMONG CRAYFISH CLAW MOTOR NEURONS DURING ACTIVE AND PASSIVE DACTYL MOVEMENTS. B. G. Lindsey and G. L. Gerstein. Dept. Physiology, Sch. Med., Univ. Pa., Philadelphia, Pa. 19104.

Spike trains of 3 crayfish claw motor neurons, the opener excitor (OE) and inhibitor (OI) and the slow closer exciter (CE), have been monitored simultaneously 1) while the dactyl is held motionless, 2) during imposed dactyl movements (reflex loop open: motor neuron axons cut distal to peripheral electrodes), and 3) during movement playback experiments. In the latter, neural activity and dactyl position were recorded during active ("spontaneous" or reflexively induced) movements. The reflex loop was then opened and the position signal played back into a galvanometer. This replicated the previous movements produced by the intact crayfish; neural activity was monitored again. Statistical analyses of the spike trains reveal that OI can be an element of more than one functional group of neurons: OI may be positively correlated with both OE and CE while OE and CE may or may not show signs of coordinated firing (Fig.). Results of playback experiments show that OI and OE can be positively correlated during active opening while the probability of CE activity is relatively low; intermittent imposed movements during this phase of the experiment show that CE can respond to proprioceptive inputs. During the playback phase OI and CE spike trains are usually temporally correlated while OE may be virtually silent. Intracellular recordings of OI and CE made while simultaneously monitoring claw joint receptors have revealed that 3 types of receptors (differentiated by responses to opening step movements of dactyl) excite both efferents. The sensitivities of these receptors are not under any known direct efferent control; therefore, movement playback technique helps characterize the contributions of central mechanisms in modulating sensory-motor interactions. In the cases in which active movements are "spontaneous", the sensory information transmitted to the CNS should in principle be the same during both movement and playback phases of the experiments.

Fig.: Cross correlograms (reference event first). Spike trains recorded simultaneously during imposed opening movements of dactyl (2-29°, 3°/sec, 26 repetitions). Number of events: OE, 318; OI, 1595; CE, 1265. Normalized ratio, events in peak/events in "background": 1.0, 1.1, 0. Control calculation (target events shifted by one stimulus cycle) raised by arbitrary amount for clarity. (NIH 1F32 NS05650-01; NS05606)



1223 ANALYSIS OF NEURAL NETWORK COMPONENTS USING SINGLE CELL ISOLATION. J. A. London* and M. B. Merickel (SPON: C. S. Carter). Dept. of Physiol. and Biophysics and Bioengineering Program, Univ. of Illinois, Urbana, IL. 61801.

Analysis of simple neural networks is often complicated by interactions between component neurons as well as by specialized cellular properties. This laboratory is approaching the problem by studying the properties of isolated neurons of the buccal ganglion of the snail, Helisoma trivolvis, using a technique based on Kostenko's method of cell isolation (Kostenko, et al, Comp. Biochem. Physiol., 1974, 49A, pp. 89-100). The neural sheath is softened by soaking the ganglion in a trypsin-hyaluronidase solution (0.25%, for 7 minutes, 25°C). Intracellular recordings taken from the same cell before and after treatment showed no change in characteristic firing patterns, action potential height and waveform. The neural sheath was then teased away using electrolytically sharpened needles, allowing the cells of the ganglion to float free of the ganglionic mass. These cells maintained characteristic synaptic activity, firing patterns and membrane properties (e.g. action potential height and width, time constant). Complete isolation was performed by cutting the axon of the cell from the soma. The larger cells of the ganglion could be followed throughout the isolation procedure visually. Large protractor motoneurons which are characterized by a membrane hyperpolarization usually followed by a burst of spikes and which are electrically coupled when in the intact ganglion showed none of these characteristics when isolated, but would still generate action potentials when stimulated. Increases in membrane time constants were measured which are consistent with the cell being "unloaded" from the rest of the network.

This technique is being used to study the mechanisms by which a network of electrically coupled neurons in the buccal ganglion (i.e. cyberchrons, Kater, S. B., Amer. Zool., 1974, 14(3), pp. 1017-1036) generates rhythmic bursting output. It has been difficult to determine whether burst generation in this network is a property of individual cyberchron neurons or an emergent network property. Dyes injected into these small cells can be used to follow specific cells through the isolation procedure. This will allow a direct comparison of cellular properties before and after isolation and observation of these cells' intrinsic electrical activity.

1224 RATE-SPECIFIC AND STATE-SPECIFIC ASPECTS OF SPONTANEOUS DISCHARGE PATTERNS IN CAT LATERAL GENICULATE UNITS. Robert W. McCarley and Odile Benoit*, Harvard Medical School and University of Paris, France.

The spontaneous discharge pattern of cells in thalamic relay nuclei is usually described in "state-specific" terms: they tend to discharge in bursts in synchronized sleep and with isolated spikes in waking (W) and desynchronized sleep (D). An alternative hypothesis is that discharge rate determines pattern. The cause of the burst pattern is unknown but juxtacellular microelectrode recordings in the lateral geniculate body (LGB) suggest that each burst can be viewed as a single event, a postsynaptic potential whose time of occurrence is marked by the first spike in the burst. The isolated spikes and the first spike in each burst can thus be characterized as the "primary events", and it is a logical first step to begin the analysis of rate-pattern relationship in the LGB with these primary events. The variance, third, and fourth moment are used as the first order pattern measures; they are directly related to aspects of histogram form and are also mathematically justified as the first three terms in a power series approximation of the density (histogram) function. First order measures are those not dependent on the serial order of intervals.

The data presently analyzed is from extracellular recordings of 10 histologically localized LGB units during spontaneously occurring episodes of W, synchronized sleep with spindles, synchronized sleep without spindles, and D. Several recordings of each unit in the same state were included in the analysis since one of the purposes of the study was to examine the rate-pattern relationships in one cell under different conditions of rate and state, as well as between cells.

A least squares linear regression analysis was done on stationary records to determine the relationship between the mean interval duration ($\overline{ISI}$) and the pattern measures of the primary events using the equation: $\text{Log } Y = A_0 + A_1(\text{Log } \overline{ISI})$ where Y was successively taken to be variance, 3rd moment and 4th moment. The percentage of variance explained was 96.4% for the variance and 91.6% and 91.8% for the 3rd and 4th moments. Inspection of the plots of the pattern measures showed no apparent difference in goodness of fit to the above regression line in comparisons of recordings of different cells and from one cell under conditions of different rates and states. These data suggest that for primary events discharge rate determines first order discharge pattern in spontaneous activity of lateral geniculate cells.

1225 MEMBRANE PROPERTIES OF BURSTING NEURONS OF ELECTRICITY COUPLED NETWORK INVESTIGATED WITH SINGLE ELECTRODE VOLTAGE CLAMP. Michael B. Merickel. Bioengineering Program and Dept. Physiol. and Biophysics, U. of Ill., Urbana, IL 61801.

The cyberchron network in the snail Helisoma is an electrically coupled population of neurons which produces the rhythmic bursting output which drives the motoneurons controlling the animal's feeding behavior. A major, unresolved problem in understanding the functioning of this network has been determining the origin and mechanism of burst generation. Burst generation can be expected to be either a property of individual cyberchron neurons or an emergent network property, two distinctly different mechanisms. Detailed analysis of the membrane properties of the cyberchrons has been hampered due to their small size, permitting only single microelectrode penetration. The single electrode voltage clamp (developed by Wilson and Goldner, 1975; J. Neurobiol. 6:411) is an essential technique enabling the membrane properties of such small, but important neurons to be examined.

Cyberchron neurons were specifically examined for the presence of a persistent inward current and associated negative resistance region which has been shown to underlie bursting in single molluscan neurons by other investigators. Steady-state I-V curves were found to be remarkably linear (small degree of delayed rectification) over the membrane potential range of -80 to -10 mV. The effects of loading on a cyberchron neuron by the rest of the electrically coupled network was constant for the range of command potentials employed and was calculated to be comparable to the loading of an axon on a soma of a non-electrically coupled neuron. It is concluded that cyberchrons do not individually have the membrane properties which have been considered to be essential for burst generation by single neurons, and therefore burst generation in the cyberchron network must rely on network interactions or the properties of some uncharacterized neuron.

Investigations are currently in progress to study the membrane properties of a newly identified but uncharacterized cyberchron neuron which appears to be the origin of a shunting process. This unusual cyberchron neuron may be a key element which regulates the effective coupling between the main population of cyberchron neurons by causing a shunt during the burst. A decrease in coupling between the main population of cyberchron neurons is in fact observed during and immediately after a burst which may be responsible for burst termination.

1226 RECRUITMENT OF MOTORNEURONS IN THE COCKROACH. D. Meyer* and P. Walcott. Anat. Sci., Health Sciences Center, SUNY at Stony Brook, Stony Brook, NY 11794.

We have been able to account for the recruitment sequence of a small population of insect motorneurons by their different innate sensitivities to depolarizing current. The sensitivity of a small number of motorneurons which innervate the flexor muscles of the coxal leg segment was studied by impaling processes of these cells in the neuropile and noting the mean firing frequency of the neurons during pulses of applied current. By plotting the mean firing frequencies as a function of magnitude of the stimulating current pulse, we were able to obtain f-I relations for a number of motorneurons. The motorneurons were identified by the amplitude of the spike height recorded extracellularly from the nerve to the flexor muscle and by measuring the tension developed by the motor unit when its motorneuron was stimulated with an intracellular current pulse. In all cases we found that the threshold for the initiation of repetitive firing and the slope of the f-I relation were strongly correlated with the mechanical properties of the motor unit. The more powerful units were less sensitive to depolarizing current. Thus the most powerful motor units having the highest threshold and smallest slope for the linear portion of the f-I relation. It has been shown that several of the flexor motorneurons could be driven by depolarizing a single interneuron (Interneuron I, Pearson and Fourtner, J. Neurophysiol. 38, 1975). When we compared the f-I plots for the flexor motorneurons which were obtained by stimulating interneuron I with those obtained by stimulating the motorneurons directly, we found that the recruitment order was the same as that predicted by the intrinsic sensitivities of the motorneurons to injected current. Furthermore, the ratios of the slopes of the f-I relations were similar whether the cells were stimulated directly or via interneuron I. These results strongly suggest that some innate property (or properties) of the the motorneurons determines their order of recruitment and also their firing frequences during behavior.

1227 INPUTS TO THE LOBSTER STOMATOGASTRIC GANGLION UNMASK BURSTING PROPERTIES IN MANY OF ITS MOTORNEURONS. David F. Russell and Daniel K. Hartline, Biology Dept., UCSD, La Jolla, CA 92093

Most of the motorneurons of the stomatogastric ganglion, including the AM, CP(DG), LC(LG), and GP(MG) gastric neurons and the LP, VD, IC, early PY, and late PY pyloric-follower neurons, show prolonged regenerative responses resembling the plateau potentials in vertebrate heart muscle. This mechanism appears to make a major contribution to both gastric and pyloric rhythms.

With CNS connections intact or following stimulation of input nerves, so that the gastric and pyloric rhythms were brisk, responses could be triggered either spontaneously or with brief weak depolarizing currents (e.g. 20-50 msec, 1-5 nA; see upper figures) and terminated spontaneously or by an IPSP barrage or with brief weak hyperpolarizing currents (lower figures), typical properties for plateau potentials. They were most easily demonstrated under hyperpolarizing offsets sufficient to stop on-going firing. Plateau potentials were usually eliminated when the input nerve (Stn) was cut or reversibly blocked with isotonic sucrose. They reappeared when the block was removed or the input nerve stimulated. We hypothesize that specific transmitter substances unmask or enhance a usually latent ability of these cells to produce plateau potentials, and possibly endogenous bursting.

Plateaus increase the gain of a neuron, so that a minimum of synaptic input switches it rapidly between a strongly firing "on" state and an "off" state, allowing rapid build-up and decay of strong output effects, e.g. on muscle tension. Bursting in many networks has been considered an emergent property of synaptic interactions among neurons that have simple repetitive-firing kinetics. Alternatively, synaptic networks could be driven by plateaus acting as a motive force; e.g. plateaus in the CP, LC, and GP clearly contribute to driving the gastric rhythm.

Endogenous properties such as plateaus could play roles in other bursting networks; they may easily be overlooked unless specific tests are applied under the right conditions.

1228 A CRITERION OF NEURONAL SPIKE TRAIN STATIONARITY BASED ON THE TEMPORAL PATTERN OF SPIKES. Arthur C. Sanderson*, Wlodzimierz M. Kozak, Jakub Segen*, and Dan Schweitzer-Tong*. Biomed. Eng. Prog. and E.E. Dept., Carnegie-Mellon Univ., Pittsburgh, Pa.

Most methods for the quantitative analysis of neuronal spike trains require that statistical properties of the spike train do not change spontaneously with time. While the mean rate of the process is a useful indication of stationarity, it is insufficient as a statistical criterion when higher order properties are being estimated. A method has been developed based on the sequential interval histogram (SQIH) technique[1] which distinguishes between mean rate stationarity and stationarity of the temporal pattern of interspike intervals. The method utilizes a peak tracking procedure applied to the mean rate normalized SQIH data. Peak location and statistical peak significance are used as features to describe the non-stationary behavior. A statistical criterion for the stationarity of the ensemble of peak parameters has been developed. The method has been applied to neuronal spike trains recorded from single neurons of the cat brain. Examples of cells in which the pattern of spike activity changes with time while the mean rate remains constant emphasize the importance of such a strict stationarity criterion for certain classes of experiments.

1229 SENSORY MODULATION OF A CENTRALLY PROGRAMMED BEHAVIOR. Karen A. Sigvardt* and Brian Mulloney. Dept. Zoology, Univ. California, Davis, CA 95616.

The neurons of the stomatogastric ganglion in the lobster, Panulirus interruptus, generate two motor patterns which control rhythmic movements of two parts of the stomach - the gastric mill and the pyloric region. The activity of the neurons which produce the gastric rhythm and the pyloric rhythm have been described and the connections of these neurons within the ganglion are well-defined. Sensory neurons in the pyloric region of the stomach alter the activity of both gastric and pyloric neurons. Specifically, the pyloric neurons, PD and LP, are inhibited; another pyloric neuron, VD, is excited; and the gastric neurons, GM and LPGN, are inhibited. These effects correlate with discrete postsynaptic potentials in these neurons. These PSPs are accompanied by bursts in the SGN and SON nerves, nerves which connect the stomatogastric ganglion to the commissural ganglia. This sensory input, then, modulates and can reset both the gastric and pyloric rhythms. Supported by USPHS Grant No. NS-12295 and the Alfred P. Sloan Foundation. Karen Sigvardt is a USPHS-NIH Postdoctoral Fellow.

1230 EFFECTS OF MECHANICAL LOADS ON EXPIRATORY NEURONS IN THE PRESENCE OF PUTATIVE TRANSMITTERS. R. Toleikis, M. Hanley* and D. T. Frazier, Dept. of Physiology and Biophysics, Univ. of Ky., Lex., Ky. 40506

Thirty phasic expiratory neurons in the area of the Nucleus retroambigualis were studied in anesthetized cats to determine the responsiveness of this functionally homogeneous population of neurons to the iontrophorectic application of the putative neurotransmitters, glutamate and GABA. Mechanical loading of expiration, both resistive and elastic, was employed to test whether the presence of these transmitter substances altered the sensitivity of the expiratory cell to known sensory inputs. Preliminary studies with glutamate and GABA have revealed that these two substances were very effective in modulating the spontaneous activity of phasic medullary respiratory neurons.

The expiratory unit activity was analyzed with respect to: spikes/burst, burst duration, interburst intervals and average firing rate. As anticipated, addition of mechanical loads on expiration caused consistent increases in all three parameters in every cell used in the study. The firing profiles (histograms) obtained for elastic loading was quite different than for resistive loading reflecting the difference in which volume information is developed and transmitted to the brainstem. Iontophorectically applied glutamate ($\bar{x}$ = 65 nA) also resulted in modest increases in all the parameters. However, it caused little change in the overall firing profile. When the loads were applied in the presence of a sustained level of glutamate the effects were additive. The general shape of the firing profile observed with loading remained essentially unchanged. Application of GABA ($\bar{x}$ = 40 nA) resulted in a significant decrease in the parameters monitored. However, as long as phasic activity remained, loads applied in the presence of GABA produced approximately the same absolute change as they did during control. Some cells exposed to high concentrations of GABA lost their phasic activity.

This study suggests that either the synaptically activated receptors are not effected by glutamate or that these particular sites are not accessible via iontophorectic application. GABA, in modest concentrations, depressed the activity of the cells in a graded fashion, but for the most part did not interfere with the overall effectiveness of the vagally mediated input.

1231 SYNCHRONOUS BURST FIRING MODES AMONG A GROUP OF COUPLED CELL MODELS. H. Wachtel Dept. of Physiology and Biomedical Engineering, Duke University, Durham, North Carolina 27706.

From our previous voltage clamp analysis of slow wave generation in Aplysia burst firing neurons, (BFN) we have derived electronic circuit models that we are now using to study the mechanics of burst synchronization among a population of coupled cells. The synaptic interaction (chemical or electrical) between pairs of BFN models is simulated using variable gain positive feedback. Several modes of achieving synchronized slow wave (and burst) activity have been noted. The simplest of these, (and the least physiological) is based on having only one cell spontaneously oscillate, and (due to tight coupling) impose its rhythm on all other cells. A more realistic case involves coupling several cells, each of which spontaneously oscillates at a somewhat different frequency, and having them phase lock together. The most interesting mode however, results from intercoupling several "sub regenerative" BFN models, none of which oscillate on their own, but which then oscillate in concert. This last mode, which involves both "endogenous" and "network emergent" behavior, is reminiscent of synchronous burst formation in various systems, including smooth muscle and epileptic foci. In these cases, the existence of oscillatory activity also depends on the number of coupled cells involved as well as their individual characteristics. The models can also be used to demonstrate how an entire population of such cells can be triggered to switch from a "stable" (not oscillating) mode to one of sustained, synchronous, bursting upon the application of a barely perceptible stimulus.

1232 PRODUCTION OF SWIMMING BEHAVIOR IN THE MEDICINAL LEECH BY STIMULATION OF A SINGLE NEURON. Janis C. Weeks* and William B. Kristan, Jr. Dept. of Biology, Univ. Ca. San Diego, La Jolla, Ca. 92093

The medicinal leech swims by undulating its flattened body dorso-ventrally, and this behavior can be recorded in the segmental nerves as alternating bursts from the dorsal and ventral longitudinal body wall motorneurons. In response to nerve stimulation, the isolated, brainless nerve cord (a chain of the 21 nearly-identical segmental ganglia and the connectives joining them) can generate this pattern quite accurately. The central oscillator consists of a network of oscillatory interneurons in each ganglion which drives the motorneurons in the proper phase relationships and also coordinates the rhythm intersegmentally.

A neuron has been discovered which, when stimulated, causes initiation and maintenance of swimming episodes in the entire isolated, brainless nerve cord. This neuron, assigned cell number 204, is an unpaired, multisegmental interneuron which occurs in most, if not all, of the segmental ganglia. During a swimming episode, the normally silent cell 204 population is depolarized and produces a burst of impulses during each ventral contraction phase. Hyperpolarization sufficient to suppress impulse activity in any two cell 204s in the cord does not affect the generation of swimming, indicating that while any one cell 204 is sufficient to initiate swimming, the activity of at least any two is unnecessary. Stimulation of any cell 204 during an ongoing swimming episode increases the cycle frequency of the entire cord for the duration of the stimulus. Using this cell as a driver, it has been possible to produce swimming in shortened lengths of nerve cord only 3 - 4 ganglia long.

While cell 204 is evidently strongly involved with the central oscillator, it is not functionally homologous to the identified members of the oscillator, as they do not possess the "command" ability of cell 204. Determining the connectivity of this neuron to other identified neurons in the leech (sensory, oscillatory and motor) should establish its role in the natural swimming behavior of the animal, and lead to new insight into how nervous systems provide for the generation, release, and modulation of centrally patterned activities.

1233 RETINOTECTAL PROJECTION AFTER TRANSLOCATION OF TWO TECTAL GRAFTS WITHIN THE SAME OPTIC TECTUM IN GOLDFISH. Myong G. Yoon. Dept. of Psychology, Dalhousie University, Halifax, Nova Scotia, Canada.

The topographic pattern of re-established retinotectal projection following various surgical manipulations of the optic tectum was studied in adult goldfish with neurophysiological mapping methods. In the first group of experimental fish, a rectangular piece of the tectal tissue was dissected out from the rostral zone, and a similar tectal piece was also dissected from the caudal zone of the same tectum. The two pieces of tectal grafts were rotated by 180° around the dorsoventral axis, and then the caudal graft was reimplanted into the rostral zone and the rostral graft into the caudal zone within the same tectum. A majority of the operated fish showed that the translocated tectal grafts (particularly, the rostral graft reimplanted into the caudal tectum) had undergone a complete or severe degeneration. In a few cases, however, it was possible to record visual responses from the surviving tectal grafts as well as from the surrounding intact area of the tectum. The re-established visual projections onto the reciprocally translocated tectal grafts showed the corresponding localized transposition along the rostrocaudal axis in addition to the 180° rotation around the dorsoventral axis of the operated tectum.

In the second group of experimental fish, a rectangular piece of the tectal tissue was dissected out from the medial zone, rotated 180°, and then reciprocally translocated with a similar 180° rotated tectal graft, dissected from the lateral zone within the same tectum. In the latter case, the re-established visual projections onto the operated tectum showed the corresponding localized transposition along the mediolateral axis as well as the 180° rotation around the dorsoventral axis of the operated tectum.

1234 MODULATION OF INPUT IMPEDANCE THROUGH RESISTIVE COUPLING.

Birgit Zipser. Dept. of Physiol., State University of New York, Downstate Medical Center, Brooklyn, N.Y. 11203.

Two classes of paired motoneurons in ganglion 6 of the leech, PS1 and PS2, that innervate the penis sheath, differ dramatically in their membrane properties, which results in a novel kind of resistive interaction. All four neurons are electronically coupled to each other. Coupling between the two PS1 is the strongest (20 to 60%) enabling them to drive each other often spike for spike as an electrical unit. The two PS2 are weakly coupled to each other (a couple of %). Coupling from PS2 to PS1 is also small.

The novel resistive interaction is brought about by current flowing from PS1 to PS2. Depolarizing current injected into PS1 elicits a significantly larger coupling potential in PS2 than hyperpolarizing current (10 compared to 4%), suggesting rectification in the coupling process. But in the case of these neurons, the asymmetry in coupling potentials does not seem to arise from the rectifying properties of junctional membrane but rather from an anomalous rectification of PS2's cell membrane.

PS2's input impedance is strongly dependent on its membrane potential. As the cell body is depolarized towards threshold, the input impedance increases tenfold. PS1's input impedance, by contrast, is constant in the vicinity of the resting potential and decreases slightly rather than increases with depolarization.

Thus, it appears that large areas of neuronal membrane of PS2 act as the rectifier. This idea is supported by the finding that PS1 can indeed modulate the input impedance of PS2. Hyperpolarizing PS1 lowers PS2's input impedance and depolarizing PS1 increases it.

Even though the coupling potentials are asymmetrical in their amplitude, they could be equivalent in inhibitory and excitatory function because of their effect on PS2's input impedance. The smaller hyperpolarizing coupling potential is significant in that it signals a decrease in PS2's input impedance. Thus, more excitatory synaptic current from other sources would be needed to bring PS2 to firing threshold.

It has been observed in several instances now in the leech that neurons within a network subserving the same function are electronically coupled. The fact that the four motoneurons to the male organ are resistively coupled is a further example. Thus, there is the possibility of delineating a functionally coherent network by using techniques that elucidate resistive junctions. (Supported by NS0577303)

NEURONAL SHAPE AND FUNCTION

1235 X-RAY MICROANALYSIS IN NEUROCHEMISTRY: LOCALIZATION OF AN *ELEMENTAL NEUROTOXIN AND MANIPULATIONS OF MITOCHONDRIAL CA++*
H.S. Adler*, J.L. Costa* and E.K. Silbergeld, NIH, Bethesda, MD 20014

The coupling of x-ray elemental analysis to electron microscopy provides a new method for studying subcellular location of elements (Somlyo et al., J. Cell Biol. (1974) 61, 723). Two problems suitable to this approach are (1) localization of elemental neurotoxins, such as Pb, whose site of action is unknown; and (2) intracellular ion changes after drug treatment. For these studies synaptosomes were purified from rat caudate, air-dried on grids and examined in the scanning-transmission mode (STEM) on a Hitachi 500 EM equipped with energy dispersive x-ray spectrometry.

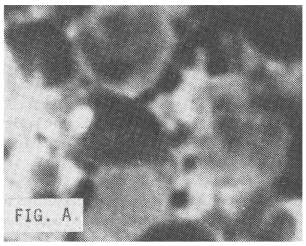

FIG. A

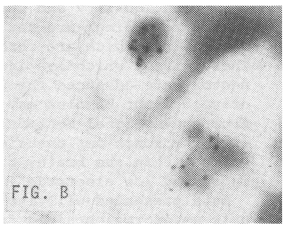

FIG. B

Air-dried synaptosomes (Fig. A, 25 KeV, 20,000x) appear as indistinct rounded shapes. Fig. B shows more lucent synaptosomal profiles at 75 KeV, 50,000x), which contain darker ovoid structures. The ovoid structures contain dense granules, which give x-ray spectra indicating Ca and P. Microprobing of the more lucent area, in contrast, gives spectra showing Na, Cl, K and P. Composition, location, and size suggest that the ovoid structures are mitochondria. In synaptosomes exposed to Pb (10^{-6} M), Pb was detected only when mitochondria were probed and was always associated with Ca and P. This suggests that Pb is transported across nerve terminal membranes and is sequestered in mitochondria. In other studies, synaptosomes and isolated mitochondria were exposed to antimycin A, reserpine, ATP, the local anasethetic N,N-diethylamino-octyl 3,4,5-trimethoxybenzoate, high Ca (4.8 mM) and 0 Na media. Changes in the intensity of the x-ray spectra for Ca were detected, consistent with the predicted effects of these treatments on Ca binding. It is concluded that x-ray microprobe with STEM electron microscopy may be useful in monitoring neurochemical processes mediated by or reflected in changes in elemental composition. Also, the technique of air drying appears to permit the study of ionic events at the mitochondrial level in synaptosomes.

1236 DENDRITIC GEOMETRY AND SPIKELESS NEURONAL COMPUTATION.
William H. Calvin and *Katherine Graubard*, Departments of Neurological Surgery and of Zoology, University of Washington, Seattle, Washington 98195 USA.

When output synapses are located near input synapses on the same cell process (axoaxonic, dendrodendritic, etc.), then local PSPs might directly affect transmitter release, especially since the presynaptic voltage threshold for transmitter release can be near the resting potential (Graubard, Raper and Hartline, this volume). Calculations using the steady-state cable equations were done for a number of different neuronal geometries, beginning with the *Aplysia* neurons whose membrane and axoplasmic resistivities were earlier determined by Graubard (Brain Res., 88:325, 1975). There is often little voltage attenuation from soma to dendritic tips, but the *attenuation from tip to soma is often severe* due to the resistance mismatch at the junction from thin to thick diameter processes. Nevertheless, *a synaptic conductance change of quantal proportions produces a somatic PSP whose size varies by little more than 20% as the site of the conductance change is moved from soma to tip.* The apparent conflict between the statements in the last two sentences is due to the compensation produced by the local size of the PSP becoming considerably larger as the conductance change is placed further out the thin dendritic process. Thus input synaptic location can be relatively unimportant for somatic PSP size. However, input synaptic location is very important when one considers what voltages are developed in thin processes where output synapses may also be located: moving an input synapse from soma to distal tip could increase this voltage more than 10-fold. *To the extent that an output synapse is isolated from the central portion of the neuron by long, thin diameter processes, it will be more heavily influenced by its neighborhood input synapses than by input synapses located centrally or upon other dendrites.* Inhibitory synapses with reversal potentials at the resting potential (pure "shunts") were also investigated for their effects upon excitatory synapses; they are more effective at reducing the PSP when they are located *at, or distal to,* the excitatory synapse. In *Aplysia* abdominal ganglion neurons, R_m is so high that little current is lost through membrane leakage within the ganglion; the above properties are entirely due to dendritic tree shape. When lobster and mammalian neurons were simulated with more typical 1000-4000 ohm·cm^2 values for R_m, leakage of current was noticeable, but the geometric effects noted above still dominate. (Supported by NIH Grants NS09677 and NS04053 and Fellowship NS05060).

1237 MORPHOLOGICAL AND PHYSIOLOGICAL STUDIES OF SENSORY INTERNEURONS IN THE CRAYFISH. Russell A. Fricke* (SPON: Donald Kennedy). Dept. of Biological Sciences, Stanford University, Stanford, CA 94305.

Using a new modification of the Timm's method for intensifying the staining of whole-mounts of cells previously filled with cobalt, the intraganglionic architecture of mechanosensory interneurons in the crayfish has been studied. Dendritic trees of these cells range along a continuum from exclusively ipsilateral to exclusively contralateral, and from complex, highly branched structures to simple patterns with relatively few branches. The topographic location of branches within the ganglion is closely related to, but not the exclusive determinant of, a cell's peripheral field. On the other hand, both branching complexity and location are related to the place occupied by a neuron in the connectivity hierarchy of central sensory interneurons. Cells located far along in the connectivity hierarchy, which are believed to receive mainly electrical synaptic input, have always been found to have simple dendritic patterns, whereas lower order cells, receiving predominantly chemical synaptic input, display considerably more complex dendritic arrangements. In this regard, sensory interneurons of different modalities (mechanoreceptive and proprioceptive) appear to resemble each other more when they occupy similar hierarchical positions than do cells of the same modality, but of different order.

1238 SPIKE COMPONENTS RECORDED IN THE SOMA OF A BIFURCATING LOCUST NEURON RELATED TO NEURAL GEOMETRY. W. Heitler* and C. Goodman* (SPON: D. Bentley). Dept. Zoology, UCB, Berkeley, CA 94720

Dorsal unpaired median (DUM) neurons are unusual amongst locust neurons in 2 respects: 1) the somata carry overshooting action potentials, 2) the axons bifurcate a short distance from the somata and exit on either side of the ganglion. Recordings from the soma of the identified DUM neuron innervating the metaextensor tibiae muscle (DUMETi) reveal 4 different spike types associated with 4 spike initiation sites (SISs). These are located 1) on the axon hillock giving rise to a soma (S) spike of 70-90 mV, 2) between the axon hillock and axon branch point giving rise to a neurite (N) spike of 20-40 mV, 3) and 4) distal to the branch point on the left and right axons giving rise to axon (A) spikes of 8-15 mV.

At spike frequencies greater than 10 Hz at room temperature or 1-5 Hz at 32°C (the preferred environmental temperature of the locust) the S spike may fail in a phenomenon similar to the initial-segment/somatodendritic break of vertebrate neurons. When the S spike fails, residual A spikes, or more rarely N spikes are revealed. A spikes usually consist of 2 more-or-less separate components, A_l and A_r, which can be correlated with action potentials in the left and right axon branches by recording spikes extracellularly in the peripheral nerves on each side. Occasionally single component A spikes occur when an action potential is initiated on only one side of the branch point. Thus action potentials may occur independently in the branches of this bifurcating neuron.

We interpret these results as indicating that there is a region of passive membrane about the branch point of the axon, such that a spike initiated in one axon branch propagates electrotonically across the branch point to the SIS on the other branch where it may (or may not) initiate a second-component A spike, and also to the neurite SIS where it may initiate a N spike. The N spike propagates to a region of low safety factor at the axon hillock where it may initiate a S spike.

In most preparations the A spike components A_l and A_r are approximately equal in amplitude, and cobalt sulfide stains show the axon branches of DUMETi to be symmetrical. However, in one case A_l was considerably smaller than A_r, and staining that neuron revealed that the left axon branch underwent a major excursion into a region of neuropil not normally invaded by DUMETi, which added at least 150 um of membrane between the branch point and the presumed SIS of the left branch. The striking correlation between the geometrical and physiological asymmetry supports our interpretation of the functional anatomy of this neuron. (Supported by NIH grant NS 09404-05)

1239 COMPUTER-AIDED RECONSTRUCTION OF GOLDFISH PHOTORECEPTOR SYNAPSES FROM SERIAL ULTRATHIN SECTIONS. D. O. Lightfoot* and W. K. Stell, Jules Stein Eye Institute, UCLA Sch. Med., and M. J. Shantz* and G. D. McCann*, California Institute of Technology.

We have analyzed contacts of photoreceptors with horizontal (HC) and bipolar cells (BC) in the retina of the goldfish. Five types of BC which contact both rods and cones can be distinguished by light microscopy, and their membrane junctions with the photoreceptors can be identified by electron microscopy, in Golgi preparations. BC types A1, A2 and A3 have thick dendrites, large somata, and long axons; their dendrites make narrow-cleft (11-13 nm) junctions, and sometimes ribbon junctions, with the receptors. BC types B1 and B2 have finer dendrites, smaller somata, and shorter axons; their dendrites make wide-cleft (16 nm) non-ribbon junctions with the photoreceptors. To further characterize the interrelations of these HC and BC dendrites with the photoreceptor synaptic endings we have used a computerized image analysis system to translate data from serial electron micrographs into quantitative form. We can retrieve descriptive data in terms of dimensions, surface areas and volumes, as well as generate three-dimensional images.

Each rod spherule contains 5-10 dendrites of second-order cells, which can be identified in serial sections by ultrastructural criteria established in the Golgi-EM studies. The single rod HC dendrite is the most prominent. It branches extensively within the invagination and around the BC dendrites, and terminates lateral to the synaptic ridge. Of the BC processes, the dendrite of type A1 is the most extensive, curving and branching as well as making extensive contact with the rod. Dendrites of the other BC's are smaller, straight and unbranched, and make less contact with the rod. Since the number of rods contacting each type of BC are known from Golgi preparations§, the total area of rod junction per BC can be calculated. We have found that the total junctional area varies dramatically from one BC type to another. Typical figures are:

BC type:	A1	A2	A3	B1	B2
Rods per BC:	218	223	100	25	20
Total junctional area: (μ^2 per BC)	138.98	30.57	1.76	1.34	0.42

These data indicate that rod pathways in goldfish are multiple and highly differentiated, and suggest that nerve cells can be further classified and characterized by quantitative properties of their dendrites.

1240 QUALITY AND LONG-TERM STABILITY OF NEURONAL UNIT RECORDINGS IN UNRESTRAINED CATS. D. J. McGinty and R. M. Harper. V. A. Hospital, Sepulveda, CA 91343 and University of California, Los Angeles, CA 90024.

We have reported studies of neuronal unit discharge from amygdala, hypothalamus, midbrain tegmentum, dorsal raphe nucleus and pontine FTG field in unrestrained cats. Our method has a number of significant advantages including simplicity of procedure, long-term stability of unit recordings, ease of simultaneous recording of 2 or more units, and absence of experimental limitations imposed by physical restraint of the animal. This presentation will show the details of electrode preparation, surgical preparation, recording equipment, and document characteristics, quality and stability of unit discharge.

Unit recordings are derived from 32μm insulated stainless steel wires which are chronically implanted in small bundles. These wires, which are individually soldered to a standard connector, are advanced through the brain with a mechanical microdrive. Eight bundles may be implanted in each cat. Differences from conventional methods include flexibility of microelectrode wires, chronic implantation and relatively slow advancement of wires within the brain, chronic solid closure of cranial openings, and low electrode impedance.

Data presented will include illustration of 16 consecutive unit waveforms obtained from pontine recordings in a single subject, stability of unit waveshapes over a 5 day period, stability of behavioral correlates of unit discharge over 5 days, and simultaneous discharge of pairs of units. Rate of unit discharge from waking, slow wave sleep and REM sleep in neuronal pairs will be given for 20 consecutive sleep-waking cycles. The ranking of unit discharge rates across units was preserved in each sleep cycle. Unit potential fields were estimated from plots of spike amplitude vs. electrode depth. Pontine tegmental cells had spike fields of 500μm.

1241 REGENERATION FOLLOWING NERVE REPAIR: THE PROPORTION OF PROXIMAL FIBERS CROSSING THE ANASTOMOSIS MEASURED BY THE AREA UNDER THE MONOPHASIC COMPOUND ACTION POTENTIAL IN RATS. Joseph M. Rosen,* Don L. Jewett, and Ernest N. Kaplan.* Department of Orthopaedic Surgery, University of California, San Francisco, California 94143, and Division of Plastic Surgery, Stanford University Medical Center, Stanford, California 94305.

Estimation of the results of different types of nerve repairs by histological methods is difficult because of the presence of nerve fibers which branch or fail to function. The height of the compound action potential provides equivocal results since it varies both with distance and conduction velocity changes.

Here we report that a quantitative estimation of the proportion of proximal fibers which function across the anastomotic site can be made by measuring the area under the monophasic compound action potential. We studied the saphenous nerves from 5 rats in vitro 8 months after severance and repair. Each nerve was stimulated supramaximally for myelinated fibers both proximal and distal to the anastomosis and the ratio of the action potential areas (recorded from the proximal end in volt-sec) were compared. The recording system was accurate to better than 1%.

As shown in Table I, control nerves from the opposite limb showed variations between proximal and distal areas less than 7% despite significant decrements in action potential heights due to dispersion (first and third column). Thus the method has sufficient accuracy to detect the changes observed in the sutured nerves (columns two and four). The results from the sutured nerves show that the distal fibers are but 47% to 74% of the proximal fibers present. This decrement may be the result of fibers which end in the scar or fibers which change their diameters so severely that centripetal conduction is blocked at the anastomosis.

In this method the distally stimulated fibers are a subset of the total population of proximally recorded fibers. Thus the interpretation of the ratios in Table I requires the not unreasonable assumption that the mean volt-sec of the fibers crossing the anastomosis recorded proximally does not differ significantly from the mean volt-sec of the total population of proximal fibers.

Table I: Expressed as %: The Ratio of the Volt-Sec Resulting from Distal Stimulation Divided by Volt-Sec Resulting from Proximal Stiulation.

	AREA		HEIGHTS	
	Control	Sutured	Control	Sutured
Median	94.6	60.5	74	42
Mean	95.5	59.2	75	41
Range	93.0-101.5	46.7-74.1	63-88	26-60

1242 HOW SHAPE CAN AFFECT EXCITATION AND PROPAGATION IN NEURONS. R. M. Westerfield* and J. W. Moore* (SPON: George Somjen) Dept. of Physiology, Duke University, Durham, N. C. 27710, USA.

We have examined the separate contributions of membrane characteristics and cell shapes to excitation and propagation of impulses in neurons by experiments and computer simulations.

Squid axons were used as the experimental preparation. An increase in the electrical diameter (a lower longitudinal internal resistance) was achieved by insertion of a low surface resistance axial wire. Computer simulations of the experimental system used the Hodgkin-Huxley equations to describe uniform membrane segments in a set of difference equations describing a cable.

In both experiments and simulations, action potentials in the larger diameter ("soma") region were similar to those seen in motor neurons under antidromic invasion, showing more than one inflection point or peak.

Similar to the lower threshold observed in the axon hillock of neurons, both the current and voltage threshold were lower in the normal squid axon adjacent to that region with the wire. Under certain conditions, impulse initiation occurred in this region when current was injected into the "soma".

NEUROPATHOLOGY AND NEUROIMMUNOLOGY

1243 THE EFFECT OF AMBIENT TEMPERATURE ON THE HYPERTHERMIA EVOKED BY ACUTE MECHANICAL DAMAGE TO THE HYPOTHALAMUS. Deborah Ackerman* and Thomas A. Rudy. School of Pharmacy, University of Wisconsin, Madison, WI 53706.

Fevers induced by prostaglandins (PG) or bacterial endotoxins (E) are functionally equivalent to an upward shift in the set-point for thermoregulation. It is characteristic of these regulated fevers that their magnitude is little affected by variations in ambient temperature (T_a) within the cool to warm range. However, if core temperature (T_c) is forcefully elevated by exposure to high T_a or if the anterior hypothalamic/preoptic region (AH/PO) is locally heated, the fever is inhibited. We have reported elsewhere (Rudy et al., J. Physiol., 1977, in press) that unilateral acute mechanical lesioning of the AH/PO in the rat evokes reliably an immediate, sustained hyperthermia which may prove useful as an animal model of the intractable hyperthermia sometimes produced by cerebral trauma in man. Since the hyperthermia in rat is susceptible to indomethacin inhibition, we suggested that PG synthesis and release is ultimately responsible for the effect.

To ascertain whether fevers produced by cerebral trauma (CTF) behave like those produced by PG and E, we examined the effect of variations in T_a on CTF magnitude. Using methods described elsewhere (vida infra), unanesthetized rats restrained at a T_a of 15, 26 or 32°C (n = 10/group) or 36°C (n = 3) were subjected to acute unilateral lesioning of the AH/PO while core temperature (T_c) was monitored continuously. Fever magnitude (ΔT_c) was defined as the difference between T_c at the time of lesioning (T_{co}) and the maximum T_c reached within 3 hr (T_{cm}).

Lesioning produced a hyperthermia which began immediately, reached a plateau within 3 hr and was maintained for 8-12 hr. Fever magnitude was not significantly influenced by variations in T_a between 15°C and 32°C ($\Delta T_c \pm$ SEM: 15° = 1.75 ± 0.21; 26° = 1.80 ± 0.24; 32° = 1.87 ± 0.36). However, regression analyses of T_{co} vs. T_c and T_{co} vs. T_{cm} revealed a tendency toward inhibition of ΔT_c by high T_{co} so that T_{cm} did not exceed approximately 40°C. This impression was strengthened by supplemental tests at T_a = 36°C. In these rats, T_{co} was elevated ($\overline{T_{co}}$ = 39.35°C) and ΔT_c was strongly attenuated ($\overline{\Delta T_c}$ = 0.42°C), producing a mean T_{cm} of 39.97°C.

Although these findings alone do not suffice to prove that CTF represents a functional elevation of the setpoint for thermoregulation, they are in substantial agreement with the effect of T_a and basal core temperature on fever evoked by agents known to act by this mechanism. The data are also compatible with the postulate that CTF is mediated by the release of prostaglandins.

1244 CALCIUM DEPOSITION FOLLOWING ELECTRICAL STIMULATION OF CAT CEREBRAL CORTEX. W.F.Agnew, T.G.H.Yuen*, P.F.Johnson*, R.H.Pudenz*, L.A.Bullara* and D.Jacques. Huntington Institute of Applied Medical Research, Pasadena, California and Department of Neuroscience, University of Florida College of Medicine, Gainesville, Florida.

The effects of electrical stimulation of the cat cerebral cortex have been evaluated by light and electron microscopy following a wide variety of stimulation parameters. Calcium deposition was prominent among numerous degenerative changes in subpial tissue following stimulation with some of the more noxious parameters, e.g. 1.1 mm disc electrode, 300 ma/cm^2, 50 pps, 120 ^{2}C/cm^2/phase of biphasic-capacitively coupled stimulus. At the light microscope level calcium deposits were detected by Kossa's Alizarin stain which increased in density with the intensity of the stimulus. With the electron microscope calcium deposits appeared as dense crystalline inclusions in several cell types and varied in size from 0.1 to 3.2 μm. These intracellular inclusions were identified as crystalline calcium hydroxyapatite by electron diffraction and the presence of both calcium and phosphorus was detected in the bodies by microanalysis using scanning-transmission electron microscope with an energy dispensive spectrometer attachment. The mechanism of the calcium deposition is obscure, however, a possible explanation is that increased cyclic AMP levels result in enhanced calcium plasmalemmal permeability known to occur following electrical stimulation of the brain. Supported by NINCDS contracts NOS-NS-0-2275 and NS-1-2286.

1245 TRANSPLANTATION OF HUMAN SCHWANN CELLS TO MOUSE PERIPHERAL NERVES Albert J. Aguayo, Jack Kasarjian*, Emil Skamene*, Patricia Kongshavn* and Garth M. Bray. Depts. Neurology & Immunology, Montreal General Hospital and McGill University, Montreal, Canada.

Schwann cells can be transplanted into nerves of mice from the same or different strains (Nature 265: 73, 1977). The present communication describes the successful transplantation of human Schwann cells into nerves of immunologically suppressed mice.

Human sural nerves were obtained from amputations and diagnostic nerve biopsies and single fascicles, 5 mm in length, were grafted between the stumps of transected sciatic nerves of C57 BL/6J mice. To prevent rejection, recipient mice received antilymphocytic serum (ALS) twice weekly.

Serial ultrastructural studies from 10 days to 3 months after grafting showed no rejection of the human grafts and demonstrated an increasing number of regenerated myelinated and unmyelinated fibers within the graft and distal stump of the grafted nerves.

To confirm the presence of human cells within the grafted segment of regenerated mouse nerves, ALS was discontinued in a group of animals two months after grafting. These animals also received 10^8 lymphoid cells obtained from syngeneic mice hyperimmunized against human tissue. Under these conditions both fibroblasts and Schwann cells were rejected in the graft but tolerated in the proximal and distal stumps of the regenerated nerves. Within the graft Schwann cells of both myelinated and unmyelinated fibers were surrounded, penetrated and replaced by mononuclear macrophages. During the period of Schwann cell rejection, many axons remained naked while others degenerated.

These studies have documented that: (1) human Schwann cells can ensheath and myelinate mouse axons; (2) human fibroblasts form the perineurium of the regenerated grafts ; (3) rejection of these regenerated xenografts is directed against nerve sheath cells and does not primarily affect axons.

These in vivo combinations of transplanted human Schwann cells and animal axons should help investigate biologic mechanisms in normal and pathologic human nerves.

1246 TISSUE REACTIONS TO VERY LONG-TERM IMPLANTATION OF CEREBELLAR STIMULATING ELECTRODES IN MONKEYS. Thomas L. Babb, W. Jann Brown*, Henry V. Soper, George M. Strain*, Jeffrey P. Lieb and Paul H. Crandall. Brain Research Institute, UCLA, Los Angeles, CA. 90024.

Previous studies of tissue damage resulting from long-term electrical stimulation of the cortex of cats (Pudenz et al., Surg. Neurol., 1975, 4:389-400) or monkeys (Gilman et al. Arch. Neurol., 1975, 32:474-477; Brown et al., J.Neurosurg., 1977, in press) have emphasized that neural damage increases directly with increased charges delivered over long periods. However, in most of these controlled studies the stimulating and control (unstimulated) electrode arrays were implanted for several months but never as long as one year. In two monkeys whose cerebella were examined after two platinum disks (each 6.8 mm^2) had been on the pia of the cerebellum for over one year there was deep compression atrophy of the cerebellum beneath unstimulated electrodes. This compression was due to a large meningeal encapsulation of the electrode array. In one of the monkeys, the opposite cerebellar cortex had been stimulated at various intervals at charges known to produce neural damage, but the encapsulation and atrophy was less than that beneath the unstimulated electrodes on the opposite paravermal cortex. These results suggest that in certain cases very long-term implantation of large electrode arrays may result in cerebellar damage greater than if the electrodes had been stimulated.

1247 THE EARLY SYMPTOMS OF MULTIPLE SCLEROSIS: EFFECTS ON SUBSEQUENT NEUROPSYCHOLOGICAL TEST PERFORMANCE. Samuel D. Brinkman and Francisco I. Perez*. Neuropsych. Lab., Dept. of Neurology, Baylor Col. of Med., Houston, Tx 77025.

Sixty MS patients were administered a neuropsychological test battery which included tests of cognitive and intellectual functioning, sensorimotor functioning, and basic motor abilities. The sample was partitioned in three different ways: 1) by duration of MS symptoms (cutoff set at nine years); 2) by type of initial symptoms (motor, somesthetic, or visual); and 3) by laterality of initial symptoms (right, left, or non-lateralized). Univariate F-tests indicated significantly lower memory functioning in patients with longer duration of symptoms. F-tests between the other two sets of groups showed no clear pattern. Discriminant functions were then calculated for each type of grouping, employing the WAIS and Wechsler Memory Scale (WMS) as predictors. The discriminant functions suggested that, on a multivariate level, tests of higher cortical functioning requiring little motor ability could significantly contribute to the differentiation of groups. Additionally, the optimum functions for classification appeared to be qualitatively different when calculated for duration groups, groupings based on type of initial symptoms, and groupings based on laterality of initial symptoms.

1248 LIGHT AND ELECTRON MICROSCOPIC STUDY OF SUPPORTING CELL PHAGOCYTIC AND GLYCOLYTIC ENZYME ACTIVITY IN PERIPHERAL NEUROPATHY. Keith A. Carson, Gary H. Duncan*, Wallace A. Ambrose*, and Jacob S. Hanker, Dental Research Center and Neurobiology Program, U.N.C. Chapel Hill, North Carolina 27514

Peripheral sensory nerves of inbred mice (dt/dt) afflicted with dystonia musculorum are known to undergo spontaneous degeneration soon after birth. Mice (db/db) afflicted with an inbred disorder resembling late onset human diabetes mellitus were found to display milder, though similar, neurologic symptoms to the dystonics late in the disease. A Schwann cell hyperplasia was noted in the trigeminal ganglion (TGG) and femoral nerves of both strains of afflicted animals. Metabolic activity of cells in the TGG was assessed by two methods: (1) localization of tail vein injected horseradish peroxidase in the TGG and (2) localization of glycolytic enzymes lactate dehydrogenase (LDH) and nicotinamide adenine dinucleotide dehydrogenases (NADH-DH) by catalytic osmiophilic polymer generation. TGG from normal and afflicted littermates were compared.

TGG stained for HRP had numerous dark granules localized within Schwann cells, satellite cells, fibrocytes, leucocytes and capillary endothelial cells, as verified by electron microscopy of adjacent thin sections. The TGG from the dystonic animals had a marked increase in cells containing HRP, while the TGG of the diabetic was not significantly different from the normal in this regard. The majority of reactive cells in the TGG of the dystonic were Schwann cells and satellite cells. Cells with stained granules were less common in normal littermates and nonexistent in uninjected control animals.

LDH staining in neurons was localized to the reticular membrane system and the axolemma. Mitochondrial staining was demonstrated under appropriate fixation conditions. In the TGG stain was also found on the plasma membrane and reticular membranes of Schwann cells, satellite cells, fibrocytes, leucocytes and capillary endothelial cells. Dystonic animals showed a marked decrease in neuronal staining. However, Schwann and satellite cell staining was increased. Stained vacuoles filled with membranous material were common in Schwann cell cytoplasm. Staining for NADH-DH shows the same differences between normal and dystonic animals, but its localization is cytoplasmic rather than in association with intracellular membranes. In the diabetic strain differences in staining for both enzymes in normal and afflicted animals could not be unequivocally demonstrated.

Although in dystonic mice the Schwann cell hyperplasia in TGG is accompanied by increased phagocytic and glycolytic enzyme activity, in diabetic mice where the hyperplasia is less marked, these metabolic changes were not evident. Supported by NIH grants DE-02668, DE-00288, HL 15888, DE 07018 and RR 05333.

1249 A COMPARATIVE STUDY OF QUANTITATIVE SENSORY TESTING AND PERIPHERAL NERVE CONDUCTION VELOCITIES IN HUMAN DIABETIC SUBJECTS. J.P. Conomy, K.L. Barnes, and A.J. Wilbourn. Dept. of Neurology and Division of Research, Cleveland Clinic Foundation, Cleveland, Ohio, 44106.

Slowing of the peripheral nerve conduction velocity is widely accepted as evidence of peripheral nerve dysfunction. It is well known, however, that there are individuals who acquire peripheral nerve disease in whom the clinical electrophysiologic studies of peripheral nerve functions remain normal. We studied a group of 15 diabetic subjects by a method of quantitative sensory testing (QST) previously described by Conomy and Barnes. This method is an adaptation of the method of limits and employs electrical stimuli to study perceptual aspects of skin sensation. Eleven subjects also underwent extensive nerve conduction velocity (NCV) studies in an effort to correlate the results of the clinical examination and of QST with NCV abnormalities. Diabetic subjects included men and women with both juvenile and adult onset diabetes, and individuals receiving insulin as well as those controlled by other drugs or diet alone. All individuals in the study demonstrated clinical signs and symptoms of neuropathic disease. QST studies showed definite abnormalities in the legs of 14/15 subjects, and in both arms and legs of 7/15. No patient with diabetic neuropathy had involvement of the arms alone. One subject, a 17 year old insulin-dependent diabetic, showed no QST abnormalities. Eleven subjects had both QST and NCV testing. Both studies were abnormal and consonant with the clinical picture in 6, and partially consonant in one. In this subject, QST abnormalities were detected in the hands and feet, while NCV's were abnormal in the feet alone. Only the QST findings were abnormal in 4 diabetics. In no individual in the QST-NCV group were both studies normal, and in none was NCV alone abnormal. Our studies suggest that while NCV's may be normal in the diabetic with clinical neuropathy, in some subjects QST defines laboratory evidence for peripheral nerve dysfunction. In many subjects both types of studies are abnormal, and are complimentary in the documentation of peripheral nerve disease.

1250 NEUROLOGICAL EVALUATION OF THERAPIES FOR CEREBRAL ISCHEMIA IN THE MONGOLIAN GERBIL. Barbara A. Dodson*, Dept. of Anesthesiology University of North Carolina, Chapel Hill, NC 27514; and Charles J. Hannan, Jr., Dept. of Radiology, Medical College of Georgia, Augusta, GA 30902.

The Mongolian Gerbil is a convenient model for cerebral ischemia (stroke) due to the absence of a posterior communicating artery in many of the animals. In this study, gerbils of either sex (50-60 gms) were anesthetized with ketamine (44 mg/kg), restrained and the left common carotid artery exposed with a midline incision. The freed carotid was clamped with a Schwartz spring clip for one hour. At the end of the hour, the animal was reanesthetized, the clip was removed, and the wound sutured. Within five minutes of clip removal the animal was given an intraperitoneal injection of either saline or experimental drug. Neurological evaluation (using a stroke index similar to that of McGraw et al. Stroke 7:485-488, 1976) commenced one hour after clip removal and was performed every eight hours for four days. Using a stroke index provided quantitation of the trauma but made the categorization of animals into either a stroked or non-stroked group difficult in many cases.

None of the groups receiving experimental drugs exhibited benefits greater than the control group. Drugs used included: DMSO (2 g/kg in 50% solution), and the following drugs dissolved in 50% DMSO in a total volume of 0.25 ml/animal: pyridinol carbamate (10 mg/kg), pentoxifylline (5 mg/kg), spermine and spermidine (10 mg/kg of each). One group of animals received a pretreatment with p-chlorophenylalanine (PCPA) (400 mg/kg) which was also found to not be significantly beneficial.

		MEAN STROKE INDEX*		
GROUP	(Mortality/Total)	1 hr.	24 hr.	Day 4
Saline	(1/27)	6.6±3.1	5.4±2.7	3.2±2.2
DMSO	(1/8)	9.7±3.8	6.3±3.4	3.6±2.3
Pentoxifyllin	(0/9)	8.3±3.5	6.4±2.8	3.7±1.3
Pyridinol carbamate	(3/8)	14 ±5.6	8.6±4.5	4.3±7.8
Spermine + Spermidine	(0/9)	14 ±2.8	5.6±3.4	3.6±1.9
PCPA	(1/5)	7 ±4.5	4.4±3.6	2.3±2.2

*plus and minus standard deviation

Dimethylsulfoxide (DMSO) has been reported to be helpful in experimental stroke (de la Torre and Hill. 1975. Dynamics of Brain Edema, p. 306, Spinger-Verlag) when administered intravenously, which may explain our lack of success with intraperitoneal injection. A larger dose of DMSO may prove beneficial (we have determined the LD 50 for DMSO in the gerbil to be 22 g/kg ± 1g), however, intravenous administration could be a critical necessity even though DMSO has remarkable tissue penetrating properties.

1251 NEW SCANNING AND IMAGING TECHNIQUES IN NEUROLOGICAL COMPUTED TOMOGRAPHY: CLINICAL ASSESSMENT. T. Blaise Fleischmann, J. M. Dooley*, H. E. Rosenbaum, Neurological Scanning Center, and Artronix Inc. St. Louis, MO. 63144.

Initially, diagnostic imaging of the brain using computerized Axial Tomography utilized very limited scan data in very limited ways. We have developed, used, and clinically assessed innovative scanning methods and presentations of scan data.

Computer programs were first of all developed to permit flexibility of scanning methods. These programs took full advantage of computerized patient positioning, low total skin dosage, 3mm thick slices, and specialized reconstruction programs available with Artronix Neuro-CAT scanner. Previous scan methodologies employed fixed procedure duration and resulted in fixed image thickness and diagnostic resolution. Neuroscan procedures which we have developed vary total scan time and patient radiation dose and result in variable image thickness and diagnostic information content. The type of scan procedure to be used is matched with patient diagnostic need at the time each patient is scheduled for examination. Scans resulting in contiguous 3,6, 9, or 12mm images can be selected. In addition, the ability to chain subprocedures permits a view of Posterior Fossa contents with 3mm images while also providing 12mm images through supratentorial structures. This capability to optimize the scanning procedure to fit patient need has led to the establishment of a variable cost structure for examinations. Application of particular scan procedures to specific cases is discussed.

Computer programs were also developed to permit flexibility of scan data presentation. For instance, clinically-useful, 3mm thick sagittal and coronal projections of intra-cranial structures are routinely obtained in seconds. These are produced from stored axial data without specialized patient positioning, rescanning, or "overlapping scanning". With growing expertise, production of coronal and sagittal images is increasingly limited to specific types of cases. However, when coronal and sagittal images are indicated, these have sometimes proven crucial in neurosurgical judgements and for exquisite localization during neurosurgery.

Other programs designed to add diagnostic flexibility to scan data presentation are discussed, including:

(1) Assessment of ventricular volume,
(2) Outlining other irregular three-dimensional intracranial areas of interest,
(3) "Region of Interest" image statistics,
(4) Linear CT density profiles in planes orthogonal to the scan plane, and
(5) Reconstructive magnification of specific areas of clinical interest.

1252 STUDY OF LDH ISOZYMES IN HUMAN BRAIN TUMORS. B. P. Garg#, M. Fredericks#, S. Hoelscher#, and R. B. Ramsey. (Spon. V. W. Fischer), Department of Neurology, St. Louis University School of Medicine, St. Louis, Mo. 63104.

We have studied the multiple LDH isozymes in 35 primary and metastatic brain tumors. It has been postulated that the pattern of LDH isozymes in various tissues is dependent upon their predominant mode of carbohydrate metabolism. It is believed that LDH 1 (H_4 form) predominates in aerobic metabolism, LDH 5 (M_4 form) in anaerobic. Availability of different types of tumors presents an opportunity to study these isozymes in the hope of finding distinctive patterns that may help in identification of each tumor type. These observations may also give some insight into tumor metabolism and aid in selection of chemotherapeutic agents.

Tumors were obtained at the time of surgery and subsequently lyophilized. LDH isozymes were separated on 5.5% polyacrylamide gels followed by staining by the standard procedures. Isozyme distribution was determined by densitometry. H/M ratios were calculated for the purpose of comparison. Preliminary experiments indicated that there was no major difference in the isozyme pattern of fresh versus lyophilized tissue.

TABLE I

Tissue	H/M Ratio Mean ± S.E.	N	p Value
Control	4.75 ± 0.55	4	
Metastatic	2.01 ± 0.44	4	<0.001
Schwannoma	2.35 ± 0.18	3	<0.02
Meningioma	3.01 ± 0.47	7	<0.05
Low Grade Astrocytoma	3.25 ± 1.11	3	>0.2
Glioblastoma	4.08 ± 0.60	4	<0.2
Malignant Astrocytoma	19.7 ± 3.62	3	<0.01
Melanoma	2.76	2	
Oligodendroglioma	6.09	1	
Chromophobic adenoma	2.81	1	
Craniopharyngioma	1.94	1	

Our control value is close to that found by others previously. Metastatic tumors had the lowest H/M values. Schwannoma, meningioma and low grade astrocytoma also had H/M ratios lower than control. Malignant astrocytomas had higher H/M values. It was found that isozyme patterns (zymograms) were quite distinctive for tumor types. These will be shown.

1253 CEREBELLAR DEVELOPMENT DURING GRAFT-VERSUS-HOST DISEASE. W. Sue T. Griffin, Judith R. Head*, and Donald J. Woodward. Dept. Cell Biol., U. Tx. Health Science Center at Dallas, Dallas, TX 75235.

Graft-versus-host disease (GVHD) is a debilitating and often fatal immunological condition induced by immunocompetent lymphoid cells "grafted" either experimentally or naturally into a foreign host which is immunologically incompetent. In laboratory rodents, GVHD can be procured by a variety of means, including injection of neonatal animals with allogeneic lymphocytes prior to maturation of immune responsiveness. Although numerous investigators have extensively described GVHD-induced alterations and lesions in various tissues, the central nervous system has been generally overlooked in studies of GVHD. The purpose of this study was to investigate whether the immunologically-mediated alterations characterizing this syndrome are accompanied by a decrease in the rate of cell proliferation in the neurogenesis of the cerebellum. We have shown that the developing cerebellum is severely affected during acute, neonatally-induced GVHD in F_1 hybrid rats. On the day of birth, (Fischer x DA)F_1 neonates were injected in the facial vein with 30×10^6 parental strain lymph node cells, a dose known to cause fatal wasting in virtually all animals. Uninjected neonates and neonates injected with syngeneic cells served as control animals. The affected animals, when compared with both control groups, showed a significant decrease in their ability to incorporate ^{3}H-thymidine into the cerebellar tissue DNA fraction on day 12. A single injection of ^{3}H-thymidine (2 µCi/gbw) was given 2 hrs before analysis. A decreased ability to synthesize DNA was also seen at postnatal days 13 and 14. By day 13, the mean DNA content per cerebellum was decreased, but not significantly so, while both RNA and protein contents per cerebellum were decreased significantly. On day 14, the DNA, RNA, and protein contents per cerebellum were significantly decreased as was the amount of ^{3}H-thymidine incorporated into the tissue DNA fraction. Treated animals were sacrificed when splenomegaly confirmed GVHD, but before whole body wasting was evident. Therefore, it appears that factors other than nutrient availability are mediating changes in cell acquisition and composition during early GVHD in developing cerebellum. These results describe a hitherto unrecognized phenomenon which could lead to deficits in brain neurogenesis as a consequence of clinically-induced GVHD during early childhood or fetal and/or neonatal acquisition of maternal lymphocytes.

1254 EARLY INTELLECTUAL DEFICIT IN FERRETS WITH CHEMICALLY INDUCED LISSENCEPHALY. R. Haddad, A. Rabe, J. Shek, R. Dumas*, and K. Wisniewski*. Neuroteratology Laboratory. Institute for Basic Research in Mental Retardation. Staten Island, NY 10314.

We have previously reported (Neuroscience Abstracts, 1976, 2, #1055) that adult ferrets with lissencephaly have a marked intellectual deficit. Lissencephaly was produced by exposing ferrets to methylazoxymethanol acetate during fetal development (i.e., a single dose of 15 mg/kg was injected in the pregnant ferret on gestation day 32). In addition to lissencephaly, all had pronounced hydrocephaly. Although hydrocephaly was evident in animals sacrificed at 6 weeks, it was more pronounced in animals sacrificed at 19 weeks, and still more severe in those sacrificed after behavioral testing at one year. These observations led us to question whether the intellectual deficit observed in the adult was primarily a consequence of a progressive hydrocephaly. We therefore prepared new animals to determine whether intellectual deficit could also be detected in young lissencephalic ferrets. These animals were tested in the Lashley III maze at the age of three months. The young lissencephalic ferrets (n=11) were significantly ($p<.002$) inferior to their normal mates (n=13) in learning the Lashley III maze and were as impaired as the adult lissencephalic group (n=7) had been on this test. As expected from previous observations (Developmental Psychobiology, 1976, 9, 311-314), the young normal group did not differ from the normal adult group (n=7).

To further analyze the nature and development of the brain lesions in the lissencephalic ferret, we studied the acute lesions in the fetus on 5 consecutive days after treatment as well as the first 6 weeks of postnatal brain development. In the fetus there were extensive necrotic foci in the developing cerebrum and in the posterior region of the dorsal mesencephalon. In contrast, no extensive foci of necrosis were found in the developing cerebellum although at birth and during early postnatal period the cerebellum of the lissencephalic ferret was much smaller and less differentiated than normal. The persistence of the external granular layer past 6 weeks in the lissencephalic, but not normal, ferret thus reflected retarded development of the cerebellum. Although ectopias could be found in the cerebellum of lissencephalic ferrets at weaning, the cerebellum approximated normal structure and size and did not show the extensive lesions seen in ferrets similarly treated in the perinatal period.

Hydrocephaly as well as lissencephaly were clearly evident before two weeks of age.

1255 ALTERED CEREBROSPINAL FLUID (CSF) COMPOSITION IN EXPERIMENTAL IMMUNE COMPLEX DISEASE. A.A. Hoffman*, R.J. Harbeck*, S.A. Hoffman*, and D.W. Shucard. Dept. Medicine and Dept. Behavioral Sciences, Natl. Jewish Hosp. and Res. Ctr., Denver, CO 80206.

It has been suggested that immune complex deposition in the choroid plexus of patients with systemic lupus erythematosus (SLE) may result in alterations in CSF constituents and possibly lead to the variable neuropsychiatric disorders observed in these patients. To assess this possibility acute immune complex disease was induced in New Zealand white rabbits by a single, large dose of bovine serum albumin (BSA). Control animals received only saline. All animals were sacrificed fourteen days later and the kidney, choroid plexus, serum and CSF obtained for analyses. Using a fluorescent antibody technique, animals of the experimental group displayed unequivocal evidence of immune complex deposits in the choroid plexus, whereas none of the controls displayed such evidence. Several animals of the experimental group also showed elevated CSF protein as compared to the control group. The concentration of albumin and immunoglobulin G (IgG) in the CSF was assessed by an electroimmunodiffusion technique. In the majority of the animals showing elevated CSF protein there was a concommitant rise in both CSF albumin and IgG. In addition, some animals displayed an elevation in their CSF IgG : albumin ratio as compared to serum values. The CSF glucose level, expressed as a percent of the serum level, was in several instances below that observed in the control animals. Furthermore, antibody to BSA was found to be elevated in the CSF of a few animals.

These results indicate that immune complex deposition in the choroid plexus, a structure in part responsible for the composition of CSF, may result in functional damage to this tissue. These results are comparable to those observed in the CSF of SLE patients with CNS involvement. This model may be useful for studying the role of immune complexes in mediating CNS abnormalities in SLE. (Supported in part by USPHS NS-12394.)

1256 A RELIABLE STEREOTAXIC TECHNIQUE BASED ON AN INTRACEREBRAL COORDINATE SYSTEM IN THE CAT. I. Ilinsky*, K. Kultas-Ilinsky, and K. R. Smith. Depts. Anat. and Surg., St. Louis Univ. Sch. Med., St. Louis, MO 63104.

A stereotaxic technique using intracerebral landmarks permits much more precision in the placement of electrodes or injection needles in discrete brain loci as compared to the classical Horsley-Clarke system based on extracranial coordinates. This technique was developed in cats whose weights ranged from 2.1 to 6.0 kg. In spite of large variations in the head dimensions it was observed that the distance between the anterior (CA) and posterior (CP) commissures was extremely constant (mean 8.1 mm; standard deviation 0.31). Thus the CA-CP line was chosen as a basic reference line for the intracerebral coordinate system and an atlas of the cat brain in this coordinate system was made. The atlas was prepared using serial histological sections cut in the transverse plane perpendicular to the CA-CP line and in the sagittal and horizontal planes parallel to the CA-CP line. The entire stereotaxic procedure was monitored by contrast ventricular radiographs. The first step involved visualization of the CA and CP in a sagittal radiograph and visualization of the midline in a transverse radiograph. The coordinates for the selected target were then determined from the atlas and transferred to the transverse and sagittal ventricular radiographs. The trajectory of the electrode or needle was monitored radiographically and corrected in each of the three stereotaxic planes. When the tip of the instrument reached the desired part of the target, a lesion or injection was made. This technique was used to place electrolytic lesions or injections of tritiated amino acids into either the anterior, intermediate, or posterior part of the substantia nigra pars reticularis in 19 cats. The technique proved to be highly accurate in that the lesions or injections were precisely confined to each of the chosen areas. In none of the animals did the lesions or injections miss the desired location. (Supported by USPHS FR 05388.)

1257 DEVELOPMENT OF A MICRO-STEREOTACTIC METHOD FOR THE LOCALIZATION AND REMOVAL OF SMALL CNS LESIONS. Deane B. Jacques, C. Hunter Shelden*, Robert E. Frazer* and Harold R. Lutes*. Huntington Institute of Applied Medical Research and Jet Propulsion Laboratories of the California Institute of Technology, Pasadena, CA 91105.

The authors describe a novel stereotactic method for the removal of CNS lesions as small as five millimeters in diameter. With the development of computerized axial tomography, such small lesions can be detected by non-invasive (x-ray) scanning with computer processing of the data and removed by a combination of apparatus and procedures described herein. Newly developed surgical instruments are mounted on a micromanipulator for guidance at the operative site. These include stereo endoscopes with xenon arc illumination; a tissue expander for exposing the operative area; a radiation tracer probe; a rotary extractor; an ultrasonic microdissection probe; an aneurysm clamp micromanipulator; and instruments for operating and removal of blood from a small intracerebral hemorrhage. The micromanipulator for guiding the tactical instruments is in turn mounted on a stereotaxic guide mechanism which accurately defines all areas of the cranium in three dimensional coordinates. The combination enables the site of a tumor, aneurysm, hematoma, etc., the three dimensional coordinates of which have been located by computerized axial tomograph scan, to be accurately accessed by the stereotaxic guide/micromanipulator assembly.

1258 A MORPHOLOGICAL STUDY OF NEURONAL ALTERATIONS IN THE CAT BRAIN FOLLOWING GLOBAL ISCHEMIA. Larry W. Jenkins*, John T. Povlishock*, and Donald P. Becker. (Sponsored by J.A. Astruc). Departments of Anatomy and Neurological Surgery, Medical College of Virginia, Virginia Commonwealth University, Richmond, Virginia. 23298.

Physiologically controlled and monitored, normothermic, adult cats ventillated on 75% N_2O and 25% O_2, were subjected to total cerebral ischemia via the ligation of all primary cranial arteries and their collaterals. During the experimental procedures systemic arterial blood gases and acid-base balance were maintained within normal limits. The ischemic insults were produced by the clamping of the brachiocephalic artery for durations of 5, 15 and 30 minutes. Immediately upon the release of the brachiocephalic clamp, the animals were perfused transcardially with aldehydes. Tissue samples from selected cortical areas were then processed for routine electron microscopy.

In all ischemic insults, cortical neuronal alterations were observed. In insults of 5 minutes duration, ultrastructural examination demonstrated nucleolar and chromatin condensation, and aggregations of nuclear interchromatic and perichromatic RNP granules. Cytoplasmic organelle changes consisted of occasional degranulation and pairing of rough endoplasmic reticulum (RER) cisternae. After 15 minutes of ischemia comparable nuclear and nucleolar changes were seen. Also, cytoplasmic changes were seen reflected in occasional dilation of rough and smooth endoplasmic reticulum, an increased number of degranulated and paired RER cisternae, and numerous mitochondria showing enlarged intracristal spaces. After 30 minutes of ischemia, the neuronal nuclei showed increased chromatin and nucleolar condensation. A decreased number of perichromatic and interchromatic RNP granule aggregates were also observed. Cytoplasmic changes were revealed by increased cytoplasmic volume, swollen mitochondria with disrupted cristae, dispersed RER cisternae and Golgi saccules, and organelle membrane disruption. On the basis of morphology alone, this data suggests that in acute ischemia (5 to 15 min.), those subcellular structures implicated in both RNA and protein synthetic pathways are the first and most severly damaged.

Aided by NIH Grant NS-12587.

1259 ANALYSIS OF MS AND CONTROL SERA BY RADIOIODINATION AND POLY-ACRYLAMIDE GRADIENT ELECTROPHORESIS. Steven Kornguth, Timothy Johnson*, Ursula Juhl*, Carol Steinhart*, John Sever and Maneth Gravell. Dept. of Neurol. and Physiol. Chem., Univ. Wis. Med. Ctr., Madison, WI 53711 and NIH Bethesda, MD.

The sera of 4 female MS patients in exacerbation, 1 male MS patient in remission and 4 control subjects (2 male, 2 female) of similar ages were obtained. The sera were centrifuged at 30,000 g for 30 min. and that supernatant was centrifuged at 100,000 g for 1 hr. The resultant pellet was homogenized in 0.1 M phosphate buffer (pH 7.0), again centrifuged at 100,000 g and suspended in 50 µl of the same phosphate buffer. The patients in exacerbation yielded 100,000 g pellets that contained 20-30 µg protein/ml serum; the pellet from the patient in remission contained 10-15 µg/ml and that from the controls contained 5-10 µg/ml. The proteins in the 100,000 g pellets were radiolabeled with ^{125}I using lactoperoxidase and H_2O_2 as the catalytic agents. The radioiodinated proteins were reduced with β-mercaptoethanol, dissociated with 1% SDS and then analyzed by electrophoresis on 28 cm long slab gels containing a 6-20% gradient of acrylamide. For each subject identical amounts of protein (50 µg) were applied to the gels for electrophoresis. After electrophoresis the gels were stained with coomassie blue, destained, dried and x-ray film was then placed over the gels. When compared with the control samples, all the MS patients in exacerbation had elevated levels of proteins (or subunits) with MW of 58,000; 53,000; 43,000. One of the patients in exacerbation had an elevated level of the 61,000 dalton protein. The patient in a state of remission had no changes in concentration of serum proteins or subunits. The identities of the serum proteins that are present in elevated concentrations in the MS patients have not been elucidated; it was previously shown in this laboratory, however, that the α_2 globulin, haptoglobin, is elevated in the serum of MS patients in exacerbation. Because of the possible viral etiology of MS, it is of interest that the nucleocapsid protein of measles also has a molecular weight of 60,000.

1260 LESIONS OF THE MYOFIBRIL IN AN EXPERIMENTAL HYPOXIC MYOPATHY RELATED TO ISOMETRIC EXERCISE. Ralph W. Kuncl. Depts. Pathology and Psychiatry, U. Chicago Pritzker Sch. Med., Chicago, IL 60637.

In non-necrotic muscle fibers the pathogenesis of the commonly occurring, nonspecific myofibrillar lesions--patchy areas of (1) disruption of normal myofibrillar banding and (2) smearing of the dense Z-band--is obscure. According to Engel (*Med Clin North Amer* 52: 909, 1968) and others, such lesions occur selectively in red muscle (are perhaps specific to soleus), and they are somehow related to mitochondria, since such lesions were not seen without decreased mitochondria but decreased mitochondria occurred without myofibrillar degeneration. I studied the development in seven different muscles of an experimental myopathy in which myofibrillar lesions are essentially the only significant pathologic change. The myopathy is produced by restraining rats after pretreating them with a psychomotor stimulant, and its extent is related to the amount of isometric exercise performed by the constantly struggling rat.

The predominant lesion, occurring in 50-60% of fibers, was extensive myofibrillar disruption, which was temporally related to the 30-fold increased plasma CPK activity that began within minutes of treatment. Focal mitochondrial loss occurred subsequent to mitochondrial degeneration within areas of myofibrillar disruption. Initially, myofibrillar disruptions contained disoriented, clumped, abnormally staining mitochondria with concentrically packed cristae. Within 24 hr after onset of myofibrillar disruption mitochondria typically were lost in disrupted foci. This correlated well with a 40% reduction in specific activity of mitochondrial succinate cytochrome C reductase (SCR) early-on after treatment and a recovery of normal specific SCR activity at 24 hr. Significant Z-band smearing occurred independently of myofibrillar disruption, being noted first at 24 hr after treatment.

Both myofibrillar lesions also occur in normal untreated control muscles. In control muscles of the lower limb Z-band smearing occurred predominantly in mitochondrial-rich (red) fibers; to the contrary, myofibrillar disruption occurred predominantly in mitochondrial-poor (white) fibers. In both experimental and untreated muscle, Z-band smearing occurred predominantly in those specially differentiated peripheral areas in the muscle fiber which are immediately adjacent to transversely coursing blood vessels. These areas normally lack mitochondria.

Thus, the focal mitochondrial *loss* that occurs in areas of myofibrillar disruption in white muscle is not of the same significance as the focal mitochondrial *absence* in areas of Z-band smearing in red muscle. In the former lesion, focal mitochondrial degradation is an early concomitant and focal mitochondrial loss a subsequent event to the myofibrillar lesion; in the latter lesion focal mitochondrial absence provides a structural substratum for the occurrence of a Z-band abnormality.

1261 ADRENAL MEDULLA SPECIFIC AND BRAIN SPECIFIC ANTIGENS DETECTED BY ANTISERA TO A RAT PHEOCHROMOCYTOMA CLONAL CELL LINE. Virginia Lee*, Lloyd A. Greene*and Michael L. Shelanski*. (Sponsored by A.V. Lorenzo). Dept. of Neuropathology, Harvard Medical School and Dept. of Neuroscience, Children's Hospital Medical Center, Boston, MA. 02115.

A rat pheochromocytoma clonal cell line, PC12, has been established and was shown to display well-defined reversible differentiated properties in response to nerve growth factor (NGF). In the absence of NGF, PC12 cells morphologically resemble mature adrenal chromaffin cells and are capable of releasing, synthesizing and storing catecholamines. After several days of treatment with NGF, PC12 cells acquire properties of sympathetic neurons in that they extend long, branching neurites and become electrically excitable. In this study antisera were prepared from guinea pigs using PC12 cells grown in the presence and absence of NGF as antigens. After extensive absorption with rat liver, kidney, spleen and thymus, these antisera retain high titers as measured by microcomplement fixation assay against PC12 cells (both NGF treated and untreated) adrenal medulla, brain and superior cervical ganglia but not against liver, kidney, spleen and thymus. Cross-absorption of the antisera with brain and adrenal medulla showed the presence of adrenal medulla specific, brain specific and PC12 cell specific antigens. Indirect immunofluorescence studies with the antisera detect antigens on both cell bodies and neurites of living PC12 cells. This indicates that at least some of the antigens are on the cell surface. Similar results were obtained with antisera which were absorbed with either brain or adrenal medulla or with both. Staining was also seen with both brain-absorbed and unabsorbed antisera in sections of the adrenal medulla but not of the adrenal cortex. Localization in brain with adrenal-absorbed or unabsorbed antisera showed diffuse staining in all areas of the brain. Adrenal medulla and brain specific antigens were not species specific since they are also found in the adrenal medulla and brain of rabbit, mouse and cat as well as rat. Among clonal cell lines tested (C_6 glioma, C1300 neuroblastoma, 3T3 & L-cell fibroblasts etc) only PC12 and clones of neural origin were recognized in the microcomplement fixation and ^{51}Cr release cytotoxicity assays by the antisera. These results indicate that PC12 cells and antisera directed against them may be used to identify specific cell markers of adrenal medullary and brain cells.

1262 THY-1—A THYMUS ANTIGEN ON RAT NEURONES AND GLIA. Jayne F. Lesley* and Vanda A. Lennon. Molecular Neuropathology Laboratory, Salk Institute, San Diego, CA 92112.

Thy-1 (θ) is a cell surface differentiation antigen expressed in developing and adult brain and on thymocytes and peripheral T-lymphocytes of rats and mice. In order to establish with which cells Thy-1 might be associated in the central nervous system (CNS), we examined serologically cell lines derived from rat CNS (Schubert et al., Nature 249: 224, 1974). CNS cells were tested with rabbit anti-rat thymocyte serum (ATS) for their capacity to absorb complement-dependent cytotoxicity of ATS for a ^{51}Cr-labelled Thy-1 positive lymphoma line. The cells were tested also by indirect immunofluorescence with sequential addition of ATS and fluoresceinated goat IgG anti-rabbit IgG. Thy-1 specificity of ATS was established by precipitation from mouse thymocytes of the ^{125}I-labelled 25,000 dalton glycoprotein bearing Thy-1 alloantigen (Trowbridge et al., Nature 256: 652, 1975) and by absorption of both cytotoxicity and immunofluorescence activities with whole rat brain or rat thymus. One of 6 neuronal lines tested and 8 of 15 non-neuronal lines absorbed anti-Thy-1 cytotoxicity. Those cells also were positive by immunofluorescence in a speckled pattern over cell bodies and processes. Cell lines negative for Thy-1 by cytotoxicity absorption were also negative in immunofluorescence assays. The possible function of Thy-1, an antigen shared by T-lymphocytes, developing muscle (Lesley and Lennon, Nature, in press), neurones and glia is open to speculation.

1263 RESISTANCE TO THE ABSORPTION OF CEREBRO-SPINAL FLUID. James A. Love*, Animal Care Centre, Dalhousie University, Halifax, Nova Scotia and Ronald A. Leslie, Dept. of Anatomy, Dalhousie University, Halifax, Nova Scotia.

The absorption of cerebro-spinal fluid (C.S.F.) has been shown to depend directly on the difference between the subarachnoid space pressure and the sagittal sinus pressure and indirectly on the resistance to absorption which normally resides in the arachnoid villae. It is generally assumed that the resistance does not change over a wide range of intracranial pressures although most authors recognize that at higher intracranial pressures the relationship between pressure flow and resistance becomes less precise.

We have investigated this phenomenon in cats and have found that the resistance to absorption decreases when the intracranial pressure exceeds 20-22 mm Hg. Furthermore, this reduction is maintained to normal intracranial pressure. The reduction in resistance is brought about by the induction of alternate absorption mechanisms which have different opening and closing pressures. The capacity and resistance to absorption of the alternate absorption system have been measured and are similar to those of the arachnoid villae. The potential of alternate absorption mechanisms for C.S.F. is great but the demonstration of such mechanisms has been open to question. We have provided physiological evidence for the presence of these mechanisms and have measured some of their characteristics.

1264 CEREBROSPINAL FLUID (CSF) L LYMPHOCYTES IN MULTIPLE SCLEROSIS (MS) PATIENTS AND NORMAL HUMANS. Roger M. Morrell, Neurology Service, VAH, and Dept. Neurology, Baylor College of Medicine, Houston, TX 77030.

Human L lymphocytes have been identified in peripheral blood, tonsils and lymph nodes in health and disease. L lymphocytes have not been identified in CSF, either in health or disease. This is the first report of their identification in normal subjects and in patients with MS, either untreated or treated with oral steroids (Medrol^{R}, 32 mg., p.o., alternate day).

Human L lymphocytes have membrane-labile IgG determinants and can be distinguished from T cells, B cells and monocytes. L cells form rosettes with human erythrocytes sensitized with IgG(EA). They do not form rosettes with sheep RBC (E), or E sensitized with IgM and mouse complement (EAC). They do not have membrane-incorporated Ig(SmIg), are not phagocytic, and are not stained by non-specific esterase.

L lymphocytes from 10 normal (non-systemic diseases not affecting the CSF, for example, herniated intervertebral disc) and 20 MS subjects were separated from T lymphocytes (E+, SmIg-, EAC-, EA-) and B lymphocytes (E-, SmIg+, EAC+, EA-) by rosetting techniques. L lymphocytes responded poorly to phytohemagglutinin, pokeweed mitogen, tuberculin and streptokinase/streptodornase. They were poor responders in mixed lymphocyte culture (MLC). L and B, but not T lymphocytes were good stimulators. In studies of antibody-dependent lymphocyte cytotoxicity using human lymphocytes sensitized with alloantibodies as target cells, L lymphocytes were effective killers, while T cells, B cells, and monocytes were not.

L cells were more numerous than B cells in normal CSF (ratio 1.7 : 1); the converse was observed in untreated MS CSF (ratio 1 : 18). Steroid-treated patients had decreased numbers of B cells, but only those with lymphopenia had decreased L lymphocytes.

Distinctive surface characteristics, function, anatomical distribution and numerical variation among normals, untreated, and steroid-treated MS patients provide evidence for a CSF L lymphocyte population. The role of this cell type in normal immunity or neuro-immunopathology is not known.

1265 PATHOPHYSIOLOGIC CORRELATIONS IN ABNORMAL CEREBROVASCULAR PERMEABILITY. K. Nishimoto*, H. Pappius*, M. Wolman*, M. Spatz and I. Klatzo. Lab. Neuropath. & Neuroanat. Sci., NIH, Bethesda, MD 20014.

Air embolism as well as occlusion of common carotid artery in Mongolian gerbils served as experimental models to correlate various parameters of the increased cerebrovascular permeability.

Disturbances of the blood-brain barrier (BBB) were evaluated with Evans Blue, sodium fluorescein, and C^{14} sucrose tracers. Changes in permeability of cerebral vasculature to these tracers were correlated with the regional cerebral blood flow (CBF), assessed radioautographically with C^{14} antipyrine method. The BBB changes were also correlated with regional glucose utilization demonstrated radioautographically with the Kennedy technique (Science, 187, 850, 1975). Water and electrolytes were measured in brain tissue samples taken from normal regions and those showing disturbances in cerebrovascular permeability.

Small amounts of air injected into the internal carotid artery resulted within a few minutes in a breakdown of the BBB, whereas changes in cerebrovascular permeability following ischemic occlusion appeared after a delay and according to the principle of the maturation phenomenon described earlier (Acta Neuropath. 32, 209, 1975).

The abnormal permeability to various tracers showed a certain selectivity favoring a longer passage of smaller molecules.

Both types of experiments demonstrated areas of increased and decreased deoxyglucose utilization.

Collected data from various parameters of experimentation will be presented and discussed.

1266 A NEW MODEL FOR DEMYELINATION WITH CONDUCTION DEFICIT IN THE FROG. Terrence L. Pencek, Brenda R. Eisenberg*, Charles L. Schauf, and Floyd A. Davis . Depts. Neurolog. Sci., Pathology, and Physiology, Rush University, Chicago, Ill. 60612.

A segmental lesion has been produced in vivo in the frog, Rana catesbeiana, by opening the perineurium in the sciatic or peroneal nerve. This has been studied by electrophysiological methods and by light and electron microscopy morphometric techniques. A similar perineurial lesion has been reported to induce focal demyelination and remyelination in rats (Brain Research 96:323). In frogs kept at 22-23°C opening the perineurium by careful surgical technique induces edema within 3-5 days, while no visible evidence can be seen in the sham operated control leg or in frogs kept at 13°C. The edema is localized to the perineurial lesion. Conduction velocity measured in vivo is decreased an average of 62% (n=7) across the lesion and not affected 1 cm. distal to the lesion. The nerve bundle cross sectional area in the experimental nerve bundle was 0.99± .15mm^2 and in the control was 0.39± .15mm^2 (n=6). Experimental nerves also had an increase in blood vessel number and size. In the lesion area, the density of fibers was decreased because of the edema. The myelin of the large nerve fibers shows extensive whorling and splitting. The nature of the lesion and conduction velocity deficit will be discussed.

Supported in part by N.M.S.S. Research Grant 1100-A-2 and by the Morris Multiple Sclerosis Research Fund.

1267 PRODUCTION OF LARGE VOLUMES OF MOUSE ANTI-MOUSE BRAIN ANTIBODIES IN INDIVIDUAL MICE. Charles See* (SPON: D. C. Wood). Psychobiology Program, Dept. Psychology, Univ. Pittsburgh, Pittsburgh, PA 15260

A major disadvantage in utilizing mice to generate antibodies is the small yield of antiserum obtained from an individual mouse. Munoz (Proc. Soc. Exp. Biol. Med. 107: 163, 1957) originally reported that the yield of antibodies from mice could be substantially increased by inducing ascitic fluid containing antibodies. However, the percentage of mice responding was relatively small. Recently, Tung, et al., (J. Immunol. 116: 676, 1976) reported an improved method for eliciting large volumes of ascitic fluid containing substantial amounts of anti-protein antibodies in about 90% of the mice innoculated. A high volume ratio of adjuvant to antigen solution (9:1) and the volume used per innoculation (0.2ml) were shown to be critical factors in producing large amounts of high titer ascitic fluid.

The present study used this improved immunization procedure to generate precipitating mouse anti-mouse brain antibodies. Swiss Webster mice were innoculated on day 0, 14, 21 and 28 with a 0.2ml of an emulsion of complete Freund's adjuvant and antigen (0.2mg brain homogenate in saline) in a volume ratio of 9:1. The ascitic fluid was tapped repeatedly beginning seven days after the last injection. This immunization protocol elicited significant quantities of ascitic fluid in greater than 80% of a large number of mice injected. The volume varied with the age of the mice with the older mice producing larger volumes. The average mortality rate before significant amounts of ascitic fluid were produced was about 15%. Two precipitin lines occurred when a 1% Triton X-100 brain extract was reacted with the ascitic fluid by double immunodiffusion. All batches of ascitic fluid produced were positive for these two precipitin lines. No precipitin lines occurred when the ascitic fluid was reacted with aqueous brain extracts. One of the precipitin lines was brain specific. This precipitin line did not occur when the ascitic fluid was reacted with 1% Triton X-100 tissue extracts of equal protein concentration from 10 other mouse tissues. Also, no reaction was observed with mouse serum.

This immunization protocol offers several advantages over more conventional procedures for generating large amounts of anti-brain antibodies.

1268 IMMUNOLOGICAL CHARACTERIZATION OF CENTRAL AND PERIPHERAL NICOTINIC CHOLINERGIC ^{125}Iα-BUNGAROTOXIN (α-BGT) BINDING SITES. R.C. Speth*, J.M.Lindstrom, F.M.Chen* and H.I.Yamamura. Univ. Ariz., Tucson, AZ 85724; Salk Inst. San Diego, CA 92112

Recent observations have suggested that myasthenia gravis is an autoimmune disease involving nicotinic acetylcholine receptors (NAChR) of muscle. The lack of any apparent direct CNS effects in myasthenia gravis could indicate that NAChR is either not important to CNS function, that NAChR in the CNS is immunologically distinct from that in muscle, or that the NAChR antibodies do not cross the blood brain barrier.

Previous studies in this laboratory and others have demonstrated pharmacologically specific, saturable, high affinity binding sites for ^{125}Iα-BGT characterized as NAChR.

To test whether central and peripheral α-BGT binding sites are immunologically similar, two series of experiments were performed. For the first series, purified NAChR from E. electricus was used to immunize rats. Immunized rats had 87.3 ± 10% of their muscle NAChR bound with antibody (Ab) while control rats had background values of 0.12 ± 1.5% of their muscle NAChR bound with Ab. Of the immunized rats, 82% were clinically myasthenic. The ^{125}Iα-BGT binding sites of muscle and brain, and the muscarinic antagonist [^{3}H]quinuclidinyl benzilate (QNB) binding sites of control and E. electricus immunized rats were assayed.

Tissue	Binding site	Control	Immunized
Rat Muscle	^{125}Iα-BGT	41.7±0.99pmole/rat	18.3±1.1pmole/rat
Rat Brain	^{125}Iα-BGT	1.88±0.06pmole/g	1.75±0.03pmole/g
Rat Brain	^{3}H-QNB	59.9±1.4pmole/g	57.2±0.9pmole/g

In a second series, we examined the antigenicity of Triton X-100 solubilized ^{125}Iα-BGT binding sites derived from rat muscle and brain to sera obtained from animals immunized with purified NAChR derived from E. electricus or T. californica.

Serum	Tissue	% of ^{125}Iα-BGT binding sites precipitated
Rat anti E. electricus	rat muscle	50
	rat brain	0
Rat anti T. californica	rat muscle	104
	rat brain	0.4-2.1
Rabbit anti T. californica	rat muscle	16
	rat brain	2

These results suggest that there is little or no cross reactivity between ^{125}Iα-BGT binding sites derived from rat muscle and brain. This indicates immunological differences in toxin binding components derived from these two areas. Supported by grants from MDA, NIH #NS-11323 NIMH # MH-25257 and RSDA to H.I.Yamamura.

1269 HISTOPATHOLOGIC EFFECTS OF PENETRATING IMPLANTS ON THE CEREBRAL CORTEX. Suzanne S. Stensaas and L. J. Stensaas. Depts. of Anat. and Physiol., Col. Med., Univ. of Utah, Salt Lake City, UT 84132.

Histopathological changes of the cerebral cortex in response to small, penetrating metal and non-metal implants were analyzed with light and electron microscopy. The needle-shaped implants were left in place during all stages of histological preparation and embedded in plastic together with the cortex. Semi- and ultrathin sections through the brain-implant boundary were classified as non-reactive, reactive, or toxic, according to the reactive cellular constituents. Among the non-reactive materials were many plastics and metals such as aluminum, gold, platinum, and tungsten. The boundary of these implants displayed little or no gliosis and normal neuropile with synapses within 5 μm of the implant's surface. The boundary of reactive materials such as tantalum or silicon dioxide was marked by multinucleate giant cells and a thin capsule (10 μm) of connective tissue. Toxic materials such as iron and copper were separated from the cortical neuropile by a capsule of cellular connective tissue and a zone of astrocytosis. Cobalt, a highly toxic material, produced more extensive changes in the zones of connective tissue and astrocytes. Implant times ranged from 50 to 723 days. These results indicate that a variety of materials are well tolerated by the brain and could be used in the fabrication of neuroprosthetic devices.

1270 EFFECTS OF CRUSH INJURY AND MYELIN INDUCTION IN SPINAL NERVE ROOTS OF DYSTROPHIC MICE. Charles A. Stirling*, (SPON: Theodore A. Slotkin). Dept. Physiol., Med. Sch., Univ. Bristol, Bristol, England.

Dystrophic mice, 129/ReJ dy/dy, have an inherited abnormality of their peripheral nervous system apparent as a lack of myelin or any other Schwann cell wrapping, termed amyelination, in localized regions of individual nerves (Stirling, J.Anat. 119: 169, 1975). The genetic mechanism which produces this lesion is not known, but two, of a number, of potential hypotheses are: 1. that the Schwann cells are irreversibly turned off from further division at too early a developmental time and 2. that the recognition of axon membrane by Schwann cell membrane is impeded in the amyelinated regions. These two hypotheses have been tested and evidence is presented against both (Stirling, Brain Res. 87: 130, 1975).

Dorsal roots of anaesthetized dystrophic mice about one month old, 6 to 15 g, were partially crushed with a pair of fine pointed forceps. The animals were then allowed to recover for between 1½ and 45 days. Three animals were labelled with tritiated thymidine for autoradiography. All the animals were perfusion fixed for electron microscopy, autoradiographs were made for light microscopy on plastic thick sections with adjacent sections used for E.M.

The Schwann cells in crush traumatized roots were found to be capable of cell division for up to at least eight days recovery time and at least 3 mm distance both proximal and distal to the site of injury. Control side, non-crushed, roots showed no labelled cells and no other signs of cell division.

In the crush regions and for varying distances either side new Schwann cell wrapping of axons was evidenced both by many more axons being surrounded and by newly dividing Schwann cells being involved. In the longer recovery animals, greater than ca. 7 days, axons were frequently found with multiple layers of Schwann cell wrapping, very early myelin condensation or a few myelin lamella. The amount of new myelin formed appeared to increase with recovery time up to 45 days, the longest time examined, but this could not be quantitated due to inevitable small differences in crushing and surgical procedure. The control side roots remained normal amyelinated dystrophic roots with little or no noticeable morphological effect from the experimental procedures.

Dystrophic Schwann cells can therefore divide given an adequate stimulus and they can recognize dystrophic axons as objects to myelinate.

1271 FASCICULAR DISTRIBUTION OF SPINAL CORD EDEMA PRODUCED BY EXPERIMENTAL CORD CONTUSION. Franklin C. Wagner,* William B. Stewart* and William F. Collins. Dept. of Neurosurgery and Physiology, Yale Univ. Sch. of Med., New Haven, Conn. 06510.

It has been reported that experimental contusion of the spinal cord produces an extravasation of proteins from vessels in the gray matter at the site of the lesion (Green, B.A. and F.C. Wagner, Surgical Neurol. 1:98-101, 1962). At subsequent intervals after trauma there is increasing involvement of the surrounding white matter. With cold lesions of the cerebral cortex, it has been demonstrated that edema spread is primarily through the white matter to adjacent gyri (Klatzo, I.; J. Miguel and J. Ostenasek, Acta Neuropath. 2:144-160, 1962). With Evans Blue as a marker, Griffiths and Miller (J. Neurol. Sci. 22:291-294, 1974) have shown centrifugal and longitudinal spread of gray matter edema in the dorsal and lateral white columns following cord contusion. The purpose of the present experiments was to determine to what extent longitudinal spread of edema occurred in the white matter of the spinal cord, since the primarily longitudinal arrangement of the long tracts might afford a more simplified analysis of the mechanisms involved.

Thirty-three cats were injected with fluorescein-labelled albumin (FLA) or fluorescein-labelled dextrans (FLD) with molecular weights of 20,000 to 150,000. The thoracic cord was subjected to a contusion of 20 gms from 25 cm. The extent of the edema was examined in animals sacrificed 8 hours after trauma. Proximal and distal to the lesion the edema had a fascicular pattern. There was edema primarily in the lateral and ventromedial white columns. These areas were not immediately adjacent to the grey matter, suggesting that the edema did not spread from the gray at that cord level. The distance of spread in the longitudinal direction was similar for the FLA and FLD molecules. The maximum area of fluorescence typically occurred several millimeters outside the hemmoraghic portion of the lesion.

The distribution of fluorescence in these experiments suggests that several mechanisms may be involved in the development and spread of edema. Two of these may be bulk flow and alteration of blood flow. Experiments are currently being performed to assess the possible role of these mechanisms in spinal cord trauma.

1272 INHIBITION OF REMYELINATION BY CYTOSINE ARABINOSIDE FOLLOWING VIRAL-INDUCED DEMYELINATION. Leslie P. Weiner, Stephen A. Stohlman.* Dept. Neur., Sch. Med., USC, Los Angeles, CA 90033.

Infection of mice with the JHM strain of mouse hepatitis virus causes demyelination as a result of cytolytic infection of oligodendroglia. In recovery, animals show remyelination beginning at day 21 post infection (PI). Recently, Herndon et al (Science 195: 693-694, 1977) have demonstrated by utilizing electron microscopic autoradiographic studies with ^{3}H-labeled thymidine that cells associated with remyelination are newly generated oligodendroglia.

This current study shows that cytosine arabinoside (ara-C), a potent inhibitor of cell multiplication and DNA synthesis, inhibits remyelination when injected into animals twice daily from day 15 to 20 PI. 4 week old outbred Swiss mice were inoculated intracerebrally with 10 LD_{50} doses. 40 percent of animals died within 10 to 12 days, and all survivors, showing no clinical signs, had evidence of active demyelination. By day 15 PI, no evidence of infectious virus could be found, and animals received 50 mg/kg of ara-C twice daily by intraperitoneal (IP) injection. At the same time, mice received 6 µc/g of ^{3}H-labeled thymidine (S.A. 40.2 c/m mole) every 12 hours. Animals receiving virus alone showed high levels of incorporated ^{3}H-thymidine measured as CPM/g of tissue and showed by autoradiography labeled CNS and inflammatory cells. The animals receiving virus and ara-C had 75% less incorporation of ^{3}H-thymidine than animals with virus alone but still more than controls inoculated with suspensions of normal mouse brain. At 20 and 34 days PI, virus-inoculated animals had active remyelination as well as a marked inflammatory response. Animals receiving virus and ara-C had little if any inflammatory cells and denuded axons as late as 14 days post ara-C (34 days PI). This absence of remyelination was accompanied by a sparsity of oligodendroglia.

From this data, it would appear that oligodendroglia proliferation is important in the myelin repair following virus-induced demyelination as evidenced by the interference of remyelination with the use of DNA inhibitors. Other mechanisms by which ara-C might interfere with remyelination will be discussed.

1273 INTRAHYPOTHALAMIC INJECTION OF DIFFERENT IMMUNOLOGICAL REACTION SYSTEMS INDUCE SPECIFIC CHANGES IN APPETITIVE BEHAVIORS. C.A. Williams and N. Schupf*SUNY, Purchase, N.Y. 10577, NYU Medical Center, New York, N.Y. 10016

ARB, a rabbit antibody produced against a membrane fraction of rat brain, was shown to depress drinking in deprived animals when introduced into the perifornical hypothalamus. This effect was identical to that produced by a complete exogenous reaction system, e.g. antiovalbumin and ovalbumin (Science, 196,328,1977). Since no common immunological event could be postulated for these similar results, the modes of action of these systems were tested utilizing a more sensitive assay based on the pharmacological induction of appetitive behavior in sated animals. Rats were prepared with cannulae in the perifornical hypothalamus, a region where direct chemical stimulation with norepinephrine (NE) is known to elicit excessive eating, to counteract carbachol induced drinking,and to depress natural thirst. Direct chemical stimulation with carbachol at the same site will elicit excessive drinking, block NE induced eating, and decrease eating in response to food deprivation.

Pretreatment with the exogenous antigen system elicited food intake in saline control animals, increased the eating response to NE treatment and suppressed the drinking response to carbachol treatment (Neurosci. Abstr., #1061,1975). In contrast, aRB did not modify the eating effect of NE or the drinking effect of carbachol. Nor did it induce appetitive behaviors in control animals not stimulated by drugs. However, pretreatment with aRB resulted in a significant increase of food intake in carbachol stimulated animals and a significant increase of water intake in NE stimulated animals. These effects demonstrate that aRB decreases the mutually antagonistic actions of NE and carbachol at this site.

The results of these experiments indicate that aRB and the defined reaction systems do not have similar modes of action on on the neural substrates mediating appetitive behavior. Reactions of extracellular soluble antigens with antibody in other tissues is known to cause noncytotoxic release of biogenic amines. In the brain model, the behavioral effects are consistent with the release of NE, although another mechanism resulting in the activation of NE dependent pathways would suffice. Antibody against membrane antigens of the brain, however, would be expected to react directly with cell surface sites. We propose that aRB acts to selectively impair the function of interneurons mediating adrenergic-cholinergic antagonism.

1274 PENETRATION OF A TRACER THROUGH CELLULAR ELEMENTS AROUND A CANNULA IMPLANTED IN BRAIN. Lawrence R. Williams* and Terence H. Williams. Dept. Anat., Coll. Med., Univ. of Iowa, Iowa City, IA 52242.

In the course of experiments requiring an implanted cannula for repeated, localized injection of agents into the septal region of the rat brain, information was sought about the tissue reaction around the cannula using electronmicroscopy. Horseradish peroxidase (HRP), Sigma Type VI (M.W. 40,000), was used as a tracer to determine whether or not the cells around the cannula would present a barrier to larger molecules. A microknife wound, made through the cannula, provided the opportunity to study the cellular changes after extraction of the knife.

Shultz and Willey (J. Neurocytol. 5:621, 1976) described the sheath of monocyte-derived, foreign body giant cells that surround electrodes 30 days after implantation. These investigators did not report on earlier time periods and a marker was not employed.

A stainless steel, 23 gauge cannula was used. Microknife wounds, 1 mm in depth, and injections of 1 µl saline or 0.2 - 1.0 mg/µl HRP at a rate of 0.05 µl/30 sec. were made via the cannula. The HRP or saline was injected 30 min. before sacrifice by perfusion fixation. Between the cannula implantation and sacrifice was an interval of 1, 3, 5, 7, 14 or 21 days.

Edema, neuron damage and phagocytosis characterized the tissue surrounding the cannula at 1-3 days survival. At 3-5 days, reactive astrocytes, monocytes and leptomeningeal cells appeared between the cannula and adjacent tissue. These cells lined most of the lesion by 7 days. At 14-21 days, the cells around the cannula were mainly monocytes and giant cells. Both kinds of cells formed a mutlilayered lining with complexly folded surface membranes. The tissue reaction around the microknife wound was similar to the reaction around the cannula.

In tissue sections, HRP reaction product appeared as a 1-3 mm wide band around the cannula. Individual variation in HRP diffusion patterns was observed, but there was a trend towards a decreased reaction product band width with increased survival time. HRP reaction product was localized primarily in the extra-cellular space (ECS) between these lining cells and in the ECS of the adjacent neuropil.

This evidence indicates that the cells surrounding the cannula do not present a substantial barrier to injected HRP during the time periods studied. The trend toward reduced penetration of the marker with increasing time after cannulation may be related to the increasing thickness and complexity of the cellular lining observed around the cannula. (Supported in part by Anatomy Training Grant GM00148 and NS11605 to T.H.W.)

NEUROTRANSMITTERS

1275 ELECTRICAL STIMULATION CAUSES INCREASED ACETYLCHOLINE SYNTHESIS IN A CRUSTACEAN SENSORY NERVE. Anthony Auerbach* (SPON: J. Sidie). Biology Dept., University of Oregon, Eugene, OR 97403.

The paired posterior stomach nerves (PSN) innervate the gastric mill region of the decapod crustacean stomach. In the crab Cancer magister it contains about 60 bipolar, anatomically homogeneous neurons with discrete dendrite, cell body, and axon regions. The PSN synthesizes acetylcholine (ACh) from choline but not any of the known transmitters derived from tyrosine, glutamate or tryptophan. PSN neurons also contain high choline acetyltransferase (CAT) activity. Thus, PSN neurons, like many other crustacean sensory systems, use ACh as their transmitter. Dendrite, soma, and axon regions all take up ^{3}H-choline and produce three major metabolites: phosphorylcholine (PCh), betaine, and ACh.

Kinetic analysis of choline transport shows both a low affinity (K_m=94 μM) and a high affinity (K_m=2 μM) component. The high affinity system predominates only when [choline] is less than 2 μM. The ratio, ACh synthesis/choline uptake, increases with decreasing exogenous [choline] in a manner consistent with coupling of ACh synthesis to high affinity transport. No such coupling is apparent for betaine or PCh. A PSN electrically stimulated (10-15 Hz) for 2-8 hrs and subsequently incubated in ^{3}H-choline and 10^{-5}M eserine synthesizes more ^{3}H-ACh than an unstimulated control PSN from the same animal. With 20 μM ^{3}H-choline, the stimulated/unstimulated (S/U) ^{3}H-ACh synthesis ratio was 1.72±0.18 (mean±SEM, n=6), while paired unstimulated controls showed the ratio 0.97±0.08 (n=4). With 1-2 μM ^{3}H-choline, the S/U ratio for ACh synthesis was 2.68± 0.27 (n=3) and a significant increase in total choline uptake was also observed (S/U=1.68±0.12; n=3). The increased ACh synthesis may result, in part, from activation of high affinity choline transport upon stimulation. However, stimulated PSNs also show increased CAT activity in cell-free assays, suggesting that electrical activity may alter other aspects of choline metabolism. These effects probably depend directly on action potentials since 1) the PSN is a primary sensory system devoid of synaptic input, and 2) antidromic stimulation produces the same metabolic changes. The metabolism of this electrical-metabolic coupling is under investigation. (Supported by NIH grants GM 00336 and NS-10614 (to D. Barker), and Sigma Xi.)

1276 SUBSTANCE P TERMINALS FORM SYNAPTIC JUNCTIONS IN SPINAL CORD. R. P. Barber*, J. E. Vaughn, J. R. Slemmon*, E. Roberts, and S. E. Leeman. Division of Neurosciences, City of Hope National Medical Center, Duarte, California 91010; and Department of Physiology (LHRRB), Harvard Medical School, Boston, Massachusetts 02115.

Molecules which react with antiserum to substance P have been localized in light and electron microscopic preparations of rat spinal cord using an immunoperoxidase method. Substance P positive (SP+) product is highly concentrated in dorsal horn laminae I-II, Lissauer's tract, a small nucleus in the dorsal portion of the lateral funiculus, and in a discrete patch just ventral to the central canal. Moderate accumulations of SP+ product are observed in portions of laminae III-V, lamina X, and in a narrow zone bordering fasciculus gracilis that expands ventrally to include nucleus cornucommisuralis dorsalis and nucleus dorsalis. The rest of the spinal grey matter exhibits extremely sparse staining. Light microscopic observations suggest that SP+ product is concentrated in fine axons and collaterals which display densely-stained varicosities and terminal puncta. These structures are closely associated with neurons and blood vessels. Electron microscopic observations reveal that certain axons and terminals contain accumulations of SP+ product associated with large, dense-core vesicles. Lesser amounts of SP+ product are sometimes associated with small, clear synaptic vesicles surrounding the dense-core vesicles. Such terminals commonly form axodendritic and axosomatic synapses, but the depositions of SP+ product are often not concentrated precisely at the "active sites" of these synaptic junctions. SP+ axon terminals also make contacts with astrocytic processes, including those which form endfeet around blood vessels. A primary afferent origin of some of the SP+ fibers and puncta is supported by the observation that ipsilateral, dorsal rhizotomies markedly reduce SP+ staining in laminae I-II. However, this staining is not entirely abolished by the lesions, and there is no obvious loss of SP+ staining in other parts of the spinal grey matter. Our findings suggest that substance P could participate in neural functions which are both spatially limited to synaptic junctions and more diffusely distributed via an involvement of the glio-vascular and ventricular system. (Supported by USPHS grants NS 12116, NS 09578, and AM 16510).

1277 POSTSYNAPTIC CORRELATES OF BARBITURATE EFFECTS OBSERVED IN TISSUE-CULTURED MAMMALIAN NEURONS. J.L. Barker and R.L. Macdonald, LNP, NINCDS and BBB, NICHD, Bethesda, Md. 20014.

Dissociated neurons derived from mouse fetal spinal cord and grown in tissue culture have been used to investigate the effects of barbiturates on neuronal membrane properties and amino acid pharmacology. Perfusion coupled with intracellular recordings revealed that anesthetic concentrations of pentobarbital (PB) reversibly abolished all synaptic activity, but did not render individual cells inexcitable, while anticonvulsant concentrations of phenobarbital (PhB) did not alter spontaneous activity, but markedly attenuated picrotoxin-produced convulsant activity.

The post-synaptic membrane mechanisms underlying barbiturate pharmacology were studied by adding Mg^{++} to the plate to suppress synaptic activity and by iontophoretically applying barbiturates and amino acids. PB directly and reversibly increased membrane conductance in a dose-dependent manner, the limiting slope of the log-log dose-response curve being about 2. These effects were Cl-dependent and antagonized by picrotoxin and penicillin. PhB either did not directly affect membrane properties (n= 16 cells) or produced small effects at large currents (>200 nA). PB and PhB potentiated GABA responses but not those of glycine or β-alanine, one molecule of either barbiturate being involved in the modulation. PB was 3-5 times more potent, prolonged GABA kinetics and lowered the limiting slope of the log-log dose-response curve from about 2 to about 1.5. PhB enhanced GABA with little change in kinetics. The results suggest that PB is GABA-mimetic and in some way participates in the GABA response, thus lowering GABA cooperativity. Although analysis of double-reciprocal plots was difficult due to the apparent change in GABA cooperativity, similar y-intercepts of the plots suggest no increase in the "maximum effect" of the GABA. PB and PhB reversibly depressed glutamate (GLU) depolarizations without altering their kinetics, with one molecule of either barbiturate being required. PB was about 3-5 times more potent than PhB. PB but not PhB indirectly depressed GLU by shunting the membrane. Analysis of the double-reciprocal plots indicated that PB and PhB antagonized GLU through a non-competitive mechanism. The threshold for enhancement of GABA and depression of GLU by the barbiturates occurred at about the same iontophoretic current. Similar differential effects on membrane properties and amino acid responses were made with the anesthetics, secobarbital and DMBB, and the anti-convulsant mephobarbital. The results suggest that barbiturate anesthetics anesthetize by directly activating GABA receptors, by potently enhancing and prolonging GABA-mediated inhibition and by depressing glutamate excitation. Anti-convulsant effects appear to result from less potent, though similar modulation of GABA and glutamate effects without direct activation of GABA receptors.

1278 EFFECT OF THYROTROPIN RELEASING HORMONE ON RAT HYPOTHALAMIC AND SEPTAL NEURONS: COMPARISON WITH NOREPINEPHRINE AND ACETYLCHOLINE. A.L. Beckman and A. Winokur.* Depts. of Physiology and Psychiatry, School of Medicine, Univ. of Pa., Philadelphia, Pa. 19104

Recent evidence has demonstrated that hypothalamic releasing factors exert an influence on the firing rate of neurons within diverse areas of the brain, suggesting a possible role as neurotransmitters. In the present study, we compared the effect of thyrotropin releasing hormone (TRH) with that of norepinephrine (NE) and acetylcholine (ACh), two putative neurotransmitters, on the firing rate of neurons in the cortex, preoptic/anterior area of the hypothalamus (PO/AH), and the septal area of urethane-anesthetized, male Sprague Dawley rats. Five-barreled micropipettes were used to record extracellular single unit discharges and to iontophoretically apply TRH (0.01M), NE (0.25M), and ACh (0.25M). Only those cells that responded to at least one of the test compounds (TRH, NE or ACh) and that failed to respond to current flow (delivered through a 0.5M NaCl-filled barrel) were included in these results. Twelve cells in the cerebral cortex were tested and none responded to TRH. However, in the PO/AH and septal area, TRH influenced the firing rate of 29 out of 43 cells (67%). The effect was uniformly one of inhibition. The majority (90%) of the cells inhibited by TRH were also inhibited by NE (N=26; 3 cells were unaffected by NE) but, by contrast, showed variable responses to ACh. These data show that TRH exhibits similar effects to NE on almost all TRH-sensitive neurons tested. The mechanism underlying these parallel effects has yet to be defined. (Supported by USPHS grant NS10597 and NIH RCDA award MH00044.)

1279 TRANSPORT AND SECRETION OF NEURAL PEPTIDES WITHIN THE CNS OF APLYSIA. R. W. Berry. Dept. Anat., Northwestern Med. Sch., Chicago, IL 60611.

Many molluscan neurons produce large quantities of low molecular weight proteins, and the somatic and axonal metabolism of these compounds have been studied intensively. However, the function of these abundant peptides is not known. Indirect evidence suggests that they are neurosecretory, but only in the case of the egg-laying hormone secreted by the bag cells of Aplysia has release been directly demonstrated (Arch, J. gen. Physiol., 59, 47, 1972). To test the assumption that such peptides are actually destined for secretion, we isolated the intact central nervous system of Aplysia in such a way that the circumesophageal ganglia could be exposed to tritiated leucine while the pleuro-visceral connective nerves and the abdominal ganglion were bathed in a large excess of unlabeled leucine. Under these conditions, labeled proteins are transported into the connective nerves and reach the abdominal ganglion within 24 hr. The predominant group of transported proteins consists of peptides smaller than 18,000 daltons. Electrical stimulation of the connective nerves releases labeled transported protein from the abdominal ganglion, and this release is inhibited in low Ca^{++}:high Mg^{++} media. The labeled protein that remains in the ganglion after stimulation is deficient in low molecular weight species. Thus, peptides synthesized by neurons of the circumesophageal ganglia are transported to the abdominal ganglion and undergo release there. In view of a previous demonstration that pharmacologically active peptides can be extracted from the circumesophageal ganglia (Ifshin, et al., Nature, 254, 72, 1975), the present data suggest that such neuroactive peptides could reach their targets not as circulating hormones, but via a synaptic mechanism.

1280 EXCITATORY EFFECTS OF THRYROTROPIN RELEASING HORMONE IN CAT SPINAL CORD. Gene Boyer* and Barrett R. Cooper* (SPON: James L. Howard). Dept. of Pharmacol., Wellcome Res. Labs, Research Tri. Pk., N.C.

Thyrotropin releasing hormone (TRH) is a tripeptide localilized in hypothalamus and also reported to have a widespread distribution through the CNS[1]. We found TRH (10 mg/kg i.v.) to produce a generalized increase in muscle tonus as evidenced by highly activated EMG recorded from flexor and extensor groups throughout the skeletal musculature. EMG activation occurred within 10 sec after TRH injection via indwelling venous cannula in restrained but otherwise untreated cats. TRH similarly increased the amplitude and frequency of the EMG in cats after midcollicular decerebration or high spinal cord transection. Studies in C_1 spinal cats revealed that TRH could transiently (3-5 min) increase EMG activity at a dose as low as 0.5 mg/kg i.v. Doses ranging from 5-10 mg/kg i.v. however, elicited a stimulation of EMG activity lasting at least 2 hrs and beyond. Curiously, tolerance rapidly developed to repeated injections of TRH. For example, 2 mg/kg i.v. increased EMG activity up to 100 fold and had measurable effects for 10 min; whereas a second dose of 2 mg/kg i.v., given 30 min after the first injection, produced only a 2 fold increase and had effects for 10 min; and a third dose of 2 mg/kg i.v. 30 min later elicited only a barely measurable response. Direct recording from L_6 or L_7 spinal cord ventral roots after laminectomy, bilateral rhizotomy of both L_6 or L_7 dorsal and ventral roots, and cord transection at C_1 revealed that spontaneous nerve action potentials occurred at a high rate after i.v. injection of TRH. Computer averaging of ventral root potentials evoked by electrical stimulation of dorsal roots in these cats showed that TRH increased the amplitude of the monosynaptic potentials and both increased the amplitude and shortened the latency of the polysynaptic potentials. None of these effects of TRH was produced by injection of T_3 or the constituent amino acids of TRH. These results and the recent discovery of TRH in the anterior horn[2] suggest that TRH may function in spinal cord neural transmission.

1281 ELECTROPHORETIC AND IMMUNOCHEMICAL CHARACTERIZATION OF CHOLINE ACETYLTRANSFERASE FROM TORPEDO. C. Brandon* and Jang-Yen Wu* (Spon: K. Matthews) Dept. of Cell Biology, Baylor College of Medicine, Houston, TX 77030

We have previously reported the purification of choline acetyltransferase (CAT), the enzyme catalyzing the biosynthesis of acetylcholine, from the electric organ of Torpedo californica, and shown it to migrate as a single band on SDS-polyacrylamide gels (Trans. Amer. Neurochem. Soc. Vol. 8, page 169, 1977). On non-denaturing 5% gels at alkaline pH, the purified protein migrates as a single band of R_f 0.32. Enzymatic (CAT) activity can be recovered by slicing the gel, and corresponds exactly to the position of the protein as visualized by coomassie staining. Cation-exchange chromatography has been reported by several authors to separate CAT into two charge isozymes (see, e.g., PNAS 70, 3749 (1973); J. Neurochem. 24, 963 (1975). These two isozymes can be separated by electrophoresis of the purified protein on 5% gels at pH 4.2 under non-denaturing conditions, and appear in approximately equal amounts. These isozymes have identical molecular weights on SDS-gels.

Using rabbits, we have obtained an antibody specific to CAT following five biweekly subscapular injections of 10 µg of the purified enzyme in complete Freund's adjuvant. The antisera thus obtained show a single precipitin band on Ouchterlony double diffusion tests against both crude CAT (1% pure) and the purified protein. Using these antibodies, studies on the species and tissue specificity and immunohistochemical localization of CAT are in progress. (Supported in part by Grant NS-13224-02 from NIH).

1282 EFFECTS OF ESERINE AND ESEROLINE ON ACETYLCHOLINE (ACh) UPTAKE IN RAT BRAIN SLICES. Virginia G. Carson, Donald J. Jenden, Ruth A. Booth* and Margareth Roch*. Dept. Biol., Chapman College Orange, CA 92666 and Dept. Pharmacol. & Brain Research Inst., UCLA Sch. Med., Los Angeles, CA 90024.

Eseroline, the phenolic hydrolysis product of eserine, has been reported to be essentially inert as a ChE inhibitor(Hemsworth B.A. and West, G.B., J. Pharm. Pharmacol. 20:406, 1968). Eserine is also a potent inhibitor of ACh uptake in brain slices(Schuberth J. and Sundwall,A., J. Neurochem. 14:807, 1967) and it was of interest to examine whether eseroline retains this property. Eseroline was prepared by basic hydrolysis of eserine in a nitrogen atmosphere followed by extraction into ether and crystallization as the hydrochloride salt (M.P. 214-215°C). Slices of rat brain cortex were incubated at 38°C in Krebs solution containing 1mM ascorbate, 50µM paraoxon and eserine or eseroline at concentration of 10^{-4}, 3 X 10^{-5}, 10^{-5}, 3 X10^{-6}, 10^{-6} or 3X10^{-7} M. Controls were identical except eserine and eseroline were omitted. After preincubating for 15 min, $^2H_3$-acetyl-$^2H_2$-choline (20µM) was added and the tubes were incubated for an additional 30 min. Both slices and supernatent were then analyzed by GCMS for Ch and ACh labelled in either Ac or Ch moiety, in both and in neither. No evidence was obtained of significant hydrolysis and resynthesis of ACh, which would yield a singly labelled product. The uptake ratio (slice/supernatent) of $^2H_3$-Ac-$^2H_2$-Ch in control slices was 2.26 ± .08 (66). Eserine and eseroline were equiactive in inhibiting the uptake, with I_{50} of 1.0 X 10^{-5}M and 1.6 X 10^{-5}M respectively. Neither compound affected the levels of unlabelled (i.e. endogenous) Ch (147 ± 4 (189) nmol g^{-1}) or ACh (31.3 ± 0.7 (191) nmol g^{-1}) or the amounts of endogenous Ch or ACh released into the bath (18.4 ± .4 (191) and no detectable nmol g^{-1} min^{-1} respectively).

We conclude that inhibition of ACh uptake by eserine depends on the eseroline nucleus rather than on the carbamate ester group which is necessary for ChE inhibition. Eseroline may be useful in assessing whether ACh uptake plays a functional role in cholinergic systems. (Supported by USPHS grant MH 17691).

1283 SUPPRESSION OF JAW-OPENING REFLEX BY MORPHINE: THE INVOLVEMENT OF CHOLINERGIC AND DOPAMINERGIC NEUROTRANSMISSION. Samuel H.H. Chan and M.K. Yip*. Dept. Life Sci., Indiana State Univ., Terre Haute, IN 47809 and Dept. Physiol., Univ. Hong Kong, Hong Kong.

The jaw-opening reflex (JOR), elicited by activating the tooth pulp afferents and resulted in the contraction of the digastric muscles, has been used as a model in the study of pain. Chan and Fung (Exp. Neurol. 53:363, 1976) have reported the suppression of this reflex by morphine in rabbits, and have suggested that the opiate may promote the release of neurotransmitters centrally which inhibit the transmission of nociceptive information from the tooth. The present study was undertaken to investigate this possible modus operandi of morphine-elicited analgesia.

Adult rabbits lightly anesthetized with pentobarbital sodium (30 mg/kg, i.v.) were used. Intrapulpal stimulation was delivered via a pair of silver electrodes implanted into the dental pulp of the left upper incisor. The evoked JORs were recorded as EMG signals from the left digastric muscle. Changes in the averaged amplitude of 30 EMGs obtained from an on-line averager, as elicited by constant intensity (3T) dental stimulations, were used as the index of pain response. Drugs were administered directly into the cerebral circulation via a cannulated carotid artery. Animals were maintained on artificial respiration throughout the recording session to eliminate morphine-induced hypoxia.

As previously observed, intracarotid injection of morphine sulfate, at a dose of 3 mg/kg, caused no or only transient inhibition on the JOR. The analgesic effects of morphine, at this dose, were significantly potentiated when physostigmine (0.1 mg/kg), an acetylcholine esterase inhibitor, was introduced 30 min after morphine administration. Such action, indicative of the involvement of cholinergic transmission, can be observed as soon as 3 min after physostigmine was delivered and can endure for at least 20-30 min. Atropine sulfate, an acetylcholine antagonist, given at doses of 1 and 5 mg/kg, nonetheless, was unable to reverse the ongoing inhibitory effects on the JOR.

Morphine, at an analgesic dose (6 mg/kg) as previously demonstrated, was observed to produce no appreciable effects on the JOR in rabbits pretreated, 45-60 min before the recording session, with a dopamine receptor blocker, pimozide (0.5 mg/kg, i.p.). Significant inhibition of the reflex, however, was achieved when physostigmine (0.1 mg/kg) was administered 30 min after morphine injection.

It would seem reasonable to postulate that morphine suppression of JORs may be exerted by promoting a change in cholinergic and dopaminergic neurotransmission. Exactly where morphine may induce such a release of neurotransmitters in the central nervous system is currently being investigated in our laboratories.

1284 A MECHANISM OF ACTION OF BENZODIAZEPINES: EFFECT OF CHLORDIAZEPOXIDE UPON GABA CHEMOSENSITIVITY AND SYNAPTIC ACTIVITY IN SPINAL TISSUE CULTURE. Dennis W. Choi*, David H. Farb*, and Gerald D. Fischbach. Dept. of Pharm., Harvard Medical School, Boston, MA 02115

The mechanism of action of benzodiazepines is unknown. Some indirect evidence suggests an interaction with inhibitory GABA or glycine pathways, but the complexity of the brain has prevented precise analysis. We have determined the effect of chlordiazepoxide (CDPX) in spinal cord cell cultures, where individual neurons can be tested directly.

Dissociated embryonic chick spinal cord neurons survive in sparse cell culture and form extensive synaptic interconnections. Individual neurons were impaled for intracellular recording, and drug responses were evoked by focal microiontophoresis, and/or by pressure ejection from large bore pipettes. All spinal neurons are sensitive to both GABA and glycine. Prior application of bicuculline, or strychnine, reversibly attenuated GABA and glycine responses, respectively.

Prior application of CDPX invariably resulted in a striking potentiation of the GABA response, while having no effect on the glycine response. The potentiation was rapidly reversible, and its magnitude was CDPX dose-dependent (between 10^{-7} M and 10^{-4} M). CDPX alone at these concentrations had no effect on resting potential or input resistance. The GABA dose-response function was markedly shifted to the left by CDPX, but the maximal GABA response was unchanged.

One mM CDPX did not affect high affinity ^{3}H-GABA uptake measured in sister cultures. Induction of GABA release cannot account for the large shift in the GABA dose-response function, because CDPX did not exert a large GABAmimetic effect. The CDPX potentiation of GABA chemosensitivity, therefore, is likely due to a direct postsynaptic action. Since CDPX is not an agonist, it probably does not act directly at the GABA binding site. It may bind to a regulatory site on or near the GABA receptor, altering the receptor's affinity for GABA. Alternatively, the binding of CDPX may alter the coupling between GABA binding and the opening of membrane channels. This type of postsynaptic facilitation may represent a novel drug mechanism.

Stimulus evoked synaptic potentials that are blocked by bicuculline are augmented by CDPX, suggesting that CDPX facilitates the action of endogenously released GABA at GABAnergic synapses. The overall effect of CDPX on ongoing spontaneous synaptic activity is one of marked inhibition. These findings may help explain some of the clinical actions of benzodiazepines on the basis of enhanced GABAnergic inhibition in the CNS.

1285 SOME ACTIONS OF CATECHOL ON DORSAL ROOT RESPONSES IN FROG SPINAL CORD. Robert A. Davidoff, John C. Hackman and David B. Ross*. Neurology Service, V.A. Hospital and Dept. of Neurology, University of Miami School of Medicine, Miami, FL 33152

Catechol is an unusual convulsant agent in that it augments spinal primary afferent depolarization (PAD). This has been attributed to the compound's ability to increase the amount of transmitter released presynaptically by nerve impulses. However, our present experiments--designed to ascertain the nature of catechol's effects on primary afferent fibers--suggest a postsynaptic mechanism of action.

We used the hemisected frog spinal cord continuously superfused with HCO_3^- buffered Ringer's solution maintained at 15°C. Using the sucrose gap technique, synaptic and amino acid-induced responses were recorded from dorsal roots (DR). Catechol, added to the superfusate in concentrations greater than 10^{-5}, consistently and significantly enhanced the amplitude and increased the duration of dorsal root potentials (DRPs) whether generated by stimulation of an adjacent dorsal root (DR-DRP) or of a ventral root (VR-DRP). The latter potential usually increased more in size (300% of control response; 60 min application) than the former (150%). The dorsal root reflex was also facilitated. These effects were only partially reversible after washing.

Although changes in primary afferent membrane potential (usually transient hyperpolarization, 0.5-0.75mV) and excitability (increased amplitude of antidromic spike elicited by Wall's technique) were noted, it is likely that the increased DRPs were caused by a postsynaptic potentialtion of the action of neutral amino acids. These substances--particularly GABA--are thought to be responsible for PAD. Thus, in Ringer's solution containing 10-20mM Mg^{++} (which suppresses synaptic activity) the amplitude of the DR depolarizations produced by GABA, β-alanine, glycine, and taurine were invariably and substantially enhanced (150-350%); durations of these depolarizations were unaffected. Similarly, catechol increased the DR depolarizations evoked by elevated concentrations of K^+ in the superfusate. Furthermore, catechol neither altered high affinity uptake of [^{3}H]GABA by cord slices nor K^+-evoked release of the same compound from similar slices.

These observations suggest that the catechol-induced enhancement of the DRP could be caused by an increased action of synaptically released GABA (or another neutral amino acid) on DR terminals and/or by an increased depolarizing effect of K^+ accumulating in extracellular spaces during the DRP. Therefore, it seems reasonable that a postsynaptic mechanism provides the basis of catechol's ability to enhance PAD. It remains to be determined what relationship this action has to catechol's convulsant properties. (Supported by VA Funds, MRIS 1769).

1286 GABA AS A NEUROTRANSMITTER IN SPINAL CORD CELL CULTURES. David H. Farb*, Dennis W. Choi*, and Gerald D. Fischbach (SPON: N. Kiang). Department of Pharmacology, Harvard Medical School, Boston, MA 02115

A great deal of circumstantial evidence has accumulated that γ-aminobutyric acid (GABA) plays a role in presynaptic and postsynaptic inhibition in the adult vertebrate spinal cord. We are attempting to demonstrate that GABA is a neurotransmitter in embryonic spinal cord cell cultures. Neurons were dissociated from 7 day embryonic chick spinal cords and were either added to established muscle cultures or grown alone. ^{3}H-GABA is accumulated in established spinal cord-muscle cocultures by a high affinity uptake mechanism (Km = 3.7 μM). Autoradiography indicates that about 50% of the neurons (defined by their ability to generate an action potential or receive synaptic input) concentrate the label. Significantly, none of the neurons that innervate muscle are labeled. Newly taken up ^{3}H-GABA was released when the cells were depolarized in 100 mM K^+. Reduction of the Ca^{++}/Mg^{++} ratio reversibly inhibited the stimulated release.

Cultured spinal cord cells synthesize ^{3}H-GABA from ^{3}H-glutamate (products identified by high voltage paper electrophoresis). The Km for glutamate is ca. 150 μM. GABA synthesis did not depend on the presence of non-neuronal cells: formation of ^{3}H-GABA was unchanged when the non-neuronal cell monolayer was stabilized by γ-irradiation (5000 Rads.) or when these cells were eliminated almost entirely by addition of 5×10^{-6}M cytosine arabinoside to the culture medium.

Nearly all of the spinal cord neurons that survive in vitro are extremely sensitive to iontophoretically applied GABA. As is the case in vivo, GABA responses were associated with an increase in membrane conductance to Cl^-. Many (but not all) of the Cl^- dependent spontaneous and stimulus evoked synaptic potentials are reversibly reduced in size by low concentrations of bicuculline and picrotoxin. Taken together these physiological and biochemical results are consistent with the notion that GABA is used as a neurotransmitter in spinal cord cell cultures. More detailed experiments at individual synapses are in progress.

It will also be important to correlate changes in function with changes in GABA metabolism. There is a 20-fold increase in high affinity GABA transport and a similar large increase in GABA synthesis during the first two weeks after plating. Accumulation of ^{3}H-GABA (synthesized from ^{3}H-glutamate) can be increased several fold by brief incubation in 5-amino-1,3-cyclohexadienylcarboxylic acid (gabaculine); a Streptomyces toxin that specifically and irreversibly inactivates GABA transaminase. (Supported by Grant NS 11160 and the Muscular Dystrophy Associations of America.)

1287 DRUG-INDUCED SHIFTS IN SYNAPTOSOME SEDIMENTATION DURING DENSITY GRADIENT CENTRIFUGATION. Joseph A. Fix* and Charles O. Rutledge. Dept. Pharmacol. and Toxicol., Sch. Pharmacy, Univ. of Kansas, Lawrence, KS 66045.

Synaptosomes from rat corpus striatum were examined for their sedimentation characteristics in sucrose density gradients after treatment of the crude synaptosomal fraction (P2) with various drugs. The aim was to test the hypothesis that an increase in the content of cytoplasmic dopamine would decrease the density of the synaptosomes by reducing osmotic water loss from the synaptosomes during centrifugation. Alterations in sedimentation characteristics were monitored by electron microscopic examination of fractions collected from the gradients, and electrochemical detection of dopamine and norepinephrine in each gradient fraction following alumina extraction and liquid chromatographic separation of the catecholamines. The major peak of dopamine observed for synaptosomes maintained in 0.32 M sucrose prior to gradient centrifugation occurs in the range of 1.05-1.10 M sucrose. In a second series of experiments the P_2 fraction was incubated in physiological buffer at 37°C with dopamine (10^{-5}M) plus pargyline (2.5×10^{-5}M). The synaptosomes were obtained by centrifugation and were resuspended in 0.32 M sucrose prior to addition to the gradient. This treatment resulted in a shift of the major dopamine peak to 0.95-1.00 M sucrose. When the experiments were repeated except that the synaptosomes were resuspended and added to the gradient in physiological buffer, there was a further shift in the major dopamine peak to 0.90-0.93 M sucrose. Electron microscopic examination of synaptosomes taken directly from the sucrose gradient fractions showed that those synaptosomes in the lighter dopamine peak were less distorted compared to dopamine synaptosomes from the heavier sucrose fractions. The synaptosomes lower in the gradient clearly occupied less volume due to their convoluted structure. The convoluted synaptosomes assumed a normal spherical shape when suspended in physiological buffer prior to electron microscopic examination. The use of drugs to alter the sedimentation of synaptosomes offers the potential of isolating synaptosomes containing primarily one neurotransmitter substance from a heterogenous synaptosomal population. Supported by USPHS NIH Grant NS 12760.

1288 GLUTAMIC ACID AND ETHANOL DEPENDENCE. William J. Freed and Elias K. Michaelis. Dept. Human Development, University of Kansas, Lawrence, KS, 66045.

The purpose of this investigation was to test the hypothesis that excess glutamate-induced neuronal excitation is responsible for the manifestations of ethanol withdrawal in animals. Male Swiss-Webster mice were made ethanol dependent by the inhalation method of Goldstein (Fed. Proc. 34: 1953, 1975), including daily injections of 68 mg/kg of pyrazole. Concentrations of ethanol in the inhalation chamber were 8.6 mg/l for the first 24 hr, 12.3 mg/l from 24-48 hr, and 13.7 mg/l from 48-72 hr. Ethanol exposure was terminated after 72 hr and seizures elicited by handling were rated on a 1 - 4 scale for at least the next 27 hr by a "blind" observer. Glutamate diethylester, a specific glutamate antagonist that produces no direct neuronal suppression of its own (cf. McLennan, Handbook of Psychopharmacology 4, p.211 Plenum, 1975) was tested for its effects on these withdrawal seizures. A dose of 480 mg/kg administered 5 hr after withdrawal decreased seizure scores by 62% over the next 3 hr, an effect that persisted for approximately 11 hr. Smaller doses, or 480 mg/kg given either at the time of removal from ethanol exposure or 2 hr thereafter, were less effective.

Behavioral activity was measured for 1 min periods in groups of 10 mice. It was found that the activity of mice undergoing ethanol withdrawal was considerably (61%) less than that of control animals. Glutamate diethylester in a dose of 480 mg/kg tended to counteract this activity decrease (by 18%, p=.064) even though this drug decreased the activity of normal controls.

To test the possibility that CNS supersensitivity to glutamate develops during ethanol dependence we administered kainic acid, a putative glutamate agonist (cf. Olney et al., Brain Res. 77: 507, 1974) to ethanol- dependent animals while these animals continued to be exposed to ethanol. A dosage level that caused convulsions in 20% of normal controls resulted in convulsions in a significantly larger (80% and 71% in two experiments) percentage of ethanol dependent animals. Chronic administration of pyrazole alone did not alter the convulsive response to kainic acid. In contrast to this result, no differences in pentylenetetrazol seizure thresholds were observed between ethanol-dependent and control animals. These findings suggest that supersensitivity to glutamate develops during ethanol dependence, and that this phenomenon contributes to the ethanol withdrawal reaction.

1289 ELECTROCHEMICAL DETECTION OF SYNAPTOSOMAL RELEASE OF ENDOGENOUS DOPAMINE. George E. Geier*, Mark A. Dayton*, and R. Mark Wightman* (SPON: H. David Potter). Chem. Dept., Indiana University, Bloomington, IN 47401.

High performance liquid chromatography with electrochemical detection has been used to study the dynamic properties of dopamine release from synaptosomes prepared from rat corpus striatum. The sensitivity (10^{-13} mole) and the specificity for catecholamines of the detection method have made it possible to rapidly measure release of endogenous transmitter from small amounts of synaptosomal preparations (0.5mg of protein). The percentage of dopamine in each subfraction (P2, P3, P2B, etc.) has been measured, with greatest yield in the crude mitochondrial (P2) fraction. The presence of 1 mM ascorbic acid in all solutions has been found essential for reproducible dopamine measurement.

Synaptosomal release of endogenous dopamine was found to increase as a function of K^+ concentration (10 mM to 150 mM) at 37°C. Electron microscopic observations indicate the effects are not due to synaptosomal lysis. Release was found to be independent of time at incubation times greater than 2 min indicating a steady state between uptake and release is rapidly established following depolarization.

Potassium stimulated release was found to be Ca^{++} dependent. Removal of Ca^{++} caused a 70% average decrease in dopamine release, while incubation of synaptosomes with Ca^{++} ionophore A23187, (Lilly) resulted in significant increase in released dopamine.

Various concentrations of ouabain, cytocholasin B, colchicine and diamide were also used to probe the mechanism of transmitter release. Ouabain, cytocholasin B and colchicine were all found to stimulate observed release to various degrees.

These data indicate that sensitive electrochemical detection systems as first described by Adams *et al.* (Anal. Lett., 6, 465 (1973)) can be successfully used to probe rapidly occuring membrane events at levels of sensitivity not obtainable by more conventional biochemical techniques. (Supported by Research Grant PHS 5 R01 NS 08309)

1290 CSF GABA LEVELS IN INDIVIDUALS AT RISK FOR HUNTINGTON'S DISEASE. B.S. Glaeser, N.V.B. Manyam*, L. Katz* and T.A. Hare, Thomas Jefferson Univ., Philadelphia, PA and Veterans Administration Hospital, Wilmington, DE

10 ml aliquots of lumbar cerebrospinal fluid (CSF) were obtained from 10 individuals in two families each of which had a parent with Huntington's Disease (HD) as established by classical symptoms and positive family history. The ages of these at-risk individuals ranged from 11 to 21 years with a mean age of 16.4 years. Clinical examination of the 10 subjects revealed no systemic or neurological abnormalities except for a mild scoliosis in one individual. Routine clinical laboratory tests of blood, urine and the CSF specimens were within normal limits in all cases.

GABA was measured in 0.5 ml aliquots of the CSF specimens by the ion-exchange/fluorometric procedure (Glaeser and Hare, Biochem. Med. 12, 274-282, 1975). This procedure for measuring CSF GABA levels has been shown to be accurate through comparison with (1) amino acid analysis, (2) the radioreceptor GABA assay procedure (Enna et al., J. Neurochem., in press) and (3) assay by gas chromatography/mass spectrometry (Huizinga et al., N. Eng. J. Med. 296, 692, 1977).

The results of the analyses showed GABA to be present in these CSF specimens over the range of 126-315 picomoles/ml (mean ± SD 217±61). Four of these individuals had CSF GABA levels below 180 picomoles/ml, whereas the other six participants had CSF GABA levels above 230 picomoles/ml. The mean values (± SD) for these two groups were 153±22 and 260±31 picomoles/ml, respectively. Statistical analysis by the chi-square test showed that these two groups had equal variance. The Student's t-test demonstrated that the difference between the mean values of the two groups is highly significant ($P < 0.001$).

Although it is not known which of the participants will develop the symptoms of HD, it can be expected that approximately half of them have inherited the disease. In view of the reported low levels of GABA in brain and CSF of HD patients, the observed bimodal distribution of CSF GABA in presymptomatic individuals may indicate potential for this type of measurement as a presymptomatic test for HD.

1291 STRAIN-DEPENDENT VARIATIONS IN BRAIN PHENYLETHANOLAMINE N-METHYL TRANSFERASE ACTIVITY: EFFECT OF PHENYLETHANOLAMINE N-METHYL TRANSFERASE INHIBITION ON EPINEPHRINE LEVELS. Menek Goldstein, Jow Y. Lew,* Andre M. Sauter* and Yoshimi Baba.* Dept. of Psychiatry, Neurochemistry Laboratories, New York University Medical Center, New York, New York 10016.

Phenylethanolamine N-methyl transferase (PNMT) containing cell bodies have been located in two cell clusters, C_1 and C_2 cell groups of the medulla oblongata, and some PNMT containing terminals were located in the surrounding regions (T. Hokfelt et. al., Brain Research 66, 235, 1974). The PNMT activity was found to be higher in the C_1 and C_2 regions of 4 week old spontaneous hypertensive rats (SHR's) than in the corresponding Wistar Kyoto (W.K.) substrain rats (Saavadra et. al., Science 191, 483, 1976). We have now examined the PNMT activity in selected regions of the brain of Sprague Dawley (S.D.), W.K. and SHR's. In all three strains the PNMT activity is significantly higher in the C_1 and C_2 regions than in the surrounding regions. Thus, the PNMT activity is higher in the regions containing cell bodies than in the regions containing terminals. The PNMT activity in the C_1 and in the C_1 surrounding regions, as well as in the C_2 and in the C_2 surrounding regions, is significantly higher in S.D. rats than in the W.K. or SHR's.

We have also investigated the effects of a selective PNMT inhibitor, SKF 64139 (Pendleton et. al., J. Pharmacol. exp. Ther. 197, 623, 1976) on brain PNMT activity and on brain epinephrine levels. The administration of SKF 64139 (40 mg/kg, i.p.) resulted in a decrease of brain PNMT activity with a concomitant decrease in brain epinephrine levels. Three hours after the administration of the inhibitor the enzyme activity was decreased by 90% in the analyzed regions of the brain (C_1 and C_2 regions, hypothalamus). The epinephrine levels reached minimum values 3-4 hours after the administration of the inhibitor. The enzyme activity remained decreased even six hours after administration of the inhibitor and at this time period the epinephrine levels were still significantly reduced. Sixteen hours after the administration of the inhibitor the enzyme activities returned almost to control values and the epinephrine levels returned to the corresponding control values. Thus, the time course of PNMT inhibition parallels with the lowering of the the epinephrine content in the brain. These results indicate that N-methylation of norepinephrine by PNMT may be one of the rate limiting steps in the formation of epinephrine in the CNS.

1292 ALTERATIONS IN TYROSINE HYDROXYLASE ACTIVITY IN RESPONSE TO DEXAMETHASONE IN A CELL LINE DERIVED FROM A RAT PHEOCHROMOCYTOMA. R. Goodman,* H. Herschman* and H. Thoenen (SPON: D.M. Nance). Dept. Biol. Chem., Sch. Med., UCLA, Los Angeles, CA 90024 and Biozentrum of University of Basel, CH-4056, Basel, Switzerland.

The Gl-3 cell line was established in cell culture from an experimentally induced rat pheochromocytoma tumor (S. Warren and R.N. Chute (1972) Cancer 29:327). The cells were grown on tyrosine-free RPMI 1640 medium in the presence of dexamethasone from the fifty-fourth to the seventy-first passage. After the seventh passage in this medium, the uncloned Gl-3 cell line exhibited an increased tyrosine hydroxylase specific activity when cultured in the presence of dexamethasone as compared to cells from which the dexamethasone had been removed. This effect on tyrosine hydroxylase specific activity appears to be limited to the glucocorticoid class of steroid hormones being elicited by corticosterone, dexamethasone and triamcinolone but not by other steroid hormones such as estradiol, progesterone or testosterone. Data on the time course and dose dependence will be presented as well as the effects of inhibitors of RNA and protein synthesis.

This cell line contains, in addition to the adrenergic neuronal enzyme tyrosine hydroxylase, the cholinergic enzyme choline acetyl transferase. The relationship between the influence of glucocorticoid hormones on the levels of adrenergic and cholinergic enzymes in these cells will be discussed. (This work is supported by NIH Post-doctoral Fellowship No. 1 F32 NS05586-01, by the Swiss National Foundation for Scientific Research, Grant No. 3.653.71 and the ERDA.)

1293 SYNAPTOSOMAL UPTAKE OF TRANSMITTER AMINO ACIDS IN THE HABENULAR NUCLEI. FURTHER EVIDENCE FOR A GABAERGIC PATHWAY. Zehava Gottesfeld* and David M. Jacobowitz (SPON: L. Herrenkohl). Lab. Clin. Sci., NIMH, Bethesda, MD 20014.

The high affinity uptake mechanism of various neurotransmitters by nerve-endings has been used as a sensitive tool to identify and localize transmitter-specific neurons and their pathways in the nervous system. The uptake of γ-aminobutyric acid (GABA) and glutamic acid has been studied and compared in the lateral habenula (LHb) and medial habenula (MHb) in the rat. Synaptosomes of isolated single LHb amd MHb nuclei were prepared from 300 μm fresh tissue slices sectioned by a vibratome. After 4 min of incubation at 24°C or 37°C in Krebs buffer containing $5x10^{-7}$ M ^{3}H-GABA, ^{3}H-glutamate or ^{3}H-glycine, the synaptosomes were collected by filtration, extracted and the neurotransmitters determined. High accumulation of GABA and glutamate was found in the habenular nuclei, whereas the uptake of glycine was low at this concentration. LHb and MHb showed a differential uptake capacity for ^{3}H-GABA and ^{3}H-glutamate. The LHb accumulated twice as much GABA and 3 times as much ^{3}H-glutamate compared to MHb. The uptake was shown to be sodium-dependent and was abolished in the presence of 0.1% Triton X-100 or hypotonic conditions. The accumulation of ^{3}H-GABA by the LHb was not affected by 10^{-5} M amino-oxyacetic acid, a GABA-transaminase inhibitor. L-2,4-diaminobutyric acid (1 mM), a potent inhibitor of GABA uptake by nerve endings, and β-alanine (0.5 mM), an inhibitor of GABA uptake in glial cells, caused a reduced uptake of ^{3}H-GABA in the LHb by 70% and 30%, respectively.

High-frequency stereotaxic lesions placed in the stria medullaris (SM), a major pathway which connects various brain regions with the habenular nuclei, resulted in a 41% and 62% decreased uptake, respectively, of ^{3}H-GABA in the LHb after 4 days or 5 weeks survival. No change was observed in the MHb.

The differential uptake of the transmitters by the LHb and MHb may indicate a higher concentration of both GABAergic and glutamate-containing terminals in the LHb than the MHb. In addition, the SM lesion-induced fall in GABA uptake is proportional to the loss of glutamic acid decarboxylase, a GABA-synthesizing enzyme, observed in the LHb (Gottesfeld et al., Brain Res., 1977, in press). This provides further evidence for possible GABAergic afferents via the SM to the LHb.

1294 GABA MEASUREMENT IN HUMAN CEREBROSPINAL FLUID: BASIC CONSIDERATIONS. M.H. Grossman*, T.A. Hare, W.W. Tourtellotte*, J.L. Alderman, L. Katz* and N.V.B. Manyam*. Thomas Jefferson University, Philadelphia, PA, V.A. Wadsworth Hospital, Los Angeles, CA and V.A. Hospital, Wilmington, DE

Parameters relevant to the clinical significance of cerebrospinal fluid (CSF) GABA measurements were studied. GABA was measured using the ion-exchange/fluorometric procedure (Glaeser and Hare, Biochem. Med. 12, 274-282, 1975).

The stability of GABA in CSF under various conditions of collection and storage was studied using lumbar specimens which were drawn and then, as quickly as possible, mixed and divided into equal aliquots. One of these aliquots was immediately frozen in dry ice and subsequently stored at -70°C. A second aliquot was also immediately frozen in dry ice but then maintained in storage at -20°C. A third aliquot was allowed to stand at room temperature for 10 min, then frozen in dry ice and stored at -70°C, and a fourth aliquot was allowed to stand at room temperature for 120 min then frozen in dry ice and stored at -70°C. The specimens were stored for 16 months before analysis. The GABA levels determined for the second, third and fourth aliquots were divided by that determined for the first aliquot to provide a ratio indicative of the change of GABA level. The data indicated that storage at -20°C was nearly equivalent to storage at -70°C (ratio = 1.12). Maintaining the samples at room temperature for 10 min did not significantly influence the GABA level (ratio = 1.01); whereas, maintaining the samples at room temperature for 120 min resulted in an increase of GABA concentration (ratio = 1.97).

GABA was also measured in lumbar CSF from 5 normal pressure hydrocephalus patients which gave a mean (± SD) value of 124±56 picomoles/ml, and in ventricular CSF from two other normal pressure hydrocephalus patients which gave values of 301 and 250 picomoles/ml.

In addition, aliquots of lumbar CSF specimens from 12 neurologically normal individuals were obtained and analyzed for their GABA content. The mean volume drawn was 19±4 ml. The mean age of the subjects was 24±3 yrs. The mean GABA level was 515±160(SD) picomoles/ml.

1295 HYPERPOLARIZING RESPONSES TO HISTAMINE (HA) IN APLYSIA NEURONS: IONIC MECHANISM AND PHARMACOLOGY OF THE HA RECEPTORS.
D.L. Gruol* and D. Weinreich* (SPON: N. Brookes). Univ. Md. Sch. Med., Dept. Pharm., Baltimore, MD. 21201.

In the cerebral ganglia of the marine mollusk, Aplysia californica, an identifiable group of neurons are sensitive to iontophoretically applied HA, a putative neurotransmitter in the vertebrate and invertebrate CNS. We have utilized electrophysiological techniques to study the ionic mechanism of the HA responses and the pharmacology of the HA receptors in these neurons. When HA was applied iontophoretically to the soma or axon hillock region of the HA sensitive neurons the most common response was a slow hyperpolarization (10-20 sec) mediated by an increased K^+ conductance. Less frequently the response was biphasic and consisted of a fast hyperpolarization ($\sim$ 2 sec), mediated by an increased Cl^- conductance, superimposed on a slow hyperpolarization identical to that described above. The slow hyperpolarization was mimicked by several HA analogues, the most potent being the H_1-agonist 2-MeHA and the H_2-agonist 4-MeHA. None of the 15 HA analogues or metabolites tested mimicked the HA fast response. The HA sensitive neurons also showed K^+ and Cl^- conductance increases to iontophoretically applied ACh. The ACh responses and anticholinergic drugs were used to evaluate the selectivity of the HA receptor antagonists. The slow HA response elicited by HA or HA agonists could be completely, selectively and reversibly blocked by bath application of the H_2-antagonist cimetidine. The other H_2-antagonists, burimamide and metiamide, gave variable results and were often non-selective. The H_1-antagonists were either ineffective (diphenylpyraline, chloropheniramine) or partially blocked (pyrilamine) the response in a non-selective manner. The fast HA response was not blocked by any of the H_1- or H_2-antagonists tested, but was completely suppressed by curare or strychnine, drugs which are thought to act on the Cl^- iontophore. These results suggest that two pharmacologically distinct receptors mediate the K^+ and Cl^- HA responses in Aplysia neurons. Neither type of receptor could be classified as H_1 or H_2 according to the criteria presently used in other systems. The selectivity and reversibility of cimetidine indicate that this antagonist should be a valuable pharmacological tool for defining putative histaminergic synapses in Aplysia and other nervous systems.

1296 INCREASE IN RAT CAUDATE NUCLEUS CHOLINE ACETYLTRANSFERASE ACTIVITY FOLLOWING CHOLINE ADMINISTRATION VIA STOMACH TUBE.
M. J. Hirsch and R. J. Wurtman. Lab. Neuroendocrine Reg., MIT, Cambridge, MA 02139.

Choline chloride (ChCl) administration, by injection (Life Sci. 16:1095, 1975), stomach tube (Neurosci. Abstr. 2:765, 1976), or via the diet (Science 191:561, 1976), elevates blood choline, brain choline, and brain acetylcholine (ACh) concentrations in the rat. Prolonged increases in both brain compounds, lasting at least 8 hours, are observed when choline is administered by stomach tube. We have utilized this technique for elevating brain ACh levels to determine whether such elevations are associated with feedback changes in the activity of choline acetyltransferase (CAT), the enzyme that catalyzes the synthesis of ACh from choline and acetyl coenzyme A.

Among normal, unfasted, 200-g rats intubated with 2.8 g/kg ChCl and killed by decapitation 8, 24, or 48 hours later, CAT activity was significantly elevated 8 hours after ChCl, and remained elevated after 24 hours. Both choline and ACh levels were elevated 8 hours after ChCl, but did not differ from control levels 24 hours later. No changes in CAT activity, choline, or ACh content were observed 48 hours after ChCl.

Hours after ChCl	CAT activity (nmols ACh formed per hr/mg tissue)		Choline % of control	ACh % of control
	Control	ChCl-treated		
8	5.11 ± 0.35	6.37 ± 0.46*	329†	136‡
24	7.35 ± 0.57	8.77 ± 0.62†	108	88
48	9.19 ± 0.73	9.29 ± 0.77	108	95

*P < 0.02, †P < 0.001, ‡P < 0.05, compared with control.

These data indicate the lack of negative feedback control of CAT activity in vivo when ACh levels are increased; no reduction in CAT activity is observed either after brief periods (e.g., as could be caused by allosteric changes or by end product inhibition) or after times that might be compatible with depressed enzyme synthesis. Moreover, CAT activity increases significantly after choline, suggesting that positive feedback mechanisms (perhaps related to excitatory collateral cross-innervation) may operate.

1297 A MAPPING OF THE DISTRIBUTION OF ACETYLCHOLINE, CHOLINE ACETYLTRANSFERASE, AND ACETYLCHOLINESTERASE IN DISCRETE AREAS OF THE RAT FOREBRAIN.
Donald B. Hoover*, Eric A. Muth* and David M. Jacobowitz (SPON: J. Tallman). Lab. Clin. Sci., NIMH, Bethesda MD 20014; and Dept. Pharmacology, George Washington Univ. Med. Cent., Washington, D.C. 20006.

Previous biochemical studies of the distribution of cholinergic markers in rat brain have generally dealt only with acetylcholine (ACh) and choline acetyltransferase (CAT). Because of the wealth of histochemical information available about the location of acetylcholinesterase (AChE)-containing neurons, we have also included this enzyme in the present mapping of cholinergic parameters in the rat forebrain. Male Sprague-Dawley rats were killed by 2.5-3.0 seconds of microwave irradiation of the head region prior to ACh determinations and by decapitation for enzyme assays. Coronal sections (300 µm) of microwave-fixed brains were cut in a vibratome using an inert fluorocarbon bath to prevent diffusion. Brains from decapitated rats were sectioned in a cryostat. Regions were dissected by a micropunch procedure and assayed for ACh, CAT, and AChE by sensitive radiometric methods. ACh, CAT, and AChE were distributed throughout the rat forebrain. Approximately a 5-fold difference was found in ACh levels between the regions with the highest and those with the lowest concentrations (see table below). The ranges for CAT and AChE were larger. ACh was found in a number of forebrain regions not previously examined. Many areas had ACh levels higher than those found in the hippocampus, a region with a well defined cholinergic input. We feel that this emphasizes the probable importance of ACh in a number of forebrain functions. A good correlation was usually found between the distribution of CAT and AChE. This information may be of value in interpreting AChE-histochemistry. The cholinergic enzymes showed less correlation with ACh levels. Such biochemical measurements should prove valuable in experimental manipulations designed to localize cholinergic pathways and in the study of drug effects of ACh concentration in discrete regions of the brain.

1298 RELEASE OF ENDOGENOUS NOREPINEPHRINE AND DOPAMINE FROM RAT BRAIN REGIONS IN VITRO.
G. Jean Kant and James L. Meyerhoff, Division of Neuropsychiatry, Dept. Med. Neurosciences, Walter Reed Army Inst. of Research, Washington, D.C. 20012

Using sensitive radioenzymatic assay procedures, it is now possible to measure the picomolar amounts of endogenous norepinephrine (NE) and dopamine (DA) released in vitro. We have previously measured the release of NE in vitro from hypothalamus, a region with a high NE concentration, in response to depolarizing concentrations of KCl, (Kant and Meyerhoff, Life Sciences, 20 (1977) 149-154). We also reported that DA was released from striatum, a region rich in DA, after incubation with KCl or d-amphetamine, (Balcom and Meyerhoff, Neuroscience Abstracts, 2 (1976) 773). We have now extended our investigation to other regions of rat brain that have much lower catecholamine levels. We find detectable release of NE and DA in response to KCl or 10^{-4}M d-amphetamine in many regions of brain.

The release of NE and DA in response to KCl stimulation was examined in 6 regions: cortex, hippocampus, hypothalamus, striatum, combined accumbens-olfactory tubercle, and substantia nigra. Tissue pieces were dissected, weighed, chopped (.3 mm^2), and washed in cold Krebs-bicarbonate buffer. The tissue was then resuspended in 1.5 ml of warm buffer with or without additional KCl (50mM) and incubated for 5 min. at 37°C. Release was terminated by pouring the tissue suspension through a millipore filter. Filtrates were assayed for NE and DA. NE release in response to KCl was detectable in all regions except striatum. Amounts released after KCl (expressed as % control) were cortex (313%), hippocampus (227%), hypothalamus (225%), accumbens-tubercle (278%), s.nigra (155%). KCl stimulated release of DA was detected in 3 regions: striatum (414%), accumbens-tubercle (282%), and hypothalamus (312%). DA was measurable in filtrates from the s. nigra but levels from control and KCl stimulated samples were equal. DA release was not detectable from cortex or hippocampus.

The release of NE and DA after incubation with 10^{-4}M d-amphetamine was measured in 11 regions of rat brain: cortex, hippocampus, hypothalamus, striatum, n.accumbens-olfactory tubercle, s.nigra, septal region, olfactory bulb, cerebellum, brainstem, and midbrain. Tissue pieces were dissected, chopped and washed in Krebs-bicarbonate prior to resuspension in 1.0 ml of warm buffer and incubation for 10 minutes with or without 10^{-4}M d-amphetamine. Release was terminated by centrifugation and the supernatants were assayed for NE and DA. d-Amphetamine stimulated NE outflow compared to control in all regions examined. DA release was markedly increased in most regions especially striatum (287%), hypothalamus (387%) and accumbens-tubercle (670%).

1299 BLOOD HISTAMINE LEVELS IN SCHIZOPHRENICS AND NORMAL CONTROLS. R.-L. Lin* N. Narasimhachari, Carl O. Kinard* and J. M. Davis. Department of Research, Illinois State Psychiatric Institute, Chicago, Illinois 60612.

The rarity of allergic diseases in schizophrenics has probably been attributed to an unusual histamine resistance. An increase of reactivity to intradermal histamine has also been found when schizophrenics improved under ECT. An increased concentration of histamine in the plasma or serum of schizophrenics was reported by earlier investigators. More recently, Pfeiffer et al[1] determined blood histamine by the fluorometric method with OPT and reported that a schizophrenic outpatients population has been found to be 50% histapenic and 20% histadelic. Members of the low histamine group have paranoia and hallucinations, while those of high group have suicidal depression.

A specific radio-enzymatic assay of histamine has been described by Kobayashi and Maudsley[2] and by Taylor and Snyder.[3] We have modified this specific method using partially purified histamine-N-methyltransferase from pork kidney as enzyme source, and high specific activity of S-adenosylmethionine (methyl ^{3}H). This enzyme preparation showed no activity of other methyltransferases such as indolethylamine-N-methyltransferase, catechol-O-methyltransferase, methanol-forming enzyme, etc. which utilize S-adenosylmethionine as methyl donor. We found that dithiothreotol enhanced histamine-N-methyltransferase activity, therefore, this thio-reagent was added to our assay system. Instead of extracting the reaction product with organic solvents, we used charcoal absorption method which has been developed for choline acetyltransferase assay by Wu et al.[4] The assay is linear from 0.5 ng to 10 ng of histamine and 1 ng of histamine gave 6,000 cpm above the assay blank. With this modified radio-enzymatic assay, we have studied the blood histamine levels of schizophrenic patients and normal controls. This study is carried out double blind with patients and normal controls. The data obtained after breaking the code of samples will be presented and the significance discussed.

1300 PHARMACOLOGY OF ^{3}H-GABA BINDING TO HUMAN CEREBELLAR CORTEX. Kenneth G. Lloyd and Syd Dreksler* Clarke Institute of Psychiatry Univ. of Toronto, Toronto, Ont., Canada, M5T 1R8.

The high affinity (K_D= 0.33 μM) sodium-independent binding of ^{3}H-GABA to human cerebellar cortex and its state in pathological conditions (Parkinson's disease and Huntington's chorea) has previously been reported by us and others. In the rat brain, the pharmacology of ^{3}H-GABA binding has been studied by Enna and Snyder (Br.Res. 100,81,1975) and has been proposed to be closely associated with the GABA receptor. We have examined the effects of various drugs on the ^{3}H-GABA binding to membranes prepared from human cerebellar cortex, by methods previously described (Lloyd et al, Br.Res.,In Press). The ID50's for ^{3}H-GABA binding of the active compounds are presented in the Table. These results are strongly supportive for the hypothesis that the ^{3}H-GABA binding in the human cerebellar cortex is to GABA receptors and that the human GABA receptor has a pharmacological profile similar to, but not identical with, that of rat brain. Thus, the relative affinities of the active drugs parallel those seen for the reversal of bicuculline on spinal interneurons (Curtis et al, Br.Res. 32,69,1971) and on the displacement of ^{3}H-GABA binding to membranes from rat brain (Enna and Snyder). The inactivity of β-alanine, DABA, AOAA and dipropylacetate indicate that the ^{3}H-GABA binding observed is not associated with neuronal or glial GABA uptake mechanisms or with the enzyme GABA transaminase. The results indicate that ^{3}H-GABA binding is a valid procedure for examining the state of GABA receptors in pathological conditions and also for the study of drug affinities to GABA receptors.

Table. ID50's for the Displacement of ^{3}H-GABA from Human Cerebellar Membranes.

Active Compounds			
ID50 0.01-0.1 μM	ID50 0.1-1.0 μM	ID50 1.0-10 μM	ID50 10-100 μM
Muscimol	GABA	Imidazole Acetic A.	Bicuculline
		δ-Aminovaleric A.	Strychnine
		β-OH-GABA	d-Tubucurare
		Homocarnosine	

Inactive Compounds (less than 50% displacement at 10^{-3}M)		
β-Alanine	Baclofen	Premarin
Procaine	Dipropylacetate	Glycine
Glutamate	Picrotoxin	Taurine
γ-Hydroxybutyrate	AOAA	Diazepam
Propoxyphene	DABA	Atropine

1301 REGIONAL DISTRIBUTION OF NEUROTRANSMITTER CANDIDATES IN THE CNS OF THE MOTH MANDUCA SEXTA, WITH SPECIAL REFERENCE TO THE VISUAL SYSTEM Gerald D. Maxwell and Jonathan F. Tait* Department of Neurobiology, Harvard Medical School, Boston, Mass. 02115

Using the radiochemical screening procedure of Hildebrand et al. (J. Neurobiol. 2:231-246, 1971) we have assayed several regions of the CNS of Manduca for their ability to synthesize acetylcholine (ACh), γ-aminobutyric acid (GABA), norepinephrine (NE), dopamine (DA), octopamine (OA), 5-hydroxytryptamine (5HT), tyramine (TA), and histamine (HA). Animals were used 2-3 days prior to adult eclosion. Brains, first thoracic, third abdominal, and fourth abdominal ganglia were removed from the animal and incubated separately in 50 μl of modified Grace's insect tissue culture medium containing the appropriate high specific activity tritium-labeled precursor compound at a concentration of 50-100 μM. After incubation the brain was dissected into antennal lobes, optic lobes, protocerebrum minus optic lobes, and subesophageal ganglion. The brain fragments and segmental ganglia were then homogenized in pH 1.9 formate-acetate buffer and the supernatant electrophoresed to separate the precursor and product. All neurotransmitter candidates were synthesized in at least some of the structures, except NE, which was not reliably detected in any of the structures. The absolute amount of neurotransmitter synthesis was greatest in the case of ACh. In particular, the ACh pool was highly labeled in the antennal lobes, which are known to contain high endogenous levels of ACh and choline acetyltransferase from the work of Prescott et al. (Comp. Bioch. Physiol. 56C:77-84, 1977). ACh was also synthesized in the optic lobes where it is probably associated with interneurons. A striking distribution of 5HT synthesis occurred; it was highly labeled in the optic lobes and abdominal ganglia, and negligibly in other brain areas, when synthesis is compared on a per gram protein basis. Further work has shown that 5HT synthesis is about five times greater in a fragment containing the lamina (first synaptic neuropil) and part of the retina containing photoreceptor cell bodies, than in a more proximal fragment containing the higher order synaptic neuropils. When the distribution of other neurotransmitter candidates found in the visual system was examined in this manner it was found that the distribution of synthesis of ACh, GABA, and HA was nearly equal in the proximal and distal fragments of the visual system. Experiments involving the incubation of fragments of retinal tissue indicate that substantial amounts of HA and GABA may be made in the retina. (Supported by NIH grant NS-11010 to Dr. John G. Hildebrand and postdoctoral fellowships from NIH and the Muscular Dystrophy Association to GDM).

1302 GLYCINE UPTAKE BY THE APLYSIA PARIETO-VISCERAL GANGLION NEURONS R3-R14. D.J. McAdoo, T.M. Iliffe*, C.H. Price and R.A. Novak*. Mar. Biomed. Inst. and Dept. HBC&G, Univ. of Texas Med. Branch, Galveston, TX 77550.

Endogenous glycine concentrations in R3-R14 are 5-20 times higher than in other Aplysia neurons[1], and R3-R14 were more intensely labeled than their neighbors in autoradiograms of sections of ganglia incubated in ^{3}H-glycine-containing sea water. Therefore, glycine uptake by R3-R14 and other identified Aplysia abdominal ganglion neurons was characterized by analyses performed on individual cell bodies dissected from ganglia incubated in artificial sea water containing labeled glycine. Glycine was taken up by R3-R14 twice as rapidly as by other Aplysia neurons, while alanine, serine and leucine were each taken up at the same rate by R3-R14 as by other Aplysia neurons. Less than 5% of the glycine taken up by R3-R14 and most other Aplysia neurons was incorporated into protein after a 1 hr incubation, though nearly half of the radioactivity in the neurosecretory bag cells was macromolecular. Some glycine was transformed into serine in all examined neurons, with the reverse reaction occurring to a lesser degree. The uptake of glycine into neurons other than R3-R14 was not greatly affected by the absence of Na^+ or the presence of Hg^{++}, while these conditions caused glycine uptake by R3-R14 to become indistinct from that of the other neurons. We therefore conclude that there is a general glycine uptake system common to all Aplysia neurons, and an additional specific one associated with R3-R14. Dinitrophenol and ouabain had little effect on glycine uptake by R3-R14 after 5 min, indicating that though glycine uptake by R3-R14 is driven by the Na^+ gradient across the cell membranes, it is not directly coupled to the activity of Na^+/K^+ ATPase. Glycine uptake by both uptake systems became saturated at about a 1 mM external glycine concentration, so both uptake systems are carrier mediated. The glycine-specific uptake system associated with R3-R14, together with the high endogenous glycine concentrations in those neurons, indicates that glycine must have a specific function in R3-R14, possibly that of a neurotransmitter.

Supported by DHEW grant 1 RO1 NS 12567.

1303 ADENOSINE-DOPAMINE INTERACTIONS IN CAUDATE SYNAPTOSOMES. Mary Michaelis, Sharie Myers*, David Goering*, and Elias Michaelis. Dept. Human Development, U. of Kansas, Lawrence, KS. 66045

The purine nucleoside adenosine (Ado) is now believed by many investigators to be a significant modulator of neuronal activity in the CNS as well as in the periphery. Adenosine's effects on c-AMP generating systems has been studied extensively as has its physiological activity in cortical neurons. This nucleoside has also been demonstrated to be transported in both retrograde and anterograde directions and to be released upon electrical stimulation. However, the exact nature of the role(s) that Ado plays in modulation of neuronal processes has yet to be fully characterized. As an approximation to further characterization of this nucleoside's influence, we have examined two possible sites of interaction between Ado and dopamine (DA) in a crude synaptosomal preparation from the rat caudate nucleus. In addition, we have examined the ability of Ado to stimulate the adenylate cyclase activity of a broken cell preparation from the rat striatum.

One of the most frequently observed actions of Ado and its analogs is an inhibition of release of neurotransmitters. Consequently, the effects of 2-chloroadenosine (2-Cl-Ado), a less readily metabolized analog of Ado, on KCl-stimulated release of DA from caudate synaptosomes have been studied by means of Millipore filtration. Synaptosomes were pre-loaded with ^{3}H-DA and release of ^{3}H-metabolites was determined after 30 sec incubation of 37° in the presence of 15mM KCl. The addition of 2-Cl-Ado (.066-6.6μM) showed a dose related inhibition of release of ^{3}H-DA and its metabolites with a maximum of 25% inhibition. This effect was greatly reduced when 50μM caffeine, an Ado antagonist, was present in the medium. In addition, synaptosomes preincubated with adenosine deaminase for 60 sec prior to addition of KCl showed an enhanced release of ^{3}H-compounds (25-30%), suggesting that more rapid termination of the activity of endogenous Ado allows for greater release of DA.

It has been proposed that Ado formation in brain proceeds from ATP through a Ca^{++}-dependent ATPase, an adenylate kinase, and finally a 5'-nucleotidase. In both spectrophotometric and radioassay methods we have found this synthetic pathway for Ado in striatal synaptosomes to be partially inhibited (15-35%) by DA in the concentration range of 0.25-5μM. These observations, in addition to our demonstration that 2-Cl-Ado and Ado itself in micromolar concentrations are potent stimulators of striatal adenylate cyclase (300-600% stimulation), suggest that Ado and DA may participate in some reciprocal interactions which could serve to modulate the final output from some striatal neurons. (Supported by DHEW Service Award HD07066 and by grant AA01911)

1304 LEVELS OF NOREPINEPHRINE IN PLASMA OF SYNCOPAL SUBJECTS. E.J. Mikkelsen*, C.R. Lake, M.G. Ziegler*#, G.L. Brown*, M.H. Ebert*. NIMH, Bethesda, MD 20014. #Univ. of Texas Med. Br., Galveston,TX

The sympathetic nervous system (SNS) is responsible for the maintenance of blood pressure upon assuming upright posture. Norepinephrine (NE) is the primary neurotransmitter of the SNS and is normally released upon standing, thus increasing peripheral resistance and maintaining blood pressure and cerebral perfusion. There are multiple physiological and psychic factors which predispose to fainting in individuals without a specific SNS defect.

In a normal population of healthy volunteers about 12% became faint with symptoms of yawning, nausea, pallor, and sweating when blood was drawn with the subjects in a standing position. Only about 4% lost consciousness. The mean (±SEM) age of the syncopal subjects was 22±2 years which was significantly ($p<0.001$) less than that of controls (36±2) who did not feel faint. Basal (resting, supine) levels of NE in 25 subjects (17 males and 8 females) who subsequently became faint after standing was 350±33pg/ml which was greater than that (281±17) of 64 control subjects of the same mean age. Basal pulse rate (P) in the fainters was also significantly higher ($p<0.005$) than in the controls (85±3 vs. 74±1 respectively). Basal blood pressures (BP) in the fainters and controls were $\frac{116\pm2}{73\pm3}$ and $\frac{112\pm2}{69\pm1}$ respectively. Blood was drawn from 12 subjects during a syncopal attack but before the subjects either sat down or lost consciousness. P was significantly elevated in these 12 dizzy standing subjects when compared to 51 comfortably standing subjects but their levels of NE (564±91) were not significantly greater than the control's value of 517±31. Concomitantly, BP was lower in the standing syncopal subjects ($\frac{93\pm4}{69\pm4}$) than in the controls ($\frac{109\pm2}{75\pm1}$).

A possible explanation for the syncope upon standing is a diminished release of NE from sympathetic nerve endings. The % increase of NE in the fainters after standing at least 5 minutes was 42±9% which is lower ($p<0.001$) than the % increase in the controls of 88±8%. P ($p<0.01$) and diastolic BP ($p<0.025$) increased more after standing in the controls (26±3% and 12±3%) than in the syncopal subjects (12±5% and 0.6±4%). Systeolic BP fell more ($p<0.02$) in the fainters (20±3%) vs. 0.7±2% in the controls after standing.

Bradycardia secondary to vagal discharge (vaso-vagal syncope) is well known. Of our 12 subjects that we measured P and NE while standing and symptomatic, 3 had pulse rates of 80 beats/min. or less, the other 9 had P over 100; NE levels were low in only one of these patients. Thus vagal discharge may have occured in 25% of our syncopal subjects and plasma levels of NE were not related to the vagal discharge.

1305 EFFECT OF DEPOLARIZING AGENTS ON THE PERCENT SATURATION OF GLUTAMATE DECARBOXYLASE (GAD) WITH PYRIDOXAL-5'-PHOSPHATE (PLP) IN RAT SUBSTANTIA NIGRA SYNAPTOSOMES. L.P.Miller*& J.R.Walters. NIH, NINCDS, Bethesda, MD. 20014.

Recent observations have shown that GAD from rat whole brain is only 35% saturated with cofactor, PLP, in vivo (Nature 266: 847, 1977). These studies also indicated the importance of using appropriate preparative procedures for investigation of the in vivo interaction of GAD with cofactor, since cofactor-mediated activation of the enzyme occurs in situ following decapitation and in vitro during homogenization. It was proposed that the low level of saturation of GAD by PLP reflects a dynamic balance between the rate of dissociation of the cofactor from the enzyme, caused by glutamate, and the rate of association of the cofactor with the apoenzyme, which is inhibited strongly by the nucleotides, ATP and ADP.

To confirm these observations and to investigate the possibility that conditions thought to increase transmitter release and turnover might be associated with alterations in the amount of GAD associated with PLP, synaptosomes were prepared from rat substantia nigra punches and incubated in Krebs-Ringer buffer. After varying periods of incubation, aliquots of the synaptosomal suspension were taken for determination of the degree saturation of GAD by cofactor. The synaptosomes were homogenized in imidazole buffer containing Triton X-100(0.5%) and ATP(5mM),included to prevent activation of the enzyme by endogenous PLP during homogenization. The homogenate was passed through a Sephadex G-25 column and analyzed for GAD activity in the presence and absence of PLP. The degree saturation of GAD was defined as enzyme activity in the absence of PLP, expressed as a % of the activity obtained in the presence of saturating PLP(50um). GAD from unincubated synaptosomes was 29% saturated with cofactor, confirming previous observations that the saturation of GAD by cofactor in vivo appears to be quite low. After 5 min of incubation at 37°C, the degree saturation decreased to 19% and remained relatively constant for 30 min. In the presence of a depolarizing concentration of K^+ (55mM), the % saturation became greater with time; a 48% increase was observed at 20 min. When veratridine was used as a depolarizing agent, this effect was even greater. The increase in the amount of GAD saturated by PLP was dependent on Ca^{++}. In the absence of Ca^{++}, the % saturation was lower than that observed in the non-K^+-stimulated controls. If conditions existing during synaptosomal depolarization can be considered comparable to those of increased transmitter release in vivo, then these results suggest that in GABA neurons increased neuronal activity may be associated with an increase in the amount of functional, PLP-saturated GAD, which, in turn, could cause a potentiation of the rate of GABA synthesis.

1306 THE RELEASE OF IMMUNOREACTIVE SUBSTANCE P AND SOMATOSTATIN FROM SENSORY NEURONS IN DISSOCIATED CELL CULTURES. Anne W. Mudge*, G.D. Fischbach, and S.E. Leeman. Departments of Physiology and Pharmacology, Harvard Medical School, Boston, Mass. 02115

Substance P and somatostatin have been shown by immunological techniques to be present in some dorsal root neurons and in their processes which terminate in the dorsal horn of the spinal cord. Considerable evidence indicates both peptides may be involved in synaptic transmission at this site and other regions of the nervous system. Cell culture provides an opportunity to study these peptides in identified populations of neurons where the neurons are easily accessible to biochemical and electrophysiological manipulations. The interpretation of biochemical data is clearer when neurons are grown in the virtual absence of nonneuronal cells.

Sensory neurons were dissociated from dorsal root ganglia of 9-day chick embryos and grown on collagen in medium containing nerve growth factor. Addition of cytosine arabinoside for three days resulted in cultures essentially free of nonneuronal cells. The surviving neurons (~20%) grew in size and developed a dense network of processes. Immunoassayable substance P increased from 100 fmol at the time of plating to 2500 fmol per dish after two weeks in culture. Immunoassayable somatostatin was approximately 250 fmol per dish at two weeks.

The cultures were incubated in HEPES-buffered balanced salt solutions containing either (a) Na^+,113mM; K^+,5.9mM; Ca^{++},1.8mM; Mg^{++}, 0.8mM or (b) Na^+,17mM; K^+119mM; Ca^{++}, 1.8mM; Mg^{++}0.8mM. During five minutes in control solution (a) the neurons released 0.35% of their substance P content; the release of somatostation was undetectable (<1.5%). When incubated for five minutes in depolarising concentrations of K^+ (b), the neurons released 4.3± 0.4% (mean ± SEM of 9 observations) of their substance P and 6.9 ±0.4% (5 observations) of their somatostatin. Repeated exposure to high K^+ solutions resulted in release of similar amounts of both peptides. There was no difference in the release of 2-^{14}C-deoxyglucose, a cytoplasmic marker, after incubation in either solution. The K^+-evoked release could be reversibly blocked by 5mM Co^{++}, a competitive inhibitor of Ca^{++} fluxes. Thus primary sensory neurons in vitro can make both substance P and somatostatin and release them in a voltage - and Ca^{++}-dependent manner.

1307 ACTIVATION OF SYNAPTOSOMAL TRANSPORT SYSTEMS BY DEPOLARIZATION. L. Charles Murrin*, Mary S. Lewis*, Nikolai Klemm* and Michael J. Kuhar, Dept. Pharmacol & Exp. Ther., Johns Hopkins Univ. Sch. Med., Baltimore, Md. 21205.

The synaptosomal high affinity transport of choline has been shown, by in vivo and in vitro experiments, to be coupled to neuronal activity; i.e., uptake is increased by increased neuronal activity in vivo and by depolarization of synaptosomes in vitro. In this study we report the effects of high potassium depolarization on synaptosomal transport of a number of compounds including adenine, adenosine, alanine, arginine, aspartic acid, choline, glutamic acid, GABA, glycine, leucine, octopamine, ornithine, phenylalanine, proline, serine, serotonin, taurine, tryptophan and tyrosine. A crude mitochondrial preparation (P_2) from rat cerebral cortex was preincubated in either normal Krebs Ringer phosphate (KRP) or 65mM K^+-KRP at 37° for 10 min. This synaptosomal preparation was centrifuged, the pellets resuspended in sucrose and used in uptake experiments (Molec. Pharmacol. 12:1082). Uptakes were carried out in KRP for 4 min. at 37° with 4° blanks. All compounds were used at a concentration of 1 μM. Depolarization increased the synaptosomal transport of several compounds which are known or suspected neurotransmitters or neurotransmitter precursors, including choline, glutamic acid, aspartic acid, glycine and phenylalanine. This was not a universal property of neurotransmitter precursors since the transport of tyrosine and tryptophan did not increase after depolarization. Similarly, the transport of many other compounds was not increased by depolarization. These include serine, taurine, proline, leucine, alanine, adenine, adenosine, arginine, ornithine, GABA and serotonin. The depolarization-induced increases in transport were found, by sucrose density centrifugation, to be associated with the synaptosomal fraction and were found to be eliminated by hypo-osmotic shock. They were also found to be dependent on membrane potential. Finally, kinetic analyses of these transport alterations were carried out.

In conclusion, it appears that depolarization of synaptosomes, which mimics increased neuronal activity, produces an increase in transport of several compounds. These in vitro data lead us to propose that certain transport systems in nerve terminals are coupled to neuronal activity, presumably for regulating neurotransmitter stores or other metabolic functions. Supported by MH 25951.

1308 AMPHIBIAN OPTIC NERVE TRANSMITTER: ACh, YES; GABA AND GLUTAMATE, NO. Robert E. Oswald* and John A. Freeman. Vanderbilt University, Nashville, TN 37232.

The amphibian retinotectal system provides a useful model for the study of molecular events associated with synaptogenesis in the central nervous system. Previous studies using labeled snake α-neurotoxins have indicated (Freeman, Nature 1977, in press) that the maintenance of retinotectal synapses in the toad B. marinus is associated with the functional integrity of the tectal nicotinic cholinergic receptor protein. The present study was undertaken to establish the identity of optic nerve neurotransmitters in this animal. Synaptosomal fractions from whole tectal homogenates were screened for high affinity uptake systems for several different possible transmitters. A saturable Na^+-dependent high affinity uptake system was present for choline ($Km=2.3x10^{-6}$ M), and also for GABA and glutamate. Significant levels of choline acetyltransferase were found in both tectum and optic nerve (192 pM and 15 pM ACh synthesized/mg protein/minute, respectively). A high tectal ACh level (61±3 nmoles/gm tissue) was also found, using pyrolysis gas chromatography-mass spectrometry on microwave inactivated tissue. Tectal synaptosomes bound α-bungarotoxin (Kd=10.78 nM); saturation of the specific toxin binding component occurred at 4.2 pmoles toxin/gm tissue. No decline in the high affinity uptake for either choline or glutamate occurred within 60 days following enucleation, although there was a significant fall in the levels of both choline acetyltransferase and ACh. The interpretation of these results should take into account the effects of any gliosis or sprouting of non-retinal terminals that might occur after enucleation. We therefore developed a technique for isolating a pure population of optic nerve terminal synaptosomes by applying the electron-dense dye Procion brown to the optic nerve. As shown by EM, the dye was subsequently transported to the terminals; these were then separated from unlabeled terminals by differential sucrose-gradient centrifugation. Optic nerve terminal synaptosomes isolated in this way possessed a high affinity uptake system for choline, but not for GABA or glutamate, and also bound α-bungarotoxin. We conclude that ACh is an optic nerve transmitter in the toad, and that ACh, GABA, and glutamate may be transmitters at other non-retinal synapses.

1309 EFFECTS OF SOMATOSTATIN ON FROG SPINAL CORD. Ante L. Padjen. Dept. Pharmacology & Therapeutics, McGill University, Montreal, Quebec H3G 1Y6

Immunohistochemical technique indicates the presence of somatostatin-like reactivity in some primary afferent neurons in mammals (Hokfelt et al., 1976, Neurosci. 1: 131). In the present study effects of somatostatin and analogs were examined in a superfused isolated hemisected frog spinal cord preparation at 15°C. Synaptic and drug evoked root potentials were recorded using sucrose gap technique on spinal roots (cf Barker et al., 1975, J. Physiol. 245: 537). Somatostatin in conc. above 10^{-6}M caused a dose dependent increase in the ventral root (VR) potential obtained by dorsal root (DR) stimulation (DR-VRP) with a several fold increase in amplitude and duration at conc. of 10^{-5}M. This increase appeared after a latency of 15-30 min and outlasted the application by 30-60 min. It did not show any desensitization. At the same time DR potentials were either slightly augmented (DR evoked DRP) or unchanged (VR evoked DRP). Trasylol (0.5 KIU/ml), a proteinase inhibitor, seemed to lower the threshold for somatostatin action. Similar effects were observed with endocrinologically active des-carboxy des-amino analog of somatostatin but not with inactive retro-somatostatin. In the presence of high Mg/low Ca Ringer or tetrodotoxin ($5x10^{-6}$M), somatostatin in the same conc. range produced a small and variable but immediate hyperpolarization (< 1 mV) of VR and DR. This direct action of somatostatin was accompanied by a selective depression of glutamate evoked responses (more than 50% at $5x10^{-6}$M somatostatin), but not of GABA evoked responses, of both VR and DR. The hyperpolarization and depression showed desensitization which was often complete in 20 min. Effects on responses to substance P were variable, presumably because of its prolonged action and the relatively fast desensitization to somatostatin.

These results are consistent with the possibility that somatostatin acts on both pre- and postsynaptic sites in the spinal cord as a neuromodulator.

1310 BARBITURATES, ANTI-CONVULSANTS AND γ-AMINOBUTYRATE RECEPTIVE SITES FROM THE MAMMALIAN CENTRAL NERVOUS SYSTEM. E. J. Peck, Jr. and B. R. Lester*, Cell Biology, Baylor College of Medicine, Houston, TX 77030.

Synaptic plasma membranes and junctional complexes derived from bovine cerebral cortex were employed to study the interaction of barbiturate and anticonvulsants with γ-aminobutyrate (GABA) receptive sites. These binding or receptive sites included Na^+-dependent, low affinity ($K_d \sim 10^{-6}$M) sites identified as neuronal transport sites and Na^+-independent, high affinity ($K_d \sim 10^{-7}$M) sites considered to be postsynaptic receptors for GABA. Using ^{3}H-GABA binding and the membrane derived sites above we have previously shown that pentobarbital does not interact directly at either GABA binding site except perhaps at extremely high (10^{-2}M) levels (Brain Res. Bull, 1:595, 1976); however, Ransom and Barker (Brain Res. 114:530, 1976) have demonstrated that pentobarbital potentiated GABA responses in cultured spinal cord neurons. Since these effects might involve pre- or postsynaptic binding or release sites for GABA, we have examined the effects of a wide variety of GABA analogs, barbiturates, convulsants and anti convulsants for their effect on synaptosomal transport and membrane binding of GABA. Pentobarbital, phenobarbital and diphenylhydantoin had no effect on GABA receptive systems. Bicuculline competitively blocks sodium independent (-Na) system while affecting the transport (+Na) site at much higher concentrations. Diaminobutyrate and and nipecotic acid affect only the transport (+Na) site. β-alanine inhibits the -Na system only. The convulsant picrotoxin had no apparent effect on either +Na or -Na systems, however, the convulsant pentylenetetrazole inhibited to 50% both +Na and -Na systems at 100mM. Its physiologically effective range was 10 to 20mM.

From studies such as these of equilibrium binding and synaptosomal transport and release of GABA we hope that the mechanism of action of pharmacologic and therapeutic agents can be explained or a molecular basis at the synaptic level. (Supported by a grant from the NIH, HD08389, and a Research Career Development Award to E. J. Peck, Jr.).

1311 EFFECTS OF BRAIN TRAUMA ON CATECHOLAMINES AND THEIR METABOLITES. E.W. Pelton, II, L.R. Nelson, and R.S. Bourke. Dept. Neurol./ Div. Neurosurg. Neil Hellman Medical Research Building, Alb. Med. Coll. Albany, N.Y. 12208.

Trauma to the central nervous system may cause both immediate damage and delayed hypoxia, edema, and necrosis. These events may involve vasospasm of the microcirculation and result from active or passive release of vasoactive monoamines from "leaky", ischemic, or injured neurons, or from failure of oxygen-requiring metabolism or energy-dependent reuptake. We have investigated effects of brain trauma on levels of catecholamines (CA) and their metabolites; physiologic requirements for changes observed; and the use of a proper reference as edema and hemorrhage affect wet weight and protein. Regional assay of norepinephrine (NE) and dopamine (DA) in experimental animals (rats and cats) was fluorometric. CA metabolites (HVA, DOPAC, and MHPG) were assayed by gas-chromatography using electron capture.

Trauma to cat brains was produced by shaking, resulting in predictable, sustained coma comparable to human disease (Nelson, L. R., Bourke, R.S., J. Neurosurg., submitted). All animals were anesthetized. Test animals were shaken with subsequent controlled hypoxia. Controls received no insult, were made hypoxic only, or were shaken without hypoxia. In some brain regions, NE was significantly diminished following both trauma and hypoxia. DA was diminished in some regions following trauma but not after hypoxia only. HVA and DOPAC levels were decreased in brainstem in hypoxic animals, particularly with trauma, but increased in cerebral hemispheres. The sediment from homogenized brain was assayed for DNA after lipid extraction and dessication by reaction with diaminobenzoic acid dihydrochloride and fluorometry. Using anesthetized rats, following trauma by weight drop to the intact skull (2800 dyne-CM) brains were immediately removed, weighed, sealed in plastic bags, and incubated at 37°C for 15 or 60 minutes. No difference in NE or DA concentrations was noted between test and control animals. However, in rats with brain left in place for 15 or 60 minutes prior to decapitation, NE concentration was diminished by 25% at 60 minutes in traumatized rats only; DA was unchanged.

Our findings suggest that 1) an intact cardiovascular system is necessary for NE to fall following trauma; 2) DNA is a practical, useful and appropriate reference point for expressing levels of catecholamines and their metabolites which obviates problems using wet weight and protein; and 3) hypoxia and/or trauma appear to have effects in some regions of brain on oxygen-requiring metabolism of CAs, or energy-dependent uptake into presynaptic terminals.

(Supported by NIH Grant NS-13042).

1312 AUTORADIOGRAPHIC STUDY OF THE SPECIFIC UPTAKE AND TRANSPORT OF GLYCINE IN IDENTIFIED APLYSIA NEURONS. Christopher H. Price, R.E. Coggeshall, and D.J. McAdoo. Mar. Biomed. Inst. and Depts. of Anatomy and HBC&G, Univ. Tex. Med. Branch, Galveston, TX 7550.

The identified neurons R3-R14 in the parieto-visceral ganglion (PVG) of Aplysia have high endogenous glycine concentrations (Iliffe et al., 1977, J. Neurochem., in press). Previous studies on R3-R14 did not demonstrate measureable quantities of established neurotransmitters; thus, glycine may fulfill this role in R3-R14. We have used standard light and electron microscope autoradiography (AR) techniques to study the uptake and fate of glycine and other amino acids in these cells. After incubation for 1 h in seawater with 8.8 µm ^{3}H-glycine and fixation in glutaraldehyde, R3-R14 contain a mean of 153 developed silver grains/ 100 µm^2 cytoplasmic area. Neighboring neurons contain only 43 grains/100 µm^2. This fourfold difference is eliminated when ^{3}H-glycine incubations were done in Na^+-free seawater or 0.1 mM $HgCl_2$, suggesting that there is an energy-dependent uptake system for glycine operating in R3-R14. Furthermore, glycine uptake is selective because alanine, serine, and leucine were taken up equally by R3-R14 and neighboring cells. R3-R14 differ from the neurosecretory bag cells of the PVG which concentrate significant quantities of all amino acids, including glycine. Radiochromatographic analyses on bag cells indicated that a large proportion of radioactivity taken up was incorporated into protein. In light microscope autoradiograms, silver grains were clustered in discrete areas the cytoplasm of the bag cells in both glutaraldehyde and formaldehyde fixed tissue. Electron microscope AR revealed high grain densities over Golgi complexes, suggesting the packaging of labeled protein into granules. By contrast, grains in R3-R14 from ^{3}H-glycine incubations were evenly distributed. Fixation with formaldehyde greatly reduced grain counts in R3-R14 (59 grains/ 100µm^2). Because formaldehyde fixes free amino acids poorly, it seems likely that most of the R3-R14 glycine is not incorporated into protein. This was confirmed by radiochromatograms of individual R3-R14 cell bodies -- less than 10% of radioactivity was associated with protein. The axons of R3-R14 travel down the branchial nerve. By incubating the PVG for periods up to 7 h and isolating the branchial nerve with a vaseline seal, we found that glycine is transported down the R3-R14 axons in large quantities at a rate of several mm/h. None of the other amino acids were so transported. We are currently determining the rate of transport. The amount of glycine transported is sufficient to allow us to trace the axons of R3-R14 to their terminals. Work supported by USPHS grants NS 12567, NS 11255, and NS 10161.

1313 ONTOGENESIS OF CALCIUM-DEPENDENT GABA RELEASE IN RAT BRAIN. Dianna A. Redburn, Diane S. Broome* and S.J. Enna, Dept. Neurobiol. and Anat., Pharmacology, U. Tex. Med. Sch., Houston, Tx. 77025.

As previously reported (Coyle, J. and Enna, S., Br. Res. 111:119, 1976), the development of the GABA uptake system differs markedly from the linear increase of other presynaptic markers such as GABA levels or glutamic acid decarboxylase activity. The activity of GABA uptake is near adult levels at birth, increases considerably above that of the adult between one and two weeks after birth, then declines toward adult levels. In the present study, the activity of the calcium-dependent GABA release system was found to increase linearly with age from birth to adult. Thus, the increased synaptosomal uptake of GABA observed at 7-8 days after birth is not associated with an increase in the size of the calcium-dependent, potassium-releasable pool. Assaying the amount of GABA released from synaptosomes in the absence of external sodium to inhibit re-uptake of the neurotransmitter, did not alter the results. Electron microscopic analysis of the synaptosomal fractions from 3, 7, 14, 21 day old and adult rats revealed a steady increase in the number of mature synaptosomes present with a concomitant decrease in microsomal contamination. Further analysis of subcellular fractions revealed an even more dramatic peak of GABA uptake activity at 7-8 days in the microsomal fraction than that observed in the synaptosomal fraction. These data suggest that the high level of GABA uptake activity observed in rat brain 7-8 days after birth is not localized to synaptic regions and may serve a function unrelated to synaptic transmission. Supported by USPHS MH-29739, The Huntington Chorea Foundation, PMA Foundation Starter Grant (SJE), and USPHS Grant EYO 1655-02 (DAR).

1314 NEUROTRANSMITTER SYNTHESIS, STORAGE AND RELEASE BY AGGREGATING CULTURES OF RAT CNS. E. Richelson and P. Honegger,* Mayo Fdn., Rochester, MN 55901

Rotation-mediated aggregating culture of mechanically dissociated fetal rat brain (Honegger & Richelson, Brain Res. 109,335-354, 1976) represents a model system for use in neurobiology and psychopharmacology. We have explored the neurochemical potentials of this system and now report further studies with these cultures. For these studies aggregates derived from fetal (15-16d gestation) brain cells and cultured for 4 wks were incubated with certain [^{3}H]precursors; [^{3}H]products were isolated from cells by 2-dimensional thin-layer chromatography. After 1 hr whole brain cultures incubated with [^{3}H]choline (5µM), [^{3}H]L-glutamic acid (GLU)(60µM), or [^{3}H]L-tryptophan (90µM) were found to synthesize per mg protein: 8 pmoles [^{3}H]acetylcholine (ACh), 125 pmoles [^{3}H]γ-aminobutyric (GABA), and 7 pmoles [^{3}H]serotonin (5-HT), respectively. After 4 hrs of incubation with [^{3}H]L-tyrosine (30µM), [^{3}H]dopamine (DA) per mg protein was: 0.7 pmole in whole brain cultures; 0.1 pmole in forebrain (telencephalon); and 8.5 pmole in hindbrain (mesencephalon-diencephalon + rhombencephalon). To determine storage and release of these putative neurotransmitters, whole brain cultures were incubated with [^{3}H]precursors for 4 hrs, washed free of extracellular tritium, and incubated for another 4 hrs in complete growth medium (DMEM, 15% FCS) under the following conditions (Table): no additions (control); veratridine (V) (50µM); tetrodotoxin (TTX) (5µM); V (50µM) + TTX (5µM); or reserpine (R) (4µM).

[^{3}H]PRODUCT	TRITIUM RECOVERED FROM AGGREGATES (% CONTROL)			
ADDITIONS:	V	TTX	V + TTX	R
Acetylcholine	45	125	-	-
GABA	140	80	80	-
Glutamate	60	95	100	-
Serotonin	30	100	-	-
Dopamine	0	220	200	0

The results with veratridine, which selectively increases the permeability of electrically excitable cells to sodium ions, suggest that a large portion of [^{3}H]ACh, [^{3}H]GLU, [^{3}H]5-HT and [^{3}H]DA was stored in a readily releasable form in electrically active cells; while the results with tetrodotoxin, which blocks the action potential, suggest that there was spontaneous electrical activity in cholinergic and dopaminergic cells in these aggregates. The effect of veratridine on GABA was opposite to that on GLU, suggesting that released GLU was utilized to synthesize GABA. Reserpine depletion of [^{3}H]DA suggests that DA was stored by cells in vesicles in these cultures. Finally, these results suggest that this model may be useful for psychopharmacological studies. (Supported by Mayo Fdn. and USPHS Grant DA 1490 and MH 27692).

1315 NET UPTAKE OF L-GLUTAMATE AND GABA BY HIGH AFFINITY SYNAPTOSOMAL TRANSPORT SYSTEMS. Robert Roskoski, Jr. Dept. of Biochemistry, Univ. of Iowa, Iowa City, IA 52242.

Reuptake of neuroactive amino acids by high affinity transport systems in the central nervous system is thought to terminate the neurotransmitter activity of these substances. This notion has been challenged since the homoexchange of synaptosomal and exogenous L-glutamate and the corresponding homoexchange of synaptosomal and exogenous GABA has been demonstrated. We reported that depolarizing media (56 mM KCl, 1 mM $CaCl_2$) lowers the GABA content of synaptosomes. In such synaptosomes, net and apparent (radioactive) GABA uptake are similar (Ryan and Roskoski, J. Pharmacol. Exp. Ther. 200, 285, 1977). We proposed that nerve terminal preparations have a limited storage capacity and when this is approached, influx and efflux occur and homoexchange results. When rat cortical synaptosomes (1 mg protein/ml) are incubated with 10 μM[^{14}C] L-glutamate, net and apparent (radioactive) uptake are similar. When the synaptosome levels are decreased to 0.5 mg protein/ml with a corresponding decrease in capacity, then net uptake becomes a fraction of radioactive uptake (exchange ensues). Furthermore, pre-incubating the synaptosomes with 50 μM L-glutamate increases the synaptosomal content. In these preparations, apparent (radioactive) uptake is less than chemical uptake indicating that exchange is occurring. Net L-glutamate uptake is Na^+-dependent and temperature-dependent. Furthermore, a 1 mM concentration of KCl or RbCl supports net L-glutamate and GABA uptake. LiCl, NH_4Cl, CsCl, and choline chloride are ineffective. L-glutamate and GABA are taken up into osmotically sensitive components. In addition, diaminobutyric acid (but not β-alanine) inhibits net and apparent GABA uptake. This suggests that GABA is taken up into neuronal and not glial elements. The demonstration of net uptake of L-glutamate and GABA by their respective high affinity systems is consonant with the idea that these systems may play a role in neurotransmitter inactivation in the synaptic region (Supported by USPHS Grant NS-11310).

1316 DEVELOPMENT OF CHOLINE ACETYLTRANSFERASE ACTIVITY IN CULTURES OF AUTONOMIC NEURONS--DEPENDENCY ON RAT AGE. C.D. Ross*, M.I. Johnson and R.P. Bunge. Dept. of Anatomy & Neurobiol., Wash. Univ. Med. Sch., St. Louis, Missouri 63110.

Under certain tissue culture conditions adrenergic neurons of rat superior cervical ganglion (SCG) develop several cholinergic characteristics. We here present data indicating that the ability of these cultured neurons to develop choline acetyltransferase (ChAT) activity is dependent upon their age when placed in culture. ChAT activity in SCG explants after 1 mo in culture was highest in explants taken from 2 day old rats (over 60 mmoles/kg. dry wt./hr, 37°) and lowest in explants from adult rats (1 mmole/kg d/hr). The ability of SCG explants to accrue ChAT activity in culture decreased markedly in explants taken from rats greater than 2 days of age; ChAT activities in explants taken from 10, 16 and 42 day old rats were 24, 7, 4 and 2 mmoles/kg d/hr, respectively. Dopa-decarboxylase (DDC) activity in explants after 1 mo in culture did not differ with respect to the age of the rat at explantation. This DDC activity (200-220 mmoles/kg d/hr) in SCG explants *in vitro* is about 70% of the activity in the adult ganglion *in vivo*. All cultures were grown in a medium previously shown to stimulate ChAT activity. The presence of heart muscle, demonstrated to increase ACh synthesis in SCG neurons (Patterson & Chun, 1977) provided an additional 2-fold increase in the specific activities of both ChAT and DDC in SCG explants from neonatal rats; ChAT activity was unchanged in SCG explants from 6 week old rats. These data are strongly supported by morphological studies. With $KMnO_4$ fixation after one month in culture vesicles in axonal varicosities related to explants from 5 day old rats were predominately clear; varicosities in cultures from adult rats contained predominately dense-cored vesicles. These data suggest that a final determination regarding neurotransmitter production is made during a "critical period" relatively late in autonomic neuron development. The SCG neuron expresses its greatest capacity to develop cholinergic mechanisms at about the 2nd postnatal day, coinciding with the time SCG axons begin reaching their target organs. The end of this critical period coincides with the maturation of these adrenergic endings, suggesting that the axonal target may be instrumental in finally determining whether the SCG neurons synthesize norepinephrine or acetylcholine. This period of neurotransmitter plasticity in SCG neurons extends several weeks beyond the time that the last mitotic activity is known to occur in this neuronal population.

1317 ACTIVATION OF CHOLINE ACETYLTRANSFERASE BY CHLORIDE: A POSSIBLE REGULATORY MECHANISM. Jean Rossier and Philippe Benda*. The Salk Inst., La Jolla, CA 92037 and Collège de France, Paris 5, FRANCE.

An extensive study on the effects of salts on the kinetic parameters of rat brain choline acetyltransferase (ChAc) shows that this enzyme is specifically activated by anions, and that among anions, Cl^- is the more effective one. These results are similar to those obtained for ChAc from the human placenta.

The amplitude of the activation of the rat brain ChAc by salt is particularly striking. Table I shows that the maximum velocity (V_{max}) of the enzyme increases 25 times when 145 mM NaCl was added to the 5 mM tris acetate buffer. In using higher ionic concentration, it was possible to obtain an up to 60-fold increase in V_{max}.

Table I shows also that in the absence of Cl^-, at low ionic strength, acetylcholine (Ach) is a good ChAc inhibitor (K_i = 0.310 mM). The Ach inhibition becomes negligible when Cl^- is increased to 145 mM (Ach K_i = 45 mM). The increase of the Ach K_i is six times more profound than the increase in choline K_m (see Table I).

The Ach concentration of the presynaptic terminals was calculated by Dunant et al. to be as high as 27 mM. Such a high Ach concentration will completely inhibit ChAc at low ionic strength, but in the presence of 145 mM NaCl, ChAc inhibition by Ach will become negligible. It may be concluded that an increase in Cl^- concentration will promote an increase in ChAc apparent velocity by two synergistic mechanisms: ChAc will become less susceptible to Ach inhibition and ChAc V_{max} will increase.

Table I. Kinetic Parameters of Crude ChAc

	Tris acetate 5 mM	Tris acetate 5 mM + NaCl 145 mM
V_{max} (Arbitrary Unit)	1.	25.
K_m acetyl CoA (μM)	0.8	3.5
K_m choline (μM)	22.	540.
K_i acetylcholine (μM)	310.	45,000.

1318 STABILITY OF CATECHOLAMINES IN POST MORTEM RAT BRAIN. Isaac F. Roubein and Larry J. Embree, Veterans Administration Hospital and Department of Neurology, Louisiana State University Medical Center, Shreveport, Louisiana 71130.

Evidence in the literature suggests that catecholamines (CA) in the brain play an important role in the pathogenesis of neuropsychiatric disorders. One approach to the study of these diseases involves the biochemical examination of brain tissues obtained at autopsy, but the main difficulty in such studies is the rapidity of post mortem changes in necropsy material. Reports in the literature indicate that while post mortem changes in the levels of CA in brain tissues have been investigated, the results are frequently conflicting.

The purpose of our study was to determine the post mortem levels of CA in discrete regions of rat brain under conditions simulating those under which human neural tissues become available post mortem. Male Sprague-Dawley rats weighing 200-300 gms were sacrificed by cervical dislocation and left at room temperature (20.5-22°C) for periods of 1 and 2 hours. The brains were left in the intact animals in order to simulate the human post mortem situation. At the end of each period, the rat was decapitated and the brain removed and immediately dissected on an ice cooled glass plate into the following regions: cortex, striatum, pons and medulla, midbrain, and cerebellum.

Spectrofluorometric determinations of norepinephrine (NE) and dopamine (DA) in these regions indicated that the decline in NE levels after 2 hours post mortem, followed this pattern: Pons and medulla > midbrain > cortex > cerebellum. In the same post mortem period striatal DA declined to about two-thirds of that in control animals. Further observations will be reported.

1319 KINETIC DATA ON THE INHIBITION OF THE CHOLINE CARRIER BY ACETYLCHOLINE MUSTARD AZIRIDINIUM ION AND ITS CHOLINE ANALOGUE.
B. Jane Rylett* and E. Howard Colhoun* (SPON: Maurice Hirst), Department of Pharmacology, University of Western Ontario, London, Ontario, Canada.

Choline mustard aziridinium ion (ChM Az) produced death in mice and rats causing signs of toxicity similar to those obtained with hemicholinium-3 (HC-3). ChM Az has been shown to inhibit choline transport in erythrocytes (Clement and Colhoun, Can. J. Physiol. Pharmacol. 53, 1089, 1975) and into rat brain synaptosomes (Rylett and Colhoun, Can. Fed. Biol. Soc. 19, 49, 1976; Can. J. Physiol. Pharmacol., in press). The present report deals with the kinetic parameters for the inhibition of choline transport by ChM Az and other Az compounds in rat forebrain synaptosomes. Apparent Michaelis affinity constants and velocities for the sodium-dependent, high-affinity and the sodium-independent, low-affinity choline transport carriers were computed by use of a four parameter non-linear iterative least squares program. This procedure, in conjunction with graphical analysis by the method of Lineweaver and Burk, revealed that ChM Az produced a competitive inhibition of the high-affinity choline carrier, with a Ki of 1×10^{-5}M. The Ki for acetylcholine mustard aziridinium ion (AChM Az), in the presence of eserine sulphate, was about 1×10^{-4}M and showed mixed competitive inhibition. Ethoxycholine mustard aziridinium ion, similar in structure to AChM Az but lacking the ester bond, did not appreciably inhibit choline transport. Evidence was also obtained that ChM Az may produce irreversible inhibition of the high-affinity choline carrier: thus, rat brain synaptosomes incubated in the presence of ChM Az, then washed 1-3 times to remove the inhibitor and resuspended in Krebs-Ringers phosphate buffer showed little reduction of the inhibition of the sodium-dependent, high affinity transport of choline. In contrast, inhibition of choline transport by HC-3 was not persistent, showing reversal when the synaptosomes were washed in a similar manner. The irreversible inhibition of the choline carrier, by ChM Az, in isolated synaptosomes appears to correlate with the results of Clement and Colhoun (Can. J. Physiol. Pharmacol. 53, 264, 1975) who first showed that the HC-3-like effect of ChM Az on the isolated phrenic nerve-rat diaphragm preparation was not abolished by repeated washing. Should ChM Az alkylate the choline carrier then a way may have been found to isolate and study the nature of the transport mechanism from nerve endings.

1320 NICOTINE STIMULATION OF THE SEPTAL AREA AND EFFECTS OF α AND β ADRENOLYTIC AGENTS ON SODIUM, POTASSIUM AND URINE EXCRETION.
Wilson A. Saad, Luiz A.A. Camargo+, José Antunes Rodrigues+ and Miguel R. Covian+. Dept. Physiol.; Sch. Dent.; FFOA - UNESP - Araraquara 14.800 - SP - Brazil.

The central regulation of Na^+, K^+ and urinary volume excretion in terms of the participation of the septal area is effected through the cholinergic system which, upon stimulation, causes increased Na^+ and K^+ excretion and lower urinary volume excretion (Saad et al., 1975). The α pathway in the cathecholaminergic system may have a facilitating effect on the excretion of the two cations and of urinary volume, and the β pathway, when stimulated, may have the opposite effect (Camargo et al., 1976). It was shown that muscarinic and nicotinic receptors may participate in the cholinergic system, and the use of α and β blockers indicates that natriuresis, kaliuresis and diuresis are partially mediated by the release of cathecholamines in the brain (Saad et al., 1976). The following experimental conditions were used in order to determine which of the two cholinergic pathways may be interacting with the adrenergic system: intraseptal administration of NaCl 0,15 M, and administration of nicotine (100 nmol) alone or preceded by the α blockers dibenamine (100 nmol) and regitin (100 nmol), and the β blocker propranolol (100 nmol).

It was observed that the natriuretic effect of nicotine was significantly reduced by the α blockers, with values returning close to control levels established with saline solution, an effect potentiated by previous injection of propranolol. Similar effects were obtained in respect to K^+ excretion, with regitin producing a clearer blocking effect. As to diuresis, the level determined by nicotine was reduced by the α blockers, with regitin causing a greater reduction than dibenamine, and with propranolol potentiating this effect.

The results as a whole seem to indicate that the cholinergic system interacting with the cathecholaminergic system may act on the regulation of Na^+, K^+ and urine excretion through the nicotinic pathway with α and β receptors.

1321 MODIFICATION OF THE CAT GANGLIONIC ACTIVITY AND GABA INDUCED DEPOLARIZATION BY PENTOBARBITAL AND FLURAZEPAM.
W. Schlosser*, S. Franco* and A. Kuehn* (SPON: L. Klevans). Res. Div., Hoffmann-La Roche Inc., Nutley, NJ 07110

Conflicting reports have appeared concerning the interaction of benzodiazepines and GABA-ergic pathways (Haefely, et al., ADVANC. BIOCHEM. PSYCHOPHARMACOL. 14: 131-151, 1975; Steiner and Felix, NATURE (London) 260: 346-347, 1976). In contrast there is general agreement that the barbiturates exert their depressant effect, in part, through an enhancement of GABA-mediated inhibition (Ramson and Barker, BRAIN RES. 114: 530-535, 1976; Nicoll, PROC. NAT. ACAD. SCI. 72: 1460-1463, 1975). In experiments using surface electrodes, we observed a depolarization of the cat superior cervical ganglion following intra-arterial injection of pentobarbital (100nM-1μM). This effect was associated with a blockade of synaptic transmission. Bicuculline (150μg) prevented the pentobarbital evoked depolarization; however, synaptic transmission remained at a depressed level. Intra-arterial injection of GABA 15 sec after pentobarbital resulted in a depolarization which summated with that produced by pentobarbital.

Flurazepam (300nM-5μM) consistently produced a depolarization of the cat ganglion and prolonged blockade of ganglionic transmission. Pretreatment with either bicuculline (250μg) or picrotoxin (500μg) reduced the duration of ganglionic blockade. Administration of GABA during flurazepam induced depolarization resulted in an attenuation of the GABA response as compared to the GABA control, while an injection of GABA after the evoked depolarization had the opposite effect, producing an augmentation of the GABA potential.

These data support the suggestion that pentobarbital mimics, to some extent, the action of GABA. In contrast, the effect of flurazepam on ganglia is more complex, consisting of a drug-induced depolarization during which the GABA response is reduced. There then follows a phase of enhancement of GABA-induced depolarization. This latter effect may be associated with either a reduction of glial cell uptake of GABA or a priming action of flurazepam on the postsynaptic membrane.

1322 ELECTRON MICROSCOPE LOCALIZATION OF ^{125}I-α BUNGAROTOXIN BINDING SITES IN THE OUTER PLEXIFORM LAYER OF THE GOLDFISH RETINA.
I. R. Schwartz and D. Bok*. Department of Anatomy and Jules Stein Eye Institute, UCLA School of Medicine, Los Angeles CA 90024.

^{125}I-α Bungarotoxin (^{125}I-αBTX), a specific ligand for the nicotinic acetylcholine (AcCh) receptor, was prepared from αBTX purified from crude Bungarus multicinctus venom and iodinated with the chloramine-T method. Isolated eyecups from goldfish (Carassius auratus) were maintained in oxygenated Ringer's bicarbonate solutions and incubated with 10^{-9} to 10^{-7} M ^{125}I-αBTX with or without inhibitors (10^{-5} M nicotine or αBTX). The eyecups were then washed, fixed and processed for light and electron microscopic autoradiography with previously published methods.

Light microscopic autoradiography showed that binding of ^{125}I-α BTX was discretely localized to the outer and inner plexiform layers (OPL + IPL) with the highest concentration/unit area in the OPL. This confirms the findings of Yazulla and Schmidt (Vision Res. 76:878-880, 1976). Labeling was suppressed in both layers with nicotine and virtually eliminated with native αBTX. Electron microscopic autoradiograms showed that the OPL label was localized in the mass of horizontal, bipolar and receptor processes that invaginate into rod spherules and cone pedicles. In rod spherules the grains were present when the invaginating processes contained bipolar elements but were absent in sections when only horizontal processes were present. In cone pedicles the grains were somewhat removed from ribbon synapses when triads included only horizontal processes but were adjacent to the ribbon synapses when bipolars were included.

While rod telodendria and horizontal cell processes within rod terminal invaginations and small horizontal processes within cone terminal invaginations cannot be eliminated from consideration as possible receptor sites, we believe the evidence indicates that some bipolar cell processes within the OPL bind ^{125}I-αBTX. If the receptors which bind αBTX in the central nervous system have the same binding properties as those in the neuromuscular junction, then, by analogy, these bipolar processes contain AcCh receptors.

1323 THE UPTAKE AND ACETYLATION OF DIMETHYLAMINOETHANOL AND ITS EFFECT IN CHOLINERGIC SYSTEMS. E.S. Sears and Alan Sconzert*. Dept. Neurol., UTHSCD, Dallas, TX 75235.

Dimethylaminoethanol (DMAE), an endogenous ethanolamine, is a tertiary analogue of choline which has been proposed as a precursor to choline through an unidentified transmethylation process. Riker has marketed the acetamidobenzoate of DMAE (Deaner^{R}) for many years as a precursor of acetylcholine but clinical trials have given conflicting results. The influence of DMAE on the cholinergic neurotransmitter system was determined in synaptosomal preparations from rodent caudate nucleus and in partially purified choline acetyl transferase (CAT).

These synaptasomes exhibited a dual uptake system for ^{3}H-DMAE which is in range with those reported for ^{3}H-choline. The Na^{+}-dependent high affinity system has an apparent Km of 1.3 x 10^{-7}M, Vmax of 1.03 x 10^{-10}M/mg protein/min, and is inhibited by hemicholinium-15. The low affinity system exhibits an apparent Km and Vmax of 3.21 x 10^{-5}M and 1.25 x 10^{-9}M/mg protein/min, respectively. At concentrations greater than 5 x10^{-6}M, DMAE competitively inhibits choline uptake. DMAE is acetylated by CAT; however, kinetic studies indicate that it has a 5-fold lower reactivity when compared to choline.

DMAE participates in the phospholipid cycle as do other endogenous ethanolamines. The low affinity uptake system which supplies choline for phospholipid synthesis appears to utilize DMAE as well. The high affinity uptake system for choline, proposed as the rate-limiting step in acetylcholine synthesis, acts on DMAE in like fashion. At certain concentrations, DMAE competitively inhibits choline uptake and may thereby alter acetylcholine synthesis. Under conditions of exogenous administration, DMAE may be taken up and acetylated in cholinergic neurons. It remains to be seen if acetylated DMAE could be released as a false neurotransmitter.

1324 DIFFERENTIAL EFFECT OF SUBSTANCE P ON TRIGEMINAL BRAIN STEM UNITS RESPONDING TO TOOTH PULP OR INNOCUOUS OROFACIAL STIMULI. B.J. Sessle, J.W. Hu, G.E. Lucier, and J.L. Henry. Fac. Dent., Univ. of Toronto, and Dept. Res. in Anaesthesia, McGill Univ.,Canada.

Substance P has recently been shown (Henry, Brain Res. 114, 439, 1976) to have a differential excitatory effect on spinal dorsal horn units responding to noxious cutaneous stimuli in the cat. This suggests that substance P may have a facilitatory role to play in spinal nociceptive pathways. The present experiments were undertaken to determine if substance P has a broader role in nociceptive transmission than simply in spinal mechanisms. Its effects were tested on single units recorded in the trigeminal spinal tract nucleus. In cats anaesthetized with chloralose, and paralyzed with pancuronium bromide (Pavulon), single unit extracellular spikes were recorded from the exposed medulla with multi-barrel micropipettes. The central recording barrel was filled with 2.7M NaCl. Peripheral barrels, used for microiontophoretic application, were filled with synthetic substance P (0.8 mM in 165 mM NaCl, acidified to pH 5.5; Peninsula Labs. Inc.), Na-L-glutamate (1M, pH 7.2; Sigma), and control solution (165 mM NaCl, acidified to pH 5.5, used to detect artifacts due to local changes in current and pH at the electrode tip). As previously described (Sessle et al., Can. J. Physiol. Pharmacol. 54, 66, 1976), peripheral bipolar electrical stimuli were delivered to the ipsilateral and contralateral canine tooth pulps and to the exposed ipsilateral infraorbital and superior laryngeal nerves and forepaw; innocuous mechanical, and noxious mechanical and radiant heat stimuli were also applied. All units which were thoroughly tested were excited by glutamate (10-50 nA). Substance P (50-100 nA) also had an excitatory effect, but only on some units. The slow time course of this effect corresponded to that previously reported in other CNS areas. Those units tested to date that were excited by substance P responded to stimulation of the ipsilateral tooth pulp; units responding only to innocuous orofacial stimulation were not excited by substance P. As the tooth pulp is generally considered to be a site from which the only sensation evoked is pain and receives only small-fibre innervation, the differential effects of substance P seen in these experiments is consistent with the earlier suggestion that substance P is involved in chemical transmission in central nociceptive pathways.

1325 NOREPINEPHRINE AND DOPAMINE IN RAT SEPTUM AFTER MICROWAVE IRRADIATION: EVIDENCE FOR TISSUE DISRUPTION ARTIFACT. Nansie S.Sharpless* and Lucy L. Brown*(SPON:R. Katzman).Depts.Neurology & Psychiatry Albert Einstein College of Medicine, Bronx, New York 10461

Recent reports indicate that post-mortem metabolism of brain catecholamines (CAs)is rapid. Increases in 3-methoxytyramine,the O-methylated metabolite of dopamine (DA) by catechol-O-methyltransferase (COMT),appear within minutes after decapitation (Carlsson et al.,1974). Because rapid heat inactivation of CAdegradatory enzymes such as COMT would allow time for precise dissection of discrete brain regions, we have studied the effect of microwave irradiation (MWR) on levels of DA and norepinephrine (NE) in rat septum and caudate nucleus. Rats were killed by: 1)decapitation at 24 C, 2) 15 sec immersion in liquid N_2, or 3) 6 sec focussed MWR (2kW at 2450 MHz). Brains were removed and placed on an ice-cooled plate under a microscope for dissection. Brain removal and dissection took 10-15 min. Dissections were verified histologically. Tissues were homogenized in ice-cold $HClO_4$, centrifuged, and aliquots of the supernate assayed for NE and DA radioenzymatically. In the septum, mean (±SE) DA levels were markedly and significantly higher ($P<0.001$) in the rats killed by MWR (27.1 ± 2.6 ng/mg protein) than in the rats killed by decapitation at 24C (12.5 ± 1.0) or by liquid N_2 immersion(14.0 ± 1.2). However, when the rats were killed 10 min before MWR, allowing time for post-mortem metabolism, DA in the septum was also increased (34.5 ± 3.9). Also, mean DA levels in the caudate were slightly lower in rats killed by MWR (86.4 ± 5.4) than in rats killed by N_2 immersion (119.2 ± 10.8), but the difference was not significant. In contrast to DA, mean NE levels were significantly lower ($P<0.01$) in the septum of rats killed by MWR (7.2 ± 0.7) than in those killed by decapitation at 24 C (11.7 ± 1.1) or by liquid N_2 immersion (11.4 ± 1.0). The marked increase in DA in the septum after both ante- and delayed post-mortem MWR and the slight decrease in the caudate suggest that DA in the septum had been augmented by influx from adjacent regions of high DA content rather than because of COMT inactivation. Similarly, the decreased NE suggests that NE in the septum had spread out to regions of low concentration. Such diffusion artifacts have also been suggested by Lenox et al. (1976). Further evidence for CA spread was obtained by histofluorescence. After MWR there was considerable cell disruption. The fluorescent CA fibers normally seen in the septum were absent and replaced by a diffuse fluorescence indicating that the membranes had broken and the CAs had spread into the surrounding area. Since 6 sec were needed to completely inactivate COMT in brain, it was not possible to shorten the MWR exposure. We conclude that MWR is not a satisfactory method to prepare brain tissue when regional CA levels are being measured.
Supported by NIH Grant No. NS 09649.

1326 IN SITU U.V. LASER STUDIES OF RAT ARCUATE NUCLEI REVEAL ENDOGENOUS FLUOROCHROMES. David Shoemaker *, Joseph T. Cummins and T. George Bidder* (SPON: Wm. G. Clark.) Addiction Research Lab. and Dept. Psychiatry, V.A. Hospital, Sepulveda, CA., 91343 and Dept. of Pharm. and Expt'l. Ther., Univ. Calif., Irvine, CA.

A recently developed U.V. laser-microfluorimeter has revealed a number of intensely fluorescent endogenous substances with highly discrete neuroanatomical localization in the rat brain. The laser-microfluorimeter utilizes a He-Cd, U.V. laser (325 nm) which excites a brilliant yellow-green fluorochrome in the rat arcuate nucleus which is superfused with Krebs-Ringer. The intense arcuate nucleus fluorescence is observed under a stereomicroscope and measured by a monochromator and photon counting system.

The fluorochrome has an emission peak at 520 nm and fades with continued illumination. Ascorbic acid inhibited this decay, indicating a possible photooxidation reaction. Numerous rat arcuate nuclei were pooled, homogenized and extracted with organic solvents. Thin layer chromatography in three solvent systems of the arcuate extract identified an arcuate fluorochrome as 6-methoxy-1,2,3,4-tetrahydro-β-Carboline (6-MEOTHβC). Identification was further supported by identical emission peaks at 520 nm and concomitant rates of photooxidation between the extract and a 6-MEOTHβC standard.

The effects of in vivo administration of pharmacological agents on the 6-MEOTHβC fluorescence in situ were measured with the photon counting system. Thus, chlorpromazine decreased the fluorescence 70% but reserpine and nialamide did not significantly change the fluorescence. 5,6-dihydroxytryptamine doubled the fluorescence and visual observation indicated a broadening of the area of fluorescence into the periventricular nuclei bordering the third ventricle. Acetaldehyde administration increased the fluorescence 40%. This latter observation is significant because β-carbolines are the condensation products of aldehydes and bioamines.

Both the localization of 6-MEOTHβC in the arcuate nucleus and its response to psychopharmacologic substances indicate a yet undefined neurohumoral function of this compound.

1327 CHEMICAL TRIGGERING OF DESYNCHRONIZED SLEEP PHENOMENA
E.K. Silberman,* J. Garfield,* R.W. McCarley, J.A. Hobson.
Lab of Neurophysiology, Dept. of Psychiatry, Harvard Med. School and Dept. of Anaesthesia, Peter Bent Brigham Hospital, Boston.

Carbachol, a long-acting cholinomemetic agent, has been found to induce a state resembling desynchronized sleep (D) when injected into the giant cell field of the cat pontine tegmentum (FTG). The drug induced state, called D carb, is characterized by EEG desynchronization, muscular atonia, and rapid eye movements, cardinal defining features of physiological desynchronized sleep. In previous work, interpretation of the potent and enduring drug effects was confounded by long (22 min) and variable latencies to onset of D carb which suggested an initial disruption of the system by the experimental procedure.

Among the possibly disrupting effects of the procedure were physical and chemical changes related to the large volumes (4µL) and complex constitution of the vehicle (artificial csf). In this experiment, we hypothesized that the immediacy and consistency of effects of microinjecting carbachol would be enhanced by decreasing the volume of a more physiologically inert vehicle.

Cannulae were implanted bilaterally in the cat FTG so that their tips lay at HC -6.5, P4.0, and LR 2.0. Carbachol, at a dose of 4µg, was infused at volumes of 1µL and .25µL, and the cat was recorded in a restraint box for 4 hours following the infusion. Carbachol produced D carb for an average of 43% total recording time, which was close to 5 times the value for control runs. The average latency to D carb in carbachol runs was 6.6 min, compared to 41.3 min to D sleep in controls. There was, however, still considerable variability of response in terms of total D carb, length of D carb periods, and latency.

Further improvement was provided by the infusion of .25µL of a 16µg/µL carbachol solution. A total of 3 carbachol infusions were performed, along with 3 controls. The average D carb time was 81%, which was more than 8 times control values. Further, all 3 latencies were under one minute, and all 3 runs were characterized by long periods of D carb (over 2 hours of initial D carb in 2 out of 3 cases).

Our refinements of technique have produced effects of greater magnitude, immediacy, and consistency than previously observed. We feel that this stems from very small volume infusions which chemically stimulate smaller, more homogeneous cell groups, with less functional disruption and less tissue destruction than in our earlier work.

1328 **THE HUMAN PLATELET AS A MODEL FOR THE SEROTONERGIC NEURON: COMPARISON OF KINETIC AND PHARMACOLOGIC PROPERTIES OF SEROTONIN TRANSPORT IN PLATELETS AND NEURONS.**
Stephen M. Stahl & Herbert Y. Meltzer, Departments of Psychiatry and Pharmacological and Physiological Sciences, University of Chicago Pritzker School of Medicine, Chicago, Il. 60637.

The mechanisms whereby human platelets transport serotonin (5HT) were explored by determining the uptake of 5HT at initial velocities over a wide concentration range. Total 5HT transport could be resolved into a saturable high affinity-low capacity active transport system plus nonsaturable passive diffusion. Previous kinetic analyses of 5HT transport into platelets and brain slices have been found to be in error and the correct kinetic constants have been recalculated here. The saturable active uptake of 5HT into human platelets is directly susceptible to inhibition by several pharmacologic agents (ouabain, metabolic inhibitors, tricyclic antidepressants) which do not inhibit the nonsaturable passive diffusion or the nonsaturable granular transport of 5HT. On the other hand, granular binding of 5HT is directly susceptible to inhibition by pharmacologic agents (reserpine, tetrabenazine, N-ethyl-maleimide) which do not directly inhibit saturable active uptake or nonsaturable passive diffusion of 5HT. Quantitative studies of platelet 5HT transport have shown that at low concentrations of 5HT, the pharmacologic and biochemical properties of total 5HT transport are determined mostly by the saturable high affinity active membrane transport system for 5HT; at high concentrations of 5HT, the properties of 5HT accumulation by platelets are determined mostly by the granular storage mechanism. Detailed comparisons of the kinetic, biochemical and pharmacologic characteristics of 5HT transport in platelets and brain support the notion that the platelet can serve as a model for 5HT transport by central nervous system neurons.

1329 ACETYLCHOLINE AND CHOLINE IN THE BLOOD OF NORMAL INDIVIDUALS AND PSYCHIATRIC PATIENTS.
W.B. Stavinoha, A.T. Modak and C.L. Bowden*.
Depts. of Pharmacology and Psychiatry, University of Texas Health Science Center, San Antonio, Texas 78284.

Recent studies in patients using physostigmine, a cholinesterase inhibitor which increases acetylcholine levels, have furthered the hypothesis that acetylcholine may be involved in the etiology of affective disorders. To ascertain whether an alteration of the central cholinergic nervous system in affective disorders might be reflected in peripheral tissues, analysis of the Ach and Ch contents of blood was carried out. To determine both Ach and Ch, blood was drawn and the enzymes immediately inactivated by injecting a 500 µl aliquot into 1 ml of a formic acid acetone mixture. Butyrylcholine was used as the internal standard and choline was esterified using propionylchloride. Acetylcholine and choline were identified by pyrolysis-gas chromatography and mass spectrometry. Quantitation was accomplished by mass fragmentography by monitoring fragments m/e 58 and m/e 71. Depressed patients (mean age 40.4) range 18-64 met research diagnostic criteria for bipolar depression, unipolar depression, depressive neurosis, or schizophrenia, schizoaffective type with depression, respectively. Control subjects were not depressed, had no history of affective disorder, nor of any psychiatric disorder within the preceding two years, nor any other medical disorder requiring treatment, (mean age 34.7) range 26-60. The value in nmol/ml ± S.D. (number of subjects) of blood for the control volunteers was acetylcholine 0.81 ± 0.45 (33) and choline 9.58 ± 7.11 (33). The values for acetylcholine for all the patients were 2.12 ± 2.14 (24) and choline 10.97 ± 7.8 (23). The acetylcholine in patients differed significantly from the controls at a level of $P<0.005$. When the patients were subdivided, the acetylcholine concentration of the depressive neurosis group was significantly different from the control group, acetylcholine 1.94 ± 1.30 (7) and choline 11.6 ± 9.7 (7). The remaining subgroups, although higher in acetylcholine content than the control, were not significantly different. The values for bipolar were 2.0 ± 2.6 (8), unipolar 2.9 ± 3.2 (5) and schizophrenia 1.8 ± 1.1 (4). For choline, the values were: bipolar 11.5 ± 9.0 (8), unipolar 71.1 ± 9.0 (5), schizophrenia 8.9 ± 1.7 (4) and depressive neurosis 11.6 ± 9.7 (7). At present, we do not know how well the acetylcholine in the blood reflects central cholinergic activity, but the data identifies a significant increase in acetylcholine in the blood over control values in a group of depressed patients.

1330 UPTAKE AND RELEASE OF ^{3}H-NOREPINEPHRINE IN ILEAL MUCOSA.
E. J. Tapper*, A. S. Bloom* and P. C. O'Connell* (SPON: M. J. Hosko).
Departments of Medicine and Pharmacology, Medical College of Wisconsin and Wood VA Center, Milwaukee, Wis. 53233.

Norepinephrine (5 x 10^{-5} M) in rabbit ileum stimulates absorption of Na^+ and Cl^-, decreases the short-circuit current, and within 2 minutes enhances maximum accumulation of cyclic GMP. We have previously found (Gastroenterology 70: 942, 1976) that high concentrations of carbachol (CARB, 10^{-3} M) have a similar effect on mucosal cell transport of ions and cyclic GMP. Our studies were performed with ileal tissue from which the muscle layers and Auerbach's plexus are removed; thereby leaving intact the peripheral autonomic innervation and submucosal plexus. In order to determine how high concentrations of CARB may have a catecholamine-like effect on transport and cGMP, we have examined first whether this preparation has a high affinity uptake for dl-^{3}H-NE (norepinephrine), and second, the release of ^{3}H-NE by CARB 10^{-3} M. The tissues were studied at 37° C in Krebs-Henseleit buffer containing pargyline and in a 95% O_2 - 5% CO_2 environment. ^{3}H-NE in concentrations from 10^{-8} - 10^{-6} M shows uptake which is linear with time up to 20 minutes. The uptake process demonstrates Michaelis-Menten kinetics with an apparent K_m of 3.2 µM and V_{max} of 2.61 nM/gm/hr (n=3). At 10 minutes this uptake process is partially inhibited (% inhibition) by cocaine (30-90 mM): 33-51%, imipramine (30 mM): 48%, and ouabain (1 x 10^{-5} M): 66%; none of these agents completely blocks the ^{3}H-NE uptake (n=5). Release of ^{3}H-NE was studied under similar conditions with tissue preloaded (^{3}H-NE, 5 x 10^{-7} M). KCl (100 mM), known to stimulate release of ^{3}H-NE in other tissues, produces release into the media of 18% (n=6) at 1 minute and 7% at 3 minutes when compared to spontaneous release. CARB 10^{-3} M produces release of ^{3}H-NE of 22% (n=6) at 1 minute, but does not increase release at 2-5 minutes.

The results of these studies indicate: 1) Ileal mucosal preparations demonstrate a high affinity uptake process for ^{3}H-NE which behaves according to Michaelis-Menten characteristics. 2) KCl produces release of ^{3}H-NE from 1-3 minutes, while CARB 10^{-3} M causes release which occurs within the first minute. 3) These data suggest that the effect of high concentrations of CARB on cGMP metabolism and/or intestinal mucosal ion transport may be related to the release of NE.

1331 CENTRAL AND PERIPHERAL DEFICIENCY OF NOREPINEPHRINE IN PARKINSON'S DISEASE AND THE EFFECTS OF L-DOPA THERAPY. P.F. Teychenne*, C.R. Lake, M.G. Ziegler*, C. Plotkin*, J.H. Wood*, and D.B. Calne*. NINCDS & NIMH, N.I.H., Bethesda, Md. 20014

A central deficiency of dopamine (DA) in parkinsonism has been established. Sensitive and specific techniques of measuring another catecholamine, norepinephrine (NE), a primary neurotransmitter in both the sympathetic nervous system and brain, have been developed. We have measured plasma and CSF NE in 21 patients with idiopathic parkinsonism, 7 who were not on medication and 14 who were taking L-dopa/carbidopa, and also in 25 control subjects of the same age group. Dopamine-beta-hydroxylase (DBH), the enzyme which converts DA (the immediate precursor of NE) to NE, was measured in plasma.

A significant deficit of NE both in the CSF and plasma was found in untreated parkinsonian patients. Supine diastolic blood pressure (BP) was lower in untreated patients compared to controls. All the patients with Parkinson's disease had lower levels of DBH. Treatment with oral L-dopa/carbidopa (1150±14: 115±1 mg/day) raised the concentration of the CSF and plasma NE but did not significantly change plasma DBH activity. Supine diastolic BP was increased significantly, with L-dopa therapy, to normal values.

Our results confirm the central depletion of NE in parkinsonism (ref) and indicate an additional reduction of peripheral NE in Parkinson's disease. These data are consistent with a possible autonomic dysfunction. The reduced central concentration of DA may reflect deficient DA present as an NE precursor, in addition to DA present as a transmitter. We are presently searching for a peripheral DA deficit in parkinsonism. Adequate L-dopa therapy without carbidopa should replenish the NE precursor, DA, and probably increase the central and peripheral NE levels toward normal. Since the patients were also taking the peripheral decarboxylase inhibitor carbidopa, our results suggest that at the doses used peripheral blockade is not complete.

Subjects (N)	Age (yrs)	Plasma NE (pg/ml)	CSF NE (pg/ml)	BP (torr)	Pulse (beats/m)	DBH (units/ml)
Untreated Parks.(7)	57 ±4	189 ±22	137 ±25	115±4 70±2	72 ±4	241 ±69
Treated Parks.(14)	60 ±2	320[1] ±58	362[1] ±145	126±4 81±2[2]	79 ±5	352 ±97
Controls (25)	55 ±1	371[2] ±42	209[1] ±25	121±4 77±2[1]	101 ±5	844[2,3] ±97

1 significantly different from untreated patients; $p<0.5$
2 significantly different from untreated patients; $p<0.001$
3 significantly different from treated patients; $p<0.001$

1332 IMMUNOHISTOCHEMICAL LOCALIZATION OF NEUROTENSIN AND ENKEPHALIN IN RAT CNS. George R. Uhl, Michael J. Kuhar and Solomon H. Snyder. Depts. Pharmacology and Psychiatry, Johns Hopkins University School of Medicine, Baltimore, MD. 21205

Neurotensin and enkephalin immunoreactivity appear in many areas of the rat brain following localization by immunohistochemical techniques. Using antisera characterized in radioimmunoassay as possessing high affinities and high degrees of specificity for the respective antigens, the indirect immunofluorescence techniques show neuron-like configurations for this immunoreactivity. In unpretreated rats, most specific fluorescence appears in fiber- and terminal-like patterns, while low-intensity fluorescence overlies some cell bodies. Pretreatment of the rats with 50 µg colchicine, given intracerebroventricularly 24-48 hrs before sacrifice, allows improved visualization of peptide-containing perikarya, as Elde and Hökfelt (R. Elde, personal communication) have also shown. Adsorption of sera with the peptides against which they are directed eliminates specific fluorescence.

Areas enriched in enkephalin and neurotensin fluorescence include the substantia gelatinosa zones of the spinal cord and the trigeminal nuclear complex, the nucleus tractus solitarius, the vagal nucleus, the periventricular thalamus, the central amygdala, the median eminence, the medio-basal hypothalamus, the stria terminalis, and the interstitial nucleus of the stria terminalis. Sparse fluorescence corresponding to both peptides is detected in the lateral reticular formation, corpus striatum, and superficial and deep layers of the cerebral cortex. Substantial neurotensin fluorescence also appears in the midbrain tegmentum, just dorsal to the interpeduncular nucleus, and in the lateral aspect of the nucleus accumbens. One of the most striking differences between the distributions of the peptides is found in the globus pallidus, which contains the densest enkephalin fluorescence in the brain, but only sparse neurotensin fluorescence.

In many areas of the brain, such as the basal hypothalamus and the central amygdala, the density of fluorescent cell bodies after colchicine treatment parallels the density of fluorescence seen in unpretreated animals. Though this suggests that many neurons containing these peptides might be interneurons, lesion studies show their involvement in brain pathways. (Supported by USPHS DA-00266 and MH-33128.)

1333 MODULATION OF ACETYLCHOLINE (ACH) RELEASE FROM SYNAPTOSOMES BY OXOTREMORINE (OT) AND OXOTREMORINE METHIODIDE (OTMI). Molly H. Weiler* and Donald J. Jenden. Dept. Pharmacol., Sch. Med., UCLA, Los Angeles, CA 90024.

Muscarinic modulation of ACh release has been observed in the exposed cortex (Mitchell, J.Physiol. 165:98, 1963), cortical slices (Bertels-Meeuws and Polak, Brit. J. Pharmacol. 33:368, 1968; Polak, Brit. J. Pharmacol. 41:600, 1971), and the longitudinal muscle strip of the guinea pig ileum (Kilbinger, N.S. Arch. Pharmacol. 287:47, 1975). In order to examine whether this modulation is exerted on presynaptic muscarinic receptors or through a neuronal feedback loop, the effect of OT on spontaneous ACh release was studied in a crude (P_2) synaptosomal fraction prepared from rat whole brains. The synaptosomal pellet was suspended in 20 vol Krebs phosphate buffer containing 40 µM paraoxon. After a 10 min incubation at 37°C the P_2 suspension was centrifuged, and the supernatant was analyzed by gas chromatography/mass spectrometry (Jenden et al, Anal. Biochem. 55:438, 1973) for ACh and choline released into the medium. Under these experimental conditions the normal rate of ACh released was constant for the time period measured (0.01 nmol ml-1 min^{-1}).

OT (1 µM) significantly reduced the spontaneous release of ACh over a 10 min period by 18%. Maximal inhibition of ACh release occurred with 10 µM OT (22%) since higher concentrations (50 and 100 µM) did not cause a significantly greater inhibition (26% and 24%, respectively). This inhibitory effect of OT (1 to 100 µM) was reversed by the addition of 10 µM atropine to the incubation medium. Atropine (10 µM) alone had no effect on the spontaneous release of ACh, and did not affect the endogenous synaptosomal ACh levels. The addition of 35mM KCl to the incubation medium also blocked the inhibitory effect of OT on ACh release. Although 35mM KCl alone slightly stimulated ACh release (~10%) it also decreased synaptosomal ACh levels by 37%.

A quaternary N-metho salt of OT was also tested for its effect on the spontaneous release of ACh from synaptosomes. OTMI (10 and 100 µM) inhibited ACh release by 29% and 40%, respectively. The inhibitory effect of this compound also was reversed by 10 µM atropine and 35mM KCl.

The data suggest that the phenomenon of muscarinic modulation of ACh release can be studied in a synaptosomal preparation. Because of the nature of this tissue preparation, neuronal feedback inhibition can be excluded as a mechanism of modulation, and the data are supportive of a presynaptic modulation of ACh release via muscarinic receptors. (Supported by USPHS grant MH 17691).

1334 ASPARTIC ACID AND GLUTAMIC ACID DECREASE WHEN PRIMARY AUDITORY TERMINALS DEGENERATE IN THE COCHLEAR NUCLEUS OF THE GUINEA PIG. R. J. Wenthold and R. L. Gulley. Laboratory of Neuro-otolaryngology, NIH, Bethesda, MD 20014.

The putative neurotransmitters, glutamic acid (Glu) and aspartic acid (Asp), decrease in the cochlear nucleus after lesion of the auditory nerve by cochlear ablation. Asp decreases with a time course similar to that of the morphological degeneration of primary auditory terminals. The level of total Asp in the cochlear nucleus has decreased nearly 10% one day after cochlear ablation and more than 30% after two days and remains at this level up to 28 days. Glu, after a slight increase one day after cochlear ablation, decreases about 12% after two days and continues to slowly decrease through 28 days. Other acidic and neutral amino acids measured either are unchanged or increase at two days after cochlear ablation.

Glu and Asp were measured in subdivisions of the cochlear nucleus two days after cochlear ablation. The pattern of decrease was similar for both amino acids. Largest decreases in Glu and Asp were in the posteroventral nucleus, auditory nerve root and the anteroventral nucleus; smaller decreases were in the granule cell region and deep layers of the dorsal cochlear nucleus. The two amino acids showed no decrease in the molecular layer of the dorsal cochlear nucleus.

Glu and Asp were measured in the cochlear nucleus of the waltzing guinea pig, a genetic mutant with progressive degeneration of the cochlea. Morphologically, most spiral ganglion cells and primary auditory terminals degenerate between the ages of 30 and 90 days. Glu and Asp decrease in the cochlear nucleus of the waltzer at this time. While the levels are normal up to 30 days of age, by 90 days, Glu and Asp are 11% and 17% lower, respectively, in the cochlear nucleus of the waltzer compared to the normal. Cochlear ablation causes a 16.7% and 30.3% decrease in Glu and Asp after three days, respectively, in the cochlear nucleus of the 90-day normal guinea pig. However, in the 90-day waltzer, these decreases are only 4.8% and 5.3% for Glu and Asp, respectively. These data suggest that Asp, and possibly Glu, may be concentrated in primary auditory terminals in the cochlear nucleus.

1335 GLUTAMATE DECARBOXYLASE AND GABA-TRANSAMINASE IN HUNTINGTON'S CHOREA. Jang-Yen Wu[1]* and Edward D. Bird[2]* (Spon: D. D. Louie), Dept. Cell Biology, Baylor College of Medicine, Houston, TX 77030[1] and Addenbrooke's Hospital, Cambridge, England[2]

It has been reported from several laboratories that there is a marked decrease in GABA level and glutamate decarboxylase (GAD) activity in certain regions of brain of patients with Huntington's Chorea. Since GAD and GABA-transaminase (GABA-T) have been purified to homogeneity and antibodies specific to GAD and GABA-T also have been obtained in our laboratory, it seems desirable to employ immunochemical methods to establish whether the lower GAD activity in Huntington's tissue is due to a decrease in number of GAD molecules or an inhibition of GAD activity. Frontal cortex and putamen from control tissue and Huntington's tissue were homogenized in double-distilled water containing 1 mM AET, 1 mM EDTA and 0.2 mM pyridoxal phosphate, pH 7.2. The homogenate was centrifuged at 106,000 x g for 45 min and the supernatant thus obtained was used for immunochemical studies. GAD activity in putamen was greatly reduced in Huntington's tissue compared to the normal tissue (2.4 x 10^{-10} vs 6.9 x 10^{-10} moles GABA formed/min/mg protein). While in frontal cortex it was only slightly reduced (4.6 x 10^{-10} vs 5.4 x 10^{-10} moles GABA formed/min/mg protein). GABA-T activity was about the same in Huntington's tissue and normal tissue (frontal cortex, 7.0 x 10^{-9} vs 6.5 x 10^{-9}; putamen 8.6 x 10^{-9} vs 9.4 x 10^{-9} moles glutamate formed/min/mg protein). In immunodiffusion tests, GAD from both Huntington's tissue and normal tissue formed a single precipitin band with antibody against GAD purified from mouse brain and both precipitin bands fused together. The microcomplement fixation curves, in term of the extent of complement fixed and the shape of the curve, were also similar for GAD from both Huntington's tissue and normal tissue. It is, therefore, concluded that the decrease of GAD activity in Huntington's Chorea tissue is probably due to a reduction in number of GAD molecules (loss of GABA neurons) and not due to an inhibition or inactivation of GAD molecules. (Supported in part by grant from Huntington's Chorea Foundation and NIH grant NS-13224).

PLASTICITY

1336 A MONOSYNAPTIC EXCITATORY FIBER SYSTEM STUDIED IN VITRO: EVIDENCE FOR AN ASSOCIATIONAL PATHWAY IN CA1 STRATUM ORIENS(?). Bradley E. Alger*and Timothy J. Teyler. Dept. Pharmacology, Univ. Calif. Sch. Med., San Francisco, Calif. 94143 and Neurobiol. Div., Northeastern Ohio Univ. Col. Med., Rootstown, Ohio 44272.

The in vitro hippocampal slice preparation has been used as a model system for the study of response plasticity in the brain (Schwartzkroin & Wester, Brain Res., 1975, 89, 107-109; Alger & Teyler, Brain Res., 1976, 110, 463-480). In correctly prepared transverse slices of rat hippocampus the principle tri-synaptic circuit described by Andersen et al (Exp. Brain Res., 1971,13, 208-221) is present and functional. The principle circuit is a tri-synaptic path: perforant path fibers to granule cells of the dentate gyrus to (via mossy fibers) hippocampal CA3 pyramidal cells and to (via Schaffer collaterals) hippocampal CA1 pyramidal cells.

This report describes and documents the presence of a major afferent input to the basal dendrites of the CA1 area. Several experiments, including laminar analysis, latency measurements, and tests of frequency following, indicate that a monosynaptic excitatory pathway synapses among the basal dendrites (stratum oriens) of CA1 cells. The results cannot be accounted for by current spreading to adjacent excitatory fiber systems. Microsurgical procedures localize the course of the fibers to the border of stratum oriens and the alveus. Intracellular recordings verify that the system does terminate on the same population of CA1 cells that receive the Schaffer projection. Two recent reports have confirmed some of these findings (Andersen et al, Nature, 1977, 266, 736-737; Lynch et al, Nature, 1977, 266, 737-739).

The major candidate for the identification of this input had seemed to be the hippocampal commissural system. This system is known to originate in the contralateral CA3, to cross in the ventral psalterium and to terminate in the apical and basal layers of CA1 (and elsewhere)(Blackstad, J.Comp.Neurol.,1956,105,417-537; Gottleib & Cowan, J.Comp.Neurol.,1973,149,393-422;Mosko et al, J.Comp.Neurol.,1973,152,163-174; Lynch et al, Nature, 1977,266, 737-739). However, lesions of the ventral psalterium or of the contralateral dorsal hippocampus fail to eliminate the potentials seen in stratum oriens. Other neuroanatomical alternatives are discussed and it is tentatively concluded that the afferents investigated here represent an ipsilateral association system in stratum oriens of CA1. (Supported by NSF grant BMS75-02802).

1337 INFANT RATS: EFFECTS OF CENTRAL GUSTATORY AND RETICULAR FORMATION DESTRUCTION UPON THE ONTOGENY OF SENSORIMOTOR AND REGULATORY BEHAVIORS. C. Robert Almli and David L. Hill*. Dept. Psychol., Ohio Univ., Athens, Ohio 45701.

Central gustatory pathways and reticular formation were bilaterally destroyed in infant male and female albino rats at 10 days of age. From the day of birth (Day-1), through surgery at 10 days of age, and through adulthood, the brain damaged and control rats received a battery of sensorimotor tests each day. The sensorimotor test battery (e.g., orientation to tactile and olfactory stimuli, vibrisseal placing, oral reflex) consisted of 10 tests. Also measured during development were consummatory behaviors following a battery of regulatory tests (e.g., amphetamine and hypertonic saline injections, food deprivation, taste preference).

Following brain damage at 10 days of age, the infant rats stopped suckling and/or feeding and drinking for up to 15 days postlesion, and hand- and tube-feeding of liquid diet was required to sustain life. These rats remained hypodipsic through sacrifice at 150 days of age. Also, body weight of the brain-damaged rats was permanently reduced by 10%. The brain-damaged rats displayed sensorimotor deficits on some tests (e.g., vibrisseal placing) for up to 22 days postlesion, while other tests (e.g., olfactory orientation) revealed little or no dysfunction. All sensorimotor deficits were transitory. These rats also exhibited a variety of deficits (e.g., attenuated water intakes during food deprivation) for the regulatory tests.

The sensorimotor and regulatory dysfunction produced with lateral hypothalamic destruction has been attributed to damage of fiber systems coursing near the LH (e.g., nigrostriatal bundle, trigeminal lemniscus, gustatory and reticular formation pathways). The present results are similar to results reported for catecholamine depletion in infant rats, and although damage to the above systems produces some of the regulatory and sensorimotor deficits seen in infant rats sustaining LH damage, LH destruction produces more severe and persistent dysfunction. Thus, LH destruction hits these fiber systems at a focal point, thereby producing greater deficits than are produced with destruction of individual fiber systems, and/or LH destruction involves other afferent or efferent fiber systems not yet fully specified.

Following central gustatory and reticular formation destruction during infancy, rats display transient sensorimotor dysfunction and permanent regulatory deficits. These results are fairly consistent with results reported for rats sustaining similar brain damage as adults, and therefore the results suggest that these brain systems have attained a degree of functional maturity by the tenth day of life for rats.

1338 HISTOCHEMICAL DEMONSTRATION OF 5-NUCLEOTIDASE IN NORMAL AND DEAFFERENTED RAT CENTRAL NERVOUS SYSTEM. K. D. Barron, G. W. Kreutzberg* and P. Schubert*. Max Planck Institute for Psychiatry, Munich, German Federal Republic.

Adult rats weighing 300-350 g were killed by intracardiac perfusion with 300 ml of cacodylate-buffered (pH 7.4) 4% formaldehyde containing 0.5% sodium chloride. Perfusate temperature was 20-22°C. After 3 hours immersion-fixation at 2-4° blocks of brain were washed 14-16 hrs. in 0.05M cacodylate-0.25M sucrose, pH 7.4, and sectioned at 60 um on a vibratome. For light and electron microscopic examination vibratome sections were incubated 60-90 mins. at 20-22° in a medium containing 1 mM adenosine-5-phosphate, 2 mM $Pb(NO_3)_2$, 5 mM $Mn(NO_3)_2$ and 50 mM tris-maleate, pH 7.0 (8.5% sucrose added for electron microscopy). Additionally 5-nucleotidase activity was mapped in 18 um sections of unfixed brains (10 mins. pre-fixation in calcium-formalin before incubation).

Light microscopically enzyme activity was related to myelinated nerve fibers of neocortex and cingulum and other brain regions. Ultrastructurally reaction product was deposited on axolemma and at the surface of myelin sheaths adjacent to apposed membranes of glial cells and other elements of neuropil.

Additionally lead precipitate resulting from 5-nucleotidase activity occurred in neuropil of olfactory system, caudate nucleus, pallidum, thalamus, hippocampal formation, cerebellar cortex and other sites. Ultrastructurally neuropilar deposits were located intercellularly, especially near boutons and smaller dendrites, often in the vicinity of, but not at or on, synapses. Plasma membranes of astrocytic processes often had associated reaction product, especially around synaptic complexes (e.g. granule cell layer of cerebellum) and small blood vessels. Neuronal perikarya lacked significant enzymatic activity.

Nonspecific deposits (substrate-lacking media) were thinly scattered over the tissue or concentrated over nuclei.

Rats were killed 4, 6, 12, 18, 30 and 52 days after right entorhinal corticectomy. Light microscopically increased enzyme activity appeared at the junction of the inner and middle thirds of the molecular layer of the ipsilateral dentate gyrus at 4 days. By 6 days the outer 2/3 of the molecular layer of the right dentate was conspicuously reactive. Increased staining had subsided at 52 days. Ultrastructurally reaction product in partly deafferented dentate molecular layer occurred intercellularly in the vicinity of boutons and axodendritic synapses and in association with astrocytic processes.

1339 MOVEMENT AFTER EXTENSIVE DORSAL RHIZOTOMY. D. Berman, A. Marti*, B. Koss* & A.J. Berman. Veterans' Administration Hospital,Bronx, N.Y. and Queens College, CUNY, Flushing, N.Y.

A variety of voluntary movements can be performed by monkeys after dorsal rhizotomy of the responding limb, even in the absence of vision. This suggests that purposive movements can be executed without peripheral sensory input, presumably via some form of central feedback mechanism. Before invoking central mechanisms, however, it is necessary to assess the contribution of sources of peripheral afference other than those provided over dorsal roots directly serving the limb. One of these originates in areas of the body contiguous to the deafferented dermatomes, particularly those areas which might be stretched or otherwise stimulated during limb movement.

Six M. Mulatta (Group I) were subjected to intradural section of dorsal roots T1-T12 bilaterally, followed two weeks later by section of dorsal roots C2-C8. Three animals (Group II) were subjected to dorsal rhizotomy C2-T3, our standard deafferentation procedure. All animals were observed for posture, locomotion, climbing and retrieval of small objects from a dexterity board. In addition, a qualitative evaluation of forelimb movements involved in reaching for a target was made in three animals from each group. No differences between groups were noted for any of these behaviors. It was apparent that, for the categories of movement studied, removal of somatic input from areas caudal to deafferentation did not alter the deficit in the forelimbs from that found after C2-T3 deafferentation alone. It was concluded that the maintenance of motor function after dorsal rhizotomy was not dependent on sensory input from these areas.

It remained possible however that information might be available via long tracts, as a result of movements of the hindlegs. An attempt was made, therefore, to section all spinal dorsal roots in one M. speciosa. This was carried out in three stages over a seven month period. C2-T3 roots were sectioned at the initial procedure, T4-T12 at the second and L1 to base of cord at the third. The deficit seen in the forelimbs was similar to and no greater than that found in animals with C2-T3 roots only sectioned. Furthermore it was possible to train this animal to move either of its forelimbs in the absence of vision for food reinforcement. Movements of the two limbs could be alternately trained and extinguished with the expected savings to criterion over successive alternations.

Postmortem examination of animals in groups I and II confirmed completeness of deafferentation. In the 'complete' deafferent, however, several rootlets were inadvertantly spared at the junctional areas between surgical stages, T4 on the right and L7-S1 bilaterally.

1340 ELIMINATION OF SINGLE NEURONS IN THE LEECH C.N.S. BY INTRACELLULAR INJECTION OF PRONASE. Douglas Bowling* and Itzchak Parnas* (SPON: T. Lamb). Dept. Neurobiol. Sch. Med., Stanford University, Stanford, CA 94305

The aim of these experiments is to kill an individual neuron together with all of its processes in the C.N.S. and then to determine whether changes develop in other neurons. For example, will sprouting occur and processes grow to form new synapses, replacing terminals removed by the operation? Even minor changes might be detectable in an invertebrate preparation, such as the leech, where the properties and connections of many identified cells have been described in detail by anatomical and physiological techniques. For such experiments, however, it is not sufficeint simply to remove the cell body of an identified neuron, since in the leech as in other invertebrates there is evidence that the distal processes can survive for weeks or even months. A solution to this is to inject the mixture of proteolytic enzymes, pronase, into the cell body through a micro-pipette. A few hours later the cell loses its resting potential and by 24 hours the peripheral axons fail to conduct action potentials. Eventually the cell body disappears and no recovery of activity can be discerned in its processes for periods of several weeks. As expected, after a specific motor cell has been injected the appropriate reflexes are lost. Anatomical evidence for the spread of pronase is provided by experiments in which the cell is first injected with HRP which is allowed to spread. Subsequently pronase is injected into the same cell. In the resulting picture, little reaction product is seen in the cell body or in processes within the neuropil. However, distant axons in roots and connectives presumably not yet reached by the pronase are black, indicating that the cell had been successfully injected with the HRP. Other cells known to be in close physical and physiological association with the destroyed cell appear to be undamaged anatomically when injected with HRP. The electrical properties and synaptic interactions of these cells also appear to be intact.

Further observations, including electron microscopy, are being made to characterize the direct effect of the pronase on the injected cells and to look for non-specific damage to other cells. Animals that have survived for weeks or months with one or more injected neurons are being examined for signs of change from the normal organization of the C.N.S.

1341 ALTERATIONS IN A SPECIFIC MEMBRANE PHOSPHOPROTEIN FOLLOWING REPETITIVE STIMULATION OF THE HIPPOCAMPUS. Michael Browning,* Thomas Dunwiddie, Willem Gispen[1]* Gary Lynch. Dept. of Psychobiology, U. of Calif., Irvine, Cal. 92717. [1]Institute of Molec. Bio., State Univ. Utrecht, Padualaan 8, Utrecht 2506, The Netherlands.

Hippocampal synaptic pathways demonstrate remarkable synaptic plasticity and there has been considerable interest in the mechanisms which underlie these processes (Nature,266,677,1977). Considerable correlative evidence has been amassed which suggests that phosphoproteins may play a role in mediating synaptic events. We tested the possibility that changes in phosphorylation are involved in modification of synaptic efficacy by using the "in vitro" assay of Routtenberg and Ehrlich (Brain Res. 92,415,1975) to index the state of phosphorylation of synaptic membrane proteins following repetitive stimulation of the Schaffer collaterals in our hippocampal slice preparation. Despite considerable variability between experiments, a single band, in the molecular weight range of 43-45,000 Daltons, demonstrated at least 15% less incorporation of label in stimulated slices when compared to unstimulated controls. Although other explanations are possible, this difference in incorporation of label may reflect a net increase in phosphorylation following repetitive stimulation thus resulting in fewer sites available for incorporation in a subsequent "in vitro" assay. Evidence pertinent to the question of whether this change is functionally tied to post-tetanic potentiation, or heterosynaptic depression (Nature, 266, 737,1977), or, for that matter, to any change in synaptic transmission will be discussed.

1342 COMPETITIVE INTERACTIONS BETWEEN DEVELOPING CILIARY GANGLION CELLS. Larry Burstein*, G. Pilar and L. Landmesser (SPON: W. Chapple). Physiology Section, Biological Sciences Group, Univ. of Connecticut, Storrs, CT 06268, and Biology Dept., Yale Univ., New Haven, CT 06510.

During embryonic development, half of the avian ciliary ganglion cells normally die. Since this cell death occurs at the time of peripheral synapse formation and is greatly enhanced by prior removal of the target tissues (ciliary muscle, iris and choroidal coat), it has been proposed that the neurons die because they have failed to effectively compete for a limited number of synaptic sites or amount of trophic substances (Landmesser & Pilar, J. Cell Biol. 1976, 68:357). The possibility that cells die because they have not reached the target was ruled out, at least for the ciliary population which innervates the iris and ciliary muscle, by showing that at St.34 all ciliary cell somas can be retrogradely labelled by incubating the iris and ciliary muscle in horseradish peroxidase (HRP). The potential competition between ciliary cells was further studied by taking advantage of the characteristic innervation pattern of the ciliary and iris muscle. The axons innervating the different targets emerge through specific nerves: Branch (Br) I (most lateral), innervates the iris constrictor and 40% of ciliary muscle; Br II (central), 20% of the ciliary muscle and the iris dilator; and Br III (medial), 40% of the ciliary muscle.

Although axons innervating the different targets are selectively grouped into different nerves, retrograde labelling of individual nerves with cobalt or HRP showed this is not associated with the position of the cell somas: these are scattered through the ganglion.

The rationale of these experiments was to remove a portion of the ciliary cells from effective competition to see if the survival of those which remained could be influenced. Intraocular axotomy of all Br at St.32 resulted in rapid death of all parent cells. Section of Br I and II alone resulted in an increased survival of those ganglion cells which sent their axons through the remaining Br III. Retrograde labelling showed the number of cells sending out axons through Br III was 144 $\pm$ 6.4% (+SD) of the contralateral side. In other words, half of the cells that normally die had survived. This was associated with an increase in the peripheral field of Br III tested electrophysiologically.

Therefore, cell death is not an inevitable phenomenon, because cell survival can be influenced by altering the balance of neurons and their interacting targets. Cells also can innervate other areas of the target, not normally available, suggesting competition at the synaptic level. Supported by NIH-NS 10338, NS 10666 and the Univ. of Connecticut Research Foundation.

1343 PROJECTIONS OF THE SUPERIOR CEREBELLAR PEDUNCLE IN RATS AND THE EFFECTS OF NEONATAL HEMICEREBELLECTOMY. Anthony J. Castro. Dept. Anat., Stritch Sch. Med., Loyola Univ., Maywood, ILL. 60153

In the first part of this study, the normal efferent distribution of the superior cerebellar peduncle (SCP) was determined in adult rats using the Fink-Heimer staining technique. Animals sustained stereotaxic transection of the SCP with a small knife and were sacrificed 3 to 9 days postoperatively. Similar to reports on other animals, the SCP (brachium conjunctivum) courses rostrally and decussates in the midbrain to the contralateral side where it bifurcates into ascending and descending limbs. Principal terminations of the contralateral ascending limb are the red nucleus and ventral thalamus. A moderate number of fibers recross in the thalamic commissure and pass to the ipsilateral ventral thalamus. Additional sites of preterminal degeneration are the oculomotor and trochlear nuclei, the nuclei of Darkschewitsch and Cajal, the lateral aspect of the periaquaductal gray extending to the pretectal region and continuing into the superior colliculus, the nucleus of the posterior commissure, the nucleus parafascicularis, zona incerta and the posterior thalamic nucleus. The contralateral descending limb passes caudally to the medulla with projections along the way to the pontine gray, the nucleus reticularis tegmenti pontis, the medullary raphe nuclei and the inferior olivary nuclei.

Ipsilateral descending projections are also observed to emerge from the SCP and to course caudally in a position medial to the spinal trigeminal nucleus. Projections from this bundle pass to the trigeminal motor nucleus and can be traced to the lateral pontine and medullary reticular formation with a few fibers passing medially to the nucleus reticularis gigantocellularis. Additional degeneration is also observed bilaterally within the vestibular nuclei with an ipsilateral bundle passing caudally into the medulla in a position just ventral to the dorsal column nuclei.

In the second phase of this study, SCP projections were examined in adult animals that sustained contralateral hemicerebellectomy at 1 to 3 days of age. In these animals aberrant projections are found to the ipsilateral red nucleus and ventral thalamus. Evidence suggestive of axonal sprouting is also observed within the contralateral oculomotor complex. These animals also display an absence of cells in the contralateral pontine gray and inferior olive and the ipsilateral lateral reticular and lateral cuneate nuclei.

1344 ENVIRONMENTAL INFLUENCES ON THE FUNCTIONAL ORGANIZATION OF THE SUPERIOR COLLICULUS IN THE GOLDEN HAMSTER. Leo M. Chalupa and Robert W. Rhoades*. Dept. Psych., Univ. Calif., Davis, CA 95616.

The response properties of visual neurons in the superior colliculus were investigated in three groups of hamsters: (1) normally reared animals; (2) visually deprived animals, reared from birth to adulthood in total darkness; and (3) strobe reared animals, raised in an environment illuminated twice every second with a very brief flash of light. For visually responsive cells, the receptive fields were plotted and the following response characteristics were investigated: (a) directional selectivity, (b) speed preferences, (c) response type and maghitude to flashed stationary spots of various sizes, and (d) response habituation.

Dark-reared animals could not be differentiated from normal animals on the basis of the incidence or preferred directions of the directionally selective cells. Furthermore, speed preferences and receptive field size and organization were the same in these two groups. Subtle neurophysiological effects of visual deprivation were indicated by the longer latencies of "on" responses to flashed spots of light in the dark-reared animals. In addition, a few cells in the dark-reared hamsters responded in a sustained fashion to flashed spots of light, while in normal animals all cells responded only phasically to light onset and/or offset.

In contrast, marked changes were apparent in the response properties of collicular neurons of the strobe-reared hamsters. These consisted of a pronounced reduction in the number of cells which showed directional selectivity. There was also a reduction in the number of cells exhibiting response suppression when stimuli larger than the activating region of the receptive field were employed. Further, in the strobe-reared animals many cells in the superficial layers of the colliculus (those dorsal to the stratum griseum intermediale) often exhibited considerable response variability, an observation common for cells in the deeper layers of normal and dark-reared animals, but rare for cells in the superficial layers

These findings indicate that in the golden hamster, visual experience plays a minimal role in the induction or maintenance of the functional organization of the superior colliculus, but an aberrant visual input during development, in this case strobe-illumination, can induce major changes in this system.

1345 INDUCED HYPEREXCITABILITY IN AN INSECT CENTRAL NEURON. Richard D. Clark* and Melvin J. Cohen (Spon: L. M. Bartoshuk). Dept. of Biology, Yale Univ., New Haven, Conn. 06520.

A mid-saggital cut separating the anterior 1/2 of the metathoracic ganglion in the cricker Acheta domesticus increases the effectiveness of synaptic input onto the dendritic tree of an identified central neuron, the contralateral dorsal longitudinal motor neuron (CDLM). A long thin neurite from the CDLM soma runs across the midline of the ganglion and gives rise to a major dendritic arborization in the contralateral ganglionic neuropile. The axon then leaves the ganglion from the side opposite the cell body. The midline section of the ganglion therefore separates the dendritic arborization and axon (distal segment of the neuron) from the soma and part of the initial neurite (proximal segment). The hyperexcitability of the experimental dendritic tree therefore occurs in the absence of an attached cell body.

The intact CDLM in control animals is not spontaneously active. Extracellular recordings from the axon and intracellular records from the CDLM dendritic arborization indicate that the normal CDLM can only be driven synaptically by two vigorous procedures: 1) grasping and probing of the mouthparts and antennal bases; 2) high voltage electrical stimulation of the rostral nerve cord at 20/sec or greater. Air puffs to the receptors of the head or the anal cerci and single shocks to the rostral cord do not stimulate this neuron in the normal animal.

In contrast, approximately 50% of the experimental animals with mid-saggital ganglionic cuts show bursts of action potentials in response to air puffs to the head or tail region and also to single weak electric shocks to the rostral cord. In some cases spontaneous action potentials could be recorded from the dendritic arborization and axon of the isolated distal segment of the neuron. This evidence of hyperexcitability is present from 5 to 38 days after midline section of the ganglion. Simultaneous extracellular recordings from the identified peripheral axon and intracellular recordings from the dendritic arborization confirmed the identity of the experimental dendritic structure within the neuropile.

Cobalt backfills of the CDLM axon and dendritic tree in experimental preparations indicate that the isolated dendritic arborization may give rise to new neurites in the region where the dendritic arborization was cut. This suggests the possibility that the hyperexcitability of the isolated dendritic tree might be due to synaptic formation on the newly induced dendritic sprouts.

1346 NORMAL INCREASE OF NEURONAL NUMBERS IN ADULT STINGRAYS. Richard E. Coggeshall, Robert B. Leonard and William D. Willis, Jr. Departments of Anatomy and Physiology & Biophysics and the Marine Biomedical Institute, Univ. Texas Med. Br., Galveston, TX 77550.

The nervous system of the Atlantic stingray, Dasyatis sabina, differs in at least three major respects from the nervous system of mammals. First, the axons of the dorsal and ventral roots do not intermingle in the peripheral nerves. Second, there are essentially no unmyelinated axons in the dorsal roots, ventral roots, and peripheral nerves. Third, and of particular importance for this report, the number of dorsal root axons, ventral root axons, dorsal root ganglion cells and ventral horn, "motor" cells increase steadily as the animal ages. To establish this last point, stingrays of different sizes were compared. In these animals the number of axons and cells mentioned above are proportional to the size of the animal with the number of ventral root axons and ventral horn motor cells increasing two-fold as the animals increase in size from 55 gm to 8.5 kg and the dorsal root axons and dorsal root ganglion cells increasing three-fold in these same rays. This finding would seem to imply that the ray is capable of 1) making new neurons in adult life and 2) wiring them into an already functioning nervous system. It is our hypothesis that the ability of fish to regenerate their central nervous systems is related to their capacity to increase neuronal numbers in adult life. This work was supported by NIH grants NS 11255 and NS 10161, and a grant from the Muscular Dystrophy Association of America.

1347 ULTRASTRUCTURAL PATTERNS IN THE LATERAL POSTERIOR NUCLEUS OF THE GOLDEN HAMSTER. Barbara J. Crain, Department of Anatomy, Duke University Medical Center, Durham, NC 27710.

During normal development, pre- and post-synaptic elements combine to form specific synaptic patterns. In order to examine the relative contributions of the pre- and post-synaptic populations to these patterns, we are studying the ultrastructural organization of the lateral posterior nucleus (LP) and comparing it to the organization that results when a normal input from the superior colliculus is removed and an input from the retina is experimentally induced.

The ultrastructure of LP is characterized by two types of synaptic complexes. The first is a "central dendrite" complex in which numerous pre-synaptic terminals synapse around and along a central dendrite. Nearly all of these terminals are medium-sized, contain round synaptic vesicles, and make multiple short asymmetric synaptic contacts onto the central dendrite. They also synapse onto terminals which contain pleomorphic synaptic vesicles and make short symmetrical or very slightly asymmetrical synapses onto the central dendrite. Terminals with pleomorphic vesicles are also found outside the complex. The second type of synaptic complex, which is sometimes found adjacent to the first, consists of a very large terminal synapsing onto many dendritic appendages of a single large dendrite. These terminals are characterized by their large size, their densely packed round synaptic vesicles, and their numerous mitochondria. They form asymmetric synapses onto appendages as well as non-synaptic filamentous contacts with the dendritic shaft. In addition to the pre-synaptic types just described, a small terminal type is found outside the synaptic complexes. These terminals have many round synaptic vesicles, are usually small, and make long, markedly asymmetric synaptic contacts onto small dendrites.

Sources of some of the axon terminals have been determined. After removal of the superior colliculus, medium-sized terminals inside the "central dendrite" complexes and small terminals outside the complexes undergo electron-dense degeneration. Removal of the posterior neocortex is followed by filamentous degeneration of large terminals and electron-dense degeneration of both small terminals and other as yet unidentified terminals outside the complexes. Rarely, terminals inside the "central dendrite" complexes also degenerate.

Removal of the superior colliculus at birth is followed in a few days by retinal synapse formation in LP, before its characteristic synaptic complexes have appeared. Experiments are in progress to determine the fate of the complexes and to describe the patterns of retinal termination under these experimental conditions. Supported by NINDS Grant #NS-09623 to W. C. Hall.

1348 PLASTICITY AND SPECIFICITY OF CONNECTIONS OF THE CORPUS CALLOSUM IN THE ALBINO RAT FOLLOWING NEONATAL LESIONS. Cassie Cusick* and Ray Lund. Depts. Biological Structure and Neurosurgery, Univ. Washington, Seattle, WA 98195.

The callosal projection of the albino rat connects homotopic regions of cortex in an orderly, point-point fashion. In addition, there is a heterotopic projection from the S1 area to S2. We investigated the properties of the developing callosal "map" to determine whether this system could compress or expand in size disparity experiments similar to those performed in the visual system of fish and amphibia. The corpus callosum first crosses the midline between the 19th and 20th day of gestation, but the axons do not begin their ascent into the cortex until the 3rd postnatal day. Animals from several litters received large lateral cortical ablations within the first 36 hours after birth. Lesions removed various amounts of cortex, usually from the level of the anterior commissure to the occipital region. After 6-18 weeks survival, longitudinal second lesions were placed in the intact hemisphere in positions which should have connected with the ablated cortex. Nonhomotopic, medially displaced degeneration was seen in Fink-Heimer material. The degeneration often is organized into discrete patches in the presumptive layers I-III, suggesting that axons are not simply "dammed up" at the edge of the remaining cortex. Small injections of HRP into the remaining cortex on the ablated side showed that the cells of origin of this aberrant projection are found in the appropriate cortical layers and in all areas of the convexity which normally provide a callosal input. Preliminary experiments on animals with lateral lesions made on fetal day 18 show that the opposite cortex appears to project more heavily onto the remaining fragment than after comparable lesions made at birth. While the callosal pathway shows the capacity to form aberrant connections within a smaller terminal area, its ability to expand appears to be rather limited: small second lesions and small ^{3}H-proline injections into the remaining cortex on the ablated side reveal no heterotopic inter-areal expansion, although the possibility of local spreading cannot be eliminated. In such cases, the projection from S1 to both its homotopic position and to S2 is maintained, indicating that callosal axons will bypass inappropriate deafferented areas rather than innervate them to form an expanded projection. These results demonstrate that size disparity mismatches can occur outside of the retinotectal projection in the developing mammalian central nervous system.

1349 ANATOMICAL AND PHYSIOLOGICAL PLASTICITY IN SINGLE IDENTIFIED MOTOR NEURONS. P. L. Donaldson* and R. K. Josephson. Dept. Psychobio., U. of Cal., Irvine, CA 92717.

The cricket, Teleogryllus oceanicus, has two excitatory axons to the extensor tibia muscle (ET) in its jumping leg. The two axons are distingushable by the contractions they elicit in the muscle--the fast axon causes large amplitude twitches, the slow axon produces low amplitude, facilitating contractions. The two axons exit the thoracic ganglion by different nerve roots (n.5 for the fast axon, n.3b for the slow) and therefore either of the axons can be sectioned without damage to the other. Sectioning the fast axon denervates a large portion of the middle of the ET but leaves proximal and distal ends of the ET still innervated by the slow axon. 30 to 60 days after sectioning the fast axon, the slow axon field of innervation is significantly expanded presumably indicating sprouting of slow axon terminals to denervated muscle fibers. Animals whose nerves are sectioned when nymphs have more rapid and more extensive sprouting than animals sectioned as adults. Expansion of the slow axon field continues with time until the muscle is reinnervated by a regenerating fast axon, which occurs rarely in animals sectioned as nymphs. Regenerating fast axons replicate the original fast axon field, including fibers normally dually innervated by the fast and slow axon. Interestingly, in 75% of the animals which regenerated a fast axon there were two or more fast axons innervating the ET via n.5 rather than the usual single fast axon. The source of these additional fast axons is yet undetermined.

After sectioning n.5, the tension initiated by stimulation of the slow axon with either single stimuli or bursts of stimuli is greater in the operated leg than in the contralateral control leg. This increase in slow axon tension begins at the time the degenerating fast axon fails to elicit contractions (7-10 days post-operative), which is before there is detectible expansion of the slow axon field, and continues until a fast axon reinnervates the muscle. Following fast axon reinnervation the tension initiated by slow axon simulation falls to the control level even though the slow axon field is still enlarged. A possible explanation for the increased effectiveness of the slow axon is that the fast axon represses slow axon transmission. In support of this hypothesis, we have found that excitatory junctional potentals (ejps) produced by the slow axon do increase when the contractions are larger and return to normal sizes when the contractions initiated by the slow axon return to normal. The fast axon did not have to innervate the same muscle fibers or even entirely regain its normal innervation pattern to exert a repressive influence on slow axon responses.

1350 INNERVATION OF HIPPOCAMPUS BY CO-CULTURED CENTRAL ADRENERGIC NEURONS FROM FETAL MOUSE BRAINSTEM. Cheryl F. Dreyfus, Michael D. Gershon and Stanley M. Crain. Dept. of Neuroscience, Albert Einstein Coll. Med., Bronx, N.Y. 10461 and Dept. of Anatomy, Columbia Univ. Coll. Phys. & Surg., N.Y. 10032.

We have attempted to determine whether central adrenergic neurons in vitro are capable of growing to and establishing functional connections with one of their normal targets, the hippocampus. Explants containing locus coeruleus and explants of hippocampus from 18-day fetal mice were maintained as co-cultures and were also grown separately. After 1-4 weeks these tissues were analyzed by glyoxylic acid-induced histofluorescence for catecholamines, by light and EM radioautography with ^{3}H-norepinephrine (NE), and by electrophysiology.

Brainstem explants continued to exhibit specifically fluorescent adrenergic cell bodies and varicose fibers after 4 weeks in culture. In contrast, no fluorescent cells or neurites could be seen in isolated hippocampal cultures at 2-3 weeks in vitro. However, when the hippocampus was co-cultured with the brainstem for 2 weeks, adrenergic fibers were seen growing out of the brainstem and entering the hippocampus. Co-cultures of brainstem and hippocampus were incubated with ^{3}H-NE (5×10^{-7}M) and the monoamine oxidase inhibitor, nialamide (10^{-5}M). Radioautographic analyses revealed that brainstem neurites which entered the hippocampus took up NE whereas neurites in isolated hippocampal explants did not. EM study of co-cultures showed varicose axon terminals within the hippocampus to be preferentially labeled.

Electrophysiological studies suggested that these adrenergic neurites within the hippocampus were functional. Complex synaptically mediated slow wave discharges could be evoked by electrical stimuli in isolated hippocampal explants. Introduction of the β-adrenergic antagonist, propranolol, at 10^{-7}-10^{-6} g/ml, did not alter these hippocampal discharges. On the other hand, in hippocampal-brainstem co-cultures, these concentrations of propranolol altered the complex hippocampal responses to brainstem or hippocampal stimuli. Similar alterations in hippocampal responses by propranolol also occurred in these co-cultures after acute transection of all brainstem neurites to the hippocampal explant. Therefore, propranolol's action was to inhibit the effect of brainstem fibers at the hippocampal level.

These experiments provide morphological and electrophysiological evidence that adrenergic neurons from fetal mouse brainstem maintained in organotypic tissue culture can grow into and functionally innervate an appropriate central target - the hippocampus.

1351 CALCIUM INVOLVEMENT IN LONG TERM POTENTIATION IN THE HIPPOCAMPAL SLICE PREPARATION. Thomas V. Dunwiddie and Gary S. Lynch Dept. of Psychobiology, Univ. of Cal.,Irvine, CA 92717

Since calcium has been demonstrated to be involved in a wide range of synaptic processes including transmitter release, frequency facilitation and post-tetanic potentiation in other systems, we sought to determine its involvement in the phenomenon of long term potentiation in the mammalian hippocampus.

Reducing the level of calcium in the bathing media of hippocampal slices from 2.5mM to 1.0mM had several effects on the physiology of this preparation. While the absolute magnitude of synaptically evoked responses (both population spike and EPSP) were diminished only slightly, paired-pulse responses were considerably augmented, particularly at short (less than 25 msec) intervals,and changes were seen in plots of stimulation voltage vs. response amplitude.

During stimulation trains delivered at moderate (e.g. 15Hz) frequencies in 2.5mM media, population spike amplitudes typically showed patterns of facilitation-depression-facilitation. The initial phase of facilitation was paralleled by increases in the dendritic extracellularly recorded EPSP, while the EPSP showed only depression during the following depression-facilitation sequence. Testing during a stimulation train via a heterosynaptic input supports the hypothesis that the initial facilitation is specific to the stimulated synapses, whereas the secondary facilitation is the result of a cell-wide increase in excitability.

Following the cessation of stimulation trains, long term potentiation was observed much more frequently in 2.5mM calcium media (52/60 slices) than in 1.0mM media (13/57 slices), suggesting an involvement of calcium in the development of this effect. As would be expected, increased levels of magnesium were also able to disrupt the potentiation phenomenon still further. Whether this is due to a direct involvement of ionic fluxes of calcium in potentiation per se, or whether it is an indirect consequence of other changes in the physiology of this preparation has yet to be determined.

1352 REGENERATION IN THE RAT SCIATIC NERVE STUDIED BY LABELING THE MOTOR FIBERS WITH AXONALLY TRANSPORTED RADIOACTIVE PROTEINS. David S. Forman and Richard A. Berenberg. Naval Medical Research Institute, NNMC, Bethesda, MD 20014.

Labeling regenerating axons with axonally transported radioactive proteins provides information about the location of the entire range of nerve fibers from the fastest growing ones to those which are trapped in the scar. We have used this technique to study the regeneration of motor axons in the rat sciatic nerve after a crush lesion. After surgically exposing the nerve in the mid-thigh it was crushed twice at the same site for 45 seconds with plastic covered jeweler's forceps. From 2 to 14 days after the crush the lumbar spinal cord was exposed by laminectomy and multiple injections of [^{3}H]proline were made stereotactically in the region of the ventral horn containing the motor neurons which supply the sciatic. Twenty-four hours later the nerves were removed, cut into 2 mm segments, and the distribution of radioactivity along the nerve was measured by liquid scintillation counting. Radioactivity in the regenerating axons distal to the crush typically exhibited a peak of radioactivity due to an accumulation of label in the tips of these fibers. After a delay of 3.2 $\pm$ 0.2 (SE) days, this peak advanced down the nerve at a rate of 3.0 $\pm$ 0.2 (SE) mm/day. The leading edge of this peak, which marks the location of the endings of the most rapidly growing labeled fibers, moved down the nerve at a rate of 4.4 $\pm$ 0.2 mm/day after a delay of 2.1 $\pm$ 0.2 days; this is the same time course as that of the most rapidly regenerating sensory axons in the rat sciatic nerve, measured by the pinch test. Another peak of radioactivity at the crush site, presumed to represent the ends of unregenerated axons or misdirected sprouts, declined rapidly during the first week, and more slowly thereafter. When normalized for differences in the amount of incorporation, the labeling pattern in different nerves on the same postoperative day was similar. Daily injection of triiodothyronine (25 µg/g) did not significantly alter the rate of regeneration measured by this method.

1353 RETENTION OF HABITUATION OF WITHDRAWAL RESPONSES MEDIATED BY THE FUNCTIONALLY TRANSECTED HUMAN SPINAL CORD. Marcus J. Fuhrer. Depts. Rehab. and Psychiat., Baylor Coll. Med., Houston, Tx. 77030.

This study was the first in a series concerned with describing stimulus conditions that facilitate or retard retention of habituation of the lower extremity flexor withdrawal reflex mediated by the transected human spinal cord. Specific purposes were to: 1) establish a retention interval that would permit reliable though not complete retention to be demonstrated; 2) assess alternative quantitative indices of habituation and sensitization for their sensitivity to retention effects; 3) evaluate effects comparatively in terms of spontaneous recovery (assessed by responsiveness to test stimuli preceding renewed repetitive stimulation) and retention (assessed by responding during the series of renewed habituating stimuli); and 4) investigate the degree to which the performance characteristics of individual subjects were consistent in separate experimental sessions. Thirteen persons with relatively long-standing transection of the cervical spinal cord participated in two daily sessions during which identical experimental procedures were conducted. Each individual had been examined neurologically by at least two examiners, and in no case was voluntary motor functioning or sensation detected below the level of the lesion. The stimulus consisted of a 40-msec. pulse train applied intradermally to the plantar surface. Response measures were based upon the integrated EMG activity of the tibialis anterior and rectus femoris muscles. The essential procedure was to stimulate repetitively at a 1/sec. interstimulus interval until EMG responsiveness was extinguished, discontinue habituating stimulation for a 3-min., stimulus-free retention interval, and then reapply the same number of 1/sec. stimuli. A total of five habituating stimulus series were applied, the only variation being that the retention interval between the fourth and fifth series was 42 min.

Reliable retention of habituation was demonstrated, with effects tending to cumulate across the first four series. The degree of initial reflex sensitization observed during repetitive stimulation decreased progressively across the four series. No evidence for retention of habituation was observed in the fifth series which was preceded by the 42-min., stimulus-free interval. There was some evidence that indices of spontaneous recovery were less sensitive to repeated stimulus series than were retention indices. Several of the performance indices showed substantial test-retest stability.

Supported in part by Research Grant NS07755-09 from the National Institute of Neurological and Communicative Disorders and Stroke and by Grant No. 16-P-56813/6-14 from the Rehabilitation Services Administration.

1354 THE EFFECTS OF SPINAL CORD TRANSECTION IN FETAL AND NEONATAL MICE. John D. Gearhart*, Mary Lou Oster-Granite, and Lloyd Guth. Dept. Anat., U. Md. Sch. Med., Baltimore, Md. 21201

Although regeneration occurs in the CNS of lower vertebrates, many investigators have found such regeneration in the CNS of both neonatal and adult mammals is limited. Since the fetal CNS has a far greater potential for repair and restitution of damaged cell populations, its regenerative capacities may resemble more closely those of lower vertebrates. We have developed reproducible in utero surgical techniques for the exposure and transection of mid- to low-thoracic spinal cords in 12-14 day gestation (vaginal plug = day 0) mouse fetuses of the Swiss and C57BL/6J strains. We have also laminectomized and transected neonatal mice within three days postnatal. Animals transected as fetuses were born by both spontaneous vaginal delivery and caesarian section. The amount and type of motor activity present in the lower limbs of adult animals of both groups have been correlated with the histologic appearance of the spinal cord. Some animals transected as fetuses were autopsied at various gestational and postnatal ages. They were compared histologically with neonatally transected counterparts to determine the pathogenesis and extent of the degenerative process, the nature and extent of scar formation, and the amount of ingrowth of fibers into the transected region. Some operated animals were completely paraplegic; in these mice nerve fibers were not seen crossing the lesion, even though scar tissue formation was minimal. Other mice showed a variable degree of motor function which correlated histologically with a variable number of fibers bridging the operative site. Further studies are presently underway to determine the extent to which the nerve fibers seen crossing the lesion represent fibers left undamaged by the operation or new fiber ingrowth.

1355 RECOVERY AFTER SPINAL NERVE LESIONS: REFLEX RECOVERY AND LOCOMOTION. Michael E. Goldberger, Jocelyn Prendergast and Marion Murray. Medical College of Pa., Phila., Pa. 19129

Reflex and locomotor recovery were examined in cats following unilateral section of spinal nerves L_5, L_6, S_1, S_2,(L_7 spared). The general nature (slowness, weakness) of the initial deficit was the same in all animals; the distribution of that deficit depended upon whether the lumbosacral plexus was prefixed or postfixed. Of the 5 hindlimb tendon reflexes (patellar, medial, and lateral hamstrings, achilles, tibialis anterior, toe jerks) only the knee jerk was always abolished. In prefixed animals, ankle and lateral hamstring jerks were abolished; tibialis and toe jerks were preserved but weak. In postfixed animals, tibialis was abolished but weak, ankle and lateral hamstring jerks remained; toe jerks were variable. Tactile placing was more impaired in the forward direction in postfixed animals (tibialis abolished; backward tactile placing more impaired in the prefixed group (achilles abolished). Impairment of medial and lateral placing showed no correlation with plexus type. Standardized locomotion (for food reward on a 9' runway) was impaired in both groups in that extension of the knee and weight bearing during stance were absent, and all movements were greatly slowed. Postfixed animals all showed slipping backward of the limb during initiation of the step and walked on the dorsum of the toes. Prefixed cats showed collapse of the whole leg during stance but did not walk on the dorsum and the leg did not slip backward. During the 1st week p.o., all spared tendon reflexes became stronger, some became hyperactive and clonic, and locomotion was much faster. The patellar tendon reflex never returned but various thigh muscle responses were elicited by skin and periosteal stimulation, which are not seen normally. The reflexogenous zone for placing spread. The abnormal locomotor pattern of the limb did not change despite the increase in tactile placing. During the second p.o. week, the animals were able, by changing the position of the limb, to use muscles (e.g. abductors) for weight-bearing when muscles usually performing this function (extensors) were paralyzed. At this time, some ankle tendon reflexes which has been abolished returned and then became brisk. This was accompanied by a change in the limb's movement pattern, e.g. when the tibialis reflex returned in a postfixed cat, the leg no longer slipped backward. This implies that the returned reflex determined the step's pattern. Increase of tendon reflex activity appeared to be more important for recovery of locomotion than increased cutaneous reflexes. Reflex and locomotor recovery could, in some instances, be accounted for by peripheral nerve sprouting of the spared L_7 spinal nerve, in others by CNS adaptation. NIH - NS11919 and PVA - P-31-76

1356 ANATOMICAL AND BEHAVIORAL PLASTICITY FOLLOWING PRENATAL REMOVAL OF DORSOLATERAL PREFRONTAL ASSOCIATION CORTEX IN THE FETAL RHESUS MONKEY. Patricia S. Goldman, Thelma W. Galkin*, Lab. of Neuropsych., NIMH, Bethesda, Md. 20014 and Edward Taub, IBR, Silver Spring, Md. 20910.

The presumptive dorsolateral prefrontal cortex was resected bilaterally in a fetal rhesus monkey at E106 (106th embryonic day) with subsequent replacement in utero and caesarean delivery near term (165 days). Cognitive functions dependent upon the integrity of this neocortical region were assessed during postnatal development. The monkey was sacrificed at 2½ years of age and its brain fixed by vascular perfusion and processed for subsequent cytoarchitectonic and hodological analysis.

The prenatally operated monkey grew to 2½ years of age without exhibiting any gross sensorimotor deficits or evidence of impairment on the classical spatial delayed response problems which depend critically upon the integrity of the dorsolateral prefrontal cortex in mature monkeys. Its performance on these tests was within the range of unoperated monkeys rather than severely impaired as in the case of monkeys with the same cortical areas removed as juveniles or adults.

The lesion performed at E106, when brain fissuration has barely begun, were bilaterally symmetrical and similar in size and topography to those performed after birth when the brain has attained the adult fissural pattern. However, the surface of the telencephalon in the monkey operated upon as a fetus exhibited marked changes in gross morphology: anomolous sulci appeared bilaterally on the lateroventral surface of the frontal lobe and some unusual sulci were also observed in locations as remote as the occipital lobe. The cytoarchitectonic composition of the cortex lining these sulci displayed the basic six-layered pattern of primate neocortex.

Perhaps the most significant finding with regard to a possible explanation of functional plasticity is that the parvocellular subdivision of the mediodorsal thalamic nucleus, which normally projects to the dorsolateral prefrontal cortex, shows little evidence of neuron loss, indicating perhaps that the parvocellular neurons have found some other cortical target for projection. This sector of the dorsomedial nucleus always degenerates following comparable prefrontal lesions performed after birth.

Thus, removal of the dorsolateral prefrontal association cortex in a nonhuman primate a full two months before birth can be followed in postnatal life by extraordinary preservation of behavioral function as well as by significant alteration in the gross morphological characteristics and thalamo-cortical connections of the brain.

1357 EFFECTS OF AXOTOMY ON SPIKING AND NON-SPIKING SOMATA OF IDENTIFIED LOCUST NEURONS. C. Goodman* and W. Heitler* (SPON: R. Zucker). Dept. Zoology, UCB, Berkeley, CA 94720

The identified neurons of locusts include (i) 'non-spiking' neurons, (ii) 'spiking' neurons with spiking axons and non-spiking somata, and (iii) 'spiking' neurons with spiking axons and spiking somata. What are the differences in ionic current channels amongst different identified neurons and are these differences stable or plastic throughout the life of the animal? We have initially approached these questions by studying the somata of two 'spiking' neurons: the fast extensor tibiae (FETi) motorneuron with a non-spiking soma and the dorsal unpaired median extensor tibiae (DUMETi) neuron with a spiking soma. We examined the ionic channels of these two neurons in normal adult animals and animals in which the peripheral axons of both neurons were axotomized or treated with colchicine.

We find DUMETi to have a spiking soma with a Na-Ca action potential; the presence of both ions is necessary for generation of an action potential. TEA has little effect on increasing either the amplitude or duration of the action potential. The non-spiking soma of FETi shows delayed rectification. TEA converts the non-spiking soma into a spiking soma with a Na-Ca action potential, very similar to the normal action potential in the soma of DUMETi. Thus, the non-spiking and spiking somata both have sodium and calcium inward current channels and the difference between them may be due to differences in the delayed outward current channels.

Axotomy or treatment with colchicine converts FETi within 4 days into a spiking soma where the major carrier of inward current is sodium ions, although the calcium channels are still present. Evidence supports the notion that increased numbers of sodium channels are added to the soma membrane. Axotomy of DUMETi converts the normal Na-Ca action potential into a predominantly Na action potential. The calcium channels are still present, but increased numbers of sodium channels in the soma membrane result in the sodium ions alone being sufficient to generate an action potential. Evidence is also presented to suggest that a non-spiking region of DUMETi in the neuropil becomes spiking after axotomy, also due to an increased number of sodium channels.

1358 CHANGES IN PROTEIN METABOLISM FOLLOWING AXONOTOMY: A TWO-DIMENSIONAL ANALYSIS. Michael E. Hall*, David L. Wilson, and George C. Stone. (SPON: Donald McAfee). Dept. of Physiol. and Biophys., Univ. of Miami, Sch. of Med., Miami, Fl. 33152.

The nerve cell response to axonotomy is known to involve changes in cell morphology and protein synthesis. These changes have been viewed by many as reflecting a biochemical reversion to an earlier developmental stage, involving an enhanced synthesis of structural proteins necessary for regeneration, with a concomitant decrease in the synthesis of functional proteins (1). In the present study, changes in protein synthesis during development and following axonotomy were analyzed using a newly developed modification of the two-dimensional gel electrophoretic technique of O'Farrell (2).

The two principal postganglionic nerves emerging from the superior cervical sympathetic ganglia (SCSG) of adult rats were either cut or crushed unilaterally. At intervals ranging from 1 to 117 days after surgery both SCSG were removed, incubated in the presence of ^{14}C-leucine and subjected to two-dimensional protein separation and autoradiography. With this technique, proteins are first separated on the basis of isoelectric point (pH 4 to 8) and then according to molecular weight (MW 10^4 to 10^5). Also, intact SCSG from 1, 2, 7 and 14 day old rats were labeled and analyzed. Changes in the synthesis of specific proteins were determined by optical-density scanning of autoradiographs.

Preliminary analysis suggests that, of the 300 to 400 proteins visualized, only a minority (about 10%) of these proteins exhibit a change in synthesis, relative to the majority of proteins, following axonotomy. Of those that do change, there are many more whose synthesis increases than there are those whose synthesis decreases. Most of those proteins showing an increase after axonotomy exhibited this increase only within the first month after surgery, with synthesis at control levels thereafter. This was true even when reinnervation of target organs did not occur. Comparison of protein synthesis patterns from immature SCSG with those from adult-control or adult-axonotomy SCSG indicated that axonotomy does not represent a reversion to an earlier developmental stage of the ganglion.

1359 EFFECT OF NEONATAL WHISKER REMOVAL ON THE SmI SOMATOTOPIC MAP OF THE RAT. H.P. Killackey, T.J. Cunningham, and G. Ivy*
Dept. of Psychobiology, Univ. of Calif., Irvine 92717 and Dept. of Anatomy, Medical College of Pa., Phila., Pa. 19129

The rodent's mystacial vibrissae and their cortical representation provide a unique opportunity to examine the developmental interactions between a peripheral receptor and the central structures to which the receptor projects. In the mouse, each vibrissa is related to a discrete group of cells in layer IV of somatosensory cortex. These groups of cells are called "Barrels" and their structural integrity is dependent on the presence of intact vibrissae during development (Van Der Loos & Woolsey,'73). In the rat a similar but less discrete structure exists and electrophysiological evidence suggests a one-to-one relationship between a vibrissa and a "Barrel" (Welker,'71). In addition, both species possess discrete thalamocortical projections whose organization is also dependent on intact vibrissae during development (Killackey, et al.,'76).

In the present study we sought to determine whether the disruptions which follow early vibrissae removal are accompanied by a relative loss of specificity between receptor and central structures. Rats with unilateral vibrissae removal on the day of birth (Row "C" or Rows "B" & "D") were prepared for electrophysiological mapping of unit clusters under urethane anesthesia. On the control side contralateral to the undamaged vibrissae, unit clusters were responsive to stimulation of one vibrissa or of several vibrissae in the same row. In a series of penetrations from caudal to rostral receptive fields progressed from row to row in an orderly fashion (Row "A" to Row "E"). In contrast, on the side contralateral to vibrissae removal, this orderly organization was disrupted. While restricted receptive fields related to the intact vibrissae could still be found, interspersed between these areas were areas which responded to stimulation of several rows of vibrissae. We also found areas between normal receptive fields which did not appear responsive to vibrissae stimulation. These results suggest that the structural abnormalities reported earlier are accompanied by an apparent loss of the strict specificity found in normal rats.

1360 SPROUTING IMPEDES REGENERATING SYNAPTIC CONNECTIONS. C-P. Ko* and S. Roper. Dept. Anat., Univ. Colo. Med. Cntr., Denver, CO 80262

Nerve regeneration readily occurs in the peripheral nervous system, but in the CNS severed nerve tracts are rarely restored. We have been investigating factors contributing to the lack of successful nerve regeneration using as a model reinnervation of the parasympathetic cardiac ganglion in frogs after partial or total denervation. We found that when one of the two nerves supplying this ganglion was crushed, it took up to one year for the damaged axons to re-establish all their functional connections. On the other hand, when both preganglionic nerves were crushed, reinnervation was rapid. The difference between the two situations is that when only part of the nerve supply was destroyed, remaining intact axons sprouted and innervated the entire ganglion before regeneration occurred. Thus, the presence of remaining normal and sprouted synapses apparently delays the re-establishment of original synaptic connections. These results were obtained by the following experiments.

Neurons of the cardiac ganglion are grouped along right and left branches of the preganglionic vagus nerves traversing the interatrial septum in the frog. When we impaled neurons with microelectrodes in isolated ganglia and recorded responses evoked by stimulating the vagus nerves, we found about 88% of the cells on the left branch were innervated by the left vagus and 52% by the right (via a chiasm between the vagal branches). 7-10 days after crushing the left vagus, the remaining intact right nerve sprouted and innervated every ganglion cell on the left branch.

However, if we waited several weeks after crushing the left vagus to allow it to regenerate, in a proportion of neurons we recorded intracellular responses evoked by stimulating the operated nerve; many of these cells still had functional inputs from the right vagus. For example, from 9-18 weeks after the operation, 19% of the neurons on the left branch were innervated by the regenerating left vagus, and 90% by the right. If we compared these data with those from animals in which both vagus nerves had been crushed, 58% of the neurons were innervated by the left and 72% by the right vagus at comparable times.

We interpret these findings as follows. Regeneration of axons after partial denervation takes place, but these terminals must compete with pre-existing normal and sprouted ones; this somehow delays the re-establishment of a functional synaptic connection. When both nerves are crushed, right and left vagal axons arrive at vacant postsynaptic sites and functional connections are rapidly restored. We are investigating possible mechanisms underlying how the presence of sprouted synapses impedes the restoration of original connections.

1361 SEQUENTIAL REMOVAL OF THE INSULAR-TEMPORAL REGION ABOLISHES PATTERN DISCRIMINATION. B.S. Layton,* A.W. Toga,* S. Horenstein and D.G. Davenport.* Departments of Neurology and Psychology, Saint Louis University, Saint Louis, Missouri 63104.

Sequential bilateral ablation of the insular-temporal region of the cat brain abolished the ability to discriminate temporal patterns of stimuli thus resembling the effect of bilateral simultaneous destruction of this polysensory area. Six adult cats were trained in a double-grill box shock-avoidance situation to detect a change in a continuous auditory temporal pattern from either soft-loud-soft to loud-soft-loud or the reverse. Each tone was 800 hz and 900 msec in duration. The tones were separated by 100 msec of silence and the triads by 2000 msec. The loud tone averaged 88 db/SPL and the soft 68 db/SPL. After achieving criterion performance of 18/20 correct detections on two successive days, the insular-temporal cortex was removed bilaterally in two cats and unilaterally in the other four. In the latter group, two cats were operated on the left side and two on the right. All animals were retrained following a two week recovery period. The bilateral animals failed to regain criterion performance, but the unilateral animals usually did so rapidly. When the latter animals had regained criterion the remaining insular-temporal region was operated and after a fortnight to recover, retraining again instituted. This time the cats failed to achieve criterion after as much as twice the number of trials required for original acquisition. A simple intensity detection task (i.e. soft-soft-soft to loud-loud-loud or the reverse) was quickly mastered. After completion of the training cycle, the animals were deeply anesthetized and killed by formol-saline perfusion. The brains were removed for anatomic verification. Lesions were somewhat smaller than intended and generally invaded some of the underlying white matter.

These results appear to confirm the dependence of temporal pattern perception on the insular-temporal region and suggest that staged lesions with interpolated practice and relatively lengthy recovery times do not attenuate the deficit in temporal pattern discrimination induced by bilateral simultaneous ablation of this region. Additionally, the comparison of these results with the anomalously accelerated rate of learning of this type of sequence discrimination observed by Colavita after bilateral simultaneous lesions of insular-temporal cortex in the three week old kitten suggests that the behavioral plasticity associated with infant lesions need not necessarily occur subsequent to serial lesions in the adult animal.

1362 **REORGANIZATION OF SYNAPTIC CONNECTIONS IN THE RAT SUBMANDIBULAR GANGLION DURING POSTNATAL DEVELOPMENT.** **Jeff W. Lichtman* (SPON: D. Purves). Washington Univ. School of Medicine, St. Louis, Mo. 63110.**

The innervation of neurons in the submandibular ganglion of neonatal and adult rats has been studied with intracellular recording, and light and electron microscopy. Intracellular recordings from neurons in isolated adult ganglia showed that individual ganglion cells are usually innervated by a single preganglionic fiber. In ganglion cells from neonatal animals, however, graded stimulation of the preganglionic nerve elicited multiple steps (about 5 on average) in the excitatory postsynaptic potential. The same result was obtained when the preganglionic fibers were stimulated at their emergence from the brainstem, indicating that neonatal ganglion cells are innervated by several different preganglionic neurons. The number of preganglionic fibers innervating individual ganglion cells gradually decreased during the first few weeks of life, and by about 5 weeks each ganglion cell was generally contacted by a single preganglionic axon. Electron microscopical counts of synaptic profiles per ganglion cell perimeter showed that the number of synaptic contacts made on each ganglion cell actually increased during the period when the number of axons innervating each neuron was decreasing. These results show that in the rat submandibular ganglion there is a reorganization of neuronal connections during the first few weeks of life which results in a transition from multiple to generally single innervation of ganglion cells. The similarity of the reorganization of initial contacts in developing muscle and the immature submandibular ganglion suggests that synapse elimination may be a general feature of neural ontogeny.

1363 CHANGES IN THE PATTERN OF RETINO-TECTAL CONNECTIONS DURING DEVELOPMENT IN THE CLAWED FROG, XENOPUS. Alison Longley* (SPON: A. E. Hendrickson). Dept of Zoology, University of Washington, Seattle, WA 98195.

Connections between the eye and optic tecta of Xenopus laevis were mapped anatomically using Wallerian degeneration following lesion of discrete regions of the eye. Connections were analyzed in adult frogs and tadpoles at stage 51, the stage at which retinal axons have grown into about the rostral one-half of the tectum.

In adults, retino-tectal connections were ordered, with nasal retina mapping to the caudal part of the tectum and temporal retina mapping rostrally. In the tadpoles, within the innervated area of the tectum, the retino-tectal connections were generally organized as in the adults, with the temporal retina mapping to the rostral part of the innervated tectum and nasal retina mapping primarily to the caudal part. But a portion of the nasal fibers consistently projected to the rostral tectum as well. Electron microscopic observations showed degenerating synaptic terminals at both rostral and caudal portions of the innervated tectum after lesion of just the nasal retina. Synaptic degeneration was not seen in control tadpoles. This indicates that initially, the axons from the nasal retina, which must cross over the rostral tectum before reaching their proper contacts at the caudal tectum, make synaptic connections over a very wide area. This suggests that during development, the retinal axons progressively sort themselves out on the tectum, perhaps on the basis of their synaptic contacts, to produce the orderly retino-tectal map seen in adults.

This research was performed in partial fulfillment of the requirements of the degree, Doctor of Philosophy, at the University of Oregon. Research support was through contracts AT(45-1)-2011 and AT(45-1)-2230 to Dr. Philip Grant and Health Sciences Advancement Award FR-06027 from the National Institutes of Health.

1364 HETEROSYNAPTIC POTENTIATION OF CA1 NEURONS IN THE HIPPOCAMPAL FORMATION: LONGITUDINAL FIELD POTENTIAL PROFILE ANALYSIS OF NEURONAL POPULATIONS. Walter C. Low* and Spencer L. BeMent, (SPON: E. Kokmen). Bioelectrical Sciences Laboratory, University of Michigan, Ann Arbor, MI 48109

The synaptic plasticity of afferent fibers to neuronal populations of the hippocampal formation has been well documented. Short-term and long-term potentiation of CA1 neurons have been observed by stimulating various afferent systems with a variety of paradigms.

We have used the in vitro hippocampal preparation to determine the activity of CA1 neurons along the longitudinal axis in response to the electrical stimulation of Schaffer collateral fibers. The amplitude of the CA1 "population spike" has been shown to be related to the sum of unitary discharges at a particular location within stratum pyramidale (Andersen, Exp. Brain Res., 13:208-221, 1971). A bell-shaped curve for the longitudinal field potential profile (LFPP) was obtained from plotting the peak-to-peak amplitude of the Schaffer collateral-CA1 (SCH-CA1) "population spike" as a function of the position of the recording electrode along the longitudinal axis. When the initial LFPP was compared with subsequent SCH-CA1 response profiles a decrement in the peak of the profiles was observed which suggests a decrease in the Schaffer collateral activation of the CA1 neuronal population.

Non-tetanic (1 cps) stimulation of the fiber system traversing the fimbria followed by the generation of the SCH-CA1 LFPP resulted in a profile with a peak amplitude similar to that of the initial LFPP. On the other hand, tetanic stimulation of the fimbria (2 seconds at 100 cps) followed by the generation of the SCH-CA1 LFPP resulted in a response profile with a peak 50% greater than that of the initial LFPP. These observations with non-tetanic and tetanic stimulation suggest that a respective reactivation and an enhanced activation of the SCH-CA1 system were induced by the prior stimulation of fibers traversing the fimbria.

CA1 population EPSPs due to Schaffer collateral activation in conjunction with fimbrial stimulation must be analyzed in order to gain a clear interpretation of the synaptic basis of heterosynaptic potentiation.

1365 ANOMALOUS INNERVATION OF THE HIPPOCAMPAL FORMATION BY PERIPHERAL SYMPATHETIC AXONS FOLLOWING MECHANICAL INJURY. Rebekah Loy and Robert Y. Moore. Dept. Neurosciences, Univ. Calif. San Diego, La Jolla, Ca 92093

In the course of studying the normal central nervous system noradrenergic (NA) innervation of the hippocampal formation (HF) we found evidence of apparent growth of peripheral sympathetic axons into the structure following mechanical lesions of the fornix and anterior hippocampus. 14 days to 3 months following unilateral aspiration transection of the anterior 2-3 mm of the HF, brains prepared by the Vibratome formaldehyde or glyoxylic acid fluorescence histochemical methods exhibit a normal pattern of locus coeruleus (LC) fibers within Ammon's horn and the area dentata. In addition, there is a new plexus of coarse, intensely fluorescent catecholamine axons which have the characteristic appearance of peripheral sympathetic fibers. This plexus extends through all septo-temporal levels of the area dentata and appears to be innervating neural tissue rather than blood vessels. The anomalous fibers are mostly smooth, non-varicose, preterminal axons, but they also form typical varicose structures identical to the terminals of the autonomic ground plexus, particularly in the infragranular hilus, the stratum granulosum and the inner 1/3 of the molecular layer. The anomalous innervation also extends into the CA3 stratum pyramidale and radiatum. All of these regions are extensively deafferented by the fimbria-fornix lesion.

A similar pattern of anomalous innervation is present in rats with bilateral LC lesions, indicating that it does not arise from the normal central NA innervation of the HF. The conclusion that the anomalous innervation arises from peripheral sympathetic axons is confirmed by the effects of superior cervical ganglionectomy in rats with LC ablation. In these brains the HF is nearly devoid of NA innervation and none of the coarse, anomalous innervation remains.

The transection of the anterior HF in this study would certainly traumatize the vasculature and its sympathetic innervation. This, in all likelihood, results in growth of severed peripheral NA-containing axons, which have ready access to the partially deafferented HF. The sympathetic fibers appear as early as 14 days after the transection and persist for as long as 5 months with no significant changes in either density or organization, indicating that this is a stable response to injury. It is not known whether this innervation is functional; if it is, such anomalous growth could have significant implications for the sequelae of injury to the CNS of both experimental animals and man. (Supported by USPHS Grant NS-12080 and postdoctoral fellowship NS-05372.)

1366 NERVE DOMAINS AND SPROUTING IN SALAMANDER SKIN. Lynn Macintyre* and Jack Diamond. M.R.C. Group in Developmental Neurobiology, Dept. of Neurosciences, McMaster Univ. Med. Centre, Hamilton, Ontario, Canada, L8S 4J9.

A quantitative physiological study has been made of the ability of intact cutaneous mechanosensory nerve fields to enlarge into adjacent denervated regions of skin in the salamander hind-limb. In most animals the dorsal limb surface divides into two fields, the anterior innervated by spinal nerves 15 and 16 anterior, and the posterior by nerves 17 and 16 posterior; there is virtually no overlapping of the two fields at the frontier between them. Within the 2 weeks following a partial denervation which leaves only nerve 15 or 17 intact in the limb, a slight increase in the field of the remaining nerve occurs at the frontier zone, and then field enlargement ceases for the following 6 to 7 weeks. Sprouting subsequently resumes, and the foreign territory is progressively invaded. This general character of field enlargement is also exhibited by the other nerves tested (e.g., 16A, 16P, and a sub-branch of 17) but the period of initial enlargement, and the duration of the "static" phase when sprouting ceases, varies for the different nerves. During this static phase however, the intact nerve fibres have not lost their capacity to sprout, and will make up field deficits caused by section of sub-divisions of the parent nerve trunk; they will also regenerate readily after they themselves are sectioned. These and other findings are consistent with the hypothesis that the nerves are allotted domains of body-space (presumably during development), and that their axons are hindered for significant periods of time from responding to the non-specific sprouting stimulus provided by denervated skin outside the domain; there is however no apparent constraint on axonal sprouting in response to similar skin located within the domain of the parent nerve.

1367 ONTOGENETIC TIME-TABLE FOR THE DEVELOPMENT OF THREE FUNCTIONS IN INFANT MACAQUES AND THE EFFECTS OF EARLY HIPPOCAMPAL DAMAGE UPON THEM. Helen Mahut and Stuart Zola*, Psychology Dept., Northeastern Univer., Boston, Mass., 02115.

Adult monkeys with either fornix or hippocampal ablations are impaired on spatial reversal and object discrimination retention tasks. At the same time, their performance is facilitated on object discrimination reversal tasks. We investigated the effects of early brain damage in 8 infants with bilateral fornix sections and 8 with ablations of the hippocampus performed between 42 and 82 days of age. Five unoperated infants, matched for age, and corresponding groups of juveniles served as control animals. Effects of surgery were first assessed post-operatively at the ages of 3 to 6 mos.

Two functions impaired, one unaffected. Early surgery affected performance on two of the three tasks: infants with either fornix or hippocampal ablations were impaired on both the spatial and retention tests. In contrast, the capacity underlying performance on the object discrimination task was unaffected: unlike adult monkeys, infants in either of the two operated groups did not show facilitation of performance.

A comparison between the performance of normal infants on all three tasks with that of normal adult and juvenile monkeys, 4 and 2 yrs of age, respectively, revealed a possible time-table for the development of different functions. Spatial reversal ability is fully developed by 3 to 6 mos., as is the ability involved in retention tests. However, on the object discrimination reversal task, the performance of normal infants, at 3 and even at 16 mos. of age, was significantly worse than that of adult monkeys. The performance of juveniles fitted between that of adult and infant monkeys. It appears, therefore, that the capacity necessary for efficient performance on this task matures fully closer to 3 than to 2 yrs of age.

Thus, the effects of early damage to the hippocampal system correspond to the presence or absence of a mature capacity at the time of surgery. The apparent "sparing" of the capacities involved in object discrimination reversal learning was due to their immaturity at around 2 mos. of age.

Recovery of initially impaired functions was assessed by re-tests at 1 and 2 yrs of age. On the whole, performance of all operated animals improved with time and practice on both the spatial and retention tasks. However, infants appeared to recover at a somewhat slower rate than juveniles with equivalent ablations. Supported by NICHD Grant HD08135.

1368 EFFECT OF PRIOR LESION OF FRONTAL CORTEX ON RECOVERY FROM LATERAL HYPOTHALAMIC DAMAGE AND ON NEOSTRIATAL DOPAMINE. L. Misantone, D. Roundtree* and L. Lombardi*, Anatomy Department, Hahnemann Medical College & Pennsylvania College of Optometry, Philadelphia Pa. 19102.

The loss of body weight and decrease in food intake seen after unilateral damage to the lateral hypothalamus (LH) is due partly to interruption of the dopamine (DA) nigrostriatal projection (NSP, Ungerstedt, '71). Prior interruption of the serotonergic projection of the dorsal raphe nucleus (DRN) to neostriatum does not protect from LH damage, nor do DRN lesions alone lower body weight (Misantone, '76). If made prior to bilateral LH lesion, bilateral FC damage ameliorates weight loss (Glick & Greenstein, '72). Since FC also projects to neostriatum, the sparing from weight loss might be due to sprouting induced within the NSP by the prior cortical damage.

Three days after subtotal unilateral FC ablation, two groups of rats showed equivalent, statistically significant body weight losses, while a third unoperated group's weight did not change. Body weights were equivalent 28-31 days later, when unilateral subtotal LH lesions of the NSP were made in all three groups. Seven days after LH lesion, body weight of a group with ipsilateral LH + FC lesions (263.2 $\pm$ 31.1g.) was significantly greater than that of groups with LH lesion contralateral to FC damage (196. $\pm$ 27.9 g.) or with LH damage alone (220.5 $\pm$ 36.0 g). Food intake followed a similar pattern. The reduction in DA concentration on the LH lesion side was equivalent in the three groups at seven days. Thus, the sparing from weight loss was not due to unequal NSP damage. DA concentrations on the side opposite to the LH lesion in both cortical damage groups was not greater than control. Therefore, increased DA content in response to vacated FC sites did not occur. The protective effect was obtained only with prior FC lesions that were ipsilateral to the LH damage. While lesions of any of the three systems (LH, DRN, FC) would interrupt projections to neostriatum, only LH lesions alone and FC lesions alone significantly reduce body weight. Thus to reduce the effect of LH damage, it appears that the initial lesion must be within a system which overlaps the LH in behavioral function as well as in anatomical projection. (Supported by Sigma Xi and MH 28782-01)

1369 PERSISTENT ENHANCEMENT OF THE MONOSYNAPTIC REFLEX AFTER DORSAL COLUMN HEMISECTION IN THE CAT. F.R. Morales* and E.E. Decima. Dept. Anat., UCLA Sch. Med., Los Angeles, CA 90024.

The aim of this project was to determine whether any changes were present in the synapses of a given axon at various periods after the section of one of its collateral branches. The synapses studied were those between 1A fibers and alpha motoneurons in the cat spinal cord. In the case of the cat, the 1A fibers from the hind leg reach the cord at the L6-S1 level and divide inside the dorsal column (DC) into ascending and descending branches. The primary afferent collaterals involved in the monosynaptic reflex (MR) to be studied arise also from these branches at the same segmental levels (L6-S1). The ascending branches continue inside the DC until segment L3 is reached, level at which they start leaving the DC in order to make synapses with the Clarke's nucleus cells (Lloyd and McIntyre, 1949).

The preliminary surgery consisted in severing the ascending branches of the 1A fibers by performing a DC hemisection at the level of L3 or L4 in adult cats. Final experiments were carried out in decerebrated-low spinal animals, and the MR of the gastrocnemius lateralis and soleus (GLS) motorpools were studied simultaneously in both sides. One month after the DC hemisection, the MR in the operated side was larger than in the contralateral (non-operated) side. This difference increased during periods of post-tetanic potentiation (PTP). Both results were observed up to four months after the operation. However, these effects were not present in animals studied four days after the DC hemisection. Similar effects during PTP had been observed in our pilot experiments with DC hemisection in rats (Decima et al., Neuroscience meetings, 1976). Two groups of control animals were also studied. One group consisted of normal (unoperated) cats and it was used to test the assumption that normal animals have symmetrical MR's (i.e., similar magnitudes of the left and right MR's recorded in the GLS pools). The other control group was a series of cats in which the dorsal root ganglion of the L3 and/or L4 segments had been removed in one side, 30 days or more before the final experiments. The purpose of this group was to assess the possible effect of partial denervation of GLS motoneurons produced by the DC hemisection, since this operation severed not only ascending, but descending branches of primary afferents as well. The results obtained with the two control groups showed similar magnitude in the MR's of the left and right GLS motorpools.

The persistent enhancement of the MR observed after an ipsilateral DC hemisection is tentatively attributed to a change in the synaptic efficacy of the 1A presynaptic terminals produced as a result of cutting 1A fiber collaterals (i.e., the ascending branches). (Supported by NINDS grant #7154.)

1370 A POSSIBLE BASIS FOR SHORT TERM STORAGE. Robert U. Muller* Dept. Physiol., Downstate Medical Center, SUNY, Brooklyn, N.Y. 11203 (Spon. Samuel Feldman)

Thin lipid membranes modified with an antibiotic called monazomycin (Mon) exhibit a strongly voltage dependent conductance which is reminescent of the K+ gating system of nerve membranes. Thus, in response to a step of voltage, the conductance rises in an "S"-shaped fashion to a steady state, while at offset there is an exponential-like decline. Two of the differences between these conductances should be noted. First, the Mon system is much slower; steady states occur after seconds rather than after fractions of a millisecond. Second, the Mon induced conductance does not depend on the presence of membrane bound channels which open or close with voltage. Instead, Mon enters and leaves the membrane as the voltage is altered; a channel is created by the aggregation of several ($\sim$6) individual molecules. The number of channels (and therefore the conductance) depends on the amount of Mon in the membrane. It is this membrane amount which is controlled by voltage. A most interesting facet of the behavior of Mon induced conductance has to do with its ease of entering and leaving the membrane; it appears that the rate constant of movement between membrane and solution is a function of the amount already in the membrane. Thus, at the end of a voltage step the molecules leave rapidly, but, as the membrane concentration declines, further exit becomes more and more difficult. As a result, residual effects of a single stimulus can be seen hours after the conductance has gone to zero, due to trapped individual molecules. Thus, in a nerve membrane, Mon could act as a parallel conductance system with a memory of past voltage changes.

The presence of such a molecule in the cytoplasm of a post-synaptic cell (or released by a pre-synaptic cell along with a transmitter) would allow for synapses whose strength is a function of their history of activity. For instance, if a Mon-like molecule entered the membrane during an EPSP and induced a K+ or Cl^- conductance, the magnitude of subsequent EPSPs would be reduced; thus we would have an habituating synapse. Simply changing the channels to Na^+ selective would produce a potentiating synapse.

Even more interesting is the possibility of building an excitatory synapse whose strength depends on the closeness in time of an EPSP and a post-synaptic action potential - a "Hebb" or successful synapse. If the synapse were located on an electrically inexcitable dendrite so that the action potential magnitude was attenuated, simultaneous occurrence of an EPSP and an action potential would lead to a much larger voltage change than either one alone, and given the right permeability properties of the newly created channels, to a potentiation of subsequent EPSPs.

1371 REINNERVATION OF PARTIALLY ABLATED TECTUM IN ADULT GOLDFISH. M. Murray and S. C. Sharma. Dept. Anat., Med. Coll. Pennsylvania and Dept. Ophthal., N.Y. Med. Coll., New York, N.Y.

When the caudal half of the tectum is removed from an adult goldfish, the entire retinal projection becomes compressed upon the remaining rostral half tectum. The optic fibers are therefore capable of reorganizing their synaptic connections while retaining their topographical order. In one group of fish, incomplete ablations of the caudal tectum were made so that the caudalmost 1/8 of the tectum was spared in addition to the rostral half. 10-12 months later, they were anaesthetized and evoked potential maps were made of the projection of the contralateral retina upon the partially ablated tectum. The fish were then perfused with a modified Karnovsky fixative and the tecta prepared for electron microscopy. The retina was found to project to both parts of the tectum but the organization of the projection differed. The nasalmost retina projects to the caudal remnant while the remaining retinal projection is compressed upon the rostral half tectum. Together these projections represent the entire retina. The caudal tectal remnant therefore retains the properties which attract the appropriate fibers and this attraction operates over a relatively large distance. The morphology of the stratum opticum and SFGS of the caudal remnant is similar to that of the rostral half tectum. They differ from unoperated tecta in that retinal fibers in the experimental SFGS are organized into fascicles which contain both myelinated and unmyelinated fibers. Thus regeneration into partial tecta is similar to regeneration into the intact tectum. The fibers which innervate the caudal remnant form a distinct bundle which leaves the rostral half tectum, passes caudally over the site of the ablation and enters the caudal remnant. The axons in this bundle at this late post-operative period are mostly myelinated and of large diameter. Axons regenerating into intact tectum are intimately associated with glial cells. In contrast, these axons are embedded in a sheath formed by a loose association of glial and meningeal cells and by abundant fibrillar material. The non-neural cells associated with regeneration of axons to the caudal remnant thus differ from those associated with regeneration into intact tectum. 1372 RECOVERY AFTER SPINAL NERVE LESIONS: REFLEX RECOVERY AND SPROUTING. Jocelyn Prendergast, Michael E. Goldberger and Marion Murray. Dept. Anatomy, Med. Coll. Penna., Phila., Pa. 19129.

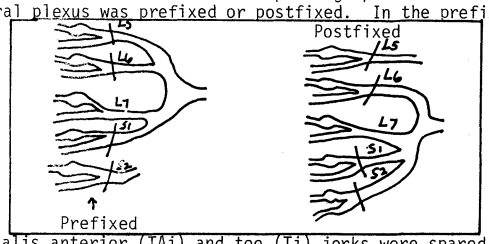
L_7 spinal nerve was isolated by unilateral section of $L_{5,6}$, and $S_{1,2}$ spinal nerves. On day 1 post-op. two different patterns of tendon reflexes were found depending upon whether the lumbosacral plexus was prefixed or postfixed. In the prefixed class



tibialis anterior (TAj) and toe (Tj) jerks were spared, ankle (Aj) and lateral hamstrings (LHj) jerks were abolished. In the postfixed class the Aj and LHj survived, TA was eliminated. The Tj in the postfixed class was unpredicable. The knee jerk (Kj) was abolished in all cats. Beginning day 3 p.o. patellar tap in both groups elicited abnormal reflex responses including internal rotation and protraction of the hip instead of the normal response leg extention. The new response may be due to an unmasking of an already existing reflex. The residual weakened reflexes became stronger, and some became clonic. Reflexes which were initially absent returned in some cats at ten days. The time course of recovery of lost reflexes was, therefore, greater than that for recovery in strength of spared reflexes. Intramuscular axons and motor end plates were studied by methylene blue staining. At 3 days p.o.: 1) muscles with normal reflex function had equivalent numbers and appearance of axons and end plates on control and denervated sides, 2) muscles with reduced reflexes showed greater numbers of degenerating axons, and 3) muscles with no reflex showed almost total denervation. By the second postoperative week collateral sprouting (increased axon branching) had developed both in muscles with initially weak and initially absent reflexes. The axons of the latter muscles were thinner, often more beaded, fewer in number, and more branched. The more normal appearance of axons in muscles with increased strength suggests that the sprouting is intrinsic (homonymous). Mediation of lost-then-recovered reflexes could be by extrinsic (heteronymous) sprouting and might take longer.

1373 EFFECTS OF NEONATAL CORTICAL ABLATIONS UPON THE RESPONSE PROPERTIES OF SUPERIOR COLLICULAR NEURONS IN THE GOLDEN HAMSTER. Robert W. Rhoades* and Leo M. Chalupa, Dept. Psych., Univ. Calif. Davis, CA 95616.

We have previously shown (J. Physiol., 1977) that the incidence of directional selectivity for superior collicular neurons in adult hamsters is markedly reduced by acute unilateral removal of the ipsilateral visual cortex. In view of the many recent anatomical demonstrations of reorganization following neonatal damage in the visual system of this, and other rodents, we sought to determine whether or not unilateral removal of posterior neocortex performed during infancy resulted in the same pattern of changes in collicular functional organization as those obtained following similar lesions carried out in adulthood.

All of the hamsters employed in this study underwent complete unilateral aspiration of posterior neocortex on the seventh postnatal day and the responses of visually activated superior collicular neurons were investigated during adulthood (5 to 9 months of age) using conventional extracellular recording and receptive field mapping techniques. In particular, we examined (a) directional selectivity, (b) speed preferences, and (c) response type, magnitude, and latency, to flashed spots of various sizes.

As was the case following lesions performed during adulthood, neonatal removal of visual cortex dramatically reduced the number of directionally selective neurons encountered in the superficial laminae of the ipsilateral superior colliculus. The distribution of preferred directions for those cells which did exhibit selectivity, like that in both normal and acutely lesioned adults, indicated a preference for movement with an upward component. The distribution of speed preferences for the cells tested in the hamsters lesioned during infancy was also different from that observed in normal adults, with the lesioned animals having a greater percentage of cells which yielded responses only to relatively slowly moving stimuli. Responses to stationary, flashed spots for collicular cells in the neonatally damaged hamsters, were, on the other hand, not appreciably different from those which we have observed in normal adult hamsters (Exptl. Neurol., 1977).

These findings suggest that the anatomical reorganization which might be expected to occur following unilateral neocortical ablations in infant hamsters (a question presently under investigation in our laboratory) may not induce corresponding changes in the collicular functional organization of this species.

1374 LOW FREQUENCY DEPRESSION IN THE IN VITRO FROG SPINAL CORD. Hilliard R. Rogers*, William B. Levy, and Duke E. Cameron*. Dept. of Psychology, UCR, Riverside, CA. 92521 and School of Medicine, Yale University, New Haven, CT. 06520.

The lateral column-ventral root reflex (LC-VRR) of the isolated frog spinal cord displays several forms of homosynaptic plasticity and is currently being studied as a model of behavioral habituation. The experiments presented here attempt to further specify the processes involved in the low frequency depression characteristic of this monosynaptic system.

2M NaCl filled pipettes were used to record extracellular presynaptic and postsynaptic focal potentials from the lumbar motoneuron pool in response to trains of 2,4, or 12 stimuli delivered to the LC at .2 or .5 Hz. Under these conditions the presynaptic potential demonstrated a decrement which closely paralled that of the postsynaptic potential and the VRR. Although presynaptic decrement could be observed in the majority of motoneuron pools sampled, many sites within these same pools did not display the phenomenon. Recordings from the LC during repetitive stimulation showed no decrement in the afferent volley during decrement of the presynaptic potential. In several preparations showing good decrement of presynaptic and postsynaptic potentials synaptic transmission was suppressed by increasing bath levels of magnesium (Mg^{++}). Though the postsynaptic potential was abolished, presynaptic decrement persisted. It was concluded that the observed presynaptic decrement was not due to decrement at the site of LC stimulation, and was independent of calcium (Ca^{++}) coupled transmitter release. In a second series of experiments transmitter release was varied by the use of high Mg^{++}, low Ca^{++}, and high Ca^{++} bathing solutions. Depression of the LC-VRR to trains of 4 or 10 stimuli presented at .2 or .5 Hz was monitored under these conditions. While changes in bath levels of Ca^{++} and Mg^{++} altered LC-VRR amplitude as predicted by the effect of these ions on the transmitter release process, such changes did not alter relative depression to repetitive stimulation.

The results of these experiments suggest that the mechanism of low frequency depression in this monosynaptic system is not one of transmitter depletion, but more likely explained by alterations of processes preceeding the influx of Ca^{++}.

1375 PLASTICITY IN THE VISUAL SYSTEM OF THE DEVELOPING CHICK. L. A. Rogers*, T. E. Finger and W. M. Cowan. Dept. Anat. and Neurobiol., Sch. Med., Washington Univ., St. Louis, MO 63110.

Chicks in which an unilateral mesencephalic alar plate ablation was performed between Stages 8 and 12 of the Hamburger and Hamilton series (about 36 hours of incubation) exhibit varying degrees of regeneration of the optic tectum. By the time of hatching, the regenerated tectum may have a volume anywhere between 20 and 65% of that found in a normal chick at the same stage of development. In the cases with the most severe loss of tectal tissue, a prominent abnormal retinal projection was observed terminating in the *ipsilateral* area pretectalis, n. lentiformis mesencephali, n. principalis precommissuralis and n. dorsolateralis anterior thalami. To reach these ipsilateral nuclei, the retinal fibers decussate in the optic chiasm and then re-cross the midline in an anomalous pretectal commissure. The magnitude of this aberrant ipsilateral projection appears to be directly proportional to the degree to which the tectum failed to regenerate.

In some chicks, the alar plate was removed unilaterally, together with either the ipsilateral or the contralateral optic vesicle. In these cases the remaining eye has been found to project bilaterally upon both the unregenerated and the regenerated tectum.

These findings resemble rather closely those of Schneider (1973) who has found anomalous projections to the thalamus in hamsters subjected to early partial or complete lesions of the superior colliculus. Both sets of observations are compatible with the view that when deprived of their principal projection field, retinal axons may expand their zones of termination as if to "conserve the quantity of their terminal arborizations". At present we have no evidence that the aberrant retinal projection upon the ipsilateral tectum in our monocular chicks is functional.

1376 EFFECTS OF PRIOR LONG-TERM TECTAL DENERVATION ON THE RETINAL PROJECTION IN GOLDFISH. Martha Romeskie and S. C. Sharma. Dept. Ophthal., N.Y. Medical College, New York, N.Y. 10029.

In goldfish, immediately following half-tectal ablation or rotation of a piece of tectal tissue combined with optic nerve cut, the regenerating retinal fibers initially project to their original tectal termination sites. Murray (J. Comp. Neur. 168:175, 1976) has proposed that this projection pattern is due to selective attraction between the regenerating axons and the degenerating axonal processes and myelin sheaths of the severed set of optic fibers and their associated glial cells. This debris is present for several months after optic nerve cut. According to this "debris guidance" hypothesis, the initial projection formed by axons regenerating to a tectum lacking degenerating debris should be compressed after half-tectal ablation and normal after tectal rotation. The present study tested these predictions.

The left eye was removed from a group of goldfish. One year later, when no debris is observed in the right tectum, the left tectum was ablated or a piece of the right tectum was rotated. The new projection from the right eye to the ipsilateral tectum was mapped electrophysiologically. In the half-tectum group, all animals in which an ipsilateral projection had formed showed strong evidence of immediate compression; thus the retinal fibers did not appear to return initially to their original tectal sites in the absence of degenerating debris.

However, in the tectal rotation group, the projection to the rotated piece of tissue was correspondingly rotated; the retinal fibers did return to their original tectal sites.

These results suggest that debris guidance may be responsible for the delay in adjustment to a size disparity between retina and tectum, but that it does not affect the retention of the original polarity of the tectum.

1377 REDUCED RATE OF SYNTHESIS OF DOPAMINE-β-HYDROXYLASE IN NUCLEUS LOCUS COERULEUS DURING THE RETROGRADE REACTION. R.A. Ross, T.H. Joh, and D.J. Reis. Lab. of Neurobiol., Dept. of Neurol., Cornell University Medical College, New York, NY 10021.

Lesions of the axons of ascending noradrenergic fibers in the posterolateral hypothalamus of rat results in a reversible reduction in the activity and amount of dopamine-β-hydroxylase (DBH)in the parent cell bodies of the nucleus locus coeruleus (LC) 7-21 days following the lesion (Ross et al Brain Res 92:57, 1975). To determine if the reduced accumulation of DBH protein during the retrograde reaction in LC neurons is due to the reduced enzyme synthesis, we followed the rate of incorporation of amino acids into DBH protein in the LC of lesioned and control rats. Electrolytic lesions were placed in the right posterolateral hypothalamus of 10 rats. Twelve days later, during the peak reduction in DBH protein, lesioned rats and unlesioned littermate controls were anesthesized and the IVth ventricle perfused for 30 minutes with 100μl of mock CSF (3.3 μl/min) containing 3H-leucine (s.a. 60 Ci/mmole) or 3H-lysine (s.a. 73 Ci/mmole) and the anesthesia discontinued. At various times thereafter (0,3,and 6 h), the rats were killed and the right LC removed. DBH protein was isolated by immunotitration with a specific antibody to rat DBH followed by SDS electrophoresis. The rate of incorporation of 3H-leucine into both DBH protein and total (TCA-precipitable) protein was linear for up to 6 hours. The rate of incorporation of 3H-leucine into DBH protein in LC of control rats was 358.3±22.6 dpm/h/2 LC. At 12 days following posterolateral hypothalamic lesion, the rate of incorporation was reduced to 221.7±16.4 dpm/h/2 LC, or to 61.8±4.5% of control ($P<.001$). The rate of incorporation of 3H-leucine into total protein did not differ in lesioned and unlesioned rats. Similar results were obtained with 3H-lysine. The percent reduction in 3H-amino acid incorporation into DBH protein closely approximates the percentage decrease in the activity and amount of DBH protein found during the retrograde reaction. We conclude that the reduced accumulation of DBH protein in the LC of rat during the retrograde reaction is due to a decreased rate of de novo synthesis of DBH enzyme protein.

1378 NEURON-TARGET INTERACTIONS EXPLAIN COMPETITION BETWEEN SALAMANDER MECHANOSENSORY AXONS. Sheryl A. Scott and Jack Diamond. M.R.C. Group in Developmental Neurobiology, Dept. Neurosciences, McMaster Univ. Med. Ctr., Hamilton, Ontario, Canada L8S 4J9.

We know that each rapidly-adapting mechanoreceptor in the dorsal skin of the salamander hind-limb is functionally innervated by only one parent axon, and is morphologically comprised of a single Merkel cell with a few closely apposed nerve terminals; each cutaneous mechanosensory axon supplies a number of such "touch spots". We have now investigated competition between axons for individual sensitive spots: (i) a "foreign" and an appropriate nerve were sectioned and encouraged to regenerate simultaneously into a denervated region of skin, and (ii) a cut nerve was permitted to regenerate into its own skin, which at the same time was becoming innervated by collateral sprouts of neighbouring intact axons. Mechanosensitive spots subsequently reappeared with a density and threshold range similar to that in normal skin, and as usual each spot was innervated by only one axon. Regenerating axons show no obvious preference for their original skin region, and indeed can be excluded from it by collateral innervation from neighbouring intact fibres. Those axons which arrive first appear to have the advantage, and establish their exclusive territory down to the level of the individual touch spots. We have provided evidence that in the salamander skin the targets for mechanosensory nerve endings are Merkel cells, and that these cells survive denervation (Cooper, Scott, Diamond: Soc. for Neurosciences Symp., 1976). Our new results support the indications that Merkel cells exert an attractive influence on cutaneous mechanosensory nerves in the salamander, and that this influence disappears when the Merkel cell becomes innervated.

1379 AN ELECTRONMICROSCOPIC STUDY OF THE MATURATION OF REINNERVATING SYNAPSES WITHIN THE SPINAL CORD OF THE ADULT CAT. R. H. Seall*, and R. E. Kingsley. South Bend Center for Med. Ed., Indiana University, South Bend, IN. 46556.

Ventral roots of L_7 were grafted to the ganglionectomized dorsal roots of L_6 in the spinal cord of adult cats according to the method of Barnes and Worrall. The underlying ultrastructural characteristics of this phenomenon during the course of reinnervation have been previously described (Seall & Kingsley). The present study characterizes synapse maturation in vivo as compared with synapse formation in tissue culture (Rees et. al.).

Two types of new synapses, those resulting from reinnervation of the spinal cord by the ventral roots, and those due to presumed axonal sprouting have been observed. They were differentiated by section of the graft prior to fixation, and noting the resultant signs of degeneration in the boutons derived from reinnervating axons. These two types of immature synapses exhibit the same pattern of maturation.

The most immature synapses which we have observed have a synaptic cleft of 150A, few vesicles, and some post-synaptic specialization. This corresponds to a stage in tissue culture which is approximately 24 hours following the initial contact between the growth cone and the neuron. We have observed both round(350A) and oval (180Ax550A) vesicles within a single immature bouton, along with occasional large (700A) dense core vesicles. As the synapse matures, the synaptic cleft widens to between 220A and 280A, a pre-synaptic density develops, and the large dense core vesicles disappear. Also, during the maturation process, the number of vesicles within the bouton increases and they assume a homogenious shape. While we have observed mature boutons containing only round or only oval vesicles, those derived from reinnervating axons all appear to have only round vesicles. In general, the maturation of developing synapses in vivo, whether derived from reinnervating axons, or from axonal sprouts, is similar to that which has been reported in tissue culture.

1380 LESION-INDUCED PLASTICITY OF HIGH AFFINITY CHOLINE TRANSPORT IN THE DEVELOPING RAT FASCIA DENTATA. David L. Shelton*, J. Victor Nadler and Carl W. Cotman, Dept. Psychobiol., Univ, Calif., Irvine, CA 92717.

After removal of the perforant path input to the rat fascia dentata at the age of 11 days, cholinergic septohippocampal fibers invade the denervated area. We have now examined the effect of this lesion on high affinity choline transport, a specific property of presynaptic cholinergic membrane. For this purpose, particulate fractions prepared from molecular (denervated) and granular layers of fascia dentata were incubated at 38°C with 0.1 μM [^{3}H] choline in the presence or absence of 0.8 μM hemicholinium (a selective inhibitor of high affinity transport at this concentration). Equivalent layers from the fascia dentata contralateral to the lesion served as controls.

Unilateral removal of the perforant path fibers increased the initial velocity of choline transport in the ipsilateral fascia dentata within 1 day. Studies conducted 5-104 days after operation showed a consistent 55-65% elevation (on a protein basis) in the denervated area. In contrast, choline transport in the granular layer was similar on operated and control sides. Treatment of the rats immediately before sacrifice with pentylenetetrazole or pentobarbital, drugs previously shown to raise or lower choline transport by drastically altering impulse flow in the septohippocampal fibers, failed to abolish the lesion-induced increase, suggesting that removal of the perforant path fibers did not elevate choline transport solely by increasing the endogenous firing rate. Calculation of choline transport on a whole regional, rather than protein, basis revealed that fasciae dentatae from operated and control sides transported choline at approximately equal rates, but on the operated side a greater percentage was transported by structures from the molecular layer and a lesser percentage by those from the granular layer. The changes in high affinity choline transport coincided spatially and temporally with the reactive growth of septohippocampal fibers. Our results suggest that septohippocampal fibers react to perforant path lesions during development by rapidly establishing more synapses than normal in the denervated area at the expense of deeper layers and that the anomalous presynaptic elements persist into adulthood. (Supported by NSF grant BNS76-09973).

1381 DEVELOPMENT OF FUNCTIONAL RETINOTECTAL CONNECTIONS IN CULTURES OF EMBRYONIC MOUSE EXPLANTS. Neil R. Smalheiser*, Stanley M. Crain and Murray B. Bornstein. Dept. of Neuroscience, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

Explants of retina and whole superior colliculi (tecta) from 13- and 14-day mouse embryos were cultured on collagen-coated coverslips in Maximow slide chambers for up to 6 weeks. Retinal explants developed characteristic "rosettes", and laminar arrays of neurons and glia (e.g. LaVail and Hild, Z.Zellf. 114:557,'71). Small isolated fragments showed diffuse neuritic outgrowth, whereas in explants of the whole eyeball, large single optic nerves emerged within the first few days after explantation. Recordings of individual retinal or tectal explants (with 3-5 μ electrodes) showed organotypic spontaneous and electrically-evoked repetitive spike and slow-wave patterns, with characteristic pharmacologic sensitivities to d-tubocurarine, strychnine, and bicuculline (10^{-6}-10^{-5}M) (Smalheiser, Crain and Bornstein, Anat. Rec. 187:780,'77). Preliminary data from two eyeballs maintained for several weeks in vitro indicate that a spike-barrage response may occur at a long latency (1-2 sec) after a light flash, but no response to light was seen in isolated retinal explants. In retinotectal co-cultures, single focal stimuli in the retinal explants (with 5-10 μ electrodes) evoked characteristic tectal responses at stimulus strengths much lower than needed to backfire tectal neurites. Stimuli applied to retinal neurites in the outgrowth far from the tectum also evoked similar tectal responses. The threshold to elicit tectal responses was low only within a narrow zone of depth in the retinal explants, similar to the optimal depth for recording retinal spike activity. These data, and other controls, indicate that functional retinotectal connections developed in vitro.

Microelectrode mapping is being used to trace growth of retinal neurites into the tectal explant, and to see if they may project to specific regionally localized sites in explants of the whole tectum (cf. sensory target zones in DRG-cord-medulla explants: Crain and Peterson, Science 188:275,'75). Electrophysiologic analyses in co-cultures of retinal pieces with whole tecta suggest that groups of individually characterized axons arising from ganglion cells in a small region of the retinal explant tend to arborize within a restricted zone of the tectal explant, while axons from another retinal locus tend to be associated with a different tectal zone. Topographic mapping of whole, oriented explants of retina and tectum is currently being pursued, both with electrophysiologic and peroxidase transport techniques.

(Supported by grants 5T5 GM 1674 from NIH; NS-06545, -06735 from NINCDS; BMS75-03728 from NSF; and the Alfred P. Sloan Found.; N. Smalheiser is a trainee in the Medical Scientist Training Program at Albert Einstein Coll. Med.)

1382 EFFECTS OF NEONATAL VISUAL CORTEX DAMAGE ON LATERAL SUPRASYLVIAN VISUAL AREA NEURONS: EVIDENCE FOR FUNCTIONAL COMPENSATION. Peter D. Spear and R. E. Kalil. Dept. of Psychology and Dept. of Anatomy, University of Wisconsin, Madison, Wisc. 53706.

Visual cortex damage in kittens produces less severe behavioral deficits than similar damage in adult cats. Indeed, the kittens may develop normal form and pattern vision in spite of the lesion. Anatomical experiments indicate that an unusually heavy projection develops from retina to thalamus to the lateral suprasylvian visual cortex (LS area) in such animals (Kalil, unpublished). In addition, there is behavioral evidence that the LS cortex is involved in the recovery of form and pattern vision following visual cortex damage in adult cats (Baumann & Spear, Brain Res., 1977, in press). These findings led us to investigate whether neonatal visual cortex damage results in altered development of the functional properties of LS cortex neurons.

Kittens received unilateral visual cortex damage (areas 17, 18, and 19) when they were one day old, and single unit recording was conducted in LS cortex when they were 7-8 months old. The receptive field properties were compared with the properties of LS cortex cells in normal cats (Spear & Baumann, J. Neurophysiol, 1975, 38:1403) and in cats with unilateral visual cortex damage incurred as adults (Spear & Baumann, Neurosci. Abs., 1975, 1:62). In normal cats, 81% of the LS cortex cells are direction selective, and most (65.5%) of the cells are binocularly driven. Following unilateral removal of visual cortex in adults, there is a marked reduction in the percent of cells with direction selective receptive fields (21.5%), and an increase in the effectiveness of stationary flashing stimuli among the non-direction selective cells. In addition, the majority of cells (56.5%) now are driven only by the contralateral eye.

The effects of neonatal visual cortex damage are very different. The receptive fields of LS cortex cells appear normal in these animals--in spite of the absence of visual cortex. Most (74.5%) of the cells are direction selective, and their directional tuning is normal. The cells respond poorly to stationary flashing stimuli, just as in normal cats. The percent of binocularly driven cells (66%) also is normal. Thus, there is a functional compensation in LS cortex following neonatal visual cortex damage. It appears that the LS cortex cells use the anomalous retino-thalamo-cortical inputs to develop receptive field properties normally provided by the missing visual cortex inputs.

1383 CELL PROLIFERATION IN THE "COMPRESSING" OPTIC TECTUM OF GOLDFISH. James A. Stevenson. Dept. Psychology, Dalhousie Univ., Halifax, Nova Scotia, Canada.

The phenomenon of visual field compression in the goldfish tectum has been demonstrated repeatedly by a series of investigators using electrophysiological, anatomical, and behavioral methods. The present experiments look at morphological changes within the tectum which accompany compression. Time series studies of cell proliferation in the halved tectum were carried out to explore the possibility that the birth of new tectal cells might induce or permit the alteration in the pattern of functional connectivity which is obtained during compression.

Sixteen goldfish received bilateral optic nerve crush and unilateral excision of the caudal half of the tectum. At five day intervals from 5 to 40 days after the operation pairs of fish were injected with tritiated thymidine and were sacrificed two days after labelling. Labelling in both the halved tecta and the contralateral control tecta was similar up to 20 days after surgery. Increased numbers of labelled cells were seen in the halved tecta of fish labelled at 25 and 35 days after surgery. This labelling was seen primarily in those tectal zones which receive direct retinal input. In addition, there was a slight increase in the number of labelled periependymal cells in the halved tecta of these fish. We have observed that these periependymal cells proliferate during tectum reinnervation.

In a second series of fish which were operated and labelled in a similar manner, but which were allowed longer post-labelling survival times, labelled cells were still seen in all tecta but appeared in equal numbers in halved and control tecta.

These results indicate the existence of a minor degree of cell proliferation during reinnervation which is augmented by half-tectum excision. It is possible that this additional proliferation is a consequence of degenerative processes which accompany the fiber and axon terminal shuffling which is required during the transition from a normal to a compressed projection pattern. The results do not support the notion of a massive cell proliferation which reconstitutes, in volume or in number, a full neuronal complement to a surgically halved optic tectum.

1384 THE PHYSIOLOGICAL EFFECTS OF MONOCULAR DEPRIVATION IN VERY YOUNG KITTENS. Richard C. Van Sluyters* and Ralph D. Freeman. School of Optometry, Univ. of California, Berkeley, Ca. 94720

Recent studies conducted in our laboratory have led us to believe that coordinated binocular vision may occur very early in a kitten's life. Optical quality and interocular alignment seem adequate to support binocular vision and neonatal surgical strabismus apparently has a disruptive effect. Given these findings, it might be expected that monocular deprivation in very young kittens would cause a loss of cortical input from the deprived eye just as it does in older kittens. To investigate this possibility, we have studied the receptive field properties of cells recorded from the striate cortex of two groups of kittens ranging in age from 9 to 23 days. In a control series of normally reared kittens, the vast majority of visually responsive neurons was binocularly driven. A second group of kittens was reared with monocular lid suture beginning at 9 days and lasting for from 6 to 14 days. The cortical ocular dominance patterns of these kittens showed a marked shift in favor of the input from the nondeprived eye. We conclude that the physiological properties of cells in the kitten's visual system can be extensively modified by altered visual experience during the first 3 weeks of life.

1385 EFFECTS OF Δ^9-THC ON FREQUENCY POTENTIATION AND RECURRENT INHIBITION IN RAT HIPPOCAMPUS. D. J. Weisz*, D. L. Gunnell* and R. M. Vardaris. Dept. of Psych., Kent State Univ., Kent, OH 44242.

The effects of Δ^9-tetrahydrocannabinol (THC) on CA1 field potentials have been previously investigated in paralyzed, locally anesthetized rats. Intraperitoneal administration of 2, 4, and 8 mg/kg THC resulted in an enhancement of spike amplitudes at 30-45 min post-injection but a depression at 120-150 min. A dose of 16 mg/kg THC depressed spike amplitudes at 30-150 min. Latencies to peak amplitude increased following THC administration. In the present investigation we examined the effects of THC on low frequency potentiation (LFP) of CA1 field potentials and on the extent and time course of recurrent inhibition in the CA1 area.

Following recovery from surgical anesthesia, recordings were made from locally anesthetized, paralyzed rats. Stimulation of the Schaffer collateral branch of the CA3 axons elicited extracellular population EPSP's and spikes from the CA1 pyramids. After a stable baseline was obtained, the CA1 population spikes were potentiated by presenting 10 stimuli at 1/sec. Then a dose of 0, 2, 4, 8, or 16 mg/kg THC was administered i.p. and LFP was produced in the CA1 pyramids at 30, 60, and 90 min after drug injection. Prior to each LFP the stimulus intensity was adjusted so that spike amplitudes were within ±.75 mV of predrug baseline. Potentiation of the CA1 population spikes was attentuated in a dose-dependent manner following administration of THC. The effect was maximal at 60 min postdrug. A dose of 16 mg/kg THC almost completely blocked potentiation at 60-90 min.

In a second study the effect of THC on recurrent inhibition was examined. The stimulus intensity eliciting maximal population spikes was used. Conditioning-test (C-T) shock intervals were varied from 20- 2000 msec. Predrug data showed that inhibition was present with 20-200 msec C-T intervals. Following the initial C-T series an i.p. dose of 0, 2, 4, 8, or 16 mg/kg THC was given. In a dose-dependent manner THC increased the range of C-T intervals over which recurrent inhibition was effective, such that after 16 mg/kg THC measurable inhibition occurred at an interval of 500 msec. While increased inhibition was observed following THC at C-T intervals of 60-300 msec, there was a tendency for disinhibition to occur at a C-T intervals of 20 msec.

1386 CHANGES IN THE ABSOLUTE VOLUMES OF THE TERMINAL FIELDS OF FIBER SYSTEMS PROJECTING TO THE FASCIA DENTATA AFTER SELECTIVE DESTRUCTION OF THE MEDIAL PERFORANT PATH. Mark J. West and Jens Zimmer*, Institute of Anatomy, University of Aarhus, 8000 Aarhus C, Denmark.

Discrete unilateral lesions were placed in the medial entorhinal cortices of one day old rats, resulting in partial destruction of the medial perforant paths (MPP) to the fasciae dentatae. Previous semi-quantitative evaluations of this type of preparation have indicated that the terminal fields of fiber projections to the zones adjacent to the MPP zone (i.e. lateral perforant path (LPP) and ipsilateral-commissural hippocampal-dentate projection (IC)) occupy a larger proportion of the mature fascia dentata than they do in normal animals. However, the absolute nature of this reorganization, which may also involve the residual MPP itself, has not been clear, in that it is not known whether the terminal fields are larger or smaller than those in the normal fascia dentata.

The absolute volumes of the terminal fields of the fiber systems projecting to the fascia dentata, as defined in Timm-sulfide silver stained preparations, have been determined with the aid of a small digital computer. A preliminary comparison of the terminal fields in the deafferented fascia dentata, with those in the contralateral control fascia dentata, indicates that the absolute volume of the terminal field of the MPP is smaller, and those for both the LPP and IC are larger, on the deafferented side. The total volume of the combined terminal fields is the same on both sides, however, suggesting that the total synaptic and dendritic volume is the same in the control and deafferented fasciae dentatae.

PSYCHOPHARMACOLOGY

1387 EFFECT OF AMINO ACID MANIPULATION ON RAT SHUTTLE AVOIDANCE PERFORMANCE.[1] Perrie M. Adams, Frnest S. Barratt, Richard R. Fritz*, Phil L. Poffenbarger* and Creed W. Abell*. Depts. of Psychiatry, Human Biological Chemistry and Genetics and Internal Medicine, University of Texas Medical Branch, Galveston, Texas 77550.

Performance of shuttle avoidance was studied in groups of rats following injection of the enzyme phenylalanine ammonia-lyase (PAL). This enzyme rapidly deaminates plasma phenylalanine and tyrosine with the resulting reduction of these brain amino acids and of Dopamine and Norepinephrine at 8 to 24 hours post-injection. Brain tryptophan and brain serotonin are significantly elevated for up to 8 hours after the enzyme administration. Groups of rats were studied at 4 or 24 hours following PAL injection or following a phosphate-buffer control injection. Performance of the 4-hour animals was significantly impaired as determined by fewer avoidance responses, slower avoidance trial latencies and slower escape trial latencies. Performance of the 24-hour or phosphate-control animals were not statistically different from each other for any of these measures. Biochemical assays on the brains of these animals confirmed the elevation of serotonin in the 4-hour group and the depletion of brain catecholamines in the 24-hour post-PAL group. These results support previous findings which suggest a serotonin mediated inhibitory mechanism. In addition, these findings support the significance of amino acid imbalance in the production of behavioral changes.

1388 DOPAMINE-β-HYDROXYLASE INHIBITORS (DBHI) REVERSE THE EFFECTS OF NEUROLEPTICS UNDER ACTIVATING CONDITIONS: POSSIBLE EVIDENCE FOR A NOREPINEPHRINE (NE)-DOPAMINE (DA) INTERACTION. Seymour M. Antelman* and Cynthia A. Black* (SPON: K.R. Carlson). Dept. of Psychiatry and Psychobiology Program, University of Pittsburgh, Sch. Med., Pittsburgh, Pa. 15260.

We have recently proposed that a stress-dependent interaction exists between NE and DA (ANTELMAN and CAGGIULA, Science, Vol. 195, pp. 646-653, 1977). This hypothesis predicts that the attenuation of certain types of behavior typically seen following interference with DA function is reversible by additionally interfering with NE function under stressful but not quiescent conditions. As a test of this hypothesis we studied the effects in rats of the DA-receptor antagonist, haloperidol, when administered alone or with one of two NE-synthesis inhibitors (DBHI's), FLA-63 or Methimazole on both stress-related eating (induced by tail-pinch) or relatively unactivated, ad-lib feeding.

The results of these experiments clearly indicated that haloperidol (at 0.2 or 0.4 mg/kg, i.p.) attenuated both tail-pinch-induced eating and ad-lib feeding (during a four-hr. test). However, while both FLA-63 (at 10 and 20 mg/kg, i.p.) and methimazole (at 25 and 50 mg/kg, i.p.) significantly reinstated tail-pinch-induced eating when paired with haloperidol, they had no effect whatever in reversing haloperidol suppression of eating in the non-stress, ad-lib situation. These results support the hypothesis that stress-related interaction exists between NE (although some other β-hydroxylated amine cannot yet be ruled out) and DA.

Tail-pinch behavior appears importantly dependent on the nigrostriatal DA pathway which seems to be reciprocally related to striatal acetylcholine (Ach). It therefore seems likely that the effects of neuroleptics on tail-pinch behavior may, in part be due to an imbalance between DA and Ach in favor of the latter. This suggests the possibility that the ability of DBHI's to counteract neuroleptic effects during activating circumstances may be due to an influence of these agents (directly or indirectly) on striatal Ach. As a preliminary test of this hypothesis, we first determined that the anti-cholinesterase inhibitor, physostigmine (0.5 mg/kg, i.p.) would attenuate tail-pinch-induced eating and then tested it on this same paradigm in combination with FLA-63 or methimazole. Just as occurred with haloperidol, both DBHI's significantly reversed the attenuating influence of physostigmine on stress-induced eating.

1389 AN EVALUATION OF THE EFFECTS OF PSYCHOTOMIMETIC DRUGS ON THE CONDITIONED EMOTIONAL RESPONSE IN RATS. John M. Beaton, Wu-Fuu Liu* and Robert S. Teague*, Neurosci. Prog. and Dept. of Pharmacol. and Psychiat., Univ. of Alabama in Birmingham, AL 35294.

It has been suggested that the disease schizophrenia may be caused by either the production, or the increased production, of a methylated psychotoxin e.g. N,N-dimethyltryptamine (DMT) or O-methyl-bufotenin. Christian et al. (Ala. J. Med. Sci., 13: 162, 1976) have shown that DMT occurs in the brain of rats and in human cerebral spinal fluid. These workers have also shown that shock stress can increase the rat brain levels of DMT approximately four-fold. This finding is of interest because it has been shown that environmental stress precipitates the hospitalization of approximately 50% of schizophrenics (Beck and Worthen, Arch. Gen. Psychiat., 26: 123, 1972).

The present study was carried out to examine the effects of various compounds, d-amphetamine, DMT, mescaline and two other agents with possible anti-DMT effects, on rat behavior before and after the addition of shock stress, via the superimposition of a conditioned emotional response (CER). Eleven, male adult Long-Evans rats were trained on a variable interval (VI) 30 second schedule of reinforcement. After initial testing of each dosage of each drug in all eleven animals the CER schedule was superimposed. This consisted of eight pairings of one minute of tone followed by a brief unavoidable shock, per session. The compounds were tested again at each dose level after the CER was well established. The data for rate of bar pressing and number of reinforcements obtained for the pre-CER were compared with the CER data.

Paired-t tests showed that the CER significantly potentiated the behavior disrupting effects of amphetamine (1.0 mg/kg), mescaline (10.0 mg/kg) and DMT (5.0 mg/kg). Neither of the postulated anti-DMT agents, N,N-diethylbutyramide (DBA) and 1-methyl-1,2,5,6-tetrahydropyridine-3-N,N-diethyl-carboxamide (THPC), which had previously been shown to block the disruption of DMT of avoidance behavior blocked the behavior disruption of DMT on this VI 30 sec schedule of positive reinforcement. However, this study has shown that the addition of shock stress via the CER schedule potentiated the disruption of the hallucinogens mescaline and DMT, and of the stimulant amphetamine. The mode of action of this potentiation, i.e. whether or not the stress led to an increase in endogenous DMT, can not be determined from this study. However, it would be of interest to examine the brain levels of DMT in rats exposed to a similar CER schedule.

1390 INTERACTIVE EFFECTS OF LITHIUM AND d-AMPHETAMINE ON THE ACOUSTIC STARTLE RESPONSE IN THE RAT. Michael S. Beattie and Donald R. Britton*, Depts. of Anat. and Pharmacol., College of Medicine, The Ohio State University, Columbus, Ohio 43210.

Lithium administration (2 meq/kg/day for 6 days) has been shown to result in attenuation of amphetamine or environmentally induced increases in locomotor activity. The present study investigated the effects of lithium and d-amphetamine on sensorimotor reactivity using the acoustic startle reflex (ASR) as a measure of responsiveness.

Male hooded rats, housed in groups of 3, were injected i.p. with 2 meq/kg lithium chloride (LiCl) on each of the 6 days preceeding ASR testing. Control animals received 2 meq/kg saline. ASR testing consisted of 50 presentations of a 105 db, 2500 Hz tone given once every 60 sec. 6 LiCl and 6 saline treated rats were tested to assess the effects of lithium on ASR magnitude and habituation. 7 additional animals from each treatment condition were given i.p. injections of d-amphetamine sulfate (2.5 mg/kg, salt wgt) 5 min. prior to testing.

Initial response magnitudes, as well as the degree of response decrement over the session, were very similar for rats treated with LiCl or saline. Amphetamine given to saline treated animals produced a marked potentiation of ASR magnitudes over the course of the session, a result consistent with previous studies (Davis et al, 1975). However, amphetamine failed to produce increased responsiveness in animals treated with LiCl. Thus, while lithium had no apparent primary effect on reactivity at the dosage and schedule employed such treatments were effective in blocking the potentiation of reactivity induced by a 2.5 mg/kg dose of d-amphetamine. These results lend support to the notion that the behavioral actions of lithium may be mediated, in part, via the actions of this substance upon catecholamine systems.

Supported in part by NIMH grant MH06748 awarded to Donald R. Meyer, Ohio State University, Dept. of Psychol. and grants from H. Sonneborn, M. Colwill, M. Weiss and H. Friedberg.

1391 A NEW ANIMAL MODEL FOR SCHIZOPHRENIA: ADRENERGIC MODULATION. R.L. Borison*, H.S. Havdala* and B.I. Diamond* (SPON: V. Nair). Illinois State Psychiatric Institute and Anesthesiology Department, Mount Sinai Hospital, Chicago, IL 60612 and 60608.

Previously we have proposed phenylethylamine induced stereotyped behavior as a new animal model for schizophrenia because phenylethylamine elicited stereotypy is more sensitive than d-amphetamine induced stereotypy to blockade by antipsychotic agents. Phenylethylamine is an endogenous amphetamine-like central nervous system stimulant which is most highly concentrated in the limbic system of human brain, and phenylethylamine urinary excretion has been reported as abnormal in schizophrenic subjects. We have previously shown that chronic phenylethylamine (50 mg/kg) induced stereotypy is qualitatively and quantitatively similar to chronic d-amphetamine (3.75 mg/kg) elicited stereotypy, but that phenylethylamine induced stereotypy is preferentially blocked by the antipsychotic agents clozapine and thioridazine (Borison et al, Life Sci., in press). We now report the effects of various adrenergic agents upon both phenylethylamine and d-amphetamine induced stereotypy. Pretreatment with the α-adrenergic blocking agents phentolamine (45 mg/kg) or phenoxybenzamine (20 mg/kg) prevented phenylethylamine behavior, whereas d-amphetamine stereotypy was only partially antagonized. In contrast, propranolol (20 mg/kg), a β-adrenergic receptor blocker, reduced slightly phenylethylamine's actions while potentiating those of d-amphetamine. The catecholamine depletor α-methyl-para-tyrosine (250 mg/kg) antagonized the stereotypies induced by either phenylethylamine or d-amphetamine. When brain norepinephrine was depleted by administration of diethyldithiocarbamate (20 mg/kg), there was a blockade of phenylethylamine behavior and an augmentation d-amphetamine evoked stereotyped behavior. Studies with the aminoacid precursor to norepinephrine, dihydroxyphenylserine (400 mg/kg), showed that both phenylethylamine and d-amphetamine stereotyped behavior was potentiated. The aminoacid precursor to dopamine, L-dihydroxyphenylalanine (50 mg/kg), antagonized both phenylethylamine and d-amphetamine stereotypy. These results suggest that the stereotypies induced by chronic phenylethylamine may be mediated via noradrenergic as well as dopaminergic systems, while d-amphetamine induced behavior is most likely mediated through dopaminergic systems.

1392 DOSE DEPENDENT PSYCHOLOGIC AND NEUROENDOCRINE EFFECTS OF DEXTROAMPHETAMINE AND METHYLPHENIDATE. Walter A. Brown, Prov. VA Hospital and Brown University, Prov., R. I. 02908.

Dextroamphetamine (DA) and Methylphenidate (MP) have well documented effects on the disposition of central catecholamines and have general arousing and euphoric effects. DA has been shown to stimulate release of growth hormone (GH) and cortisol while MP stimulates GH release but not cortisol release. This study is directed toward identifying the dose response characteristics of the various psychologic and endocrine effects of DA and MP and examining the relationships among the psychologic and endocrine effects. Clarification of these relationships could provide a step toward elucidation of the central mechanisms mediating the psychologic effects of DA and MP.

49 healthy young adult men (mean age 24) ingested identical capsules containing either 20 mg DA, 10 mg DA, 20 mg MP or 10 mg MP on a double blind basis. Blood samples drawn during baseline and at 15 min. intervals for 2 hours after drug ingestion were assayed for GH, cortisol, and amphetamine (A), by radioimmunoassay. Before and 90 mins. after drug ingestion subjects completed the Nowlis Mood Adjective Check List (MACL) scored for 7 scales related to anxiety, activation and euphoria and 4 scales of the Addiction Research Center Inventory (ARCI) related to the psychologic dimensions of arousal and euphoria.

Dose (mg/kg) of DA was significantly correlated with peak serum A concentration ($r = .60$; $p = .002$) with increment in serum GH ($r = .60$; $p = .002$) and with increase on the ARCI euphoria scale ($r = .48$; $p = .009$). Dose of MP was significantly correlated with increase on an MACL euphoria scale ($r = .41$; $p = .027$) and showed a trend toward positive correlation with GH response ($r = .32$; $p = .092$). Increment in serum cortisol and psychologic changes along dimensions of activation and arousal were not dose dependent. GH response to both DA and MP was selectively correlated with responses on several scales related to the general dimension of euphoria while cortisol response was positively correlated with responses on scales measuring both arousal and euphoria.

These data suggest that dose of DA and MP is selectively related to the GH and euphoric responses. These two responses may be mediated by a central neurophysiologic process which differs from that which mediates the cortisol response and general arousal. The selective dose dependency of GH and euphoric response and their positive correlation points to a common neurochemical process, possibly involving dopamine, mediating these psychologic and neuroendocrine events.

1393 DISSOCIATION OF ACTIVE FROM PASSIVE COMPONENTS OF SEXUAL BEHAVIOR IN FEMALE RATS BY DESTRUCTION OF BRAIN CATECHOLAMINE-CONTAINING NEURONS. Anthony R. Caggiula*, James G. Herndon, Jr.*, Robert Scanlon*, Deborah Greenstone*, Wilson Bradshaw* and Donna Sharp*. Psychobiology Program, Dept. Psychology, Univ. of Pittsburgh, PA 15260 and Yerkes Primate Center, Emory Univ., Atl. GA 30322 (SPON: M. Alexander).

We have recently reported (Herndon et al., 1976) that an intraventricular 6-hydroxydopamine (6-OHDA) treatment, which produced moderate depletions of telencephalic norepinephrine (NE) and dopamine (DA) (66% and 56% respectively) resulted in moderate increases in the frequency and intensity of lordosis (the passive component of sexual behavior) in females given low doses of estradiol and tested with male rats. This effect could be markedly intensified by the addition of the CA synthesis inhibitor, α-methyl-p-tyrosine (100 mg/kg). However, neither condition resulted in the display of soliciting behavior (the active component). These results, suggesting differential effects of CA depletion on the active and passive components of female sexual behavior, have been substantiated and extended as follows.

First, ovariectomized female rats were given a hormone treatment (8 μg/kg estradiol benzoate) which normally supports only low levels of lordosis responding and no soliciting behavior. When subjected to an intraventricular 6-OHDA regimen (with pargyline pretreatment) which produced a more substantial CA lesion (85% and 95% depletions of caudate DA and cortical NE respectively), these females exhibited a 300-350% increase in the intensity and frequency of lordosis behavior, but absolutely no soliciting behavior over the 3 weeks of testing.

Second, in females given a hormone regimen (50 μg/kg estradiol benzoate plus 500 μg progesterone), which supported maximal levels of lordosis and soliciting, the same 6-OHDA treatment prolonged the average duration of lordosis while actually decreasing the incidence of soliciting behavior.

Third, we addressed the question of whether the increase in receptivity that was obtained by 6-OHDA might be due to a drug-induced release of adrenal progesterone. Experiments utilizing dexamethasone suppression of adrenal function, documented by RIA measurement of circulating progesterone, clearly show that the dramatic increase in lordosis responding produced by 6-OHDA was not associated with any measurable release of progesterone.

These results suggest an important refinement in current hypotheses relating brain CA activity to global behavioral categories such as "male" or "female" sexual behavior, and, more generally, in hypotheses dealing with the role of CA systems in sensorimotor responsiveness.

1394 RED CELL BOUND BUTAPERAZINE AND THERAPEUTIC RESPONSE IN SCHIZOPHRENIA. R.C. Casper, D.L. Garver, S. Chang, S. Ericksen, H. Dekirmenjian, J.M. Davis. Ill. State Psychiatric Inst., & Dept. Psychiatry, Abraham Lincoln School of Med., Chicago, IL 60612.

We report data relating plasma and red blood cell (RBC) butaperazine (BPZ) to therapeutic response in 23 schizophrenic and chronic schizoaffective patients during the first 2 weeks of steady dose treatment. Therapeutic response was monitored by % change in serial modified New Haven Schizophrenic Indices during the 2 week period. Mean plasma and mean RBC BPZ from day 4 through 14 of treatment was computed from data based on the assays according to the method of Dekirmenjian. Multiple curve fittings relating plasma and RBC BPZ separately to % therapeutic response revealed that the best fit was to a quadratic polynomial for both plasma ($r^2 = .267$) and RBC ($r^2 = .597$) BPZ. RBC BPZ fit significantly better ($z = 1.99$; $p<.05$) than did plasma BPZ to therapeutic response data. The data demonstrated a "therapeutic window" for blood levels of BPZ, both above which and below which schizophrenic symptoms are less well controlled by BPZ. Moreover, therapeutic response correlates better to levels of BPZ bound to the RBC than to the BPZ in plasma. RBC BPZ may better reflect quantities of drug which are effective in regulating the activity of central nervous system dopamine receptors.

1395 INVESTIGATION FOLLOWING ACUTE AND CHRONIC D-AMPHETAMINE TREATMENT IN THE GERBIL. MaryLou Cheal. Neuropsychology Laboratory, McLean Hospital, Belmont, MA 02178.

Interest in environmental stimuli often appears inappropriate in humans with amphetamine psychosis and in animals given large doses of amphetamine. Although the stereotypic behaviors elicited with amphetamine have been described as evolving from investigative behavior (Ellinwood, Sudilovsky, & Nelson, Am. J. Psychiatry, 1973, 130, 1088-1093), these fragments of normal behavior patterns become abnormally repetitious. Rats have been noted to persistently sniff at a particular area; cats move their heads as if looking around; and monkeys develop more complicated movements, coordinating hand and eye. Such behaviors often involve excessive grooming movements. In our laboratory, gerbils emit a repetitious sequence of paw licking and face washing. It is not known whether these investigatory behaviors are internally generated and not related to the stimulus, or whether the animal becomes more responsive to the object of investigation.

To answer the question, gerbils were chosen because of their extremely active, investigatory nature, and were presented with either a novel object or a socially relevant odor within a small enclosure. Following treatment with low acute (0.5-2.0 mg/kg) or chronic (0.5 mg/kg) doses of d-amphetamine or NaCl, gerbils displayed normal levels of investigation and subsequent habituation to either the object or the odor. If the object was moved to the opposite side of the arena following habituation, investigation was again elicited. Moving the odor did not renew interest. Acute treatment with 3.0 mg/kg d-amphetamine induced stereotypies in all animals and the amount of investigatory time was significantly attenuated. However, there was still significant habituation, and a significant increase in investigation when the object was moved. We conclude that, in the gerbil, amphetamine does not cause increased responsiveness to stimuli. In fact, gerbils respond selectively to specific stimuli in spite of the probability that internally generated amphetamine-induced stereotypies are competing with stimulus-elicited investigation.

1396 ACETALDEHYDE MEASUREMENTS FROM BREATH SAMPLES. H. Dix Christensen, Arthur Zeiner and Jane Drake*. Depts. Pharm., Med., and Psychiat. and Behav. Sci. Univ. of Okla. Health Sciences Center, Oklahoma City Okla. 73190.

Alveolar air concentrations of acetaldehyde should essentially reflect the biotransformation of acetaldehyde from ethanol. For many ethnic studies multiple samples need to be collected in the field. Acetaldehyde and ethanol levels were compared in breath directly and by a trapping procedure developed by Dr. Pellizzari of the Research Triangle Institute. Six fasted subjects drank within ten minutes 0.66 ml/kg of ethanol as a 20% solution in orange juice. A series of alveolar air samples were collected over three to five hours by having the subject exhale deeply at the end of normal expiration through a teflon tubing into a 25 ml serum bottle. The internal standard consisted of 12.5 ng isobutyaldehyde. For analysis one ml of headspace was used either directly or after trapping with 100 µl of 0.04M sodium metabisulfite and later released by heating to 60°C for 50 minutes with 100 µl of 0.25M "Clark and Lub's Borate Buffer" pH 8.5. There is about 65% recovery of acetaldehyde after trapping and release. Acetaldehyde and ethanol concentrations were determined by a gas chromatograph method using a Hewlett-Packard Model 402 gas chromatograph with a hydrogen flame detector. The 6 ft long, 1/8 inch i.d. glass column was packed with Porapak P 100/200 mesh. The operating temperatures were: column 110°, detector 210°C and injector port temperature 150°C. Retention times were methanol 1.6, acetaldehyde 2.2, ethanol 3.2, acetone 5.4 and the isobutyraldehyde 10.0. Elimination of moisture is critical for the direct breath method. The trapping method is effective for acetaldehyde but not ethanol.

Ethanol concentration in alveolar air increased rapidly with a $t_{1/2}a$ of 15 ± 1 minutes, reaching a peak of 32 ± 3 µg/100 ml at 37 ± 4 minutes and declined linearly with a $t_{1/2}e$ of 122 ± 7 minutes. Acetaldehyde kinetic parameters were $t_{1/2}a$ of 18 ± 1 minutes with a plateau concentration of 475 ± 18 ng/100 ml from 41 ± 3 minutes to 119 ± 14 minutes then with a $t_{1/2}e$ of 205 ± 32 minutes. Zero time was the start of drinking.

Acetaldehyde plateau levels are apparently a function of the metabolism of the individual rather than the ethanol levels. Freund and O'Hollaren (J. Lipid Res. 6 471, 1965) reported similar results of acetaldehyde rise, plateau and then decline when ethanol concentrations return to 15-25 µg/ml alveolar air range. The trapping-release method permits analysis of acetaldehyde up to a month from time of sample collection.

Supported in part by Medsera Inc. C76-01.

1397 BEHAVIORAL, BIOCHEMICAL AND MORPHOLOGICAL CHANGES AFTER INTRASTRIATAL INJECTIONS OF KAINIC ACID (KA). B. R. Cooper*, R. M. Ferris* and H. L. White*. (SPON: Warren C. Stern). Dept. of Pharmacol., Wellcome Res. Labs, Research Triangle Pk., N.C. 27709

Intrastriatal injection of KA, a cyclic glutamate analogue, has been reported to produce biochemical changes characteristic of Huntington's chorea through a selective "excitotoxic" action on acetylcholine and GABA containing neurons, sparing dopamine terminals (McGeer & McGeer, Nature 263, 517-518, 1976). It was of interest to determine how prior treatment with KA would alter the response to dopamine agonists. In our initial experiments, the effects of apomorphine were compared to those of d-amphetamine after unilateral intrastriatal injections (1 µl) of KA (1 µg - 3 µg). Rotation ipsilateral to the injection occurred after treatment with both compounds when animals were tested 2 to 30 days after KA, suggesting lesion of cells containing DA receptors. Analysis of the injected (3 µg) versus contralateral untreated striata revealed choline acetyltransferase (ChA) and glutamic acid decarboxylase (GAD) were reduced by 60% and 85% respectively 48 hrs after KA. Tyrosine hydroxylase (TH) activity remained near control levels up to 5 days but then began to decrease by 8 days after treatment. Thirty days after treatment, GAD, ChA, TH activity, as well as weight of the injected striatum were greatly reduced. Similar, but less pronounced effects were seen at lower doses of KA (1 µg - 2 µg). Reduction of GAD, ChA and TH activity and striatal mass suggests a less specific neurotoxic action of KA than proposed by earlier investigations. The apparent specificity for GAD and ChA containing cells but not dopamine (TH containing) fibers up to 8 days after injection may reflect different time courses for degeneration of cells versus fiber terminals. While KA may not be a very "selective" neurotoxin, it is interesting to note that reduced striatal mass has been found in advanced cases of Huntington's disease.

1398 DISTRIBUTION OF BUTAPERAZINE BETWEEN ERYTHROCYTES AND PLASMA PROTEINS. H. Dekirmenjian, J.I. Javaid, D.L. Garver, S. Chang, J.M. Davis. Ill. State Psychiatric Inst., Chicago, IL 60612.

Recently we noted that red blood cell (RBC) levels of butaperazine (BPZ) correlated better with clinical response than did plasma levels (Am. J. Psychiat. 134:304, 1977). Most of the plasma drug is bound to blood proteins (95%-96%). Protein bound BPZ is ionized: thus, it is not soluble in lipids and will not pass the blood brain barrier. It would be expected that the free base, being soluble in lipids, will pass the blood brain barrier. If so, central nervous system drug levels will be in equilibrium with the free drug levels in the plasma. To investigate the rationale of why RBC levels should better reflect improvement in patients, in vitro experiments were carried out to determine whether RBC levels better reflected the free levels of the drug than the plasma. Human blood was obtained from control subjects in EDTA. RBC and plasma were separated and RBC washed 2 times with tris buffer. One ml of washed RBC and 1 ml of plasma were incubated with varying amounts of BPZ at 37°C for 5 min. RBC and plasma were again separated and BPZ determined in both of the fractions. The following experiments were carried out to observe their effect on BPZ binding to RBC: effect of time of incubation, increasing BPZ concentrations, varying pH of incubation buffer, effect of dilution of plasma, BPZ binding to bovine serum albumin, effect of dilution of bovine serum albumin, binding of the drug to RBC ghosts, and binding of the drug to rat synaptosomal membrane and rat RBC ghosts. From the above experiments, it could be shown that as the free BPZ levels increased in plasma so did the RBC bound BPZ. Thus there was an equilibrium between free drug levels & RBC levels. This was not a function of pH difference between plasma (pH = 7.4) and RBC (pH = 7.2) but was due to mass action of increasing levels of the unbound drug, in the plasma.

1399 MORPHINE INDUCED STEREOTYPY: IS IT DOPAMINE, NOREPINEPHRINE, OR ACETYLCHOLINE? B.I. Diamond*, H. S. Havdala*, F. Lemus* and R.L. Borison* (SPON: W. Harrison). Departments of Anesthesiology and Neurology, Mount Sinai Hospital, Chicago, IL 60608.

The chronic administration of morphine to rats produces tolerance to its behaviorally depressant effects and evokes hyperactivity and stereotyped behavior (Randrup et al, 1976). This stereotyped behavior mainly consists of oral self-directed behaviors, i.e. gnawing at paws, and is qualitatively similar to amphetamine induced stereotypy. Considering that psychoactive drugs capable of producing stereotypy, i.e. d-amphetamine and phenylethylamine, are believed to do so by affecting central dopaminergic mechanisms, we now report pharmacological studies aimed at better understanding the mechanisms underlying morphine stereotypy. We administered morphine (20 mg/kg) daily for three weeks to produce stereotypy. The latency to onset of stereotypy was five minutes and duration of stereotypy was greater than three hours. Stereotyped behaviors consisted of gnawing at the cage floor grid and paws, increased exploratory activity and hyperreactivity. We found that chronic morphine pretreatments sensitized animals to the stereotyped behavior induced by d-amphetamine (3.75 mg/kg) or phenylethylamine (40 mg/kg) (doses which are per se subthreshold for eliciting stereotypy). Moreover, acute pretreatments with d-amphetamine or phenylethylamine potentiated morphine evoked stereotypy. The antipsychotic neuroleptic dopamine blockers haloperidol (0.5 mg/kg) or pimozide (1 mg/kg) completely blocked morphine stereotypy, whereas neuroleptics with few extrapyramidal side-effects, clozapine (30 mg/kg) or thioridazine (50 mg/kg) increased to thirty minutes the latency to onset of morphine stereotypy. The cholinergic receptor blocking agent trihexyphenidyl (50 mg/kg) failed to alter morphine behavior, but in contrast when central acetylcholine levels were raised by pretreatment with physostigmine (0.5 mg/kg), there was a delay in onset and an antagonism to morphine stereotypy. When α-adrenergic receptors were blocked with phentolamine (45 mg/kg) there was an increase in latency to onset of stereotypy of one hour before normal morphine stereotypy was generated. Our results suggest that chronic morphine stereotyped behavior sensitizes adrenergic receptors in both the neostriatal as well as the meso-limbic system and is dependent, at least in part, upon central noradrenergic and dopaminergic mechanisms.

1400 SELF-STIMULATION: EVIDENCE FOR TOLERANCE TO NEUROLEPTICS IN THE FRONTAL CORTEX. Alan J. Eichler*, Seymour M. Antelman* and Larry Kairns* (SPON: M. H. Bennett). Psychobiology Program, Dept. of Psych., Univ. of Pittsburgh, Pittsburgh, PA 15260.

Since the discovery by Thierry, et al., (Brain Res., 50: 230, 1973) of a dopaminergic (DA) innervation of the cerebral cortex, this area of the brain has been considered as a possible site of action of anti-schizophrenic agents (neuroleptics). Biochemical evidence suggests that this area does not become tolerant to the effects of neuroleptics when they are administered for 11 days (Scatton, et al.,Brain Res., 109: 184, 1976). If borne out by longer term studies, these data would lend credence to a cortical DA hypothesis of schizophrenia, since tolerance does not develop to the antipsychotic properties of the neuroleptics.

We, therefore, re-examined the question of tolerance in the cortex of rats by determining the effects of long-term spiroperidol administration on electrical self-stimulation (SS) of the frontal cortex. Spiroperidol was given daily for 4 weeks in doses of 31,62 and 125ug/kg, and bar-press rates were observed both during drug administration and withdrawal. In contrast to results which we have previously reported for the nigrostriatal bundle (NSD; Eichler, et al., Neurosci. Abst., 2: 1225, 1976), 31 and 62ug/kg failed to depress frontal cortical SS when initially injected. Decreases in rate at these doses appeared only after 2-5 days of continued treatment. Approximately 2-3 weeks into the injection period, animals administered 31ug/kg began to increase their rate and were pressing at 140% of baseline by the time of withdrawal. At 62ug/kg, bar-pressing was virtually abolished from the 5th injection day until withdrawal. Animals receiving 125ug/kg did not press throughout the drug period. During withdrawal, however, significant rate increases (25-200%) at all doses occurred, which persisted unabated for at least 5 weeks.

The acute insensitivity of frontal cortical SS to doses of spiroperidol capable of producing severe depressions in SS from the NSD is consistent with the known relative DA turnover changes produced by neuroleptics in these systems. These data also argue against a performance deficit as totally responsible for neuroleptic-induced decreases in NSD SS.

The rate increase observed at 31ug/kg of spiroperidol during treatment, as well as the sustained withdrawal rate increases at all doses, indicate that tolerance to neuroleptics may occur in the cortical DA system of rat brain. The failure of previous reports to observe biochemical tolerance could be due to an inadequate period of neuroleptic administration. These results are at variance with the suggested involvement of cortical DA in the antipsychotic properties of neuroleptics, if such extrapolations can, indeed,be made from rat brain.

1401 ALTERATION IN MOTOR FREQUENCIES WITH DOPAMINE AGONISTS AND ANTAGONISTS. Everett H. Ellinwood, Jr. and M. Marlyne Kilbey. Dept. Psychiat., Duke Univ. Med. Ctr., Durham, NC 27710.

Although diseases of the extrapyramidal system are often expressed as changes in the intrinsic frequency of motor behavior (often tremor), little information exists in the literature on the frequency effects of drugs affecting the extrapyramidal and mesolimbic systems. This report will describe the differences in movement frequency in rats induced by dopamine agonists and antagonists. Movement is quantified with an electronic transducer and the analog output is analyzed and expressed as power spectrums. Changes in the power for specific frequencies provide a statistically significant dose-response curve for such drugs as apomorphine and amphetamine. Whereas traditional neuroleptics demonstrate a linear dose-response antagonism of amphetamine-induced frequency changes, clozapine induces a biphasic response. Differences in the alterations of specific frequencies may reflect a differential effect on mesolimbic vs. the striatal dopamine system.

1402 EFFECT OF CHRONIC L-DOPA ON APOMORPHINE-INDUCED ROTATION AND SNIFFING IN RATS. Cheryl Ezrin-Waters* and Philip Seeman. (Spon: Y. Israel). Pharmacology Department, University of Toronto, Toronto, Canada.

In order to study changes in dopaminergic brain sensitivity, the effect of chronic L-DOPA on apomorphine-induced behaviour was studied, using two types of tests.

1) L-DOPA (20 mg/kg) and carbidopa (2 mg/kg) p.o. were administered daily for 21 days to male Wistar rats. The animals received an acute injection of apomorphine (8, 16, 32 mg/kg i.p.) and the total number of rotations per minute were monitored over a 30 minute test period, during which six one-minute observations were made on each animal.

2) L-DOPA and carbidopa were given for 16 days to a second group of rats. Acute injections of apomorphine (0.5 - 2.0 mg/kg i.p.) resulted in sniffing behaviour and this was measured by direct observation.

After 2-3 weeks on the L-DOPA-carbidopa combination, many animals became tolerant to the apomorphine-induced turning. Preliminary results indicate that chronic L-DOPA alters the apomorphine-induced sniffing.

1403 APOMORPHINE, BUT NOT CLONIDINE, REPAIRS DEFICITS IN LOCOMOTOR AND INVESTIGATORY EXPLORATION AFTER ABLATION OF DOPAMINE AFFERENTS TO LIMBIC FOREBRAIN AND ANTEROMEDIOVENTRAL STRIATUM. J. Stephen Fink and Gerard P. Smith. Dept. Psychiatry, Cornell Univ. Medical College and E.W. Bourne Behavioral Res. Lab., The New York Hospital, White Plains, N.Y. 10605

Bilateral injections of 6-hydroxydopamine (6-OHDA) in the anterolateral (AL) hypothalamus after pretreatment with desmethylimipramine (DMI, 25 mg/kg, i.p.) produces deficits in locomotor exploration (LE) in an open field (OF) and loss of dopamine (DA) fibers in mesolimbic, mesocortical and anteromedioventral striatal terminal fields (Neurosci. Abst. 2:454, 1976). After AL 6-OHDA-DMI injections there is little or no loss of catecholamine (CA) fibers in the norepinephrine (NE)-rich neocortex and hippocampus suggesting that DA loss within limbic forebrain and anteromedioventral striatum is sufficient, and NE loss in neocortex-hippocampus is not critical, for the deficits in LE. The present studies extend these observations to determine (1) if AL 6-OHDA-DMI injections produce deficits in investigatory exploration (IE) and (2) the effect of systemic administration of the DA agonist, apomorphine, and the α-adrenergic agonist, clonidine, on the exploratory deficits after AL 6-OHDA-DMI injections.

After AL 6-OHDA-DMI injections rats made fewer approaches to a novel object located in an alcove in the animals' home cages. After apomorphine (31-62 µg/kg, i.p.) AL 6-OHDA-DMI rats made more approaches to a novel object, but not to a familiar object or to an empty alcove. In AL 6-OHDA-DMI rats apomorphine (16-125 µg/kg, i.p.) increased LE in a novel, but not familiar, OF. The same doses of apomorphine decreased IE and LE in control rats. Because LE and IE after apomorphine in AL 6-OHDA-DMI rats is greater when the OF and object are novel than when they are familiar these responses are not simply increased random motor activity. Clonidine did not change (1 µg/kg) or decreased (100 µg/kg) IE and LE in both AL 6-OHDA-DMI and control rats.

We conclude (1) ablation of DA afferents to limbic forebrain and anteromedioventral striatum produces deficits in IE and LE, (2) NE afferents to neocortex and hippocampus do not appear to be critical to normal IE and LE in these tasks, (3) systemic administration of apomorphine after DA denervation of limbic forebrain and anteromedioventral striatum increases IE and LE to a novel, but not familiar, object and OF, and (4) DA afferents to mesolimbic, mesocortical and anteromedioventral terminal fields may subserve a permissive("arousal") function for LE and IE in the intact rat brain.

1404 ENHANCEMENT OF L-TRYPTOPHAN-INDUCED DEPRESSION OF SYMPATHETIC PREGANGLIONIC NEURONS BY LITHIUM. Donald N. Franz* and Chaichan Sangdee* (SPON: D.M. Woodbury). Dept. of Pharmacology, Univ. Utah Col. Med., Salt Lake City, Utah 84132

Previous studies in cats indicate that 5-HT precursors depress the excitability of sympathetic preganglionic neurons (SPGNs), apparently by inducing spontaneous release of 5-HT from inhibitory bulbospinal 5-HT neurons (Neumayr, Hare & Franz, Life Sci. 14:793, 1974). This system was employed as a model to test the hypothesis that lithium enhances the uptake of L-tryptophan by central 5-HT neurons thereby increasing 5-HT synthesis (Knapp & Mandell, J. Pharmac. Exp. Ther. 193:812, 1975). In unanesthetized spinal cats, microelectrode stimulation of bulbospinal excitatory pathways in the dorsolateral funiculus of the cervical spinal cord at 10/min evoked brisk sympathetic discharges from SPGNs that were recorded from upper thoracic preganglionic white rami. Sizes of evoked discharges were analyzed every 5 or 10 min by signal averaging. Evoked discharges were gradually depressed to about 50% 3 hr after LiCl (2 mEq/kg), but this effect was prevented in cats depleted of 5-HT by pretreatment with PCPA. This indicated that lithium had no effect on the excitatory pathway. L-tryptophan (100 mg/kg) alone produced little or no depression. However, 3-4 hr after LiCl, this dose of L-tryptophan gradually depressed evoked discharges by about 30%. Onset was about 30 min and maximal depression was reached about 1 hr later and maintained for several hrs. After chronic LiCl pretreatment (1 mEq/kg twice daily for 3 days), L-tryptophan (100 mg/kg) rapidly depressed evoked discharges by about 60%; onset was about 10 min and maximum effect was established 30 min later and maintained for several hours. Plasma levels of lithium (8-10 hrs after last dose) ranged between 1.2 and 1.8 mEq/L (mean, 1.5). Acute lithium pretreatment had no detectible effect on depression after 5-HTP (30 mg/kg), but chronic pretreatment almost doubled the effect of this dose. These results support the proposal that lithium increases the uptake of L-tryptophan and 5-HTP by central 5-HT terminals and thereby enhances 5-HT synthesis.

1405 POSSIBLE FELINE ANALOG OF TARDIVE DYSKINESIA. Robert B. Glassman, Harriet N. Glassman* and Christopher Frew*. Dept. Psychol., Lake Forest College, Lake Forest, IL 60045

Some psychotic patients who have been maintained on neuroleptic medication over a period of months to years develop a dyskinetic syndrome involving active movements of tongue and jaw. Considerable research has tended to localize the action of neuroleptic drugs at dopaminergic synapses in the corpus striatum (Snyder, et al., Science, 1974). Tardive dyskinesia may depend on changes in excitability there (Klawans, Amer. J. Psychiat., 1973) or elsewhere (Glassman, Behav. Sci., 1976). Cats are being prepared with chronically implanted gross electrodes at multiple subcortical and cortical loci, for recording of EEG and evoked potentials (EPs) over a period of months or years before, during, and after chronic administration of neuroleptics. In four animals so far we have seen increases in licking movements, "fly-chasing" movements of the skin of the back, and paw shakes, related to the drug treatment. These animals were observed during a three-month baseline period before being placed on chlorpromazine (25-35 mg/day orally). In the clearest case, the average number of licks was 10.8 per five-minute observation interval, taken on 13 occasions during baseline. During one month on chlorpromazine this average dropped to 6.7 licks. Following withdrawal, this animal has maintained a rate of approximately 233 licks per five minute period for a week, to date. Two other animals exhibited increased licking transiently after withdrawal. A fourth began to increase licking during the period of drug administration after 1½ weeks (6.3 licks/5' before vs. 189 licks/5' during). Additional data from other animals suggest that in some cases there may be a permanent increase in licking following longer maintenance on drug. Some of the licking behavior includes a wide opening of the mouth and lip licking; most becomes integrated into grooming behavior. To date, we have seen no consistent correlation across subjects between licking and EEG or EPs, but some individual cases show changes from baseline which appear linked to the drug treatment. For example, in one animal EPs recorded at several loci in basal ganglia (non-noxious shocks to forelimb in unanesthetized animals) increased only during drug treatment (300µV to 600 µV, at one point, negative, 5 msec. latency). In another case, a late, slow component of the sensorimotor cortical evoked potential was lost when the animal was placed on the drug and has not reappeared during 5 days since withdrawal.

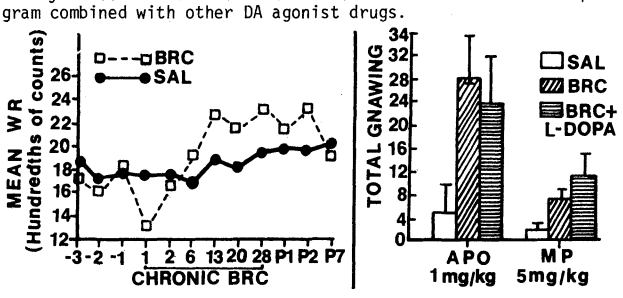
1406 BEHAVIORAL SUPERSENSITIVITY TO BROMOCRIPTINE IN MICE. Paul B. Hicks*, J. Randolph Strong*, Robert C. Smith, and Thaddeus Samorajski, Tex. Res. Inst. Mental Sciences, Houston, Tex 77030.

Bromocriptine (BRC, CB-154) has behavioral properties of a directly acting DA agonist (Brit. J. Pharm. 56: 59, 1976), although recent research also indicates effects of BRC on pre-synaptic dopamine neurons (Neurosci. Abst. 2: 500, 1977). One case study (Lancet 2: 571, 1976) reported emergence of psychosis in a patient treated with BRC + L-DOPA after discontinuation of BRC and suggested that this might involve development of supersensitivity to DA receptors with chronic BRC treatment. We investigated tolerance and supersensitivity in mice who received 30 day chronic i.p. drug administration of either: 1) BRC 30 mg/kg i.p., 2) BRC 30 mg/kg i.p. + L-DOPA ∿ 1.8 mg/kg in food, 3) L-DOPA ∿ 1.8 mg/kg in food, or 4) Saline i.p. (SAL). There was a rapid development of tolerance to the effects of bromocriptine on depressing wheel running seen on the first day of BRC administration and a reversal of drug's effects as evidenced by a significant increase in wheel running (wk) compared either 1) to the BRC mice's pre-drug baseline or to 2) same day SAL controls, both during chronic administration and after termination of BRC. After termination of chronic treatment, BRC mice showed greater knawing after apomorphine (APO) 1 mg/kg and methylphenidate (MP) 5 mg/kg than SAL controls. The combination of BRC + L-DOPA had similar effects on wheel running and knawing, with a slightly greater effect on MP induced stereotyped behavior. The behavioral supersensitivity was short lived; by day 7 post-BRC wheel running had returned to SAL control levels and in week 2 the differential effects of APO and MP on BRC mice decreased considerably. Since BRC is effective in Parkinson's disease, and may be combined with other DA agonists such as L-DOPA, our results suggest a mechanism for the emergence of potential psychiatric and dyskinetic side effects when BRC is used in a treatment program combined with other DA agonist drugs.



1407 EFFECTS OF SELECTIVE CATECHOLAMINE RECEPTOR BLOCKERS ON AMPHETAMINE AND APOMORPHINE POTENTIATED ACOUSTIC STARTLE RESPONSE IN RATS. John H. Kehne* and Charles A. Sorenson. Neuroscience Program, Amherst College, Amherst, MA 01002.

It has been suggested that catecholamine (CA)-containing neurons exert a facilitatory influence on the amplitude of the acoustic startle response (ASR) in rats, based largely on the finding that treatment with high doses of amphetamine augment startle amplitude (Davis et al., Psychopharmacol., 43:1, 1975). The individual contributions of norepinephrine (NE) and dopamine (DA)-containing neurons in mediating this potentiation of startle amplitude are unclear, although a primary role for DA neurons has been suggested by the finding that low doses of the DA agonist apomorphine cause large increases in startle for the first forty minutes after injection (Davis & Aghajanian, Psychopharmacol., 47:217,1976). In an effort to clarify the individual roles of NE and DA-containing neurons in amphetamine and apomorphine potentiation of startle amplitude, rats were pretreated with either the DA receptor blocker pimozide or the alpha-NE receptor blocker phenoxybenzamine, and then treated with either d- or l-amphetamine, or apomorphine, in doses known to cause reliable increases in startle amplitude. If DA-containing neurons are primarily responsible for startle potentiation, then pretreatment with pimozide, but not with phenoxybenzamine, should block these effects. As expected, the pimozide pretreatment did completely block the facilitating effects of amphetamine and apomorphine. Furthermore, the phenoxybenzamine pretreatment did not block the d-amphetamine effect on startle, but it did block or markedly attenuate the effects of l-amphetamine and apomorphine. One possible interpretation of these results is that the startle-potentiating effects of d-amphetamine are mediated through a different CA pathway than are the effects of l-amphetamine and apomorphine, the latter effects being mediated through DA and NE neural systems that are in series. (Supported by the Alfred P. Sloan Foundation).

1408 EFFECT OF TAIL OF CAUDATE LESIONS ON SPONTANEOUS AND AMPHETAMINE-INDUCED LOCOMOTION IN RATS. Robert D. Kerns*, Amanda M. McGee*, and Luis A. Baez. Dept. Psychol., Southern Illinois University, Carbondale, Il., 62901.

Bunney and Aghajanian (Science, 1976,192,391-393) have reported that lesions of the tail of the caudate or of the crus cerebri in rats produce an increase in the firing rate of neurons in the substantia nigra. These data are consistent with other evidence suggesting that the activity of dopaminergic neurons is influenced by feedback connections from forebrain areas to which they project. Since dopaminergic mechanisms have been implicated in the control of behavioral arousal (Creese and Iversen, Brain Research, 1975,83 419-436; Roberts et al.,Brain Research,1975,93, 441-454), it might be predicted that a release of nigral neurons from inhibitory control should result in increased behavioral arousal. Bunney and Aghajanian (1976) also reported that tail of caudate lesions blocked the inhibitory action of d-amphetamine on the firing rate of substantia nigra cells, suggesting that this effect is also mediated by striatonigral connections. Thus, it might also be expected that similar lesions should potentiate the effects of d-amphetamine on behavior. The present study was designed to investigate both of these hypotheses.

In the first experiment, 18 Long-Evans adult rats were housed in stabilimeter cages with food and water freely available. After a habituation period of 36 hours, bilateral electrolytic lesions of the tail of the caudate were performed in nine rats and sham lesions in the remaining animals. Daily locomotor activity was then measured continually for four days following surgery. Locomotor activity of the lesioned group was markedly higher than that of the shams during the four days of observation and this effect was statistically significant ($p < 0.01$). Activity (stabilimeter crossings) of the lesioned group during the first postoperative day was over seven times higher than that of the shams, and it was still double that of the sham group by the fourth day.

In the second experiment, a group of ten animals with lesions of the tail of the caudate and ten sham lesioned animals were injected with 1.0 mg/kg d-amphetamine sulfate one week after surgery. Stabilimeter activity was recorded during five hours following drug administration. The mean activity of the lesioned group was 243 counts, whereas that of the sham group was 123 counts, a statistically significant difference ($p < 0.01$). A second group of animals was tested with d-amphetamine five weeks after surgery. Although the response of the lesioned group was higher than that of the shams (lesioned mean: 445; sham mean: 283) this difference failed to reach statistical significance. These data, then are consistent with the concept of a functionally significant striataonigral feedback projection.

1409 SIALIC ACID/2-DEOXYRIBOSE AS BIOCHEMICAL MARKERS FOR REGIONAL DIFFERENCES IN BRAIN EFFECT OF ACUTE AND CHRONIC ETHANOL. W. R. Klemm and R. L. Engen*, Dept. Biol., Texas A&M Univ., College Station, Tx. 77843 and College Vet. Med., Iowa State Univ., Ames, Iowa 50010.

Sialic acid, the generic term for a family of acidic aminosugars that are incorporated in both glycoproteins and glycolipids, is a potential source for many steric specificities of neuronal and glial membranes. Moreover, the association with membranes allows sialic acid to serve as a possible marker of membrane alteration or development. Therefore, we wished to compare acute and chronic ethanol effects on sialic acid. Experiments were conducted in 50 adult, male Wistar rats, housed in groups of 5. After a 1-month acclimation period, when body weights were reduced 13% from a beginning mean level of 407 grams, experimental rats drank ad libitum a vitamin-fortified diet (Nutrament) which was adulterated with an ascending series of ethanol; ethanol intake ranged from 10-18 gm/kg/rat/day and did not vary much with concentration (5 to 15%). Controls were fed an equal total volume, made isocaloric with sucrose. Rats were sacrificed weekly for 4 weeks, and an acute challenge dose of ethanol (2 gm/kg, IP) was given 45 min prior to sacrifice of both control and ethanol-consuming rats (which were tolerant after 1 week). Some controls were challenged only with saline. Data from all groups replicated our earlier findings of regional differences in sialic acid (descending concentration: telencephalon → cerebellum → medulla). Also replicated was the observation of about a 4-fold higher level of cerebellar deoxyribose, which was measured as a necessary adjunct in the analysis procedure (autoanalyzer modification of the Warren-Delmotte methods). Saline-challenged controls that were sacrificed at 4 weeks had increases throughout the brain in both sialic acid and deoxyribose. Ethanol-challenged controls had a slight, nonsignificant tendency for less sialic acid, but a marked decrease in cerebellar deoxyribose. In contrast, such a challenge of rats on the ethanol diet caused no such decreases; significant differences in both sialic acid and deoxyribose were evident within 2 weeks, especially in the cerebellum.

If we can assume that sialic acid levels reflect the relative amount of cell membranes, and that deoxyribose reflects the number of cells, results in saline-challenged controls suggest that growth may have occurred during the 3 weeks, even though rats were fully adult. For the ethanol data, two interpretations must be considered; namely, that the chronic treatment either 1)created a tolerance which protected cells from damage by the challenge dose of ethanol, or 2) killed neurons, and then the smaller and more numerous glial cells proliferated.

1410 MUTUAL ANTAGONISM OF BEHAVIORAL EFFECTS OF TRH AND THIOBARBITURATE ON AN OPERANT TASK IN RHESUS MONKEYS. Fredric H. Klopf*, Gary W. Kraemer*, William T. McKinney (SPON: Robert E. Bowman). Dept. Psychol. Psychiat. Univ. of Wis., Madison, WI 53706.

The effects on operant response rate of 20 mg/Kg of thyrotropin releasing hormone (TRH) and 12.5 mg/Kg sodium thiamylal (surital^{R}, P.D.) administered alone or in combination were examined on a variable interval schedule for sugar water reward in 8 rhesus monkeys. The subjects were segregated into 2 groups of 4 on the basis of baseline response rate. The high response rate group had a mean rate of 13.1 responses per minute while the low rate group had a mean rate of .36 responses per minute over a 2-hour test duration. Administration of TRH or thiamylal alone decreased rate of response in the high rate group while increasing response rate in the low rate group. These effects were over 2 hours in duration for both agents. When TRH and thiamylal were given together, the response rate altering effects of either drug given alone were cancelled and response rate approximated the baseline rate. This effect occurred when subjects had high or low baseline rates and despite the fact that the effects of either of the agents given alone were in the same direction. Results suggest that both TRH and thiobarbiturate have rate dependent effects on this operant task in rhesus monkeys but that regardless of the direction of effect, the behavioral effects of thiobarbiturates and TRH are mutually antagonistic. These findings confirm and extend previous studies documenting reversal of barbiturate effects by TRH and further suggest that thiobarbiturates may antagonize some central effects of TRH. Antagonism of a central TRH receptive mechanism may be another way in which barbiturates act to alter brain function.

1411 Acute and Chronic Effects of d-Amphetamine: Behavioral and Neurochemical Specificity. Larry Kokkinidis* and Hymie Anisman* (SPON: T. Picton). Department of Psychology, Carleton University, Ottawa, Ontario, Canada.

Acute and chronic effects of d-amphetamine were evaluated in five behavioral tasks, locomotor activity, stereotypy, stimulus perseveration, startle reflex and circling. Following administration of 10 mg/kg of the drug over five successive days tolerance was observed to the perseveration, startle reflex and rotational behavior induced by the drug, whereas the intensity of locomotor activity and stereotypy either increased or remained unchanged. Treatment with alpha-methyl-tyrosine (AMPT) (250 mg/kg), antagonized the effects of d-amphetamine in each of the behavioral tasks. Treatment with Bis-(4-methyl-1-homopiperazinyl-thiocarbonyl) disulfide (FLA-63) (40 mg/kg) on the other hand, only antagonized the effects of amphetamine on stimulus perseveration, startle response and circling, whereas locomotor activity and stereotypy were unaffected by dopamine-Beta-hydroxylase inhibition. Since AMPT reduced dopamine by 40 percent and norepinephrine by 49 percent, whereas FLA-63 reduced norepinephrine by 47 percent with no effect on whole brain dopamine levels, it is likely that these behaviors are subserved by noradrenergic activity. This finding taken together with the fact that tolerance was not observed to the locomotor and stereotypic effects of the drug, whereas the perseverative, circling and startle tendencies were attenuated with chronic drug treatment, suggests that tolerance may occur exclusively to behaviors mediated by norepinephrine.

1412 EFFECTS OF ALTERATIONS IN BIOGENIC AMINE METABOLISM ON THE PROTEST-DESPAIR RESPONSE TO PEER SEPARATION IN RHESUS MONKEYS. Gary W. Kraemer*, Fredric H. Klopf*, Steven J. Suomi* and William T. McKinney. Dept. Psychiat and Psychol. Primate Lab. Univ. of Wis., Madison, WI 53706.

Separation of rhesus monkeys from their mothers may result in a protest-despair response which is qualitatively similar to that shown by some human infants following separation from their mothers. The behavioral features of this biphasic effect, characterized by an initial phase of agitation and increased vocalization (protest) followed by decreased activity, huddling and failure to attend to the external environment (despair), have been labeled as anaclitic depression in humans. On the basis of this etiological and behavioral analogy, many investigators have suggested that despair in monkeys may serve as a primate model of some forms of human depression.

Rhesus monkeys raised without mothers in a peer group may also show a protest-despair response following separation from the peer group. The peer separation paradigm differs from mother-infant separation in that the group can be repeatedly separated and reunited, each separation resulting in a qualitatively and quantitatively similar response. This suggested that the repeated peer separation paradigm could be used to evaluate the interaction of alterations in catecholamine (CA) or indolamine (5HT) metabolism with despair in primates by administration of drugs altering biogenic amine metabolism or placebo across repeated peer separations.

In a series of repeated peer separations involving 2 groups of 4 rhesus monkeys, it was found that: a) alteration of CA metabolism with doses of alpha-methyl-para-tyrosine (AMPT) as low as 25 mg/Kg/day potentiated the despair stage following separation while having no effect on group behavior preseparation; b) inhibition of dopamine beta hydroxylase (DBH) with Fusaric acid in doses as low as 5 mg/Kg resulted in less despair behavior; c) inhibition of tryptophan hydroxylase with parachlorophenylanine (PCPA) had no effect on despair behavior in doses up to 200 mg/Kg/day over a 12-day period.

Therefore, alterations of CA metabolism which may not have detectable behavioral correlates in a social situation may significantly alter the response to peer separation in rhesus monkeys. On the basis of the known effects of the enzymatic inhibitors used, the data suggest that small decrements in norepinephrine (NE) and dopamine (DA) metabolism may potentiate despair behavior while reduction of NE alone, with a possible increase in DA following inhibition of DBH, ameliorates post-separation despair. A role for NE and DA in the mediation of despair in monkeys is supported by these studies.

1413 EFFECTS OF AMINO ACID PRECURSORS ON MONOAMINERGIC SYSTEMS IN TERRITORIAL AGGRESSION. S. M. Lasley, J. B. Thurmond*, and J. W. Brown*. Neuropsychopharm. Program, Univ. of Louisville, Louisville, Ky. 40208.

The monoamine precursors L-tyrosine, L-phenylalanine, and L-tryptophan were administered by diet and measures of aggressive behavior recorded. The dietary regimens, which were designed to enhance catecholaminergic and serotonergic functioning, were found to differentially affect the territorial-induced attacks in mice. Male CF-1 mice were maintained on a semi-synthetic 12 percent casein protein diet for 2 weeks, then switched to diets modified by the addition of a 4 percent L-amino acid supplement, or 4 percent casein (control). Measures of aggressive behavior and open-field locomotor activity were obtained before and after the dietary supplements were administered. Resident mice fed supplements of L-tyrosine displayed a marked increase in the number of attacks on intruders and shorter attack latencies, but their locomotor activity was unaffected. L-phenylalanine supplements alone or in combination with L-tyrosine reduced the latency to attack and increased motility but did not affect the number of attacks. As a whole, the group of animals fed L-tryptophan showed no changes in aggression or motility.

In order to more closely control the amount of amino acid an individual animal receives, the precursors were also administered by injection. Biochemical determinations of monoamine levels and turnover have also been made to assess the effects of the diets - especially L-tryptophan's effects - and provide a firmer base for conclusions.

1414 DOPAMINE RECEPTORS IN NORMAL AND SCHIZOPHRENIC HUMAN BRAINS. Tyrone Lee and Philip Seeman. Pharmacology Department, University of Toronto, Toronto, Canada.

In order to find out whether dopamine receptors in the brains from schizophrenic (SZ) patients differ from those in normal human brains, dopamine receptors in such brains were measured using ^{3}H-apomorphine or ^{3}H-haloperidol (Seeman et al., Proc. Nat'l. Acad. Sci., 73: 4354, 1976).

Post-mortem human brains were used. Control normal tissues were obtained through the hospital pathologist from persons who had died from non-neurological causes, while the schizophrenic brain tissue samples were contributed by Dr. W.W. Tourtellotte (NINCDS/NIMH Human Neurospecimen Bank, Los Angeles). Tissues were homogenized, incubated with ^{3}H-apomorphine or ^{3}H-haloperidol and the mixture filtered through GF/B filters and washed. Specific binding of the radioligand was defined as that amount of isotope bound in buffer minus that amount bound in the presence of (+)-butaclamol.

The highest specific binding of ^{3}H-apomorphine was in the dopamine-rich regions:

Caudate nucleus	31	fmoles/mg protein
Putamen	39	"
Nucleus accumbens	30	"
Septum	35	"

Binding to other regions was not significantly different from background (less than 10 fmoles/mg).

The specific binding of ^{3}H-haloperidol (fmoles/mg) to normal and schizophrenic brain tissues was as follows:

NORMAL	CAUDATE	PUTAMEN	N. ACCUMBENS	FRONTAL CORTEX
CAL-136	35±3	45±3	37±2	23±2
CAL-246	32±7	34±7	38	25±5
CAL-154	41	48	-	19±4
CAL-173	45±8	42±6	-	27±6
SCHIZOPHRENIC				
CAL- 18	81±8**	79±6**	-	22±3
CAL-237	91±8**	67±3**	66±4*	28±4
CAL-249	84±9**	68±4**	65±5*	23±5

*P < 0.01; **P < 0.001 (compared to the averaged normals).

It is not yet clear whether the apparently increased number of receptors in the SZ brains is independent of previous drug history.

1415 SITE-SPECIFIC EFFECTS OF ACUTE AND CHRONIC AMPHETAMINE ADMINISTRATION ON SELF-STIMULATION RESPONDING. Nancy J. Leith and Robert J. Barrett*, (SPON: Wolf D. Dettbarn). Dept. of Pharmacol., Sch. Med., Vanderbilt Univ., Nashville, TN. 37203

Following the initial report by Leith and Barrett (Psychopharm. 46: 19, 1976) that tolerance develops to amphetamine's facilitation of MFB self-stimulation responding, Anderson et al., (Brain Res. 1977) demonstrated that the precise location of the electrode in the hypothalamic region is critical in this phenomenon. Although the drug facilitated responding in all animals, tolerance developed only with placements that were in dorsal or medial hypothalamic regions. In an attempt to delineate more precisely the brain pathways that are involved in the development of tolerance, animals were implanted in specific brain areas that support self-stimulation (locus coeruleus (LC), ventral noradrenergic bundle (VNB), periventricular noradrenergic bundle (PNB), substantia nigra (SN), or A_{10} region) and tested following both acute and chronic amphetamine administration. The drug (0.5-0.75 mg/kg d-amphetamine sulfate) facilitated responding in all animals although the magnitude of the effect varied. VNB animals showed only slight facilitation even at the higher dose whereas in LC and PNB animals the drug effects were marked. Chronic treatment, during which no testing occurred, consisted of 3 injections daily for 4 days beginning with 1 mg/kg and incrementing in 1 mg/kg steps at each injection. Forty-eight hours after the last injection, animals were again tested for facilitation with 0.5-0.75 mg/kg d-amphetamine sulfate. All animals with electrodes aimed at the SN (n=5) developed tolerance while none of the PNB (n=5) animals did so. In the cases of the LC (n=5), VNB (n=4) and A_{10} (n=9) regions, some animals developed tolerance while others did not. In addition, testing on the subsequent day with no further drug administration showed that nearly all animals (90%) exhibited a marked depression of responding and this depression was independent of whether or not tolerance had developed. Thus, even within these relatively homogenous brain regions, slight variations in electrode site make a critical difference. The necessary conclusion from these data, then, is that self-stimulation responding in the two groups of animals (tolerance and no tolerance) is mediated by different anatomical and/or biochemical substrates which chronic amphetamine effects differentially.

1416 EFFECT OF CHLORDIAZEPOXIDE (CDP), D-AMPHETAMINE (AMP), MORPHINE (MOR) AND ZIMELIDINE (Z) ON LATERAL HYPOTHALAMIC (LH) SELF-STIMULATION (SS) FOLLOWING 4-CHLORO-AMPHETAMINE (PCA) INDUCED SEROTONIN (5HT) DEPLETION. S.A. Lorens. Dept. of Pharmacol., Univ. of Iowa, Iowa City, IA 52242.

Although brain stimulation reward appears to be mediated primarily by catecholaminergic systems, 5HT seems to play an important regulatory role. Thus, reduction in central 5HT concentration can lead to major changes in SS behavior depending on the site stimulated. Recently, we found that intra-midbrain 5,7-dihydroxytryptamine (5,7-DHT) injection reduced regional forebrain 5HT levels and enhanced LH SS responding. The facilitatory effects of AMP, CDP, and MOR, furthermore, were potentiated. In view of the importance of the method of 5HT depletion in determining behavioral changes (Lorens, Ann. N.Y. Acad. Sci., in press), the effects of the long term 5HT depleting agent, PCA, were examined.

All methods have been published (Psychopharmacologia, 1976, 48:217). Following stabilization of responding at threshold current intensity, rats received PCA (10.0 mg/kg; n=4) or saline (S; 1.0 ml/kg; n=4) i.p. PCA suppressed LH SS 0.5-8.0 hr. post-injection. The response outputs/10 min. of the PCA and control groups, however, did not differ over the subsequent 17 days.

Drugs were administered i.p. after a control session according to the following schedule: on post-PCA day 6 (S, 1.0 ml/kg), 7 (CDP, 2.0 mg/kg); 9 (S), 10 (AMP, 0.1 mg/kg); 12 (S), 13 (MOR, 5.0 mg/kg, s.c.); 15 (S), 16 (Z, 10.0 mg/kg). CDP enhanced SS responding 0.5 hr. after injection, while AMP was without effect. No differences between the PCA and control groups were found. MOR suppressed SS 1 hr. after injection in both groups, but the response output of the PCA group was greater 3 hr. post-injection. Z reduced (20%) SS responding 2 hrs. post-injection in the control group, but not in the PCA group.

Although PCA acutely suppresses LH SS, it does not appear to produce long term changes in SS response output. PCA *antagonized* the suppressive effects of Z, a selective 5HT uptake inhibitor (Ross and Renyi, Neuropharmacol., 1977, 16:57), and potentiated the facilitatory influence of MOR. PCA did not alter the effects of low doses of CDP and AMP on LH SS.

Distinctions between the effects of 5,7-DHT and PCA on SS behavior could be due to a different pattern and degree of regional 5HT depletion and resulting receptor supersensitivity. The results, nevertheless, are not inconsistent with the hypothesis that 5HT is involved in modulating brain stimulation reward, and in mediating the behavioral effects of chlordiazepoxide, amphetamine, morphine, and Zimelidine.

1417 CHLORPROMAZINE REVERSAL OF AMPHETAMINE STEREOTYPY IN AMYGDALOID RATS. Irwin N. Lourie* and Michael M. Krieger* (SPON: N. S. Thampi). Research Dept., Norristown State Hospital, Norristown, PA 19401.

An observational method for the analysis of d-amphetamine (AMP) effect on behavior in rats was developed which distinguishes a dose related continuum of behavior from hyperactivity through marked stereotypy. The procedure consists of analysis of videotape observations of normal and abnormal components of exploratory (E) and paired interactive (I) behavior. Bilateral radiofrequency lesions were placed in the amygdala (A) of ninety-six day old male NSH rats (n=10) resulting in extensive damage to basolateral and corticomedial structures. Controls (C) consisted of a similar group of sham operated animals. After 14 days of recovery animals were run daily in an open field until behavior stabilized (8 days). Three days of baseline and four days of drug trials were run. Drugs consisted of i.p. administration of 2, 4, and 10 mg/k AMP given 30 minutes prior to observation and 10 mg/k AMP preceded by 8 mg/k chlorpromazine (CPZ) given 15 minutes previously. (A) without drugs showed a typical response: rapid habituation of E and deficits in I with concommitant increases in noninteractive behavior. Both groups showed similar responses to AMP with differences consistent with lesion effect.

Reversal of 10 mg/k AMP with 8 mg/k CPZ produced a marked difference in response. For attending behavior (nonambulatory, motor activity) A showed 55% as the intense stereotyped pattern as compared with 10% for C. Thus A shows considerably less reversal response to CPZ suggesting that an intact amygdala is necessary for maximizing this effect.

1418 THYROTROPIN-RELEASING HORMONE (TRH) ELEVATES CEREBELLAR cGMP LEVELS. R.B. Mailman, R.A. Mueller, G.D. Frye* and G.R. Breese. Departments of Psychiatry, Pharmacology and Anesthesiology, and the Biological Sciences Research Center. University of North Carolina School of Medicine, Chapel Hill, North Carolina 27514

Numerous behavioral studies have indicated that TRH has central actions unrelated to its effects on the anterior pituitary. No parallel changes in CNS biochemistry have been reported. These studies investigated the effects of drug treatments on guanosine-3', 5'-monophosphate (cGMP) levels in the cerebellum of Sprague-Dawley rats. After drug treatment, the animals were killed with focused microwave irradiation (3.5 kw, 2.0 sec; Gerling-Moore Metabostat), the cerebellum was removed, homogenized in 0.4 M $HClO_4$ and centrifugated at 3000 g for 20 minutes. Aliquots of the supernatants were brought to pH 6.2 with TRIS base and analyzed for cGMP, cAMP or TRH levels by radioimmunoassay. Intravenous administration of TRH (10 mg/kg) increased cerebellar cGMP from c.12 to c.24 pmoles/mg protein. cAMP was not altered by TRH. The change in cGMP induced by TRH was dose-dependent up to 10 mg/kg, but administration of more than 10 mg/kg caused no further increase in cGMP. Cerebellar TRH "immunoreactivity" increased from c.800 ng/g cerebellum at 10 mg/kg of TRH to > 4800 ng/g at 30 mg/kg. Hypophysectomized rats responded identically to i.v. administration of 10 mg/kg TRH, indicating that the changes in cGMP were not due to actions on the pituitary. Similar dose dependent rises in cGMP in the cerebellum were seen after intracisternal injection of 3-100 µg TRH. All doses caused significant elevations, with 100 µg TRH causing a 70% increase in cGMP. The time course of both TRH and cGMP levels in the cerebellum was compared after a single i.v. injection of 10 mg/kg. Levels of cGMP were maximal at 2.5-7.5 minutes after administration of TRH, and then rapidly fell to control values by 30 minutes post-injection. This time course reasonably paralleled TRH-immunoreactivity in these samples. Many previous behavioral studies on TRH have measured its antagonism of the effects of ethanol or pentobarbital, drugs which also have been reported to cause pronounced falls in cerebellar cGMP levels. TRH significantly antagonized the decrease in cGMP caused by either ethanol or pentobarbital, and could completely prevent the decrease caused by low doses (c.1.5 g/kg) of ethanol. The effects of TRH on cerebellar cGMP provide definitive biochemical evidence that TRH has a central action unrelated to its endocrine actions. (Supported by USPHS Grants #AA-02334, AA-05047, MH-14277 and the Alfred P. Sloan Foundation.)

1419 TOLERANCE TO THE EFFECTS OF Δ^9 TETRAHYDROCANNABINOL IN ADAPTED AND NONADAPTED RABBITS. Parthena Martin* and Paul Consroe. Department of Pharmacology and Toxicology University of Arizona, College of Pharmacy, Tucson, Arizona 85721.

Although tolerance to the effects of marijuana or Δ^9 tetrahydrocannabinol (THC) occurs in many species including pigeons, rats, chickens, dogs, monkeys, frogs and man, Lipparini et al. (Physiol. Behav. 4:527-532, 1969) reported no attenuation of electroencephalographic (EEG) or behavioral responses in one rabbit given THC (3 mg/kg, i.v.) daily for 6 days. In the present study, 4 New Zealand White rabbits previously adapted to the test chamber, were given THC (.5 mg/kg, i.v.) daily and tested daily for 12 days. Since environmental familiarity has been shown to influence the acute effects of the cannabinoid (Pharmacol. Biochem. Behav. 3:173-177, 1975), 3 rabbits not previously adapted to the testing milieu were injected daily with the THC (in their home cages) but tested in the chamber only on the 1st and 12th day of cannabinoid administration. A vehicle control (10% Tween 81-saline) baseline was recorded for all 7 rabbits 1 day before THC administration. EEG, quantified by frequency analyses of delta (.5-4Hz), theta (4-8Hz), alpha (8-13Hz) and beta (13-40Hz) abundance, was recorded from the motor cortex and hippocampus for 20 minutes following THC administration. Concurrently, durations of standing, sprawling and activity were measured. Overall, adapted rabbits exhibited less delta and beta and showed a trend toward more theta and alpha cortical EEG content; they were also less behaviorally active than nonadapted rabbits. After the first administration of THC adapted rabbits exhibited more theta than nonadapted rabbits and this difference persisted with chronic THC administration. In adapted rabbits, no differences were found in EEG activity between THC and vehicle control at anytime. Behaviorally, the first injection of THC induced sprawling, reduced activity and eliminated standing behaviors. By the 12th day of THC administration, sprawling had disappeared and activity and standing tended to increase above that of baseline levels. In nonadapted rabbits, THC initially produced an increase over baseline in delta abundance of the cortical EEG which returned to baseline level by the 12th day of cannabinoid administration. Activity increased above baseline then tended to decrease with chronic administration of THC while standing tended to increase with chronic THC. These data show that tolerance to the effects of THC occurs in rabbits and that acute and chronic effects produced by THC are influenced by environmental factors. These data are also consistent with observations in other species that tolerance develops to the depressant properties but not to the stimulant effects of THC. (This research was supported by NIDA grant #DA 01448.)

1420 PHYSIOLOGICAL TOLERANCE TO SELF-ADMINISTERED d-AMPHETAMINE AFTER CHRONIC d-AMPHETAMINE INJECTIONS. Thomas McCown*, and Robert J. Barrett* (SPON: N. Leith). Dept. Pharm. Sch. Med., Vanderbilt U., Nashville, Tenn. 37235.

Rats were implanted with chronic intravenous cannulae and trained to bar press for intravenous, self-administered dextroamphetamine (d-AMPH). When baseline responding stabilized, the animals were removed from the test situation and subsequently injected, three times a day, for four days with increasing amounts of d-AMPH (total=78mg/kg) (Leith and Barrett, Psychopharm. 46: 19-25, 1976). Thirty hours after the last injection, the animals were tested and all animals significantly increased the amount of self-administered d-AMPH, as compared to baseline administration. Approximately three to four weeks of drug abstinence was necessary before the animals returned to a baseline administration.

Brain clearance and brain levels of d-AMPH, after an intravenous dose of d-AMPH, in either chronic d-AMPH or saline treated animals, were measured by the methyl orange assay (Axelrod, JPET 110: 315-326, 1954), and no differences were found in either index. The increased amount of d-AMPH administration cannot be attributed to metabolic tolerance.

These data indicate that drug self-administration in rats is a useful paradigm to study tolerance to the rewarding effects of d-AMPH and may be useful in understanding the mechanisms mediating the mood elevating properties of the drug, observed in humans.

1421 SEX-RELATED DIFFERENCES IN AMPHETAMINE-INDUCED ANOREXIA AND HYPERTHERMIA. Edwin Meyer, Jr.*, Andrew Werber* and Loy D. Lytle (SPON: L.N.Irwin). MIT, Cambridge, MA 02139.

Although the locomotor stimulant, anorexic, and hyperthermic effects of amphetamine have been well characterized in adult male animals, little information exists regarding possible sex-related differences in these drug actions. Recently, we have shown that female adult rats injected with 1.0 mg/kg of d-amphetamine sulfate are more active, for longer periods of time, than are comparably treated adult male animals. The sex-related differences in the stimulant actions of amphetamine correlate closely with sex-related differences in the accumulation of the drug in brain: whereas the half-life of amphetamine in the brains of adult male rats is only 40 minutes, it is approximately 70 minutes in adult female animals (Meyer, E. and Lytle, L.D *Fed. Proc. 36: 1033 (Abstr. 4012), 1977*).

We now report that amphetamine-induced changes in food intake and body temperature are also greatly protracted in adult female rats compared to adult males. In the first experiment, 100 day-old male or female albino rats were deprived of food and water for 24 hours, and then were injected with 0.75, 1.5, or 3.0 mg/kg of d-amphetamine sulfate (salt weight) or the 0.9% saline vehicle (1 ml/kg). Food and water were immediately returned to these animals, and total intake was measured hourly for up to 8 hours post-injection. All animals injected with amphetamine became anorexic in a dose-related manner following the drug treatment; however, female rats were made anorexic for longer time periods at each dose of amphetamine than were the male rats

In a second experiment, adult male or female rats were acclimated to a warm (25° C) environment for an hour, and were then injected with 1.0, 3.0, or 9.0 mg/kg of d-amphetamine sulfate or with the 0.9% saline vehicle. Food and water were removed, and rectal temperatures were measured at 30 minute intervals for up to 8 hours post-injection. All amphetamine-treated animals were made hyperthermic in a dose-related manner; however, the drug-induced hyperthermia was temporally much longer in female rats compared to males treated with the lower amphetamine doses Interestingly, no sex-related differences in amphetamine-induced hyperthermia were observed at the highest (9.0 mg/kg) dose of the drug.

The sex-related differences in the behavioral and physiological effects of amphetamine may be related to sex differences in the rates at which amphetamine is metabolized: 1) pretreating adult rats with a hepatic microsomal enzyme inhibitor (SKF-525A) blocks the metabolism of amphetamine and protracts its behavioral and physiological effects; and 2) male rats metabolize amphetamine (via para-hydroxylation) more rapidly than do female animals (Supported in part by NIMH grant MH-25075 and by an Alfred P Sloan Foundation Fellowship in Neurosciences)

1422 PSYCHOMOTOR STIMULANTS AND AGGRESSION IN MICE. K. A. Miczek, J. M. O'Donnell*, and V. S. Harris*. Dept. Psych., Carnegie-Mellon Univ., Pittsburgh, PA 15213.

Anecdotal and experimental observations suggest that amphetamines and other psychomotor stimulants increase aggressive behavior in several species, including man. We investigated the effects of d-amphetamine, methamphetamine, methylphenidate, cocaine, and L-DOPA on aggressive behavior between resident and intruder mice. Male resident mice were isolated or housed with a female, and were tested either in their homecages or in neutral cages with group-housed male intruder mice. Drugs were given to either the resident or the intruder mouse i.p. in a volume of 1 ml/100 g b.w. The test duration was 5 min after the first attack, 5 min being the maximal attack latency. All tests were videotaped and two observers recorded frequency and duration of agonistic and non-agonistic acts and postures. We found that (1) all drugs decreased the frequency of attack, sideways threat movements, and tail-rattle in a dose-dependent manner, the highest doses producing statistically reliable, strong suppression (2, 8 mg/kg d-amphetamine, methamphetamine and cocaine; 48, 96 mg/kg methylphenidate; *100, 200* mg/kg L-DOPA); (2) isolated mice were 2-4 times less sensitive to the antiaggressive effects of d-amphetamine, methamphetamine, cocaine, and L-DOPA, than mice housed with a female, whether tested in their homecages or in neutral cages; (3) 2 mg/kg d-amphetamine suppressed attack, sideways threat movements, and tail-rattle in tests 5, 15, and 30 min after injection, while non-agonistic locomotion remained unaffected; (4) doses of d-amphetamine and cocaine which suppressed attack did not alter non-agonistic locomotion, but the same doses of methamphetamine and methylphenidate increased locomotion, and L-DOPA nonspecifically decreased all agonistic and non-agonistic behaviors; (5) non-drugged resident mice attacked intruders which were given 8 mg/kg d-amphetamine or methamphetamine, or 96 mg/kg methylphenidate more frequently than those given saline; (6) administration of d-amphetamine (8 mg/kg), methamphetamine (8 mg/kg), or methylphenidate (48, 96 mg/kg) to intruder mice increased escape frequency and decreased the duration of the defensive upright posture, while increasing non-agonistic locomotion. By contrast, L-DOPA nonspecifically suppressed all intruder behaviors. We conclude that d-amphetamine, methamphetamine, methylphenidate, cocaine, and L-DOPA fail to increase any element of the species-specific pattern of attack behavior in mice, but rather decrease this behavior. The specific antiaggressive effect of psychomotor stimulant drugs could not be mimicked by L-DOPA, which had entirely nonspecific suppressive effects on all aspects of behavior. (This research was supported by USPHS Grant DA 01502).

1423 EFFECTS OF REDUCING BRAIN CATECHOLAMINES ON ACTIVITY AND ON METHADONE INDUCED CHANGES IN ACTIVITY OF DBA/2 AND C57BL/6 MICE. Lawrence D. Middaugh, Samuel K. Parrish, Jr.* and John K. Nash.* Depts. of Biochem. and of Psychiatry and Behav. Sci., Med. Univ. of South Carolina, Charleston, SC 29403.

A number of reported studies demonstrate that various inbred strains of mice have different behavioral responses to psychoactive drugs. Many of these responses are thought to be mediated via drug action on neural systems utilizing catecholamines as neurotransmitters and it has been hypothesized that strain differences in these systems might account for the different responses to drugs. The narcotic analgesics, morphine and methadone have been reported to increase turnover of dopamine in rat brain. In addition, both drugs increase activity of C57 BL/6 (C57) mice but reduce activity of DBA/2 (DBA) mice. Strain differences in catecholamine systems may count for the different behavioral response to narcotic analgesics. The purpose of the experiments reported here was to determine the effect of reducing brain catecholamine concentrations on activity of C57 and DBA mice and on the methadone inducèd changes in activity of the two strains.

α-Methyl-p-tyrosine methyl ester hydrochloride (AMPT)(150, 175, 200, 250 and 300 mg/kg) was injected I.P. (.02 ml/g body weight) 3 hr prior to a 5 minute activity test. The three highest doses produced significant and increasing reductions in activity of C57 mice but did not alter activity of DBA mice.

In the second experiment AMPT (150, 175 or 300 mg/kg) was injected 3 hr prior to killing and brains were assayed for norepinephrine (NE) and dopamine (DA). Increasing doses of AMPT reduced NE and DA to about the same degree in both strains of mice. NE was reduced by 14%, 19% and 32% for C57 mice and by 8%, 25% and 33% for DBA mice. DA was reduced by 10%, 16% and 21% for C57 mice and by 11%, 12% and 18% for DBA mice.

In the final experiment, mice were injected I.P. with AMPT (175 mg/kg) or its water vehicle three hours prior to testing and then subcutaneously with methadone hydrochloride (15 mg/kg) or its saline vehicle 5 min prior to testing. As previously reported, methadone increased activity of C57 mice and decreased activity of DBA mice. AMPT at this dose did not alter the activity of either strain. Pretreatment with AMPT however, did attenuate the methadone induced elevated activity of C57 mice but did not alter the reduced activity of DBA mice.

The results of these experiments demonstrate first, that catecholamine reduction influences the behavior of C57 mice more than that of DBA mice. Second, an adequate store of catecholamine is required for methadone induced elevated activity (observed in C57 mice) but appears to be unrelated to the depressed activity (observed in DBA mice) following methadone injections. Supported in part by Gen. Med. & Fac. Res. Approp. and by PHS Grant DA01750-01.

1424 EFFECTS OF MONOACYLCADAVERINES ON MOLLUSCAN NEURONS. Mark Miller* and Matej Stepita- Klauco. Dept. of Biobehavioral Sciences, Univ. of Conn., Storrs, Conn. 06268

The presence of acylated cadaverines -- monoacetylcadaverine and monopropionylcadaverine in the mammalian brain and blood has been recently demonstrated by high resolution mass spectrometry (Dolezalova et. al., Mass Spectrometry in Drug Metabolism, pp. 201-213; Plenum, 1977). The effects of these compounds upon identified neurons in the suboesophageal ganglia of the land snail Helix aspersa were tested in this study. The membrane potential was recorded intracellularly and the compounds were iontophoretically applied from multibarreled micropipettes onto somatic and axonal regions of studied neurons.

A very slowly decrementing depolarization lasting for up to one minute was produced in many cells. This depolarization was concomitant with the reduction of the membrane resistance. In addition, both the number and amplitude of spontaneously occurring postsynaptic potentials were very often increased for up to several minutes following the application into the neuropil.

Interactions of these compounds with some neuropharmacological agents were also investigated. Priming iontophoresis of a phenothiazine derivative fluphenazine was found to potentiate the depolarizing effect of monopropionylcadaverine. This effect underwent a rapid desensitization and could rarely be elicited in more than two consecutive repetitions. Longer intervals between administrations increased the probability of obtaining responses.

The effects of monoacylated cadaverines could be obtained by releasing about 1 pmole of the tested substance from a pipette containing it in a 500 mM solution. In contrast, iontophoresis of cadaverine alone was unable to produce any of the aforementioned responses. It is suggested that the acylation of one amino group of cadaverine could render a compound which is capable of exerting neuromodulatory effects.

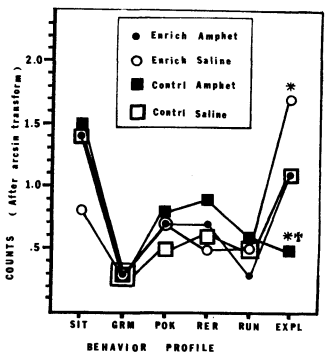
1425 ENVIRONMENTAL ENRICHMENT AND ATTENTIONAL DEFICITS DURING AMPHETAMINE WITHDRAWAL. K. Nau*, H. Schreiber, R. Bell, J. Newbery* and J. Elias*. Dept. Psychol., Texas Tech U., P.O. Box 4100, Lubbock, TX 79409.

Well-known is that environmental enrichment may influence brain morphology and physiology in addition to its behavioral effects. Recent studies in our laboratory have shown that prolonged amphetamine or apomorphine administration (Schreiber, et al., Pharmac Biochem Behav:5, 687, 1976; Schreiber, et al., in prep.) may diminish response to a novel object independently of other behavioral effects during drug withdrawal. The present study showed that environmental enrichment ameliorated the diminished reaction to novelty seen after amphetamine administration. Male Fischer rats were placed in an enriched environment every other day from 26 to 100 days of age (D/age) or were left in their individual home cages. At 150±5 D/age, rats were randomly assigned to a d-amphetamine or saline injection group. Amphetamine was injected twice daily for 4 days at 2.5 mg/kg, s.c., followed by twice daily injections of 5.0 mg/kg, s.c. for 4 days. On Day 9, all Ss received saline injections. Home cage observations showed no differences among groups in general activity level (Figure not shown). However, when a 5.5 cm high X 3.5 cm diameter cylinder was placed in the home cage, Ss which had received amphetamine showed significantly less attention to the cylinder than did Ss which had received saline. As shown in the figure below, enriched, saline-injected Ss (N=3) showed greater exploration than control, saline-injected Ss (N=3). Moreover, enriched, amphetamine-injected Ss (N=4) showed more exploration of the object than control, amphetamine-injected Ss (N=3). No significant differences were detected among the other responses observed (sitting, grooming, nose-poking, rearing and running).



*indicates signif. diff. $p < .05$ from other drug group (amphet vs sal)

†indicates signif. diff. (enrich vs control)

1426 EFFECT OF THREE BENZHYDRYL PIPERAZINES ON CONDITIONED AVOIDANCE BEHAVIOR IN THE RAT. Gary D. Novack, Larry G. Stark, and A. James Hance*. Dept. Pharmacol., Univ. Calif. Davis Sch. Med., Davis. CA. 95616

The effect of three benzhydryl piperazines, SC-13504 (an anticonvulsant), hydroxyzine (HDX, an anxiolytic) and chlorcyclizine (CCZ, an antihistaminic) on conditioned avoidance behavior in the rat has been observed. CCZ and HDX (10 to 80 mg/kg, i.p.) decreased both pre-tone avoidances (secondary conditioned responses) and post-tone avoidances (conditioned avoidance responses) at doses one-fourth to one-half of those which abolished escapes. High doses of HDX and CCZ elicited tremors and seizures. SC-13504 (20 to 160 mg/kg, p.o.) did not significantly decrease pre-tone or post-tone avoidances, nor elicit any gross behavioral effects.

The failure of SC-13504 to significantly decrease conditioned avoidance responses is consistent with previous reports of its minimal effects on behavior. Additionally, SC-13504 has been reported to be a more effective anticonvulsant than HDX or CCZ (Novack and Stark, Proc. West. Pharmacol. Soc., in press). Based on its minimal behavioral effects, SC-13504 appears to be the most selective anticonvulsant of the three benzhydryl piperazines tested here.

1427 EFFECTS OF THE TRICYCLIC ANTIDEPRESSANTS DESIPRAMINE AND DOXEPIN ON ANTICHOLINERGIC AND CNS ACTIVITY IN NON-DEPRESSED VOLUNTEERS. George R. Peterson*, Russell M. Hostetler*, Barry Blackwell*, Ronald Kuzma*, and Allen B. Adolphe. Depts. of Pharmacology & Psychiatry, Sch. Med., Wright State U., Dayton, OH 45435, and Epidemiology and Biostatistics, University of Cincinnati College of Medicine, Cincinnati, OH 45267.

Using methodology developed by this group (Blackwell et al, Psychopharmacologia 25:205, 1972), dose response relationships for anticholinergic activity, quantified by measurements of salivary flow, and mood, quantified by Clyde Mood Scale factor scores for subjective CNS states, were demonstrated for tricyclic antidepressant drugs (TADs). In the most recent study, the widely used TADs desipramine (Norpramin) and doxepin (Sinequan) were compared. The trial was of double-blind crossover design involving 10 non-depressed female volunteers, with each subject randomly assigned to each of 5 treatments (5 x 5 Latin square). Placebo and doses of 50 and 100 mg for both drugs were used. Salivary flow, an index of anticholinergic activity, was significantly depressed by active drug treatment. Doxepin, however, produced significantly greater reduction in salivary flow than desipramine at the higher dose ($p<0.05$). The Clyde Mood Scale factor scores for the subjective states of "friendly", "aggressive", "dizzy", "clear thinking", "sleepy" and "unhappy" were also tabulated. Significant differences were observed in 4 of the 6 scores: "sleepy", "friendly", "aggressive", and "clear thinking" ($p<0.05$). In 1 of the 4 ("sleepy"), the impairment produced by doxepin was significantly greater than desipramine's at both doses ($p<0.05$). The quantified Clyde Mood Scale scores are in good agreement with the subjective complaints volunteered by the study participants. In addition, the subjects consistently made more complaints and rated these experiences more severe after taking doxepin than after desipramine at both doses. These observations, and related clinical studies by this group involving other TADs (imipramine and amitriptyline), are in good agreement with recently reported in vitro and animal studies relating anticholinergic and CNS effects to one another and to TAD structure. These studies have succeeded in demonstrating concurrent anticholinergic and sedative effects although dose response relationships for the separate actions have differed.

1428 MAO INHIBITION AND THE EFFECTS OF CENTRALLY ADMINISTERED LSD, BROM-LSD (BOL), SEROTONIN (5-HT) AND 5-METHOXYTRYPTAMINE (5-MT) ON THE CONDITIONED AVOIDANCE RESPONSE (CAR) IN RATS. Walter C. Prozialeck and W.H. Vogel, Department of Pharmacology, Thomas Jefferson University, Philadelphia, PA 19107

In order to clarify the behavioral effects of 5-HT, 5-MT, LSD and BOL, we examined the effects of these compounds on the CAR in normal and iproniazid pretreated rats. In addition, we determined the brain levels of centrally administered LSD and 5-MT at a time after injection that coincided with the peak behavioral activity of these compounds.

Drugs, dissolved in artificial CSF (10 μl), were injected into the right lateral ventricle via chronically implanted canulae. Behavioral tests were conducted in a standard shuttlebox apparatus (Cohen et al., Psychopharm. 12, 1214, (1972).

The intraventricular administration of artificial CSF, BOL (5μg), 5-HT (creatinine sulfate complex, 8.5 μg) and 5-MT (hydrochloride, 5-μg) had no significant effect on CAR performance. LSD (5μg) produced a marked disruption of the CAR lasting for $\sim$15 min. Iproniazid pretreatment alone (50 mg/kg 15 hrs prior to testing) had no effect. Following iproniazid pretreatment, 5-MT caused a marked disruption of the CAR with an increase in escape time and a decrease in the number of premature responses. 5-HT had a less pronounced but still significant effect on the CAR and increased reaction time. BOL had no effect. Surprisingly, the behavioral response to LSD was abolished by iproniazid pretreatment. This decrease in the response to LSD was also observed when the compound was given I.P. (300 μg/kg).

Ten minutes after intraventricular administration, whole brain levels of 5-MT were markedly higher in the iproniazed treated animals (1.5$\pm$.1μg) than in the non-treated animals (.06$\pm$.01 μg). Levels of LSD were not affected by MAO inhibition (.19$\pm$.10 μg vs. .15$\pm$.02 μg for the controls).

In summary, our data show a marked reduction in the behavioral effects of LSD and a marked increase in the effects of 5-MT and 5-HT following MAO inhibition. Levels of injected 5-MT are significantly elevated after MAO inhibition which probably results in the increased behavioral effects, whereas levels of LSD are not affected while the behavioral response is abolished. These findings, along with the fact that each drug has a slightly different effect on shuttle-box performance, suggests that LSD, 5-HT, and 5-MT may each exert their behavioral effects via different mechanisms within the CNS.

1429 AUGMENTED BEHAVIORAL RESPONSIVENESS TO CENTRALLY ADMINISTERED CATECHOLAMINE AGONISTS FOLLOWING LONG-TERM AMPHETAMINE TREATMENT. George V. Rebec and David S. Segal. Dept. Psychiat., Sch. Med., UCSD, La Jolla, CA 92093.

We have previously reported that long-term administration of d-amphetamine produces a progressive augmentation of amphetamine-induced psychomotor stimulation in rats. To determine the involvement of central mechanisms in the augmented behavioral response and to rule out changes in peripheral dispositional factors, we monitored the behavioral response to a variety of direct and indirect acting catecholamine agonists infused into the lateral ventricle of freely moving rats pretreated with subcutaneous injections of saline or 5.0 mg/kg d-amphetamine for 4 consecutive days. Infusion cannulae were stereotaxically implanted in the lateral ventricle at least one week prior to the initiation of the experiments. Approximately 24 hours after the last systemic injection of saline or d-amphetamine, the animals were connected to an intraventricular infusion apparatus and allowed one hour of habituation. Various doses of the test drugs were infused at a rate of 20 μl/hr for up to 3 hours. In amphetamine pretreated rats, an intraventricular infusion of d-amphetamine elicited a 50-100 per cent greater increase in locomotor activity than in saline pretreated controls. The behavioral response to central administration of direct acting catecholamine agonists (apomorphine, dopamine, norepinephrine) was also enhanced in rats receiving long-term amphetamine treatment. These results suggest that a facilitation of catecholaminergic transmission is involved in the chronic amphetamine-induced behavioral augmentation.

1430 The effect of Tryptophan Depletion on Brain 5-HT and the Response to Ethanol Administration. R.F. Ritzmann and B. Tabakoff Dept. of Physiology, U. of Ill. Medical Center, Chicago, IL.

Interactions of ethanol with serotonin (5-HT) systems in brain have been the subject of much recent research. In the present study 5-HT levels were modulated by omitting tryptophan (TRY) from the diets of mice for 4 days. Control mice received a similar diet with TRY added. Mice were pair fed to obtain equal control for weight loss. Two additional group fed the TRY deficient diet were given either daily injection of kynurenine (KYN) (75 mg/kg) or a single injection of TRY (75 mg/kg) 3 hours before testing. The result of these treatments on brain TRY and 5-HT was a 60 % reduction in TRY and a 50 % reduction in 5-HT in the mice receiving the low TRY diet as compared with normal pair fed animals. The single injection of TRY restored both TRY and 5-HT, while KYN had no effect on these levels. In the first series of experiments, the ability to metabolize ethanol was determined. Blood samples were taken at various times after the ethanol injection (3 gm/kg), and the amount of ethanol was determined by gas chromatography. Additional mice were decapitated and brain ethanol levels were measured. These studies indicate that the low TRY treatment results in a slower rate of ethanol metabolism. The daily treatment with KYN reversed this effect while the single injection of TRY was ineffective. Similarly treated groups of mice were used to determine the effect of the dietary treatments on sleep time and ethanol induced hypothermia. The results of these studies indicate that the low TRY fed mice were more sensitive to ethanol on both variables than normal TRY fed controls. The single injection of TRY reversed this increased sensitivity while KYN only slightly reduced this effect. These results indicate the effects of acute ethanol on sleep time and hypothermia may be mediated by 5-HT. The mechanism of this response is currently under investigation in our laboratory.

1431 EFFECTS OF PROPRANOLOL AND PHENTOLAMINE ON LOCAL CEREBRAL GLUCOSE UTILIZATION IN THE RAT. Helen Savaki*, Massako Kadekaro* and Louis Sokoloff. Laboratory of Cerebral Metabolism, NIMH, Bethesda, Md. 20014.

Propranolol blocks the action of sympathomimetic amines on β-adrenergic receptors whereas phentolamine blocks many responses that involve α-adrenergic receptors. The [^{14}C]deoxyglucose method measures the rates of local cerebral glucose utilization, and it has proved useful for mapping functionally related areas of the brain in various physiological and pathological states. This method has been applied to study the effects of propranolol and phentolamine administration in the rat. Normal conscious rats were infused intravenously with 0.25, 0.5, or 1.0 mg/Kg/min of propranolol or 0.25, 0.5, or 0.83 mg/Kg/min of phentolamine. Forty min after the administration of the drug local cerebral glucose utilization was measured during a 45 min period. Propranolol caused dose-dependent reductions in cerebral glucose utilization in several regions of brain, most prominently in the structures of the auditory pathway. Phentolamine also caused local reductions of cerebral glucose utilization in a number of cerebral structures but, in contrast to propranolol, caused increases in glucose consumption in the auditory system. These results suggest that adrenergic synapses may play an important role in the function of the auditory pathway of the rat.

1432 THE BEHAVIORAL EFFECTS OF CHRONIC ADMINISTRATION OF D-AMPHETAMINE AND APOMORPHINE AND THE DEVELOPMENT OF CONDITIONED STEREOTYPY. STANLEY R. SCHIFF* AND WAGNER H. BRIDGER. ALBERT EINSTEIN COLLEGE OF MEDICINE, DEPARTMENT OF NEUROSCIENCE, BRONX, NEW YORK 10461.

Male, hooded rats were randomly assigned to drug groups (1) saline control, (2) amphetamine hydrochloride 1.0 mg/kg, (3) amphetamine hydrochloride 6.0 mg/kg, (4) apomorphine 2.5 mg/kg, (5) apomorphine 5.0 mg/kg , and (6) pseudo-conditioning control-saline as drug treatment with amphetamine 1.0 mg/kg following the experimental session. The experimental session was conducted as nearly as possible at the same time each day, and consisted of (1) weigh animal, (2) expose to tone (CS) for 1 min. in injection cage, (3) inject animal with drug (UCS) and immediately place in observation aquarium, (4) score animal's behavior (UCR) for 2 min. intervals at 7 min., 16 min., and 25 min. post injection, (5) return animal to home cage. The behaviors (1) licking, (2) chewing, (3) head bobbing, (4) sniffing, (5) crossing(forepaws crossing into separate quadrants of the observational cage - frequency), (6) rearing (both forepaws leave floor - time and frequency), (7)forepaw pacing, and (8) grooming , were rated blind using microswitches and automatic counters through a two-way mirror from a sound-proof room. Day 1 was a baseline saline control day for all animals, days 2-11 were drug treatment days, while days 12-16 were again saline days. Significant conditioning was found for the head bobbing component of stereotypy for the amphetamine groups only, although not for locomotor (5 and 6) or other components. In addition, head bobbing showed potentiation over trials (Amp 1 mg/kg) , while licking and chewing showed tolerance over trials (Apo 5 mg/kg).

1433 NEUROLEPTIC ANTAGONISM OF BEHAVIORAL EFFECTS INDUCED BY 5-METHOXY N,N-DIMETHYLTRYPTAMINE IN MONKEYS. R.F. Schlemmer, Jr., N. Narasimhachari, & J.M. Davis. Ill. State Psychiatric Inst., Chicago, IL 60612.

5-Methoxy N,N-dimethyltryptamine (5-MeODMT) has been reported to be hallucinogenic in humans and has been considered as a possible endogenous psychotogen. We have previously reported that administration of 5-MeODMT to monkeys induces profound alterations in social and solitary behavior (Comm. Psychopharmacol. 1:105, 1977). Acute & chronic administration of 5-MeODMT, 0.25 mg/kg, to selected members of primate social colonies induces dog-like wet shakes, involuntary limb jerks, hypervigilance, & occasional stereotypies. The same dose decreases social groom & increases submissive gestures in most treated animals. Because of the similarities of several of the behavioral changes induced by 5-MeODMT to changes induced by d-amphetamine in this species, the effect of a neuroleptic agent on 5-MeODMT-induced behavioral changes was studied. Following the assessment of behavioral effects induced by i.m. administration of 0.25 mg/kg 5-MeODMT to selected members of a Stumptail macaque social colony, the experiment began with a 5 day baseline observation period. Haloperidol (HAL), 0.05 mg/kg, was then administered i.m. twice daily for 7 consecutive days. During the following wk., HAL and 5-MeODMT, 0.25 mg/kg, were administered concomitantly. Behavioral observation by an experienced, "blind" observer occurred for 1 hr. daily for 5 days each wk. The last HAL dose was given 2½ hrs. prior to observation. On designated days, vehicle or 5-MeODMT was administered i.m. to the treatment group monkeys 5 mins. prior to observation. HAL antagonized 5-MeODMT-induced hypervigilance while reducing the number of wet shakes induced by the hallucinogen. HAL also antagonized 5-MeODMT-induced increases in submissive gestures. A tongue protrusion dyskinesia induced by 5-MeODMT in 1 monkey was antagonized by HAL. However, the HAL + 5-MeODMT treated monkeys did not appear normal, frequently assuming abnormal postures & staring into space. 5-MeODMT-induced limb jerks were not antagonized by HAL in all treated monkeys. Social grooming scores, reduced by 5-MeODMT alone, were not returned to baseline levels by HAL. Pilot studies in individual monkeys with the neuroleptic methiothepin (MET) have yielded more favorable results. MET, 0.1 mg/kg, administered i.m. 2 hrs. prior to observation antagonized 5-MeODMT-induced wet shakes, limb jerks, & hypervigilance. These monkeys did not assume abnormal postures. Studies concerning the effect of MET on 5-MeODMT-induced behavior in primate social colonies are presently underway in our laboratory.

1434 EFFECTS OF INFANTILE STRESS ON ADULT AMPHETAMINE-INDUCED LOCOMOTOR ACTIVITY. H. Schreiber, K. Nau*, J. Elias*, J. Eatwell*, P. Reid* and R. Bell. Dept. of Psychol., Texas Tech Univ., P.O. Box 4100, Lubbock, TX 79409.

This study determined whether mild stress in infancy influences adult responsiveness to d-amphetamine. Fischer rat pups were removed from the nest for 3 min daily for days 2 through 7 after parturition in a typical early handling (EH) procedure (See Denenberg, 1967). Control (C) pups were left undisturbed except to cull litters (N=8). At 100±5 and 350±5 days of age (D/age), male Ss were tested once in a cross maze and once in an open field. At 350±5 D/age, Ss were tested once in a passive avoidance task. At 365±5 D/age, Ss were tested in a shock avoidance, T-maze discrimination learning and reversal task. These non-drug data are to be reported elsewhere (Elias, et al., in preparation). At 450±30 D/age (at least 2 wks after completion of the T-maze task), EH Ss were randomly assigned to a d-amphetamine (2.5 mg/kg, 2.5 mg/cc, s.c.) group (EH/Amph, N=5) or a saline group (EH/Sal, N=4). Also randomly assigned were non-handled subjects (C/Amph, N=7; C/Sal, N=7). Ss were injected once daily 30±5 min prior to observation for 2 min in a Y-maze over 8 days. As expected, C/Amph Ss showed significantly more locomotor activity than C/Sal Ss on the initial injection. Also as expected, C/Amph Ss showed progressively more stereotypy and progressively less locomotor activity across the 8 days of injection. EH/Amph Ss showed significantly less locomotor activity than C/Amph Ss on the initial injection; however the locomotor activity level of EH/Amph Ss failed to decline across injections despite an increase in stereotypy. Because EH/Amph Ss did not show elevated locomotor activity levels when later tested in the Y-maze in the absence of amphetamine injection, drug-conditioning of activity levels (See Pickens and Dougherty, 1971) could not explain the failure of this group's activity level to decline. No differences were found in urinations/defecations or in number of Y-maze arms entered. These results, which essentially replicated previous work in our laboratory (Schreiber, et al., in preparation), indicated that early infantile stress could influence the level of d-amphetamine-induced locomotor activity in adult animals. However, in contrast to previous work in our laboratory, this finding indicated that early handling's influence on amphetamine-induced locomotor activity was not tied to the level of amphetamine-induced stereotypy through response competition or interference.

1435 EFFECT OF SELECTIVE REDUCTION OF BRAIN CATECHOLAMINES ON ACTIVITY AND AVOIDANCE PERFORMANCE IN THE DEVELOPING RAT PUP. Bennett A. Shaywitz, Todd C. Grey*, and Judith W. Gordan*. Dept Ped. and Neuro., Yale Un Sch. Med., New Haven, CT. 06510.

Abundant evidence from several lines of investigation suggests that the phenomenon of behavioral arousal observed in the developing rat during the first month of postnatal life is related to the maturation of catecholaminergic (CA) mechanisms. We have recently reported that selective depletion of brain dopamine (DA) in the neonatal rat pup at 5 days of age results in increased activity between 2 and 3 weeks of life and significantly impaired performance in active avoidance tasks at 20 and 26 days of age compared to litter mate controls. In order to determine whether these effects are influenced by DA or noradrenergic (NE) pathways we have extended our observations to include rat pups depleted of both CA as well as to animals depleted of NE selectively. Depletion of CA was accomplished utilizing intracisternal administration of 6-hydroxydopamine hydrobromide (6-OHDA). Activity in a normal developing rat pups in all control groups was comparable and followed the pattern described previously by us, averaging 23.0 ± 2.78% at 8 days and 35.4 ± 3.03% at 12 days of age. By 15 days activity has increased to 44.3 ± 3.72% and declined at 19 days to 40.6 ± 3.17%. Rat pups selectively depleted of NE exhibited a similar developmental profile and did not differ from controls except on day 8 when they were significantly less active, (averaging 15.9 ± 3.02%, P<0.025). Rat pups depleted of both CA were also a less active on day 8 as well as day 12 of age but by 19 days of age activity had increased significantly to 54.4 ± 5.24% (P<0.025) and remained increased at 23 days as well. Rat pups depleted of DA selectively were significantly more active than those depleted of both CA at all ages tested. Performance in both T-maze and shuttle box did not differ from controls in NE depleted animals but was significantly impaired in rat pups depleted of DA or depleted of both CA (P<0.001). Whole brain NE was reduced to 62.4% of controls in NE depleted rats. This reduction was evident in hypothalamus (28.4% controls) and pons-medulla (81.0% controls). Whole brain DA and NE averaged 60.6% and 42.6% respectively in animals depleted of both CA. In these animals, NE was reduced in hypothalamus (19.8% controls) and pons-medulla (38 6% controls) while DA was reduced in striatum (21.2% controls). Whole brain DA averaged 35.5% in DA depleted pups with depleting of 98% in striatum, 28.6% in hypothalamus at 87.3% in olfactory tubercles. Our results support the notion that the phenomenon of behavioral arousal observed in the first month of postnatal life is mediated via dopaminergic mechanisms.

1436 THE EFFECTS OF SELECTED CNS STIMULANTS ON JUVENILE PRIMATE SOCIAL & SOLITARY BEHAVIOR. F.K. Siemsen*, R.F. Schlemmer, Jr., R.C. Casper*, D.L. Garver, & J.M. Davis. Ill. State Psychiatric Inst. & U. of Ill. Med. Ctr., Chicago, IL 60612.

Chronic administration of d-amphetamine (d-A) to juvenile monkeys induces several behavioral changes unlike those seen with similar administration to adult monkeys of the same species (Psychopharmacol. Comm. 2:49, 1976). On the basis of this finding, the behavioral effects of other selected CNS stimulants were examined in members of a juvenile primate social colony. Stimulants selected for this study included d-A, imipramine (Imip), pemoline (Pem) & caffeine (Caff). d-A, Imip, & Pem are all effective in treating hyperkinetic children, while Caff lacks this property. 3 members of a stable, peer-raised, juvenile Stumptail macaque social colony of 6 monkeys were selected to receive treatment during the expts. Each expt. began with a baseline observation period (base) of no less than 3 weeks. Following each base, the expts. consisted of n.g. administration of d-A 0.5 mg/kg for 4 wks., Imip 3.33 mg/kg for 3 wks., Pem 2.5 mg/kg for 5 wks., or Caff 10 mg/kg for 4 wks. Social & solitary behavior of each of the 6 monkeys was observed & recorded by an experienced, "blind" observer. d-A, Imip, & Pem all significantly decreased play activity from base levels, while all 3 significantly increased social grooming from base. d-A, Imip, & Pem all decreased vigilance scores from base levels also. Only d-A & Pem induced stereotyped behavior & significantly increased self grooming scores. d-A & Imip significantly increased huddling with eyes open. On the other hand, Caff failed to alter solitary play activity, vigilance, & self grooming from base. Caff reduced social groom from base. Similar behavioral changes induced in juvenile monkeys by the 3 antihyperkinetic agents, but not by Caff, suggests that drug-induced reduction of play activity & vigilance with increased social groom may be indicative of possible antihyperkinetic properties of drugs. To test a new drug in this paradigm, nomifensine (Nom) was administered n.g. to the same 3 juvenile monkeys. Following a 4 wk. base, Nom was administered at doses of 0.05, 0.075, 0.1, 0.15, 0.2, & 0.3 mg/kg. Each dose was given for 1 wk. Observation procedures were identical to those used previously. Nom at 0.2 mg/kg, significantly elevated social & self grooming from base. The 2 lower doses of Nom significantly elevated solitary play. However, solitary play scores showed a dose-dependent decrease from 0.05 to 0.2 mg/kg of Nom. In addition, no social play or invitations to play were observed in Nom-treated monkeys above the 0.1 mg/kg dose. It appears that Nom induces some behavioral changes in juvenile monkeys similar to d-A, Imip, & Pem. These results suggest that Nom may prove effective in the treatment of hyperkinetic children.

1437 DISCRIMINATIVE EFFECTS OF COCAINE IN THE RHESUS MONKEY. William Slikker, Jr.* and Keith F. Killam, Jr.* (SPON: Larry G. Stark). Dept. of Pharm., Sch. Med., UCD, Davis, CA 95616.

Rhesus monkeys were trained to discriminate various unit doses of cocaine from vehicle in a previously described threshold determination paradigm (The Pharmacologist 18:197, 1976). After establishing a stable intravenous cocaine threshold dose, various anorectic agents and vehicle were administered on test and control days interposed between threshold determination days.

THRESHOLD DETERMINATION DAY

P	S	S	X	X	S	S	2X								
SA							2X	2X	2X	2X	2X	S	S	S	S

CONTROL DAY

P	S	S													
SA				S					S						
INJ			V		V		V		V						

TEST DAY

P	S	S													
SA											S	S	S	S	S	S	S	S
INJ			V		Y		2Y		3Y									

(P=Prime by remote infusion; SA=Self-infusion by animal; INJ=IM injection; V=Vehicle; S=Saline; X=Drug x; Y=Drug y)

The smallest intramuscular (IM) dose to evoke 15 minutes of consistent responding was determined for each drug and ranged from 0.13-2.93 μmol/kg IM (0.025-1.25 mg/kg IM): d-methamphetamine<d-amphetamine<mazindol<cocaine<diethylpropion<phenmetrazine<phentermine<phendimetrazine<ephedrine. The duration and rate of responding increased in a dose-related manner for each agent. However, an inverted U dose response was observed in that the largest dose of each drug (20-40 X threshold) diminished responding in the middle of the session. In contrast, 3 structurally related agents, clortermine (0.1-2.0 mg/kg IM), chlorphentermine (0.1-3.0 mg/kg IM) and fenfluramine (1.0-4.0 mg/kg IM) produced less responding than did vehicle.

1438 EFFECTS OF β-CARBOLINES AND SEROTONERGIC DRUGS ON AUDIOGENIC SEIZURES IN DBA/2J MICE. David L. Sparks* and Neil S. Buckholtz. Dept. Biochem. and Dept. Psychiatry. Behav. Sci., Med. Univ. S.C. Charleston, SC 29403.

McIsaac et al. (J. Neurochem. 19, 1203, 1972) reported that 6-methoxy-1,2,3,4-tetrahydro-β-carboline (6-MeO-THBC)(100 mg/kg) increased brain concentration of serotonin approximately two-fold, and we (Buckholtz, Pharmac. Biochem. Behav. 3, 65, 1975) have shown that 6-MeO-THBC (100 mg/kg) effectively blocks audiogenic seizures (AGS) in 21 day-old DBA/2J mice 2 hr after injection. The present series of studies determined time- and dose-response effects for this blockade of AGS and compared 6-MeO-THBC with drugs sharing some common effects.

At a 100 mg/kg dose, 6-MeO-THBC was effective at blocking AGS between 10 min and 12 hr after injection, with maximal inhibition at 1 hr. The dose-response effect at 1 hr showed that 6-MeO-THBC was effective at blocking AGS at doses between 25 and 100 mg/kg with a maximal effect at 100 mg/kg. Other β-carbolines were also tested at 1 hr at a 50 mg/kg dose, and their effectiveness at blocking AGS relative to 6-MeO-THBC (50 mg/kg) was as follows: 6-MeO-THBC = THBC > norharman > 6-MeO-tetrahydroharman > tetrahydroharman. Pretreatment with the proposed serotonergic receptor blockers cyproheptadine (7.5 mg/kg), methergoline (3 mg/kg), and methysergide (5 mg/kg), the 5-hydroxytryptophan (5-HTP) decarboxylase inhibitor RO4-4602 (25 mg/kg), or the monoamine depletor reserpine, had no effect on the action of 6-MeO-THBC.

Reference drugs with known actions were also tested. These included the following: the monoamine oxidase (MAO) inhibitors pargyline (50 mg/kg) which effectively blocked AGS, and clorgyline (5 mg/kg) and deprenyl (5 mg/kg) which had little or no effect; the uptake blockers chlorimipramine (25 mg/kg) which blocked AGS and fluoxetine (Lilly 110140, 10 mg/kg) which had no effect; the serotonergic receptor agonists quipazine (10 and 20 mg/kg) which blocked only the death component and 5-methoxy-N,N-dimethyltryptamine (5 mg/kg) which had no effect; the serotonin precursor 5-HTP (50 and 100 mg/kg) blocked AGS.

From these data we cannot isolate any one particular action of 6-MeO-THBC (e.g. increased serotonin concentration, uptake inhibition, MAO inhibition, receptor agonist) which produces the blockade of AGS. It may be that some or all of these acting together are involved. However, the fact that none of the receptor blockers affected the response to 6-MeO-THBC may indicate that 6-MeO-THBC acts on a population of serotonergic receptors not affected by these blockers or that it is involved with another neurotransmitter which cannot be manipulated by serotonergic drugs. (Supported in part by P.H.S. grant MH-26712).

1439 COMPARATIVE EFFECTS OF HALLUCINOGENIC DRUGS ON ROTATIONAL BEHAVIOR FOLLOWING UNILATERAL 6-HYDROXYDOPAMINE LESIONS. Michael E. Trulson, Arlene D. Stark* and Barry L. Jacobs. Dept. Psychol., Princeton Univ., Princeton, NJ 08540

The dopaminergic actions of various hallucinogenic drugs was assessed by examining their effects on turning behavior in rats with unilateral 6-hydroxydopamine lesions of the nigro-striatal pathway. LSD (0.1 and 0.2 mg/kg) produced strong contralateral turning, indicating that it is a potent dopamine receptor agonist, while BOL (5 mg/kg), a non-hallucinogenic congener of LSD, was found to be a weak dopamine receptor agonist. STP (2 and 5 mg/kg) and mescaline (50 and 100 mg/kg) produced significant ipsilateral turning, indicating that these compounds have a moderate dopamine-releasing action. DMT (10 and 20 mg/kg) and 5-M-DMT (0.75 and 1.25 mg/kg) produced weak ipsilateral turning, which, however, was not significantly different from that produced by the non-hallucinogenic compounds tryptamine (40 mg/kg) or scopolamine (0.25 mg/kg). Psilocin (1 to 20 mg/kg) produced no significant turning in either direction.

Previous studies revealed that a common property of many hallucinogenic drugs is their ability to inactivate the brain serotonin system by depressing raphe neuronal activity. Furthermore, the relative potency of hallucinogens in depressing the activity of raphe neurons generally parallels their potency on psychological and perceptual measures in humans (LSD > STP > Psilocin > DMT > Mescaline). Together, these studies suggested that the efficacy of a drug in producing an hallucinogenic experience may be a function of the drug's effect on raphe neurons. However, the present data demonstrate that the more potent hallucinogens also activate dopamine receptors, either directly or via the release of stored dopamine. Thus, the present data, in conjunction with previous studies, indicate that while inactivation of the brain serotonin system may be a necessary and sufficient condition for hallucinogenesis, the ability to activate dopamine receptors may be an important additional factor which determines the potency of hallucinogens.

1440 PHENELZINE POTENTIATION OF 5-METHOXY N,N-DIMETHYLTRYPTAMINE-INDUCED BEHAVIORAL CHANGES IN PRIMATE SOCIAL COLONIES. C.B. Tyler, R.F. Schlemmer, Jr., N. Narasimhachari, G.N. Pandey, & J.M. Davis. Ill. State Psychiatric Inst., Chicago, IL 60612.

5-Methoxy N,N-dimethyltryptamine (5-MeODMT), a hallucinogen, has been reported to induce abnormal behavior as well as altering normal affiliative behavior in monkeys. A previous report indicates that 5-MeODMT-induced hyperactivity in rats is potentiated by monoamine oxidase (MAO) inhibition. To study the effect of this combination in monkeys, a stable social colony of 5 adult Stumptail macaques was divided into 2 treatment groups of 2 & 3 monkeys respectively. The experiment started with a 1 week behavioral baseline when vehicle (Veh) was injected in all 5 animals prior to observation. At designated times during the study, each group received an i.m. injection of 5-MeODMT at doses of 50, 200, & 250 µg/kg for 5 consecutive days each. The group not treated with 5-MeODMT at that time received Veh i.m. Also during the study, each of the 2 groups received n.g. treatment with the MAO inhibitor, phenelzine (PHZ) 4 mg/kg/day in 2 divided doses for 14 days. The 1st week of PHZ treatment, this group received Veh; while the 2nd week of PHZ, the group received 5-MeODMT, 50 µg/kg. MAO inhibition was determined by assaying platelet MAO activity using ^{14}C-tyramine as substrate. By day 7 of PHZ, all PHZ-treated monkeys had at least 90% MAO inhibition with a mean ± SEM of 96.1% ±0.9%. Behavioral observation of the colony by an experienced, "blind" observer occurred for 1 hour, 5 days each week, beginning 5 mins. after injection. At 250 µg/kg, 5-MeODMT induced dog-like wet shakes, involuntary limb jerks, & hypervigilance while decreasing social groom & increasing submissive gestures in some treated animals. PHZ + 5-MeODMT 50 µg/kg increased wet shakes, limb jerks, & vigilance above levels seen with 50 µg/kg of 5-MeODMT alone. The combination also induced stereotyped behavior & reduced social grooming to a greater extent than 5-MeODMT alone. It appears that MAO inhibition potentiates at least some of the behavioral effects of 5-MeODMT. This suggests that 5-MeODMT may, at least in part, act through monoamine systems.

1441 PHARMACOLOGICAL KINDLING PRODUCED BY THE LOCAL ANESTHETIC-LIKE PESTICIDE, CHLORDIMEFORM. George K.W. Yim*, William R. Pfister* and Vickie Nolan*. (SPON: R.G. Babington). Dept. Pharmacology and Toxicology, Purdue University, West Lafayette, IN 47907.

Chlordimeform (CDM) has a number of actions common to local anesthetics (i.e. nerve conduction blockade, amygdaloid EEG seizure activity, convulsions, cardiovascular depression, etc.) and induces behavior characteristic of the serotonergic syndrome described by Jacobs (Life Sci. 19: 777-786, 1976). Since pharmacological kindling had been demonstrated with cocaine and lidocaine, the effects of subconvulsive doses of CDM were examined in rats. The daily administration of 60 mg/Kg CDM (i.p.) resulted in the progressive development (kindling) of seizures (100% response in 10 days). Spontaneous (pre drug) seizures also developed at a parallel rate with a 5 day lag period. This kindling phenomena was reversible; by fifteen days after drug cessation, only 50% of the animals showed spontaneous seizures. Although cropophagia and consumption and growth rates were decreased. These results suggest that pharmacological kindling is a phenomena common to convulsant local anesthetics. Besides the kindled seizures, a progressive development of tremor, spasticity, hyperreactivity and increased locomotor activity was also observed following the chronic 60 mg/Kg daily doses of CDM. In naive animals, these components of the serotonergic syndrome could only be obtained by higher single doses of CDM. The studies provide another example of pharmacologically kindled behavior. (Support in part by grants from NIH (NS 12077) and EPA (R-803965).

RECEPTORS

1442 SPECIFIC ^{3}H-MUSCIMOL BINDING TO SYNAPTIC GABA RECEPTORS. Beaumont, K.*, Chilton, W.*, Yamamura, H.I. and Enna, S.J., U. Arizona, Coll. Med., Tucson; U. Wash., Seattle; U. Texas Med. Schl., Houston.

Muscimol (3-hydroxy-5-aminoethylisoxazole) is a structural analog of γ-aminobutyric acid (GABA) and has been shown, both neurophysiologically and biochemically, to be a potent GABA receptor agonist. In man, after systemic administration, muscimol is soporific at low doses and hallucinogenic at high doses. Since it is possible that the behavioral effects illicited by this drug are partially due to an action at a receptor other than the GABA site, the characteristics of high affinity ^{3}H-muscimol binding were studied in brain to determine the specificity of this agent for the synaptic GABA receptor. Rat brain synaptic membranes (2 mg protein) were incubated for 15 min at 4° in 6 ml 0.05 M Tris-citrate buffer (pH 7.1 @ 4°) containing 1.5 nM custom tritiated muscimol (0.28 Ci/mmole) in the presence or absence of various concentrations of unlabeled compounds. The reaction was terminated by a 10 min centrifugation at 48,000 x g and, after rinsing, the pellet was dissolved and analyzed for radioactivity. Specific ^{3}H-muscimol binding was found to be saturable with a high affinity (K_d = 2.2nM). The regional distribution of ^{3}H-muscimol binding is strikingly similar to that reported for GABA receptor binding with the cerebellum > cerebrum > striatum > hippocampus > midbrain > hypothalamus > medulla-pons > spinal cord. ^{3}H-Muscimol binding is also pharmacologically identical to GABA receptor binding with only those drugs and amino acids which are known to neurophysiologically interact with the GABA receptor having any potency in displacing ^{3}H-muscimol. The binding is stereospecific with the neurophysiologically active isomers of GABA receptor agonists and antagonists having a greater affinity for the binding site than the inactive isomers. The results suggest that muscimol is a highly specific GABA receptor agonist which can be used to better understand the behavioral, biochemical and pharmacological characteristics of the GABAergic system. Supported by USPHS MH-27257 and an NIMH RCDA (HIY), and USPHS MH-29739, The Huntington Chorea Foundation, Pharmaceutical Manufacturers Association, and Merck Sharp & Dohme Co. (SJE).

1443 DIFFERENTIATION OF ANGIOTENSIN AGONISTS AND ANTAGONISTS AT MAMMALIAN BRAIN ANGIOTENSIN RECEPTORS. James P. Bennett, Jr. and Solomon H. Snyder. Dept. Pharmacology and Psychiatry, Johns Hopkins Univ. Sch. Med., Baltimore, MD. 21205

Under appropriate conditions [^{125}I]-(Ile$_5$) angiotensin II (^{125}I-AII) binds to mammalian brain membranes reversibly, and with high affinity (K_D=0.2 nM), and is displaced by unlabeled angiotensin peptides in a manner consistent with physiological interactions with angiotensin receptors (Bennett and Snyder, JBC 251:7423, 1976). ^{125}I-AII binding to brain and adrenal gland membranes is reduced 80-90% by decreasing the [Na^+]in the incubation buffer from 150 mM to 10 mM. Small cations (Na^+, Li^+, K^+) are more effective than larger cations (Rb^+, Cs^+, Hex^+, $(Et)_4N^+$) in reversing the decrease in ^{125}I-AII binding in 10 mM Na.

Sarcosine$_1$leucine$_8$angiotensin II (S_1L_8AII), a potent angiotensin antagonist, can be iodinated by the Chloramine-T procedure to s.a. of 600-700 Ci/mmol. ^{125}I-S_1L_8-AII binds to rat or calf brain and rabbit adrenal gland membranes reversibly and with high affinity (K_D=0.3 nM in calf brain). In 150 mM Na^+ buffer unlabeled angiotensin peptides displace ^{125}I-S_1L_8-AII binding with potencies very similar to their potencies at displacing ^{125}I-AII binding, suggesting that ^{125}I-S_1L_8-AII also labels physiologically relevant angiotensin receptors. Unlike ^{125}I-AII binding to brain and adrenal, ^{125}I-S_1L_8-AII binding is reduced only about 25% by decreasing the [Na^+] to 10 mM. The potencies of unlabeled angiotensin antagonists at displacing ^{125}I-S_1L_8-AII binding to brain receptors are reduced 2-4 fold by reducing the [Na^+] to 10 mM. In contrast, the potencies of unlabeled angiotensin agonists at reducing brain ^{125}I-S_1L_8-AII binding are reduced 20-50 fold by lowering the [Na^+] to 10 mM.

Saturation studies of ^{125}I-AII binding to calf brain membranes indicate that the binding affinity is reduced about 20-fold by decreasing the incubation buffer [Na^+] from 150 to 10 mM with no decrease in the number of binding sites. This reduction in ^{125}I-AII binding affinity results from a 20-fold decrease in the apparent association rate constant in 10 mM compared to 150 mM [Na^+] with little change in the apparent dissociation rate constant.

In summary, reducing the incubation buffer [Na^+] selectively reduces the affinity of angiotensin receptors in brain and adrenal for angiotensin agonists. Angiotensin receptor binding studies using ^{125}I-S_1L_8-AII can discriminate in vitro between agonists and angtagonists. These findings are consistent with the existence of distinct agonist- and antagonist-preferring conformations of brain and adrenal angiotensin receptors and a selective interaction of [Na^+] with the agonist-preferring conformation. 1444 *REGULATION OF NICOTINIC ACETYLCHOLINE RECEPTOR IN BRAIN.* *Ronald J. Bradley, Barbara J. Morley, Joan F. Lorden, George B. Brown and George E. Kemp*. Neurosciences Prog., Sch. Med., Univ. of Ala. B'ham., Birmingham, AL 35294.*

Nicotinic acetylcholine receptor (nAChR) has been identified in mammalian and avian brain by both in vivo and in vitro labelling of α-bungarotoxin. α-bungarotoxin binding is not uniformly distributed throughout the rat CNS and corresponds well with known cholinergic markers. The variables which regulate the concentration of these binding sites have not been studied.

We have investigated several methods which might alter nAChR concentration in brain, including cross-breeding, lesions, prolonged drug administration and dietary choline loading. C57BL and DBA inbred mouse strains are known to differ in their level of cholinergic markers and in their response to cholinergic drugs. We have dissected and biochemically investigated α-bungarotoxin binding in cortical, hippocampal, hypothalamic, and brainstem reticular formation samples from C57 and DBA parental strains, their F_1, F_2, B_1, and B_2 crosses and their reciprocal crosses. C57BL mice have a larger brain weight and a greater number of α-bungarotoxin binding sites in most areas which indicates a dominant mode of inheritance. Females of all crosses have a greater concentration of nAChR and a higher concentration of protein. Reciprocal crosses did not differ in protein or nAChR indicating that maternal effects are not a significant environmental variable. Lesions of areas containing high concentrations of nAChR produce increases in nAChR and protein levels in cholinoceptive areas.

We have not yet found a drug regimen which produces alteration of nAChR concentration, but administration of choline in the drinking water produces an increase in nAChR throughout the brain without a parallel change in protein level.

This work was supported in part by NSF Grant #BNS 75-14321 and NIMH Grant #1 T32 MH14286.

1445 COMPARISON OF AGONIST AND ANTAGONIST BINDING TO β-ADRENERGIC RECEPTORS IN THE CEREBELLUM. David B. Bylund, David C.U'Prichard and Solomon H. Snyder. Dept. of Pharmacology and Psychiatry, Johns Hopkins Univ. Sch. Med., Baltimore, MD. 21205

The properties of the β-adrenergic receptors in the calf cerebellum have been studied using an antagonist ligand [^{3}H]dihydroalprenolol (DHA) and an agonist ligand [^{3}H]epinephrine (EPI). At 25°C, the specific binding of both ligands to a crude particulate fraction is rapid, reversible, and saturable. The binding is stereospecific with the (-)-isomers of both agonists and antagonists being 30-150 fold more potent than the corresponding (+)-isomers.

Ligand	Inhibition of Specific Binding IC_{50} nM [^{3}H]DHA	[^{3}H]EPI
(-)-isoproterenol	100	2
(-)-epinephrine	300	20
(-)-norepinephrine	5,000	200
(+)-isoproterenol	6,000	300
(-)-propranolol	1	2
(±)-butoxamine	3,000	12,000
(-)-practolol	15,000	7,000
(+)-propranolol	130	60

Epinephrine is much more potent than norepinephrine in inhibiting the specific binding of both radioactive ligands, which suggests that the receptors are of the β_2 type. Furthermore, the β_2 antagonist, butoxamine, is more potent than the β_1 antagonist, practolol, in inhibiting specific [^{3}H]DHA binding, although they are about equally effective agaonist [^{3}H]EPI binding. The IC_{50} values for the agonists are at least 10-fold lower in inhibiting agonist binding than in inhibiting antagonist binding. This observation indicates that the β-receptor may have agonist and antagonist conformations similar to the opiate, dopamine, α-adrenergic and serotonin receptors. On the other hand, in frog erythrocyte membranes agonists had equal potencies in inhibiting the binding of an agonist and an antagonist ligand to β-receptors (Lefkowitz and Williams, PNAS 74:515, 1977). In contrast to the cerebellum, the β-receptors in the cerebral cortex, as well as the other regions of the calf brain appear to be of the β_1 type and [^{3}H]EPI binding to these receptors cannot be demonstrated. The β-receptors in the cerebellum of several other species such as lamb, dog and rat are also found to be of the β_2 type when assayed using [^{3}H]DHA. There is a wide variation in the apparent number of cerebellar β-receptors with calf ≥ lamb > dog > rat. Under our conditions, [^{3}H]EPI binding to β-receptors is observed only in the calf and lamb. (Supported by NIH grants MH-05063 and MH-18501.)

1446 α-BUNGAROTOXIN BINDING TO CHICK SYMPATHETIC NEURONS Salvatore Carbonetto*, Douglas M. Fambrough, and Kenneth J. Muller, Dept. of Embryology, Carnegie Institution of Washington, Baltimore, Md. 21210.

α-Bungarotoxin (α-BuTX) binds to primary cultures of chick sympathetic neurons as well as to chick sympathetic ganglia. Light autoradiographs of cultured neurons incubated with ^{125}I-α-BuTX show that the toxin binds specifically to neurons and that this binding is completely blocked by curare (10^{-4}M).

Chick sympathetic neurons in culture have acetylcholine (ACh) receptors and iontophoresis of acetylcholine onto neurons, as early as three days in culture, produces depolarizing responses in these cells. The ACh response is quickly blocked by curare (10^{-4}M) but can still be recorded in cultures treated with α-BuTX (1μg/ml). Curare also blocked ACh responses recorded in neurons that were pre-treated with α-BuTX. Extracellular recording from an in vitro preparation of the lumbosacral sympathetic chain of 18 to 20 day embryos revealed a "ganglionic potential" that was thought to be synaptically mediated because stimulation of the post-ganglionic nerve produced little or no response in the pre-ganglionic nerve and also because curare (10^{-5}M) reversibly blocked the response. Application of α-BuTX in concentrations up to 60μg/ml had no effect on the ganglionic potential, though it seems clear from autoradiographs that the drug can readily diffuse into the ganglion.

The α-BuTX binding molecule in chick sympathetic neurons is an integral membrane protein. Binding of α-BuTX to a detergent extracted membrane fraction of sympathetic ganglia is saturable and is blocked by d-tubocurarine. Characterization of this molecule has been difficult since α-BuTX binds reversibly to neurons, dissociationg with a half-time of 3.5 hrs at 23°C. However, when α-BuTX is crosslinked to its receptor with glutaraldehyde, dissociation is reduced to less than 10% for 24 hrs at 23°C. On sucrose gradients this "fixed" toxin-receptor complex cosediments with α-BuTX-ACh receptor complexes extracted from cultures of chick muscle (10s). Thus, the α-BuTX binding molecule in chick sympathetic neurons remains a candidate for the neuronal ACh receptor. However, the failure of α-BuTX to affect cholinergic responses in these cells weakens the case for this interpretation and suggests that caution be used in biochemical and anatomical studies of α-BuTX binding in the nervous system.

1447 MULTIPLICITY OF OPIATE RECEPTORS: IMPLICATIONS FOR METHODOLOGY IN THE OPIATE RECEPTOR BINDING ASSAY. E. E. Codd* & W. L. Byrne. Dept. Biochem. UTCHS, Memphis, TN 38163.

While opiates produce in vivo a multiplicity of effects (antinociception, hypothermia, respiratory depression, peristaltic diminution, etc.), the phenomena of cross-tolerance between opiates and the blockade of opiate action by specific antagonists have pointed to a common receptor site. Recently, however, evidence for receptor heterogeneity has been found: high doses of levorphanol failed to protect against naloxone-precipitated withdrawal (JPET, 182:189, 1972). Differences were found in opiate binding properties of narcotic receptors from guinea pig ileum and rat brain (Acta Pharm. Toxic., 37:211, 1975). Morphine and pentazocine appeared to act on separate receptors to produce their analgesic effects, but on similar receptors to produce their respiratory effects (Opiates and Endogenous Opioid Peptides, p.281, 1976). Three classes of opiate receptors have been distinguished by differential actions of classes of morphine-like and nalorphine-like drugs (JPET, 197:517, 1976). We report here evidence for multiple brain opiate receptors in an inbred strain of mice, C57BL/6J. According to an opiate receptor binding assay on a crude particulate preparation, there are more opiate antagonist than agonist receptors. Competition experiments studying the binding of 1nm ^{3}H-dihydromorphine (DHM), ^{3}H-morphine or ^{3}H-naltrexone in the presence of unlabeled morphine, naloxone or naltrexone show differences. Morphine competes more effectively with ^{3}H-DHM or ^{3}H-morphine, while naloxone competes more effectively with ^{3}H-naltrexone. These relationships also hold in the presence of 100mM Na^{+}. Heterogenity in the opiate receptor population calls into question the practice of using a fixed unlabeled control for nonspecific binding without regard for whether the labeled drug is an agonist or an antagonist. A case might be made for the use of the radiolabeled and unlabeled forms of the same drug (Acta Pharm. Toxic., 37:211, 1975), but what "displacer" would one use in competition experiments between two different drugs? The use of a large excess of unlabeled drug to eliminate "non-specific" binding has carried over into work on endorphins. But why should an opiate be used as a standard in defining the binding of the hypothesized endogenous ligand(s) for the receptor? Furthermore, our work (Prog. Neuro-Psychopharm, 1977) shows that double reciprocal plots of the inhibition of DHM or naltrexone by partially purified endorphin extrapolate to 100% inhibition of binding without correction for supposed "non-specific" binding. These results call for more limited and careful use of controls for presumed non-specific binding in assaying for the opiate receptor.

1448 DIFFERENTIAL LOCALIZATION OF DOPAMINE RECEPTOR ^{3}H-HALOPERIDOL BINDING AND ADENYLATE CYCLASE. Ian Creese, Robert Schwarcz*, Joseph T. Coyle and Solomon H. Snyder. Dept. Pharmacol., Johns Hopkins Univ. Sch. Med., Baltimore, MD. 21205.

The characteristics of ^{3}H-haloperidol (HAL) binding to rat striatal membranes and of the dopamine-stimulated adenylate cyclase (DAC) in rat striatal homogenates suggest that both may be related to dopamine (DA) receptors. Both exhibit a similar agonist specificity with apomorphine and DA > norepinephrine >> isoproterenol and stereospecificity with respect to butaclamol antagonism. However, although neuroleptic antagonism of HAL binding correlates well with in vivo pharmacological activity as DA antagonists, the butyrophenone and related neuroleptics are too weak relative to the phenothiazines in antagonizing DAC. This different pharmacological profile suggests that HAL binding and DAC may not be identifying the same receptor sites.

Stereotaxic injection of kainic acid (KA) into rat striatum has been shown to lead to degeneration of both GABAergic and cholinergic neurones intrinsic to the striatum while sparing the DA input. Since pharmacological evidence suggests that DA receptors may be present on the intrinsic neurones, HAL binding and DAC were measured following unilateral striatal KA injections. Two days following injection DAC was reduced by 80-90% in the injected striatum compared to the uninjected side. However, HAL binding was reduced by only 20%. HAL binding continued to fall over 6 days post-lesion reaching a minimum of 40-50% of control by day 6. These decrements were maintained for at least 22 days. Enzymatic assays indicated about a 60% loss of choline acetyltransferase (CAT) and glutamic acid decarboxylase (GAD) but no reduction in tyrosine hydroxylase (TH) activity at this time. Since histological analysis indicated a severe loss of striatal neurones with a reaction gliosis most of the DAC is probably neuronally located. Since nigro-striatal 6-hydroxydopamine lesion or midbrain hemisection does not reduce HAL binding it would appear that the remaining HAL binding sites are not DA autoreceptors. Additional possible sites for HAL binding are DA receptors on presynaptic terminals of other neurones innervating the striatum, blood vessels or glial cells. Since a major striatal afferent pathway arises from the cortex, large unilateral cortical lesions were made by knife cuts or aspiration. Five days after such lesions HAL binding was reduced by 25-50% with little change in TH or GAD activity. DAC and CAT were reduced, perhaps indicating some trans-synaptic phenomena.

These results indicate that the DAC and HAL binding sites in the striatum may be located on different neuronal structures and that some HAL binding may represent presynaptic DA receptors. (Supported by DA-05328, MH-26654, MH-18501, NS-13586 and NIMH RCDA's to JTC and SHS.)

1449 CLONIDINE IS A POST-SYNAPTIC α-ADRENERGIC ANTAGONIST IN THE RAT PAROTID: CORRELATION OF [^{3}H] DHE BINDING AND K^{+} RELEASE. J. N. Davis, W. Maury*, and E. Hoyler*. VA Hospital and Duke University, Durham, NC 27705.

The rat parotid gland offers unique advantages for the study of post-synaptic α-adrenergic receptors. Preparations of dispersed parotid acinar cells have no apparent pre-synaptic elements and release K^{+} when exposed to α-adrenergic stimulation. α-Adrenergic membrane receptors can be measured in dispersed cells and membranes from the parotid with [^{3}H] dihydroergocryptine (DHE) radioligand binding. We studied the effect of clonidine on K^{+} release and DHE binding in the parotid. Clonidine was potent in displacing [^{3}H] DHE from membrane binding sites (K_D = 0.1 μM), but did not cause K^{+} release from dispersed cells even up to concentrations of 100 μM. Instead clonidine was a potent competitive antagonist of epinephrine-induced K^{+} release (pA_2 = 0.3 μM). Preliminary data suggest that naphazoline and ST 600, related imidazoles, are also α-antagonists in the parotid. These data show that the α-adrenergic blockade by clonidine results from an interaction with post-synaptic α-adrenergic membrane receptors. This is the first report of the α-adrenergic blocking action of clonidine in a peripheral tissue and suggests that parotid α-receptors may differ from other peripheral α-receptors. Since DHE binding sites in rat central nervous system resemble DHE binding in parotid, receptors with properties similar to parotid α-adrenergic receptors may be present in brain. Whether the central hypotensive action of clonidine results from its α-adrenergic agonist or antagonist properties remains to be determined.

1450 DEPRESSION OF CUTANEOUS MECHANORECEPTOR RESPONSE TO MECHANICAL STIMULATION BY SKIN COOLING. E. Djalali* (SPON: E. R. Perl). Dept. Physiology, Univ. North Carolina, Chapel Hill, NC 27514.

Activity of single cutaneous sensory units with myelinated afferent fibers was recorded from centrally-cut peripheral nerve of barbiturate-anesthetized cat with micropipette electrodes, in the fashion described by Burgess and Perl (J. Physiol. 190: 541-562, 1967). The sensory units were classified according to the criteria described by Burgess, Petit and Warren (J. Neurophysiol. 31: 833-848, 1968). When a stable recording from a low threshold mechanoreceptor was attained, its response to a standardized, effective stimulus, such as the rapid movement of a camel's hair brush across the receptive field, was averaged over 25 trials; repeated averages gave reproducible and stable values. The skin of the receptive field was then cooled by contact with a small thermode held at 0°C and the mechanical stimulation repeated. A total of 45 hair follicle receptors (predominantly G-1 type) and 30 "field" receptors have been tested with various degrees of transient or persistent cooling. All have shown substantial (50-75%) depression of the mechanically-induced response. This depression occurred whether or not the cutaneous cooling evoked a response. These results suggest that the common experience of decreased tactile perception and acuity in skin areas exposed to a cold environment probably has a peripheral receptor origin. (Supported by a grant from USPHS, NS 10321-06.)

1451 STATIC SENSITIVITIES OF SPINDLE Ia and II AFFERENTS IN NORMAL AND STEROID-INDUCED ATROPHIC MUSCLES. E. Eldred and B.R. Botterman*. Dept. of Anatomy and Brain Res. Inst., UCLA, Los Angeles, CA 90024.

A comparison of the static sensitivity of Ia and II afferents of de-efferented medial gastrocnemius muscles in normal and steroid-treated male cats was undertaken with two objectives: 1) to determine on a statistically reliable basis how these afferents may differ in static responsiveness, and 2) to test for effect on spindle function of a form of atrophy free of the alteration in muscle length inherent in other models of atrophy. Regression lines calculated for firing rates attained during stepwise stretch of the muscle showed for both afferent types a high degree of correlation between rate and muscle lengthening beyond the length threshold for firing. This permited meaningful comparison of position sensitivities. These, normalized with respect to resting length of the muscle, were significantly greater for group II fibers (63.2 imp/sec/total passive length range) than for Ia afferents (41.3). Rates for group II fibers were also somewhat greater for spontaneously firing units, non-spontaneous units at their length thresholds, and all units at half and near-maximal steps in muscle lengthening. Thus, under these conditions of progressive stretch within the physiological range, group II discharge is at all lengths of the passive muscle slightly more than that of Ia afferents, the difference becoming somewhat greater at longer lengths. This pattern should be reflected in total volumes of inflow reaching the cord, since the numbers of Ia and II axons from this muscle is said to be equal.

In atrophic muscles of cats given triamcinolone (4 mg/kg) for 10-14 days the only clear differences from values in the control animals were greater proportions of Ia and II units firing spontaneously and somewhat smaller length thresholds. This indicates that atrophy to the extent of a 30 to 40% loss in muscle weight may have relatively little effect on static sensitivity of the spindles; it suggests also that effects of steroid treatment on sensory endings may be less than that shown to occur in motor endings.

1452 ALPHABUNGAROTOXIN RECEPTORS IN THE REGENERATING RETINOTECTAL SYSTEM OF GOLDFISH. Andrew Francis*, Nisson Schechter*, and M.S. Gazzaniga, Dept. Psychology and Long Island Research Institute and the Dept. of Psychiatry and Behavioral Science, SUNY Stony Brook, N.Y. 11794.

Regeneration of the crushed optic nerve in several species has been well-studied anatomically, behaviorally and electrophysiologically. The regeneration of the optic nerve and its reinnervation of the optic tectum in goldfish is an established model system for the study of this phenomenon. A large body of evidence exists showing that the tectum is an organized array of specific loci to which the optic nerve fibers specifically connect. In our efforts to understand the molecular mechanism of these events, we have followed the number of α-bungarotoxin (α BuTx) sensitive receptor sites in the goldfish optic tectum after optic nerve crush and during regeneration.

Right sided intraorbital nerve crush was performed on large (10-12 cm) common goldfish maintained on a standard diurnal cycle. After various survival periods freshly excised left and right optic tecta were individually homogenized in a 200 μl volume (10 mM sodium phosphate, 0.4 mM phenylmethyl sulfonyl fluoride, .013 mM dimethylformamide, 1 mM sodium EDTA, 0.02% sodium azide) at pH 7.2 using a glass micro tissue grinder.

Tissue homogenates were incubated in the presence of an excess of I-125 α BuTx (spec. act. 10^6 ci/mole) and counted after a centrifuge assay. All counts were corrected for nonspecific binding by subtraction of controls obtained in the presence of a several hundred-fold excess of noniodinated toxin. CPM per tectum or per mg of tectum were expressed as a ratio (left:right) in order to control for variations in tectal mass between fish.

The results show a sharp drop (at least 30%) in the concentration of α BuTx sites in the deafferented tectum at 6-10 days, followed by a correlated increase in receptor sites as vision returns. These data are not inconsistent with a chemoaffinity model of specific reconnection during regeneration. At the same time, it would appear that the number of sites depends on the presence of viable optic fibers, thereby suggesting that there is a dynamic interaction between regenerating fibers and presumed postsynaptic sites. This suggests that the chemoaffinity mechanism does not involve the regenerating fibers seeking particular static targets. In continuing studies, we are applying this technique to other retinotectal phenomena, such as compression, to gain insight into the actual synaptic changes in this system.

Aided by USPHS Grant 25643 awarded to M.S.G.

1453 PRODUCTION AND REVERSAL OF THREE MANIFESTATIONS OF DOPAMINE RECEPTOR SUPERSENSITIVITY. Arnold J. Friedhoff, Helen Rosengarten, Kenneth Bonnet and Murray Alpert. Dept. Psychiatry, Sch. Med., NYU, New York, NY 10016.

We have found that chronic administration of haloperidol to rats followed by a washout period results in the production of increased stereotypic response to apomorphine, increased specific binding of dopamine to striatal tissue and increased activity of dopamine stimulated adenylate cyclase. Administration of l-dopa for 10 days to half the supersensitive group, followed by washout, resulted in reversal of all of the manifestations of supersensitivity. This effort presumably occurred by increasing the dopamine impinging on the receptor.

1454 AN α-BUNGAROTOXIN BINDING COMPONENT FROM DROSOPHILA MELANOGASTER. Janice I. Gepner*, Bent K. Schmidt-Nielsen*, Reid W. von Borstel*, E. J. Wolinsky* and Linda M. Hall. Dept. of Biology, MIT, Cambridge, Mass. 02139

An ^{125}I-α-bungarotoxin binding component from Drosophila melanogaster has been characterized in both particulate and solubilized crude extracts. This component has the properties expected of an acetylcholine receptor. The ^{125}I-α-bungarotoxin binding has been shown to be specific by three criteria: 1) it saturates for increasing concentrations of ^{125}I-α-bungarotoxin; 2) it shows the expected pharmacological specificity of a nicotinic acetylcholine receptor; and 3) it is localized to synaptic areas of the Drosophila central nervous system where acetylcholine is thought to be the neurotransmitter. Partial purification of this component has shown it is sedimented at 20,000 x g (20 minutes). Two procedures have been developed for screening for receptor mutants. In one method, nicotine-resistant mutants have been isolated and extracts of these mutants have been tested for altered ^{125}I-α-bungarotoxin binding properties. The second approach involves a screen for isoelectric focusing variants. Preliminary experiments have shown that the Drosophila receptor-toxin complex is slightly more basic than the Torpedo receptor-toxin complex.

1455 INCREASE IN THE DOPAMINE RELEASE FROM THE RABBIT CAROTID BODY IN VITRO WITH INCREASING HYPOXIA. C. Gonzalez* and S. J. Fidone. Dept. Physiol., Sch. Med., Univ. Utah, Salt Lake City, UT 84112.

It is now well documented that dopamine (DA) is the principal catecholamine contained in the Type I cells of the carotid body (c.b.), and it has been suggested that during natural stimulation release of DA from the Type I cells may function to modulate the activity of chemoreceptor nerve fibers which terminate upon these cells. In the experiments reported here, we measure directly the DA released by the rabbit c.b. in vitro and demonstrate that the rate of DA release increases with increasing levels of hypoxia. Further, we have studied the relationship between DA release and chemoreceptor impulse activity recorded from the carotid nerve.

C.b.'s with their attached nerves were removed from adult rabbits, cleaned and then incubated at 37°C for 2 hrs. in modified Tyrode's containing 40 μM ^{3}H-Tyrosine. After incubation, the c.b.'s were mounted in a specially-constructed temperature and humidity controlled chamber in which the c.b. rested in a tiny platinum wire basket. Carotid nerve action potentials were recorded with a suction electrode and counted with the aid of a window discriminator and digital counting system. Tyrode equilibrated with 100%, 50%, 20%, 10% and 0% O_2 in N_2 and containing 5.7 μM harmaline and 100 μM propylgallate (to prevent the enzymatic degradation of DA) was superfused over the c.b. and collected in vials containing a carrier mixture to prevent degradation of DA. The labelled DA was adsorbed on alumina, eluted with acetic acid, identified electrophoretically, combusted in a sample oxidizer and counted in a liquid scintillation counter.

During superfusion with 100% O_2, DA was released at a rate of 1-2picogrs./c.b./5 min. collection period. During superfusion with 50%, 20%, 10% and 0%, this resting rate of DA release was increased by factors of 1.25, 12, 30 and 50 times, respectively. The study of the relationship between DA release and chemoreceptor discharges is at an early stage, but it appears that with weak hypoxic stimuli there is an approximate proportional increase in DA release and impulse activity, while with stronger stimuli the increase in DA release exceeds the increase in impulse activity. This latter observation may result in part from spuriously low nerve impulse counts due to occlusion by overlap of impulses at high discharge rates. Also, we have found that the presence of MAO and COMT inhibitors attenuates the duration and frequency of the chemoreceptor impulse discharge to strong hypoxic stimuli.

1456 REGULATION OF PHOSPHORYLATION OF THE ACETYLCHOLINE RECEPTOR. Adrienne S. Gordon* and Ivan Diamond. Dept. of Neurology, University of California Medical Center, San Francisco, CA 94143.

We have recently shown that at least one subunit of the acetylcholine receptor (AChR) is phosphorylated by an endogenous membrane protein kinase activity present in AChR-enriched membranes from Torpedo electric organ (Gordon, et al., Nature, in press). Phosphorylation of the AChR requires 100m M K^+ and is inhibited by carbachol (Gordon, et al., PNAS, 74:263 (1977)). We now present data further characterizing the phosphorylation of the AChR. There is an absolute requirement for K^+. NH_4^+ and Li^+cannot substitute for K^+. Na^+ inhibits phosphorylation at high concentrations. Phosphorylation requires the presence of Mg^{++}. Mn^{+2} and Zn^{+2} stimulate phosphorylation at low concentrations, but inhibit at higher concentrations. Ca^{+2} cannot substitute for Mg^{++}. At Ca^{+2} concentrations up to 20mM, there is no measurable phosphorylation. Phosphorylation of the AChR is not stimulated by either cAMP or cGMP at concentrations from 10^{-5} -10^{-8} M under a variety of incubation conditions. Data will also be presented on the effects of cholinergic agonists and antagonists on phosphorylation of the AChR.

This is the first demonstration that the AChR is phosphorylated by an endogenous membrane protein kinase. Phosphorylation of the AChR in electric organ membranes is specifically dependent on K^+ and Mg^{++} and may be regulated by cholinergic ligands. These results provide support for the hypothesis that phosphorylation of the AChR may be an important regulatory step in the response of the post-synaptic membrane to a nerve impulse.

1457 HORMONAL AND IONIC INFLUENCES ON α-NORADRENERGIC RECEPTORS IN MAMMALIAN CNS. David A. Greenberg, David C. U'Prichard and Solomon H. Snyder. Depts. of Pharmacology and Psychiatry, Johns Hopkins Univ. School of Medicine, Baltimore, MD. 21205

Techniques for labeling central α-noradrenergic receptors have recently been developed, using the α-agonists [^{3}H]clonidine, [^{3}H]-epinephrine and [^{3}H]norepinephrine, the α-antagonist [^{3}H]WB-4101, and the mixed agonist-antagonist [^{3}H]dihydroergokryptine (DHE). Since striking effects on the receptor binding of [^{3}H]opiates are observed in the presence of sodium ions, we have investigated the possibility of similar influences with respect to the α-receptor. A variety of monovalent cations exhibit differential effects on the binding of [^{3}H]α-agonist and antagonist ligands. NaCl at 150 mM reduces the binding of [^{3}H]agonists by about 80% without reducing binding of the [^{3}H]antagonist WB-4101. Other sodium salts affect α-receptor binding similarly while potassium and lithium salts are less potent, suggesting that the cation is responsible for the observed decrease in binding. Dixon plots of binding inhibition by NaCl characterize the principal effect as a reduction in the maximal number of α-receptor binding sites. Choline chloride also potently inhibits α-receptor binding, with [^{3}H]agonist ligands most profoundly affected. Binding of the mixed agonist-antagonist [^{3}H]DHE is inhibited to an extent intermediate between the effects on pure agonist and antagonist ligands. The differential influences of ions on [^{3}H]agonist and [^{3}H]antagonist binding sites lend further credence to the "two-site" model of α-receptor function.

The possible involvement of central α- and β-receptors in the apparent adrenergic imbalance of dysthyroid states has also been investigated by administration of thyroid hormones and antithyroid agents to adult and perinatal rats. Such treatment has been reported to produce alterations in myocardial α- and β-receptor binding (Ciaraldi and Marinetti, Fed. Proc. 36:916, 1977; Williams et al., Clin. Res. 25:458A, 1977). The effects of these manipulations on the binding properties of α-noradrenergic ligands and on the β-receptor marker [^{3}H]dihydroalprenolol in the brain will be discussed. (Supported by USPHS grants MH-18501, MH-33128, MH-05105 and DA-05052.)

1458 MODEL FOR TRANSMITTER-MEDIATED EXTRA-RETINAL PHOTOTRANSDUCTION IN APLYSIA CALIFORNICA. Ronald D. Grisell* and Michael C. Andresen* (SPON: F. H. Rudenberg). Department of Physiology and Biophysics, University of Texas Medical Branch, Galveston, TX.

A three compartment, diffusion + reaction model has been developed for certain light sensitive cells in the central ganglia of the marine mollusc Aplysia californica. The R_2 giant neuron and the ventral photoreceptive cell respond to illumination with a graded hyperpolarization due to an increase in membrane permeability to potassium. Three morphological elements are considered: a lipochondrial compartment which contains the chromophore and acts as a transmitter source, a cytoplasmic compartment, and a compartment near the membrane which contains the transmitter-activated potassium conductance channels. Diffusion equations are defined for each compartment. Two chemical reactions are considered major factors in determining the final response kinetics. In the lipochondrial compartment a reaction rate equation governs a reuptake process of the transmitter and a binding reaction in the membrane compartment describes the interaction of the channels with the transmitter. The cytoplasmic compartment is assumed to serve as a diffusional conduit for the transmitter and to make no dynamic contribution to the response.

A fit of data at varying temperatures enable the model to predict that the rising phases of impulse and step responses are governed primarily by diffusion, whereas the falling phases are determined by reaction rate. These data also indicate a slight nonlinearity, which is included in the model as a bimolecularity of reaction, and which is further supported by good predictions of double impulse responses. Moreover, geometric parameters of the model allow comparison of R_2 and the VPN which have different radii.

1459 PHOTOAFFINITY LABELING OF NORADRENERGIC BINDING SITES WITH ^{3}H-1-NOREPINEPHRINE. Kim Allyn Heidenreich* and Edith D. Hendley. Dept. Physiol. & Biophys., Univ. Vermont Coll. Med., Burlington, VT 05401.

Catechol containing compounds are photosensitive to ultraviolet light (UV) and form covalent bonds with binding proteins in membrane preparations upon exposure to UV. Thus, the natural agonist, norepinephrine (NE), can serve directly as a photoaffinity label for macromolecules which bind it. Previous studies using catecholamine agonists suggest that they bind to a heterogeneous group of specific and nonspecific binding sites. Irreversible binding of NE allows for the use of very low concentrations of ligand, thus providing for selectivity of high affinity sites, and allows for gel electrophoresis of these binding proteins so that they can be separated and characterized. Synaptosomal membrane fractions of rat cerebral cortex were incubated with 1-2 nM ^{3}H-1-NE at 37°C for 10 min, then placed over ice in a cold room, and exposed to UV irradiation for various time periods. Following irradiation, half of the samples were incubated with nonradioactive 1 mM 1-NE to displace any radioactive ligand that did not bind covalently. Results indicated that the binding was irreversible after UV exposure. Total binding in samples exposed to UV was at least 10-fold greater than that in nonirradiated samples. At all times observed, binding was reversible in the absence of UV. The binding sites were saturable, and bound 0.247 pmoles ^{3}H-1-NE per mg of synaptosomal membrane protein. Simultaneous incubation of ^{3}H-1-NE with unlabeled 1-NE reduced covalent binding up to 90%. 1-NE at less than micromolar concentrations was more potent in displacing ^{3}H-1-NE than was d-NE. Covalent binding was inhibited by 60% with 0.1 mM phentolamine. At the same concentration binding was not inhibited by propranolol. Our results indicate that the photoaffinity labeling technique can be used to bind the natural agonist irreversibly to relevant noradrenergic binding sites. The pharmacological data suggest that a fraction of these binding sites may represent the alpha-adrenergic receptor in the rat cerebral cortex. We are further characterizing these binding proteins by SDS gel electrophoresis. Preliminary electrophoretic analysis indicated that the radioactive ligand bound selectively to a small fraction of the membrane proteins. (Supported by NIH grant # MH 25811).

1460 CHARACTERIZATION OF Na-INDEPENDENT (Na-I) and Na-DEPENDENT (Na-D) GABA BINDING TO BRAIN MEMBRANES. Robert Hitzemann*, Yasushi Ohizumi* and Horace Loh* (SPON: E. Callaway). Depts. Psychiatry and Pharmacology, University of Calif., San Francisco, CA 94143.

Enna and Snyder (Brain Res. 100: 81, 1975) have demonstrated that there are both Na-I and Na-D binding sites in brain membranes. These authors suggested that the Na-I binding is occurring to physiologically pertinent receptors while the Na-D binding is occurring to glial GABA transport sites. Using the high affinity transport of β-alanine (ala) into nerve endings (Hitzemann, Fed. Proc. 36: 968, 1977) as a model for glial GABA transport, we have attempted to examine the hypothesis of Enna and Snyder concerning Na-D binding. IC-50 values for β-ala transport and Na-D binding were determined for the following compounds: GABA, β-guanidopropionic acid, 3-OH-GABA, bicuculline, imidazole-4-acetic acid, trans-2-aminocyclopentanecarboxylic acid (ACPC), cis-3-ACPC, trans-3-ACPC, cis-3-aminocyclohexanecarboxylic acid, β-ala, strychnine, γ-guanidobutyric acid, 2,4-diaminobutyric acid, taurine, glycine, proline, α-ala and serine. The correlation coefficient between β-ala transport and Na-D binding was not significant (r = 0.04). Furthermore, we observed that the rank order of the various compounds to inhibit Na-D binding was similar to the rank order of their potency to produce GABA-like neurophysiological effects. Thus, we conclude that Na-D as well as Na-I binding may be occurring to pertinent receptors. The subcellular distribution of the Na-I and Na-D binding sites was examined. The Na-I sites were found to be associated with nerve ending membranes while the Na-D sites were found to be associated with microsomal membranes. The size of the Na-I sites in nerve ending membranes and the Na-D sites in microsomal membranes were characterized using cis-3-ACPC (amino-N to carboxy-C, 4.1 Å) and trans-3-ACPC (amino-N to carboxy-C, 4.8 Å). For Na-I binding the IC-50 values were cis-3-ACPC, 2.5×10^{-5} M, and trans-3-ACPC, 2.0×10^{-7} M. For Na-D binding the IC-50 values were cis-3-ACPC, 4.1×10^{-6} M and trans-3-ACPC, 1.6×10^{-6} M. These data suggest that the size of the Na-I site is greater than the Na-D site. Interestingly, these data are analogous to the situation reported by Nicoll (Brit. J. Pharmacol. 59: 303, 1977) for the depolarizing GABA receptor on primary afferents and the hyperpolarizing GABA receptor on motorneurons. (Supported in part by USPHS grants, DA-00564 and MH-25487.)

1461 CHARACTERIZATION AND ISOLATION OF SEROTONIN BINDING PROTEIN(S) IN RAT BRAIN BY AFFINITY CHROMATOGRAPHY AND GEL ELECTROPHORESIS. Louise L. Hsu* and Robert B. Chang* (SPON: John Doherty). Dept. Psych., Univ. Chicago, Chicago, IL. 60637

The serotonin (5-HT) affinity gel beads were synthesized according to the method of Cuatrecasas (J.B.C. 245: 3059, 1970) by coupling 5-HT with p-diazonium-benzamido-hexyl-Sepharose. The membrane (P_2D) and soluble(S) fractions of nerve endings were prepared from whole rat brains by the method of Gray and Whittaker (J. Anat. 96: 79, 1962) with slight modifications. Aliquots of the S and Triton X-100 treated P_2D fractions were incubated separately with 5-HT Sepharose gel beads in 0.025 M Na-phosphate buffer (pH 7.5) at 37°C for 20 minutes. At the end of incubations, the reaction mixtures were centrifuged at 20 K rpm for 20 minutes and the supernatants were separated. The beads were washed twice with phosphate buffer by vortexing and centrifuging at 20 K rpm. Then the presumed 5-HT-binding protein(s) were eluted from the gel beads with 10^{-5} M of d-LSD, l-LSD, methiothepin (MET) and cyproheptadine (CYP) consecutively. Disc gel electrophoresis revealed at least 5 protein bands at 1/3 of the gel length from the origin, a medium size band at 1/2 and 2 broader bands at 2/3 down the gel. Likewise, the MET and CYP eluates also showed the same 2 bands around 2/3 down the gel. Furthermore, the d-LSD eluate of the Triton X-100 treated P_2D fraction demonstrated 3 more bands beyond 2/3 down the gel and at least 2 more bands between origin and 1/3 down the gel, in addition to all the 5 bands observed in the d-LSD eluate of the S fraction. On the other hand, the l-LSD eluate of P_2D showed 1 extra band in the middle of the gel and also 3 bands beyond 2/3 down the gel. MET and CYP eluates showed similar bands as d-LSD did but a lot lighter. In separate experiments, the end supernatant fraction from whole brain (Se, the soluble fraction further separated from vesicles) was incubated with [C^{14}] 5-HT (10 nM) in the presence of pargyline at 37°C for 20 minutes and applied to polyacrylamide gels for electrophoretic analysis of both the protein and the [C^{14}] 5-HT binding patterns. At least three [C^{14}] 5-HT binding peaks were observed after gel electrophoresis. These data indicated that there might be multiple forms of 5-HT-binding protein in both the soluble and the membrane fractions of the nerve endings in rat brain.

1462 AGONIST OCCUPANCY OF α-ADRENERGIC RECEPTORS ON HUMAN PLATELET MEMBRANES INHIBITS CYCLIC AMP PRODUCTION. Marian S. Kafka, John F. Tallman and Craig C. Smith*. Adult Psychiat. Br., NIMH, Bethesda, MD 20014.

In the human platelet prostaglandin E_1 (PGE_1) activates adenylyl cyclase and increases cyclic AMP (cAMP) production. l-Norepinephrine (NE) inhibits PGE_1-stimulated cAMP production. Phentolamine, phenoxybenzamine, and dihydroergocryptine reverse the NE inhibition of PGE_1-stimulated cAMP production but propranolol and alprenolol do not, indicating that NE acts through an α-adrenergic mechanism. [^{3}H]dihydroergocryptine binds specifically to human platelet membranes. The binding is saturable and the single class of binding sites has a high affinity for [^{3}H]dihydroergocryptine. Binding is stereospecific as l-epinephrine (E) and NE potently inhibit binding, whereas d-norepinephrine is much less potent. The α-adrenergic antagonists phentolamine and phenoxybenzamine, and the α-adrenergic agonists NE and E, are potent inhibitors of binding whereas the β-adrenergic agonist isoproterenol and the β-adrenergic antagonist propranolol are weak inhibitors. The potencies with which the α-adrenergic agonists and antagonists inhibit PGE_1-stimulated cAMP production correlate well with the potencies with which these agents inhibit [^{3}H]dihydroergocryptine binding. NE and E inhibition seem to be mediated through a decrease in the apparent affinity for PGE_1 of the prostaglandin binding site which stimulates cAMP production. The relative percentage of NE inhibition is independent of temperature.

Platelet α-adrenergic receptors, occupied by agonists, inhibit PGE_1-stimulated cAMP production and may mediate a physiologically important early step in platelet aggregation. It is possible for the first time to assess directly α-adrenergic function in a variety of clinical conditions.

1463 CHARACTERIZATION OF AN α-BUNGAROTOXIN BINDING COMPONENT FROM CHICK BRAIN. C. Marchand*, G. Wang* and J. Schmidt* (SPON: W. Van der Kloot). Dept. Biochem., SUSB, Stony Brook, NY 11794.

Snake α-toxins, including α-bungarotoxin (α-BuTX), bind with high affinity and specificity to acetylcholine receptors (AcChR) in skeletal muscle and electric organ. α-BuTX has been found to bind to specific receptors in membrane preparations of the CNS as well, but so far physiological effects of this toxin on neuronal AcChRs have not been observed. In an attempt to elucidate the reasons for the central ineffectiveness of α-BuTX we have begun to analyze the interactions of receptor, toxin and cholinergic ligands in preparations from the CNS and skeletal muscle of the chick.

Newly-hatched chicks contain high levels of α-BuTX binding sites (G. Wang & J. Schmidt, Brain Res. 114, 524-529 (1976)) in their CNS, especially in the optic tectum and retina. Animals were sacrificed during their first four days after hatching, the optic lobes quickly removed and homogenized in phosphate buffer containing 1% of the nonionic detergent Triton-X-100. After centrifugation for 30' at 100,000 x g the supernatant was analyzed for toxin binding activity using the DEAE cellulose disk assay (J. Schmidt & M. A. Raftery, Analyt. Biochem. 52, 349-354 (1973)).

It was found that, whereas binding of α-BuTX to muscle extracts is irreversible, binding to CNS receptor is reversible, with a K_D of 2×10^{-10} M. The half life of the CNS receptor-α-BuTX complex is 2.3 hours, but is significantly reduced in the presence of the cholinergic ligands nicotine, acetylcholine, carbamylcholine and hexamethonium. The dissociation studies suggest that nicotinic ligands and α-BuTX bind to separate or partially separate sites; it is therefore conceivable that the central inefectiveness of α-BuTX is due to either the non-identity of the sites for toxin and neurotransmitter, or else to the rapid release of α-BuTX, induced by AcCh under in vivo conditions.

Chick brain homogenates were fractionated according to Gray & Whittaker (J. Anat. 96, 79-88 (1962)) and close to 40% of the α-BuTX binding activity recovered in the nerve ending fractions. After labelling with ^{125}I-α-BuTX synaptosomal membranes were reacted with the crosslinking agent suberimidate. SDS polyacrylamide gel electrophoresis of treated membranes followed by autoradiography revealed two radioactive bands with apparent molecular weights of 60,000 and 250,000 daltons respectively.

1464 A COMPARATIVE PHARMACOLOGICAL STUDY OF CAROTID BODY CHEMORECEPTORS. L. Monti-Bloch* and C. Eyzaguirre. Dept. Physiol., U. of Utah Col. Med., Salt Lake City, UT 84132.

Carotid bodies and their own nerves were excised from rabbits or cats, cleaned of surrounding connective tissue and placed in a chamber through which flowed mammalian saline equilibrated with different gas mixtures. pH was adjusted to 7.43 for the cat and to 7.4 for rabbit preparations using HEPES-NaOH buffer. Temperature was kept at 36-37°C. Single fibers were isolated, recorded from and identified as chemosensory by their response to hypoxia, hypercapnia, acidity and interruption of flow. Drugs dissolved in saline were applied upstream in volumes not exceeding 25 µl. In the rabbit, carbachol (1-10 µg) and ACh (1-50 µg) usually depressed the discharge and this was followed by discharge increase. Nicotine (1-20 µg) induced receptor stimulation in sigmoidal fashion with a linear relationship between 5 and 10 µg. Nicotinic stimulation was blocked by d-tubocurarine (10^{-6} g/l). Pilocarpine (1-20 µg) induced discharge depression following a negative sigmoidal curve. There was a negative linear relation between 2.5 and 10 µg. Pilocarpine-induced depression was blocked by atropine (10^{-6} g/l). Dopamine (1-100 µg) always increased chemoreceptor discharge also following a sigmoidal curve. The response was linear between 10 and 50 µg. In the cat, carbachol, ACh and nicotine (same doses as those used in rabbits) always induced chemoreceptor stimulation. Pilocarpine (up to 20 µg) had no effect on chemosensory discharges. Dopamine (1-200 µg) always depressed the discharge showing a sigmoidal curve with a negative slope. The response was linear between 10 and 100 µg. These experiments indicate that cat carotid body chemoreceptors only have nicotinic sites while rabbit receptors have both nicotinic and muscarinic sites. Nicotinic receptors appear to be excitatory while muscarinic ones seem to be inhibitory. These preparations may have excitatory dopamine receptors in rabbits and inhibitory ones in cats.

Work supported by NIH grants NS 05666 and NS 07938.

1465 *REGIONAL DISTRIBUTION OF NICOTINIC ACETYLCHOLINE RECEPTOR IN RAT BRAIN.* *Barbara J. Morley, Joan F. Lorden, George B. Brown, George E. Kemp*, and Ronald J. Bradley. Neurosciences Prog., Sch. Med., Univ. of Ala. B'ham., Birmingham, AL 35294.*

Several studies have identified nicotinic acetylcholine receptor (nAChR) in the mammalian nervous system; however, a thorough and detailed description of the regional distribution of nAChR from brain is not available. Using biochemical assays and/or light autoradiography of labelled α-bungarotoxin, the following areas have been found to contain at least moderate amounts of nAChR: cortex, colliculi, olfactory tubercle, hippocampus, lateral geniculate nucleus, and hypothalamus, while the caudate and cerebellum contain neglible amounts of toxin binding.

When expressed as fm toxin per mg protein, the brainstem contains a high concentration of nAChR.

The present investigation was undertaken to extend the description of the regional distribution of nAChR in brain primarily to include several brainstem nuclei, utilizing a biochemical assay for ^{125}I-α-bungarotoxin. The following areas were found to contain significant amounts of nAChR (expressed as fm toxin/mg protein): cortex (52); hippocampus (50); hypothalamus (75); raphe (62); brainstem reticular formation (54); superior olivary complex (30); cochlear nucleus (44); inferior colliculus (69); olfactory bulbs (32); and olfactory tubercle (36). Areas containing little or neglible nAChR include: caudate (16); septum (15); and cerebellum (8).

The effect of several pharmacological agents on toxin binding to preparations from the various brain areas was also investigated. Nicotinic, but not muscarinic agonists and antagonists, were effective in blocking toxin binding. Decamethonium produced the greatest variability in toxin binding among brain preparations suggesting the possibility of a differing conformation of nAChR throughout brain. Mecamylamine, a ganglionic nicotinic blocker, was ineffective in blocking toxin binding in all prepartions, even at 10^{-4} M.

This work was supported in part by NSF Grant #BNS 75-14321 and NIMH Grant # 1 T32 MH14286.

1466 DOPAMINERGIC AND CHOLINERGIC RECEPTORS IN STRIATAL AND LIMBIC REGIONS AFTER CHRONIC HALOPERIDOL. P. Muller, J. Bowles* and P. Seeman, Department of Pharmacology, University of Toronto, Toronto, Canada.

It is known that chronic neuroleptic treatment produces an apparent dopaminergic supersensitivity in animals. In order to determine the biochemical basis of this supersensitivity, the amounts of dopaminergic and cholinergic receptors were measured in the limbic and striatal regions of rat brain after chronic treatment with haloperidol (10 mg/kg for over 6 weeks, given p.o.). Dopamine receptors were measured using either butaclamol-specific binding of ^{3}H-apomorphine (Seeman et al., Proc. Nat. Acad. Sci. 1976, 72, 4376) or of ^{3}H-haloperidol (Seeman et al., Nature 1976, 261, 717). Acetylcholine receptors were measured with ^{3}H-quinuclidinyl benzilate (Yamamura et al., Life Sci. 1976, 18, 685).

The chronic haloperidol treatment increased the specific binding of ^{3}H-haloperidol by about 40% in striatal homogenates and approximately 25% in mesolimbic tissue. The specific binding of ^{3}H-apomorphine also increased in both the striatum and the mesolimbic structures. The binding of ^{3}H-QNB was not altered in cortex, hippocampus mesolimbic areas and the striatum following the treatment.

The results suggest a degree of selectivity of chronic haloperidol on the receptor profile in different brain regions. (Supported by the Ontario Mental Health Foundation and the Medical Research Council of Canada).

1467 SUBUNIT STRUCTURE OF ACETYLCHOLINE RECEPTOR FROM RAT MUSCLE. Neil M. Nathanson*, Stanley G. Froehner*, Crispin Weinberg*, and Zach. W. Hall. Dept. Physiology, Sch. Med., UCSF, San Francisco, CA 94143.

Acetylcholine receptor from denervated rat leg muscle was purified 48,000-fold by affinity chromatography on concanavalin A-Sepharose and cobrotoxin-Sepharose. A control preparation containing only contaminants was made by performing a parallel purification with α-bungarotoxin added to the preparation prior to the cobrotoxin-Sepharose step. Comparison of the receptor and control preparations showed that the receptor was greater than 90% pure. Examination of the purified receptor by polyacrylamide gel electrophoresis in sodium dodecyl sulfate revealed two major polypeptide chains with apparent molecular weights of 45,000 and 51,000 daltons, along with minor components of 49,000, 56,000, 62,000 and 110,000 daltons. After alkylation of the receptor preparation with an affinity reagent for the acetylcholine binding site, 4-N-maleimidobenzyltri [^{3}H] methylammonium ion (^{3}H-MBTA), two peaks of radioactivity were obtained, with positions corresponding to molecular weights at 45,000 and 49,000 daltons. Radioactivity in both peaks was absent after prior incubation of the receptor with neurotoxin. To develop procedures for examining the small amount of junctional receptor in normal muscle, purified extrajunctional receptor was radioiodinated and further purified by sucrose gradient sedimentation. After electrophoresis in SDS and autoradiography, each of the polypeptide chains described above could be identified.

1468 CHEMORECEPTORS OF THE RAT KIDNEY. Giorgio M. Recordati‡ Nicholas G. Moss* and Linda E. Waselkov*. (SPON: D.L. Trevino). Depts. Physiol. and Med., University of North Carolina, Chapel Hill, N.C.

It is known that there are mechanosensitive nerve endings in the kidney, which respond to changes in arterial perfusion pressure, venous and ureteral pressures. Indirect observations suggest, however, that other kinds of receptors, such as chemoreceptors, might exist within the kidney. To investigate this possibility the electrical activity of afferent fibers has been recorded from the renal nerves of rats during experimental conditions which were designed to differentiate between mechanosensitive and chemosensitive endings. The experiments were carried out on male Sprague-Dawley rats, anesthetized with nembutal, paralyzed with gallamine and artificially ventilated. The right kidney was exposed through a paravertebral incision and the renal nerves were dissected from the renal hylus to the coeliac ganglion, decentralized and placed on bipolar hook electrodes. Twenty multifiber preparations (spontaneous activity of 0.2-3 imp/sec) were studied during renal ischemia produced by complete occlusion of the renal artery. In every instance the afferent activity began increasing 20 sec after the start of occlusion and reached a peak firing rate of 200-400 imp/sec after 40-60 sec of occlusion. The release of the renal artery occlusion was accompanied by a cessation of the discharge and was followed by a brief period of depressed spontaneous activity. The same multifiber preparations were also markedly activated after 60-120 sec of systemic hypoxia and hypercapnia produced by stopping the respirator pump. Single units which were sensitive to renal ischemia and systemic asphyxia were then selected in order to study their responses to changes in intrarenal pressure. Ten single units were unaffected by changes in arterial blood pressure in the range of 40-140mmHg produced by occlusion of the abdominal aorta below the renal arteries and by hemorrhage. All of them, however, were activated when the blood pressure was lowered below 30-40mmHg by an extreme hemorrhage. Increases in venous pressure, produced by occlusion of the inferior vena cava just above the level of the renal vein, caused an inhibition of three spontaneously active units. The same maneuver, when applied 30-60 sec after the start of a renal artery occlusion, was also effective in decreasing the activation, produced by renal ischemia, of four other units. In this case the deactivation of the units was accompanied by a visible backflow of venous blood into the pale cortex of the ischemic kidney. Increments in ureteral pressure amounting to 30-40cmH_2O were not accompanied by any consistent alterations in the discharge of four single units studied. These results indicate that the nerve endings which are sensitive to renal ischemia and systemic hypoxia and hypercapnia, might be defined as renal chemoreceptors.

1469 EFFECT OF CONTINUOUS PRESENCE OF ANTIBODY TO CHOLINERGIC RECEPTORS DURING SYNAPSE FORMATION IN VITRO. Rosemary P. Rees, Mohyee E. Eldefrawi* and Amira T. Eldefrawi*. LNNS, NINCDS, NIH, Bethesda, MD 20014 and Departments of Anatomy and Pharmacology, University of Maryland School of Medicine, Baltimore, MD 21201.

Preparations of nicotinic acetylcholine receptors purified from the electric organs of Torpedo ocellata were used to immunize rabbits. Receptor antibodies were detected by complement fixation with a titer of 1:320. The purified immunoglobulins contained 10 mg protein/ml estimated by the Lowry method. Application of rabbit serum, followed by labeling with goat anti-rabbit peroxidase conjugate resulted in patches of label on the surfaces of isolated rat superior cervical ganglion neurons. These patches were thought to be indicative of the location of acetylcholine receptors because no labeling was found in similar experiments using control rabbit serum. Cultures were also labeled at various times prior to and after synapses had been formed on their somata by neurites growing out from explants of rat thoracic spinal cord. Prior to contact by these neurites, patches of label were distributed unevenly over the neuronal somata. After synapse formation, labeling was heavy at synaptic clefts although some label was also present on neuronal somata away from synapses.

Cultures of superior cervical ganglion neurons combined with spinal cord explants were also grown in the presence of either serum or immunoglobulins diluted 1:10 with culture medium. Normal stages in synaptic development predominated for the first 48 hrs after neurites contacted ganglion cell somata. In older cultures, many examples of mature synapses were found which were not attached to ganglion cells. Early stages of synapse formation and incoming spinal cord neurites tipped by normal growth cones were also seen at the neuronal surface side-by-side with detached and degenerating synaptic boutons. None of these secondary changes were found in cultures grown in medium containing control serum. Thus, the presence of antibody to acetylcholine receptors does not appear to prevent initial stages of synapse formation, but does affect adhesivity and maintenance of mature synapses.

1470 ABSENCE OF NEGATIVE COOPERATIVITY OF BINDING OF NERVE GROWTH FACTOR TO EMBRYONIC CHICK SENSORY GANGLION CELLS. Richard J. Riopelle Ronald M. Harris-Warrick, Arne Sutter* and Eric M. Shooter. Dept. Neurobiol. Stanford Univ. Sch. Med. Stanford, CA 94305.

A number of studies have demonstrated specific nerve growth factor (NGF) binding to responsive tissues. Herrup and Shooter (PNAS 70,3384,1973) and Banerjee et al. (PNAS 70,2519,1973) using different tissue preparations found homogeneous saturable binding sites with dissociation constants of 10^{-10}M. Frazier et al. (J. Biol.Chem. 249,5513,1974) using homogenates of chick sensory and superior cervical ganglia detected multiple affinities of binding and presented evidence for cooperative interactions among receptor or ligand molecules. The question of site heterogeneity and cooperative interactions was reinvestigated using viable cell dissociates of 8-day-embryonic chick sensory ganglia and preparations of ^{125}I-βNGF which showed minimal non-specific binding (<5% of total). The binding of ^{125}I-βNGF revealed two distinct saturable binding sites with dissociation constants of K_d(I) : $2x10^{-11}$M and K_d(II) : $1.5x10^{-9}$M as measured by steady state and kinetic experiments. Ligand-ligand interactions do not complicate analysis of binding data because βNGF retains its dimeric character at concentrations below 10^{-12}M (M. Bothwell, unpublished data). The characteristics of the dissociation of ^{125}I-βNGF from sensory ganglion cells suggest that the binding sites I and II are distinct and do not result from intermolecular interactions of ligand or receptor. When dissociation is initiated by the addition of excess unlabelled βNGF to cells previously exposed to ^{125}I-βNGF, the dissociation pattern is biphasic. The ratio of the fast (K_{-1}(II) > $5x10^{-2}$ sec^{-1}) to slow (K_{-1}(I) = 10^{-3} sec^{-1}) dissociating components is dependent upon the concentration of ^{125}I-βNGF used to achieve steady state. This ratio varies according to the relative occupancy of the two sites as predicted from equilibrium binding data. The rates of dissociation of ^{125}I-βNGF following dilution into buffer alone or into buffer containing excess unlabelled βNGF was compared. For each concentration of ^{125}I-βNGF studied, there is a finite dilution factor above which the rate of dissociation of the ligand is the same whether or not unlabelled βNGF is present (100x at $4x10^{-12}$M; 1500x at $1.2x10^{-9}$M). By diluting labelled cells into buffer containing unlabelled cells it was possible to show that rebinding of ^{125}I-βNGF occurs at insufficient dilutions. Site heterogeneity is further supported by results showing that site I and site II are affected independently by different experimental conditions (A. Sutter et al., these proceedings). Supported by grants NINCDS NS04270, Deutsche Forschungsgemeinschaft, Medical Research Council of Canada.

1471 PEPTIDE ISOLATED FROM HUMAN BLOOD THAT INHIBITS N-METHYLTRANSFERASE ACTIVITY AND ETORPHINE BINDING. Helen Rosengarten, Marvin H. Lerner and A.J. Friedhoff Dept Psychiatry Sch. Med., NYU, New York, NY 10016.

We have previously demonstrated the presence of a low molecular weight peptide that inhibits both N-methyltransferase activity and etorphine binding to rat brain receptor (Abstract, meeting of American Society of Neurochemistry, Vancouver, March 1976; Pharm. Biochem. Behavior 5, supplement 1, p 147, 1976; and Life Sciences vol. 20, p 775, 1977). The apparent molecular weight of this peptide is 1500 and 1300. Here we present evidence that a similar peptide inhibitor of NMT activity and etorphine binding is also present in human red cells and plasma. The peptide is present in relatively high concentration in human blood, and IC_{50} is less than 10^{-7}M for both activities. This peptide may act as a regulator of N-methylation and a modulator of receptor function. The amino acid composition of the peptide has also been determined.

1472 COLCHICINE REVERSIBLY INHIBITS ELECTRICAL ACTIVITY IN ARTHROPOD MECHANORECEPTORS. Rollie Schafer, Paul D. Reagan, and Ngozi Okafo*. Dept. Biol. Sci., NTSU, Denton, TX 76203.

The dendrites of cockroach tibial spine mechanoreceptors contain hundreds of free microtubules. Could their presence be related to the generation of electrical activity by the receptor?

Deflection of a spine excites a single mechanoreceptor present the spine's base, producing a train of action potentials. The duration of the train and the frequency of spiking within the train are proportional to the strength and rate of mechanical stimulation.

Continuous perfusion of an excised leg over a period of 4 hr results in no response decrement. Perfusion with 10 mM colchicine decreases train length and spiking frequency within 5-7 min. The response reaches approximately one-fourth of its initial value by 20 min after the beginning of colchicine perfusion. The response returns to its initial level after reperfusion of the inhibited leg with perfusion solution lacking colchicine. The time courses of inhibition and recovery are comparable.

Irreversible inhibition is produced by perfusion with 1 mM vinblastine sulfate in perfusion solution containing 1% dimethyl sulfoxide. Control perfusion with 1% DMSO produces no effect. Perfusion solution containing 70% deuterium oxide is inhibitory. Deuterium oxide does not inhibit over short time spans at concentrations of less than 50%, nor does it counteract inhibition by 10 mM colchicine.

Overnight incubation in 10 mM colchicine does not inhibit axonal conduction in desheathed crab leg nerves or frog sciatic nerves. Thus, by analogy, the colchicine effect on cockroach mechanoreceptors is probably an effect on the sensory dendrites or soma. Colchicine may be affecting (1) intracellular microtubules, (2) membrane-associated tubulin, (3) other membrane components through nonspecific binding, or (4) axoplasmic transport of essential materials to the sensory dendrites.

1473 OPIATE RECEPTOR LIGAND IN CEREBROSPINAL FLUID: A SIMPLE RADIORECEPTOR ASSAY REQUIRING NO PRELIMINARY PURIFICATION. Haruo Shibuya*, Donald L. Bowie*, and Candace B. Pert. Sect. on Biochem., Adult Psychiat. Br., NIMH, Bethesda, MD 20014.

Based upon the ability to displace [^{3}H]dihydromorphine binding to opiate receptors, Terenius and Wahlström[1] have reported that purified, concentrated extracts of human cerebrospinal fluid (CSF) contain morphine-like material. We report a very sensitive and specific radioreceptor assay procedure which detects opiate peptides in the .05 pmole range. This enhanced sensitivity conveniently makes analysis of "raw," unextracted CSF possible.

[^{3}H]-D-Ala^2-met-enkephalinamide (47 Ci/mmole), an enzyme-resistant enkephalin analog,[2] binds with high affinity (0.1 nM) to a site on rat brain membranes which appears in the presence of $MnCl_2$ and a warm (25-37°C) incubation temperature.[3] Displacement of [^{3}H]-D-Ala^2-met-enkephalinamide from this Mn and temperature-dependent site, which is highly and specifically sensitive to opiate peptides, provides the basis of a radioreceptor assay which requires 100 µl aliquots of "raw" CSF.

To determine the molecular weight of the CSF material, lyophilized monkey lumbar CSF was applied to a calibrated Sephadex column (G-25, 2 x 40 cm) and eluted with 1% acetic acid containing 0.1% BSA. Analysis of the neutralized fractions revealed a single peak of molecular weight 1200-1500. This peak did not coincide with the very large peak of UV_{280} absorption which emerged in the void volume, nor the fractions where a [^{3}H]-met-enkephalin standard emerged. The opiate ligand in CSF does not cross-react in a radioimmunoassay which recognizes leu-enkephalin and, to a 5-fold lesser extent, met-enkephalin. Opiate ligand activity can be completely absorbed out of CSF by a single passage through an XAD-2 Amberlite column. The opiate ligand in CSF, which is resistant to inactivation by incubation with brain membranes, is certainly neither met- nor leu-enkephalin, and has a smaller molecular weight than C-fragment (β-LPH-61-91).

In preliminary experiments with lumbar CSF from drug-free patients, the morphine-equivalent opiate receptor ligand content (pmoles/.1 ml CSF ±SD) of 5 schizophrenics, 5 depressed patients and 9 personality disordered individuals were respectively 4.4 ±2.1, 4.3 ±2.1 and 3.6 ±5.9. Serial samples of ventricular monkey CSF contain gradually altering opiate ligand content which fluctuate in a broad range from 0 to 15 pmoles/.1 ml CSF and appear unrelated to episodes of repeated footshock.[4]

1474 BIOCHEMICAL PROPERTY OF SEROTONIN-BINDING PROTEIN.
Jean C. Shih, School of Pharmacy, USC, Los Angeles, California 90033.

Using 5HT-affinity chromatography, two serotonin-binding proteins (SBP) may be isolated from rat brain synaptosomal membrane. These membrane proteins were solubilized by 0.1% Emolphogen. One of them was eluted from the column by 10^{-4}M chlorimipramine (CIP), the other one was eluted by 10^{-4}M Lysergic Acid (LSD). Similar protein fraction may be obtained by eluting the column with 10^{-6}M CIP or 10^{-6}M LSD. Under appropriate condition, each of the four concentrated protein fraction (10^{-6}M, 10^{-4}M LSD eluted protein fraction and 10^{-6}M, 10^{-4}M CIP eluted protein fraction) revealed one protein band on SDS-gel electrophoresis, their molecular weight were about the same. When 5HT-affinity column was eluted by 10^{-6}M or 10^{-4}M 5HT instead of 10^{-6}M or 10^{-4}M LSD. Similar protein band was obtained. This result again suggested that LSD binding to SBP might be replaceable by 5HT.

10^{-6}M and 10^{-4}M LSD eluted protein (LSD-SBP) were pooled for the following studies. Approximately 1-2 µg purified LSD-SBP might be obtained from 1g (net weight) of rat brain. The purification was achieved for about 816 fold.

When purified LSD-SBP was incubated with 10^{-7}M H^3-5HT in 0.01M Tris-HCl buffer 7.4 with 0.1% Ascorbic acid at 37°C for 10 min. Significant H^3 label is detected in the protein fractions separated by gel filtration. If bovine serum albumin was incubated with H^3-5HT under the same condition, No H^3 radioactivity was detectable in the protein fractions. Furthermore, H^3-5HT binding to SBP was saturable (H^3-5HT concentration increased from 10 to 600 nM). By scatchard plot, two binding sites were observed. n_1 = 30 p mole/mg, kd_1 = 855nM
n_2 = 4.0 p mole/mg, kd_2 = 25nM
Since 10^{-6}M and 10^{-4}M LSD eluted protein were pooled for these experiments, whether the two different binding sites were contributed by the same SBP or different protein with similar molecular weight is not clear at the present time. 1475 CHARACTERIZATION OF TWO DISTINCT CLASSES OF HIGH AFFINITY BINDING SITES FOR NERVE GROWTH FACTOR ON SENSORY GANGLIA CELLS FROM CHICK EMBRYOS.
Arne Sutter*, Richard J. Riopelle, Ronald M. Harris-Warrick and Eric M. Shooter. Dept. Neurobiol., Stanford Univ. Sch. Med., Stanford, CA 94305.

The binding of nerve growth factor (βNGF) to viable cell dissociates from sensory ganglia of 8-day-old chick embryos was reinvestigated using ^{125}I-βNGF preparations which showed minimal non-specific binding (<5% of total binding). The analysis of steady-state and kinetic data revealed two distinct saturable binding sites with dissociation constants of K_d(I) = 2 x 10^{-11}M and K_d(II) = 1.5 x 10^{-9}M. The ratio of the number of type I to type II binding sites is 1:5. At 37°C the binding characteristics of site I were studied in steady-state as well as in kinetic experiments and the data were in concordance. From association rate measurements at βNGF concentrations less than 2 x 10^{-11}M the rate constant k_{+1} (I) of 2 x 10^7 L Mol^{-1} sec^{-1} was determined. The dissociation rate constant for site I is k_{-1} (I) = 10^{-3} sec^{-1}. Numerous sets of data show that the two sites are distinct and not the result of cooperative interactions of ligand or receptor (R. Riopelle et al., these proceedings). In order to determine whether heterogeneity of the βNGF binding is due to the heterogeneity of the cell populations in the ganglia dissociate, neuronal cells were separated from non-neuronal cells by means of their decreased ability to adsorb to plastic culture dishes. Binding of βNGF to site I could not be detected on the non-neuronal cells, whereas the neuronal cell population was enriched in this high affinity binding. Single cell bioassay results and data from developmental studies support the hypothesis that binding to the high affinity site (I) is required for neuronal differentiation. The half maximal stimulation of neurite outgrowth from single cells by βNGF occurs at 10% occupancy of site (I) and only 0.2% occupancy of site (II). Preparations of βNGF modified by carboxy-terminal arginine cleavage which show unaltered affinity for site (I) but a 10-fold reduced affinity for site (II) in binding assays are as effective as native NGF in the single cell bioassay. The development of sites I and II was analyzed at various embryonic stages. Binding to site II is measurable at all stages studied. However, site I binding is not present at embryonic day 4, becomes measurable at embryonic day 6 and increases up to embryonic day 8. The appearance of site I during embryonic development correlates well with the period during which mediodorsal neurons, the putative target cells of NGF within the sensory ganglia, undergo their final division and begin to differentiate. 1476 CONFORMATIONAL REQUIREMENTS FOR THE ^{3}H-APOMORPHINE RECEPTOR: STEREOSPECIFIC BINDING OF 2-AMINOTETRALIN DERIVATIVES.
J.L. Tedesco, J. Bowles*, J.D. McDermed* and P. Seeman. Pharmacology Department, University of Toronto, Toronto, Canada.

Certain hydroxylated derivatives of 2-aminotetralins stimulate dopaminergic systems apparently by acting as dopamine receptor agonists. At very low doses they can induce stereotypy and/or emesis (McDermed et al., J. Med. Chem. 18, 362, 1975). They are relatively rigid analogues of dopamine in various conformations.

Competition for ^{3}H-apomorphine (3.5 nM) binding sites in calf caudate crude homogenate was tested with the above derivatives. Both butaclamol-stereospecific (124 fmoles/mg protein, K_D = 3.5 nM; Seeman et al., P.N.A.S. 73, 4354, 1976) and apomorphine-specific sites (250 fmoles/mg protein, K_D = 1.4 nM) have been demonstrated. We now report:

1. The (-)-enantiomer of 5-hydroxy-N,N-dipropyl-2-aminotetralin (or 5-OH-AT) had an IC_{50} of 18 nM, having 19-fold more potency than (+)-5-OH-AT in competing for specific or butaclamol-stereospecific ^{3}H-apomorphine sites.
2. Scatchard analyses show virtually identical densities of ^{3}H-apomorphine receptors stereospecific to either 70 nM (-)- and (+)-5-OH-AT or to 1 µM (+)- and (-)-butaclamol (124 and 110 fmoles/mg protein respectively). The respective dissociation constants (5.2 nM and 3.5 nM) were also similar.
3. The IC_{50} for (±)-5-OH-AT was 16 nM, having 35-fold greater potency than (±)-7-OH-AT and 60-fold greater than (±)-6-OH-AT.
4. All 6,7-dihydroxy-2-aminotetralin derivatives used were potent competitors for ^{3}H-apomorphine receptors regardless of the degree of N-alkylation (up to N,N-dipropyl substitution).
5. The 5,6-dihydroxy-2-aminotetralin derivatives showed highest affinity as N-methyl, N,N-dimethyl or N,N-diethyl derivatives (IC_{50} values of 11, 12 and 7 nM). They almost invariably showed from 3 to 60 times less affinity than did their 6,7-dihydroxy counterparts.

(±)-5-OH-AT should be more potent than (±)-7-OH-AT in competing for ^{3}H-apomorphine binding since the former shares the same dopamine-moiety conformation with apomorphine. It is surprising that the 5,6-dihydroxy derivatives were generally less potent than the 6,7-dihydroxy derivatives. This could suggest the existence of two high-affinity apomorphine receptors.

1477 ALTERED INSULIN BINDING TO CIRCULATING MONONUCLEAR CELLS IN MYOTONIA DYSTROPHIA.
Gerald J.M. Tevaarwerk*, Kenneth P. Strickland*, Chao-Hsiung Lin* and Arthur J. Hudson. Depts. Med., Biochem. and Clin. Neurol. Sci., UWO, London, Ont. N6A 5A5

Peripheral insulin resistance is an integral feature of myotonia dystrophica (MD) but the cause is unknown (Tevaarwerk and Hudson, J. Clin. Endocrinol. Metab. 44:491,1977). In the current study insulin resistance was investigated by comparing insulin binding to circulating mononuclear cells from MD and normal subjects. Mononuclear cells from 12 fasting MD patients and 12 age and weight-matched normal control subjects were isolated by gradient centrifugation of 300 ml of whole blood in a Ficoll-Hypaque mixture (Boyum, J. Clin. Lab. Invest. 21, Suppl. 97, 51, 1968). The binding assay was done according to the procedure of Schwartz et al (Proc. Nat. Acad. Sci. 72:474,1975) using ^{125}I monocomponent insulin alone and in the presence of gradually increasing amounts of unlabeled insulin. Binding was expressed as a percentage of the total ^{125}I-insulin that was bound per 10^6 monocytes. Basal serum insulin levels in the MD and control groups were measured by radioimmunoassay.

The mean (± SEM) insulin binding was 0.65 ± 0.10% in the MD subjects as compared with 1.26 ± 0.08% per 10^6 monocytes in the normal group. The addition of unlabeled insulin decreased labeled insulin binding to 0.35 ± 0.04% and 0.84 ± 0.13% per 10^6 monocytes for the MD and normal groups, respectively. The decrease in the normal group is significant ($p < 0.005$) but the initial low binding in the MD group prevents accurate measurement of inhibition of binding by the unlabeled insulin. From these results it is concluded that there is significantly decreased insulin binding to circulating mononuclear cells in MD. The decrease in binding in MD may be due to a reduced number of insulin receptors per cell or to a decrease in receptor affinity. The mean (± SEM) basal insulin levels were 19.8 ± 4.8 µU/ml in MD as compared with 8.2 ± 0.9 uU/ml in normal subjects ($p < 0.05$). The increased basal insulin level may be responsible for the decrease in binding; alternatively, both may be different manifestations of an as yet unrecognized mechanism producing insulin resistance in MD.

1478 α-BUNGAROTOXIN BINDING IN THE BRAIN OF THE HORSESHOE CRAB, LIMULUS POLYPHEMUS. William E. Thomas* and James G. Townsel (Spon: John S. Thomas), Departments of Biochemistry and Physiology, Meharry Medical College, Nashville, Tennessee 37208.

Acetylcholine (ACh) has been shown to be a sensory neurotransmitter in certain invertebrate species (Florey, 1973, J. Comp. Physiol. 83: 1; Sorenson, 1973, Biol. Bull. 144: 180; Hildebrand, et al., 1974, J. Neurochem. 23: 951). Recent investigation of the ventral nerve cord of Limulus has revealed the presence of significant levels of the ACh biosynthetic enzyme, choline acetyltransferase (Malthe-Sorenssen and Emson, 1976, J. Neurochem. 27: 341). These investigators suggest that ACh may serve as a sensory transmitter in Limulus. If ACh is a sensory transmitter in Limulus; then, the central nervous system should contain cholinoceptive cells. The nicotinic cholinergic receptor (AChR) is a reliable indicator of nicotinic cholinoceptive cells. The AChR can be identified by its affinity for the α-neurotoxins. Thus, we have initiated studies on the binding of (^{125}I) α-bungarotoxin to membrane fragments prepared from Limulus brain tissue.

In this tissue, toxin binding saturates in the range of 25 to 30 nM with maximum binding of 3-8 pmoles per mg of protein. The binding has a $t_{½}$ of 60sec., which yields a K_1 of 3.38 x 10^5 M^{-1} s^{-1}. Pharmacological studies show that binding is inhibited by both cholinergic agonists and antagonists. I_{50}'s for inhibition by d-tubocurarine, decamethonium, carbachol and atropine are 6 x 10^{-7}M, 10^{-5}M, 10^{-4}M, and 8 x 10^{-5}M, respectively. The saturation kinetics appear consistant with toxin binding to multiple sites. Moreover, the rate of dissociation of bound toxin indicates the presence of more than one species of toxin binding components. Toxin binding activity was solubilized with Triton X-100. Velocity sedimentation studies of this solubilized activity were performed on linear sucrose gradients (5-20%). Three separate components were detected with sedimentation coefficients of 8s, 15s, and 16.8s. These results are consistent with the suggested sensory transmitter function of ACh in Limulus.

1479 EFFECTS OF PROTEIN REAGENTS ON GAMMA-AMINOBUTYRIC ACID RECEPTOR-IONOPHORES IN CRAYFISH MUSCLE AND RAT BRAIN. M.K. Ticku* and R.W. Olsen. Dept.Biochemistry,Univ.Calif.Riverside, CA 92521.

The functional groups involved directly or indirectly in action of the inhibitory neurotransmitter γ-aminobutyric acid(GABA) are of interest in understanding receptor-ionophore function at the molecular level. Reagents for specific amino acid residues were found to inhibit the postsynaptic response to GABA in crayfish muscle and also to inhibit GABA receptor binding in crayfish muscle and mammalian brain.The physiological postsynaptic response to GABA involves an increased chloride conductance, which is inhibited noncompetitively by the convulsant drug picrotoxin (Takeuchi & Takeuchi(1969)J.Physiol.205,377).The anion selectivity and pH dependence(greater conductance on the acid side of neutrality) suggest that the GABA-regulated Cl^- ionophore contains a fixed + charge(Takeuchi & Takeuchi(1967)J.Physiol.191,575),possibly a protonated histidine.GABA was previously shown to cause a picrotoxin-sensitive specific increase in permeability to radioactive Cl^- in crayfish abdominal muscle(Ticku & Olsen(1977)Biochim.Biophys.Acta 464,519).This postsynaptic response to GABA,but not background Cl^- flux,was inhibited by preincubation of the tissue for 20 min at pH 6.0(22°)with 0.1-1 mM diethyl pyrocarbonate(DEP),reagent which covalently modifies primarily histidine residues under these conditions. Sulfhydryl group reagents such as N-ethyl maleimide(NEM) did not significantly inhibit the synaptic GABA response,although inhibiting GABA transport in this tissue(Olsen et al,(1975)Mol. Pharm.11,566).Radioactive GABA binding sites having the properties of postsynaptic receptor sites were measured in membrane fractions of crayfish muscle(Meiners et al.(1977)Fed.Proc.36,801)and rat brain(Olsen & Greenlee(1976)Fed.Proc.35,1947).These GABA receptor binding sites were inhibited by 1mM DEP at pH 6,consistent with DEP block of GABA synapses, and a possible role of a histidine residue in the binding of GABA to its recognition site(receptor)or subsequent GABA receptor-regulated Cl^- flux.Binding of GABA to nonreceptor,sodium-dependent uptake-binding sites in crayfish muscle was not affected by DEP,but was inhibited by sulfhydryl reagents. Picrotoxinin at 0.2 mM did not inhibit GABA binding to presumed receptor sites.A biologically active analogue, α-dihydropicrotoxinin(dHP),was made radioactive and found to bind to a limited number of saturable sites in postsynaptic membrane fractions of crayfish muscle and rat brain which appear to be related to picrotoxin's physiological site of action in blocking GABA synapses(Ticku(1977)Fed.Proc.36,751).GABA did not inhibit dHP binding in either tissue, nor did the protein reagents DEP or NEM. This supports the idea that picrotoxinin inhibits GABA synapses at a site distinct from the GABA receptor, perhaps allosterically.

1480 BIOCHEMICAL CHARACTERIZATION OF BRAIN NICOTINIC CHOLINERGIC RECEPTOR. Richard S. A. Tindall, Dept. Neurology, Southwestern Med. Sch., UTHSCD, Dallas, Texas 75235

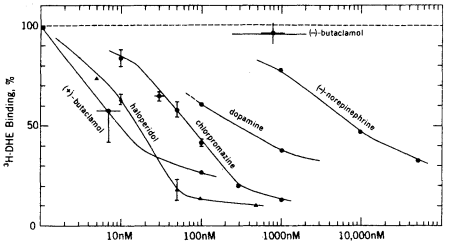
Biochemical assays of CNS acetylcholine receptors have demonstrated two types to be present; nicotinic and muscarinic. Employing an affinity ligand binding assay utilizing the iodinated nicotinic ligand alpha-Bungarotoxin (^{125}I-αBGT), we have determined the concentration of nicotinic acetylcholine receptors (nAChR) in bovine CNS structures. Toxin binding is present diffusely in cortex and subcortical nuclei, with greatest concentration in limbic structures. These data will be presented. Striatal structures known to possess high concentration of muscarinic receptor demonstrate low toxin binding (nAChR concentration). The distribution of nicotinic and muscarinic receptors differ as demonstrated by ligand assays.

Partial purification of CNS nAChR from bovine brain has been carried out. Cerebral cortices were homogenized in 0.32M sucrose and the P_2 (crude mitochondrial) fraction suspended in 2% Triton X-100, 0.05M sodium phosphate buffer p7.4, with PMSF present. After overnight stirring and centrifugation at 105,000 xg for 60 min., the supernatant (triton extract) was applied to an affinity column composed of the α-neurotoxin of Naja naja kaouthia coupled by cyanogen bromide to Sepharose 4-B. The column was then washed with 0.5% Triton-X-100 in phosphate buffer, and elution of the receptor from the affinity column carried out by incubating with 1mM benzoquinonium chloride in 0.1% Triton X-100 in phosphate buffer. The eluted fraction was concentrated, applied to a sucrose gradient (5-20% in 0.1% Triton X-100 in phosphate buffer and sedimented for 21 hours at 37,000 RPM (SW 41 rotor). Following fractionation, the protein peak was pooled, concentrated and aliquots were assayed for ^{125}I-αBGT binding.

Samples were reduced and dissociated (2-ME) and electrophoresed on poly-acrylamide gels containing SDS. The components of our nAChR preparation as so determined will be presented.

1481 BRAIN DOPAMINE RECEPTOR BINDING OF ^{3}H-DIHYDROERGOCRYPTINE. M. Tittler*, P. Weinrich* and P. Seeman, Pharmacology Department, University of Toronto, Toronto, Canada.

Although ^{3}H-DHE (dihydroergocryptine) binds to pituitary dopamine receptors (Caron et al., Fed. Proc., 1977), this ligand also binds to α-adrenergic receptors in the brain. In order to use ^{3}H-DHE as a ligand for brain dopamine receptors, we measured ^{3}H-DHE binding in the presence of 500 nM phentolamine, a concentration which saturates α-receptors but does not affect dopamine receptors. The K_D was 0.7 mM (calf caudate homogenate).



The inhibitory concentrations for various drugs (IC_{50} values in Fig.) are similar to those which inhibit ^{3}H-haloperidol binding (Nature 261, 717, 1976) in the striatum, and to those which inhibit ^{3}H-DHE binding in the pituitary (Caron et al.). Caudate and pituitary dopamine receptors are thus very similar.

(Supported by the Ontario Mental Health Foundation, the Medical Research Council of Canada, and the Connaught Foundation of the University of Toronto).

1482 ENDOGENOUS CORTICOSTERONE (B) IN INTACT STRESSED RATS: REGIONAL BRAIN CYTOSOL BINDING. Barbara B. Turner, Jerry Schielke* and Bernard J. Carroll*. Mental Health Research Health Research Institute, University of Michigan, Ann Arbor, Michigan, 48109.

Previous studies on the brain content of glucocorticoids have used either adrenalectomized (ADX) animals injected with 3H-B or total B levels in the brains of non-perfused, intact animals. We have examined the brain distribution of endogenous B cytosol binding following stress in the intact rat. Bound B, total B and the number of unoccupied sites, was assessed in 8 and 3 brain regions respectively in stressed and ADX adult male rats. At 1000h after 30 min. shaker stress, atrial blood was withdrawn for plasma B determination and the rats perfused. Brain regions from 4-5 animals were pooled and homogenized (20 ml/g) in Tris-EDTA buffer, pH 7.4. Free steroid was removed by dextran-charcoal. All samples were extracted into CH_2CL_2, chromatographed on LH-20, and B levels measured by radioimmunoassay. Unoccupied sites were estimated by the addition of 3H-B (3.5 x 10-8M) to aliquots of the homogenate.

In the stressed rat, the pattern of regional binding differed dramatically from that previously reported in the ADX rat: the pituitary, not the hippocampus, showed the highest binding expressed as f moles/mg protein: pituitary 693, preoptic 362, septum 289, hypothalamus 239, amygdala 154, cortex (CX) 168, hippocampus (HC) 186, and midbrain (MB) 134. Mean plasma B value was 58 ug%, which resulted in a brain B level of 7.5 p moles/mg protein. The number of total binding sites (endogenous + 3H-B) in the 3 regions studied (CX, HC and MB) showed little regional difference. ADX animals had a mean plasma B value of <1 ug%. Total binding sites in ADX rats were higher than in intact rats, with HC showing the greatest number of sites as expected. The results 1) support the concept of the pituitary as the primary site of glucocorticoid feedback control, 2) indicate that the ADX rat is not an adequate model for physiological studies of brain-glucocorticoid interaction, 3) suggest that brain regions other than the HC need closer investigation in stress studies. (Supported in part by NIMH training grant 07417 to B.T.)

1483 DISCRETE BINDING OF [^{3}H]EPINEPHRINE TO CALF BRAIN α- AND β-NORADRENERGIC RECEPTORS. David C. U'Prichard, David A. Greenberg and Solomon H. Snyder. Depts. Pharmacology and Psychiatry, Johns Hopkins Univ. Sch. Med., Baltimore, MD. 21205.

In the presence of 1 mM pyrocatechol, the catecholamine neurohormone [^{3}H]epinephrine displays saturable, high affinity binding to α-noradrenergic receptors in most gray matter regions of the calf brain. Specific binding was highest in the frontal cortex, with other cortical areas, hippocampus, amygdala and hypothalamus having 60-80% of frontal cortex values. The thalamus and caudate nucleus had appreciable α-receptor [^{3}H]epinephrine binding, about 50% of frontal cortex, whereas midbrain and brainstem regions were much lower. White matter areas possessed very low levels of specific binding. At 37°C, the K_D of [^{3}H]epinephrine was 18 nM, whereas after incubation at 25°C the affinity of [^{3}H]epinephrine was increased to a K_D of 5 nM, without alteration of the B_{max}. At all temperatures and in all regions, specific binding possessed α-receptor SAR, with epinephrine a 2-3 times more potent inhibitor than norepinephrine, and 500 times more potent than isoproterenol. Phentolamine, clonidine and ergot alkaloids had K_i values in the 1-10 nM range. High levels of α-receptor binding were found in calf cerebellum, about 60% of that in frontal cortex, and when specific α-receptor binding in that tissue was blocked with phentolamine, a significant portion of the residual binding, displaceable by propranolol, showed characteristics of binding to noradrenergic receptors of the β_2 type. Specific binding of [^{3}H]epinephrine to β-receptors was saturable, with a K_D of 30 nM at 25°C. Isoproterenol was a very potent inhibitor of β-receptor binding, with epinephrine and norepinephrine 10 and 100 times weaker respectively. Propranolol and alprenolol were as potent in competing for binding as isoproterenol, but other β-antagonists were substantially less potent. Stereospecificity of catecholamines and antagonists at β-receptor binding sites ranged from 20 to 100 fold in favor of the (-)-isomers. Binding of [^{3}H]epinephrine to β-receptors was not observed in any other calf brain region. Numerous previous attempts to demonstrate specific binding of endogenous catecholamines to α-, and especially β-receptors in various tissues have been unsuccessful. The discrete binding of [^{3}H]epinephrine to both α- and β-receptors in calf cerebellum reported here provides a suitable model for examining differential effects of ions, temperature-induced receptor interconvertibility and cellular localization of cerebellar α- and β- sites. These results will be discussed. (Supported by USPHS grants MH-18501, MH-33128, MH-05105 and DA-05052.)

1484 VOLTAGE DEPENDENT MODULATION OF β-ADRENERGIC RECEPTOR MEMBRANE BINDING IN RAT BRAIN SLICES. H. R. Wagner* and J. N. Davis (SPON: E. W. Busse). VA Hospital and Duke University, Durham, NC 27705.

Incubation of rat cerebral cortex slices with the β-adrenergic agonist, isoproterenol (ISO), leads to a dose-dependent decrease in β-adrenergic receptor (βAR) binding sites as measured with the βAR ligand, [^{3}H] dihydroalprenolol (DHA). We previously suggested that the ISO-induced decrease in DHA binding sites represents βAR desensitization in brain slices. During the course of those studies, we observed that factors which depolarize brain slices also produce a rapid recovery of lost DHA binding sites. To systemically investigate the effects of membrane voltage on the ISO-induced loss of DHA binding sites, we exposed slices of rat brain cerebral cortex to 10 μM ISO for 30 minutes. Various depolarizing agents were added for the final 10 minutes of this period. At the end of the incubation, membranes were prepared from slices, extensively washed to remove any traces of ISO, and βAR binding was measured by incubation with 10 nM [^{3}H] DHA followed by rapid filtration. ISO-incubated slices had 70% of the DHA binding found in membranes from control slices incubated in buffer alone. Exposure of ISO-treated slices to high K^+ (50 mM), grayanotoxin (10 μM), or batrachotoxin (10 μM) in the continued presence of ISO restored DHA binding to 96%, 95%, and 100% of control. Exposure of slices to grayanotoxin (10 μM) did not restore DHA binding in a Na^+-free (choline) buffer or when the slices were pretreated with tetrodotoxin (10 μM). Pretreatment of slices with EDTA and removal of Ca^{++} from the incubation did not prevent grayanotoxin reversal of DHA binding. These data support our previous proposal that the ISO-induced loss of DHA binding sites represents βAR desensitization. Our results suggest that membrane depolarization resensitizes βARs through a voltage-dependent movement of Na^+ ions and that βAR desensitization like nicotinic cholinergic and α-adrenergic receptor desensitization is regulated in part by membrane voltage.

1485 DIFFERENTIAL DEVELOPMENT OF β-ADRENERGIC AND DOPAMINE RECEPTOR-CYCLASE SYSTEMS IN CULTURED AGGREGATES OF BRAIN CELLS FROM THE PRENATAL RAT. Kenneth G. Walton, Ronald Majocha,*G. Robert DeLong* and Ross J. Baldessarini. Mailman Research Center, McLean Hospital, Belmont, MA 02178 and Dept. of Neurology, Massachusetts General Hospital, Boston, MA 02114.

Working independently, DeLong (Dev. Biol. 22:563, 1970) and Seeds (PNAS 68:1858, 1971) developed techniques for maintaining rodent brain cells as spherical reaggregates of dissociated cells by growing the cells on a rotary shaker. Brain-cell aggregates grown in this manner show changes in culture which resemble the changes known to occur in intact developing brain. Examples include biochemical differentiation, specific cell sortings and synapse formation. We have begun studies on receptor-adenylate cyclase systems in these aggregates with the hope of using this preparation to increase our understanding of the characteristics and plasticity of such receptor-cyclase systems as well as their role in synaptic transmission and possible role in brain development. Using aggregates prepared from cells of whole brains of 17-day prenatal rats we have found separate stimulations of cyclic AMP levels mediated by β-adrenergic and dopamine receptors in intact aggregates. A similar degree of stimulation (about 2-fold) was obtained through each of these receptor systems after one day in culture, with a gradual increase in stimulation over the next 9 days. Between 10 and 18 days in culture, the β-adrenergic-receptor-mediated stimulation increased dramatically to 7-8 fold whereas the dopamine-receptor-mediated stimulation increased only to 4-5 fold. Both the magnitude and the time course of the changes in β-adrenergic receptor-cyclase resemble those known to occur in intact rat brain during early development. For example, Harden et al. (Brain Res. 125:99, 1977) found a dramatic increase in β-adrenergic receptor during the second postnatal week in cerebral cortex. These results suggest that brain-cell aggregates will prove valuable for studying receptor-cyclase systems in intact cells and possibly also for studying aspects of brain differentiation and development relating to the cyclic nucleotides.

1486 OVERLAP OF DOPAMINE- AND SEROTONIN-DISPLACEABLE LSD BINDING IN COW CAUDATE. Patricia M. Whitaker* and P. Seeman (Spon: J. Warsh). Pharmacology Department, University of Toronto, Toronto, Canada.

Lysergic acid diethylamide (LSD) has been reported to exert its effects either through actions in the dopaminergic (Pieri et al., Nature 252: 586, 1974) or in the serotoninergic system (Bennett and Aghajanian, Life Sci. 15: p. 1935, 1974). Our work suggests that, at least in some circumstances, these two neurosystems may share a common set of receptors for LSD.

The binding of ^{3}H-LSD was done on homogenates of calf caudate nuclei (Seeman et al., P.N.A.S. 72: 767, 1975). ^{3}H-LSD binding was also measured in the presence of excess (1 µM) dopamine, serotonin or epinephrine, or in a combination of these.

LSD was found, by Scatchard analysis, to occupy sites equivalent to 825 fmoles/mg, with a K_D for these sites of 8.4 nM. The number of ^{3}H-LSD sites dropped to 615 fmoles/mg in the presence of excess dopamine (DA), and to 525 fmoles/mg in the presence of excess serotonin (5HT). However, when both neurotransmitters (DA + 5HT) were present in excess, the number of ^{3}H-LSD sites was still only reduced to 565 fmoles/mg.

If the receptor sites occupied by these two substances were completely separate, one would expect a cumulative decrease in ^{3}H-LSD binding, i.e. to about 315 fmoles/mg. The fact that the decrease was not this great suggests that dopamine and serotonin are displacing ^{3}H-LSD from similar or closely related sites, with the possible exception of approximately 50-90 fmoles/mg which appear to be purely serotoninergic sites.

Epinephrine had no effect in reducing binding of ^{3}H-LSD, suggesting that these receptors are not involved in LSD binding. As would be expected, therefore, in the presence of excess epinephrine plus excess serotonin or dopamine, the resultant decrease in binding was identical to that seen in the presence of serotonin or dopamine alone.

This work suggests that at least a considerable proportion (over 75%) of the serotonin and dopamine receptors overlap with each other, insofar as they contribute to the binding of ^{3}H-LSD. (Supported by Ontario Mental Health Foundation and the Medical Research Council of Canada).

1487 INNERVATION OF SOME DEEP TISSUES IN THE THORACOLUMBAR REGION OF MAMMALS. David G. Whitlock, Priscilla A. Ledbury*, Lanay J. Land, and Ralph A. W. Lehman*. Dept. of Anat., Univ. of Colo. Med. Sch., Denver, CO 80262.

Few studies have been made of the innervation of deep tissues; the only notable exception being investigations of the innervation of muscle spindles and Golgi tendon organs. In our experiments autoradiography has been used to examine some deep tissue pathways and their terminations in the thoracolumbar region of mammals. Concentrated L-3,4(n)^{3}H-proline (0.2-1.2mCi/µl) was hydraulically injected into either a mid-thoracic dorsal root ganglion or a celiac collateral ganglion of anesthetized monkeys or cats. After a post-injection survival period of 7-14 days the animals were reanesthetized, transcardially perfused with Bouin's solution, and all tissues of interest were removed, embedded in paraffin, serially sectioned at 3-5 microns and prepared for autoradiography.

Following such an injection into a T-8 dorsal root ganglion, radioactivity was observed in two types of receptor-like structures in the thoracic wall. The first of these structures occurred in clusters adjacent to the intercostal muscles. Each element appeared to be innervated by a single labelled axon. They apparently did not contain either intrafusal fibers or evidence of secondary innervation. Usually they were tightly adherent on one side to the fleshy belly of the muscle and were never associated with the tendons. The second type of receptor-like structures we observed consisted of small nodules attached to the walls of the intercostal veins. A single labelled axon could be traced into each nodule where it terminated, as indicated by a spray of silver grains overlying the nodular structure and directed towards the vein lumen. We conclude that both of these structures must be afferent in character for their innervation could only have come from the labelled cell bodies of the injected mid-thoracic ganglion.

Injection of radioactive proline into a celiac collateral ganglion gave rise to a small number of labelled axons distal to the ganglion. Some of these axons could be traced through the connective tissue sheath surrounding the adrenal and along the connective tissue septa within the adrenal cortex into the adrenal medulla. A single labelled axon could be traced within the medulla to its apparent termination on the wall of a medium sized artery. This termination, we believe, is part of a visceral motor system. It may modulate the activity of the adrenal medulla through control of its blood supply.

SLEEP

1488 TEMPORAL CHARACTERISTICS OF SLEEP IN MICE. Helen A. Baghdoyan* and Matej Stepita-Klauco (SPON: V. L. Friedrich). Dept. of Biobehavioral Sciences, U.Conn., Storrs, Ct. 06268.

Sleep in mice (C57BL/6) was studied by means of chronic (3-4 weeks) polygraphic recording. The method employed time compressed (TC) EEG and head movement signals which were continuously recorded on chart paper (3 mm/min.). Portions of the raw EEG were simultaneously recorded on magnetic tape for subsequent spectral analysis. The pen record of the TC signal was assessed visually. Three states of vigilance were recognized: waking, REM sleep and NREM sleep. The reliability of the TC signal for assessing the behavioral states of the animal was tested by comparing the coincidence of states obtained by a)scoring the pen recorded TC signal and b)behavioral observation of the animal with concurrent examination of the raw EEG displayed on an oscilloscope. Scored and observed states were compared for 10 second epochs. Their matching was expressed as a percentage of the total duration of each state over the time interval of the experiment. Comparisons were made for scored (TABLE I) and observed (TABLE II) states taken as the reference and expressed in percents of the duration of the state listed in the left column ± S.E.M (N=5).

TABLE I	SCORED	O B S E R V E D		
		WAKE	NREM	REM
	WAKE	91.19 ± 3.77	6.56 ± 2.84	2.25 ± 1.33
	NREM	11.93 ± 2.52	84.50 ± 2.70	3.56 ± 1.46
	REM	16.30 ± 4.66	18.75 ± 2.13	64.95 ± 6.32

TABLE II	OBSERVED	S C O R E D		
		WAKE	NREM	REM
	WAKE	73.96 ± 4.27	21.78 ± 4.90	4.26 ± 1.26
	NREM	2.91 ± 0.98	93.12 ± 1.05	3.08 ± 0.36
	REM	6.78 ± 4.12	25.42 ±10.32	67.80 ± 6.95

The time spent in each state per day showed small variations. During a 24 hour period 613.8 ± 13.9 min.(42.7%) were spent in waking and 824.3 ± 13.9 min.(57.3%) in sleep. The sleeping time consisted of 739.3 ± 12.7 min.(51.4%) of NREM and 85.0 ± 3.4 min. (5.9%) of REM sleep. Spectral analysis revealed a dominant frequency in the range between 6-9 Hz. for both waking and REM sleep. This activity was most prominent during REM sleep, whereas in waking additional activity at lower frequencies was present. The mean peak frequencies for waking (7.41 ± .25 Hz., N=14) and REM sleep (8.00 ± .12 Hz., N=13) were not significantly different. The mean peak frequency for NREM sleep was 2.34 ± .21 Hz. (N=20). No cortical spindle activity during NREM sleep was observed.

1489 ACTIVE SLEEP REVERSES RESPIRATORY FAILURE IN HYPOXIC KITTENS. T. L. Baker* and D. J. McGinty. V. A. Hospital, Sepulveda, CA 91343 and University of California, Los Angeles, CA 90024.

We assessed the effects of chronic intermittent hypoxia upon sleep patterns, respiration, and cardiac function in 10, 20 and 40 day old kittens. Forty kittens at each age were isolated in Plexiglas chambers at 21% O_2 (controls), 10% O_2 or 7% O_2 for four 2-hour 'conditioning' sessions daily for three or eight days. Kittens were surgically implanted with chronic electrodes for measurement of EEG, EOG, neck EMG, EKG and with a nasal thermistor to measure respiratory air flow. Physiological parameters and a time code were recorded polygraphically and on magnetic tape. Each minute of polygraphic data was scored as waking (W), active sleep (AS), quiet sleep (QS) or transitional-indeterminate (T). Respiratory rate and variability, and heart rate and beat-to-beat variability were derived by computer analysis.

At all ages hypoxia reduced AS and augmented QS and T. Individual epochs of AS were shorter and less frequent in hypoxic subjects compared to controls. Similarly, frequency and length of QS epochs was increased. During experimental hypoxemia, some kittens repeatedly exhibited a respiratory 'failure' syndrome during QS, T or W. These episodes consisted of slow apneustic-type breathing accompanied by bradycardia and other EKG irregularities. Active sleep onset consistently stimulated respiration and heart rate and rectified irregularity in these functions, thereby reversing hypoxemic 'crises.' Hypoxic kittens that exhibited most severe cardiopulmonary failure and died showed more extensive suppression of AS than other subjects in their respective age groups.

We hypothesize that neural control of respiration during AS is stable and resistant to hypoxemia. Active sleep may serve a protective function during hypoxemic stress, especially during development. This theory is consistent with a recent report that sleep-related respiratory depression in infants (Ondine's Curse) is reversed during AS. Hypoxemia and sleep-related respiratory failure have also been implicated in the Sudden Infant Death Syndrome (SIDS). The natural predominance and tenacity of active sleep in the newborn may explain the paradoxically rare occurrence of SIDS in the first month of life.

1490 CHARACTERIZATION OF SYNAPTIC POTENTIALS INDUCED BY RETICULAR FORMATION STIMULATION ON TRIGEMINAL MOTONEURONS DURING SLEEP AND WAKEFULNESS. Scott H. Chandler*, Yoshio Nakamura*, and Michael H. Chase (SPON: R.E. Hall). Depts. Physiol. and Anat., Sch. Med., UCLA, Los Angeles, CA 90024.

We have previously reported that excitation of the ponto-mesencephalic reticular formation induces, in trigeminal jaw-closer motoneurons, depolarization during wakefulness and quiet sleep, and hyperpolarization during active sleep, i.e., state-dependent response-reversal. We have investigated the nature of these synaptic potentials in 4 cats which were unanesthetized and freely-moving (with the exception of head restraint). They were implanted under nembutal anesthesia with standard EEG, EOG and EMG recording electrodes. Jeweler screws were fixed in the mandibular canal to stimulate the inferior dental nerve. Bipolar stimulating electrodes were implanted in the mesencephalic Vth nucleus and the nucleus reticularis pontis oralis. 3 M KCl or 2 M K-citrate micropipettes were used (with tip resistances of 8-15 megohms) for intracellular recording from trigeminal motoneurons. A short train of conditioning pulses (1-3 pulses; 500 cps; .3 msec) was delivered to the nucleus reticularis pontis oralis at a rate of 1/sec. The amplitude of the control depolarizing potential increased and decreased, respectively, when hyperpolarizing and depolarizing currents were passed through the recording electrode. Therefore the depolarizing potential is membrane potential dependent and can be considered to be an EPSP. The hyperpolarization induced by reticular stimulation during active sleep was compared with the somatic IPSP evoked by inferior dental nerve stimulation following the 1)injection of chloride into the cell and 2)alteration of the membrane potential by passage of current from a K-citrate electrode. The hyperpolarization to reticular stimulation during active sleep was much less sensitive to injected current from a K-citrate microelectrode than the somatic IPSP induced by inferior dental nerve stimulation. When chloride was injected into the cell the IPSP to inferior dental nerve stimulation was reversed in polarity while the hyperpolarization to reticular stimulation was only reduced in amplitude. Therefore the synaptic basis for the reticular response-reversal can be explained as follows: During wakefulness and quiet sleep a short latency (3-5 msec) postsynaptic depolarizing potential occurs. During active sleep the depolarization is reduced in amplitude and a longer latency and duration hyperpolarization emerges which is also postsynaptic. However, on the basis of its reduced sensitivity to chloride injection we conclude that this area of the reticular formation exerts its inhibitory effect through a system(s) which has its inhibitory input located predominately onto the dendrites of the motoneurons. Supported by USPHS 09999.

1491 TRIGEMINAL MOTONEURON SPIKE POTENTIAL ACTIVITY DURING SLEEP AND WAKEFULNESS: CORRELATIONS WITH NECK EMG DISCHARGE. Michael H. Chase, Scott H. Chandler*, Benjamin Chang*, and Yoshio Nakamura*. Depts. Physiol. and Anat., Sch. Med., UCLA, Los Angeles, CA 90024.

The modulation of electromyographic (EMG) activity during sleep and wakefulness has been extensively studied for the past twenty years. These studies have described both phasic and tonic variations in the level of EMG activity as a correlate of the animal's state. We have monitored the discharge and membrane potential activity of trigeminal motoneurons and correlated this activity with variations in neck EMG, which in the cat, is typically used as general indicator of state-dependent variations in motor discharge. In 4 chronic cats that were undrugged, intact, normally respiring and freely-moving (with the exception of head restraint), micropipettes (filled with 2M K citrate; tip resistances of 8-15 megohms) were inserted into 20 electrophysiologically identified trigeminal motoneurons. The activity of these (jaw-closer) motoneurons was correlated with the EMG of the neck musculature during sleep and wakefulness. High motoneuron discharge rates were observed during wakefulness, when EMG activity was greatest. In general, bursts of EMG activity were accompanied by a decrease in membrane potential and an increase in spike potentials. Reduction in EMG activity was accompanied by an increase in membrane polarization and decreased spike activity. During quiet sleep the rate of spike activity was also correlated with tonic and phasic EMG discharge in the same manner as during wakefulness. During active sleep the membrane potential increased by as much as 10 mV. This increase was accompanied by a decrease in neck EMG activity and trigeminal motoneuron discharge. However, in conjunction with bursts of neck EMG activity and phasic muscular twitches, the level of motoneuron polarization decreased phasically and spike activity was initiated. This correlation was typically present, but not absolute. These findings indicate that the control of motor activity in the trigeminal system reflects the phasic and tonic modulation of spinal cord motor activity and exhibits state dependency of both membrane potential and spike discharge. The basis for this control at a synaptic level can now be studied by utilizing the intracellular technique to determine the causal processes which control the level of polarization and discharge of motoneurons during sleep and wakefulness. Supported by USPHS NS 09999.

1492 RESPIRATORY RESPONSES TO AIRWAY OBSTRUCTION DURING SLEEP AND WAKING IN THE DOG. Susan DeMesquita* and Eugene Aserinsky. Dept. Physiol., Sch. Med., Marshall Univ., Huntington, WV 25701.

Nine adult dogs with in-dwelling tracheostomy tubes were monitored for respiratory parameters during 8-hr sleep trials with the tubes patent for 4 hrs, and partially plugged for 4 hrs -- the diameter of the orifice being reduced by ca. half to an end diameter of 2 to 4 mm. The partially occluded airway caused labored breathing in the waking state but did not prevent the onset of sleep. The purpose of the experiment was to determine how physiological responses to stress might differ during different states of consciousness.

Records were scored min by min for each of three states (Waking, REM Sleep and Non-REM Sleep) which had been identified by EEG, neck EMG and EOG. Airway obstruction had no signif. effect on total sleep time, REM % and REM Pd. duration. With the airway patent, the mean± S.D. values for TST, REM % and REM Pd. duration were 136±37 min, 17.1±6.2% and 5.7±1.4 min, respectively; the corresponding values while the tubes were plugged were: 146±35 min, 17.7±5.7% and 5.5±1.0 min. However, preliminary analysis of eye mvt data suggests a marked increase in REM density (eye mvts/min) during airway obstruction.

Mean respiratory values obtained while the tracheal tubes were unobstructed and then obstructed are tabulated below:

	WAKE		Non-REM SLEEP		REM SLEEP	
	Unobst.	Obst.	Unobst.	Obst.	Unobst.	Obst.
Breaths/min	80	52	19	16	18	13
V (l/min)	7.4	4.8	3.1	2.3	3.3	2.2
Insp. (sec)	0.5	0.7	1.1	1.5	1.2	1.6
Exp. (sec)	0.5	1.1	0.8	2.1	0.8	2.1
$P_A CO_2$ %	4.4	5.2	5.4	6.1	5.3	5.9

A direct effect of increased airway resistance was a signif. ($p<.01$) increase of ca. 35% for inspiratory duration and over 100% for expiratory duration in all three states of consciousness. This led to signif. decreases in respiratory rate and min volume in the three states but the mean tidal volumes did not change. Compensation was not complete in view of the signif. rise of alveolar CO_2. The relatively low CO_2 values in Waking may have been due to hyperventilation accompanying awareness of the experimental situation.

While the initial or control values in Waking were different from the sleep states, the respiratory responses to the stress were proportionately the same in all three states. These results do not support the notion that REM sleep is a time of especial vulnerability to stress.

1493 A NONLINEAR CLASSIFIER FOR AUTOMATED SCORING OF SLEEP STAGES IN CATS: DEVELOPMENT AND USE IN EVALUATING DRUG EFFECTS. A. T. Dren*, W. J. Giardina, C. H. Nute*, J. P. Hansen*, W. G. Jochimsen*, A. N. Mucciardi* and R. Shankar*. Abbott Lab., No. Chicago, IL 60064 and Adaptronics, Inc., McLean, VA 22101.

An adaptive learning network sleep stage classifier (ALNSSC) was developed for automatic scoring of sleep stages in the cat. Using heuristic classification algorithms, ALNSSC was trained on a data base of over 4,000 manually scored epochs obtained from 5 cats implanted with EEG, EMG and EOG electrodes. Calibrated electrophysiological signals were amplified with a Grass Model-78 polygraph. For each animal, the analog output of the polygraph was collected and digitalized on a PDP 11/50 computer in consecutive 20 second time blocks (17 seconds of data) for at least 8 continuous hours. These data were transformed using a Fast Fourier algorithm to provide a total of 35 parameters for each epoch: power spectra of the 3 EEG leads in 2 Hz band widths and total power readings of the EMG and EOG leads. For training the classifier, the epochs were manually scored according to a 4 stage classification: awake, spindle sleep, slow wave sleep and rapid eye movement sleep (REM). The mean agreement of ALNSSC computed sleep stage determinations to manually derived scores was 83% with a range of 78% to 93%. Data base considerations and characteristics of the sleep stage prototypes will be available for discussion. In its present configuration, the PDP 11/50 parameterizes the polygraph signals on-line and compares the digitalized data to sleep stage prototypes in the classifier at the end of each experimental session. Data from up to 4 separate experimental chambers can be processed simultaneously for a maximum of 15 continuous hours. Epochs have been lengthened to 30 seconds and the ALNSSC classifies each into one of the 4 stages. Auxiliary programs calculate numerical values for the amount of time in each stage and the relative percentage of each sleep stage, and provide temporal graphic displays of sequential changes in sleep patterns. The latency to sleep onset and to the first REM period are also obtained from the computer output. The application of the ALNSSC to pharmacologically altered sleep patterns will be illustrated with data obtained with psychostimulant and CNS depressant drugs.

1494 MULTIPLE UNIT ACTIVITY DURING TONIC AND PHASIC REM SLEEP: MODIFICATIONS BY PROTEIN SYNTHESISINHIBITORS. René Drucker-Colín, José Bernal*, Francisco Díaz-Mitoma* and Jorge Zamora*. Dept. Biol. Exptl. Inst. Biol. Univ. Nac. Autónoma de México. México, D. F.

Rapid Eye Movement (REM) sleep can be divided into periods with phasic activity (REMp) and periods with tonic activity (REMt). The object of this study is to determine whether inhibitors of protein synthesis modifies such periods. Twenty cats were stereotaxically implanted with microelectrodes (60 µm) in the hipocampus (H), midbrain reticular formation (MRF) and in some cases in the amygdala and cerebellum. The animals were additionally implanted with screw electrodes in the cortex, and external canthus of the eye, a bipolar electrode in the lateral geniculate (LGB) and electrodes in the muscles of the neck. Multiple unit activity (MUA) and the sleep-wake cycle of each cat was recorded several times for periods varying between 5-12 hours following the administration of saline, anisomycin (5-10 mg/kg), and cloramphenicol (50-100 mg/kg). Some cats were also recorded for 2 hours following the administration of amphetamine (10 mg/kg). The results of these experiments showed during control recordings that REMf and REMt alternated in a cyclic fashion, but only when the duration of the REM sleep periods was longer than 6 minutes. It was also found that in 31 of 83 long REM periods during REMf the frequency/sec of MUA in H was low (4.50 ± 0.36) and high in MRF (11.25 ± 0.76) while during REMt MUA frequency in H was high (10.22 ± 0.52) and low in MRF (4.21 ± 0.30). The same inverse phenomenon was observed following amphetamine, during presence or absence of eye movements. Following the administration of anisomycin and cloramphenicol the frequency of REM sleep decreased, and there was augmentation of REMt, while PGO spikes decreased. Also it could be observed that there were periods of REM without atonia. It is suggested that the inverse and oscillatory changes in excitability and their modifications produced by protein synthesis inhibitors may provide support for the idea that REM sleep represents a period during which the brain "reprogramms" itself.

1495 COMPARISON OF REVERSIBLE CRYOGENIC BLOCKADE TO IRREVERSIBLE LESIONS IN THE PONTINE TEGMENTUM OF CATS. Loyd L. Glenn, Wesley B. Leung*, and William C. Dement. Department of Psychiatry, Stanford University School of Medicine, Stanford, CA 94305.

Bilateral lesions of the dorsolateral pontine tegmentum can produce hallucinatory behavior in animals during REM sleep. This is presumably due to an abolition or counteracting of the neural mechanisms underlying the muscular atonia seen during REM sleep. We attempted to reversibly produce REM sleep without atonia by cryogenic blockade of this region. Three cats were implanted for cortical, ocular, and PGO wave recordings, in addition to the bilateral placement of cryodes in the dorsolateral pontine tegmentum. The cryodes consisted of two concentric, uninsulated, stainless steel cylinders (22 gauge O.D.) cooled at the tips by the flow of cold, pressurized helium (-70°C. @ 200-600 PSI). Cats were deprived of REM sleep for 24 hours before experimentation on a slowly moving treadmill, then atraumatically restrained within a sound-attenuating booth. Pairs of subdermal electrodes were inserted into four muscles for the recording of general electromyographic activity. Cryode coolings occurred on alternate REM periods in 30 second pulses. Rather than increasing postural tonus during REM sleep, unilateral and bilateral cryogenic blockade always caused a strong arousal to wakefulness. To investigate the reason for the difference between effects obtained by cryodes from that of electrocoagulation, irreversible electrolytic or cryogenic lesions were made through the cryodes. These lesions, made under restrained, unanaesthetized conditions, produced an immediate long-lasting arousal for 6 to 30 hours, followed by the gradual reappearance of NREM sleep. The arousing effect of temporary cryogenic blockade is probably related to the initial longlasting wakefulness seen after a lesion, but the chronic effects of a lesion do not occur in such short duration blockades. The proper placement of the cryode tips is indicated in each cat by (1) the transient appearance of REM sleep without complete atonia after the cryode placement alone, (2) the total suppression of REM sleep by irreversible cryogenic and electrolytic lesions made through the cryodes, and (3) the histologically verified placement of cryode tips in regions established by others to produce REM sleep without atonia when lesioned. The initial wakefulness seen after irreversible lesions in the dorsolateral pontine tegmentum are similar to the effects of temporary blockade of this region. However, this study and the work of others indicates that the chronic effects of permanent lesions do not predict the effect of a temporary cryogenic blockade in the same region.

496 THE EFFECT OF REM SLEEP DEPRIVATION ON STIMULUS-BOUND EATING THRESHOLDS. R. Halperin*, J. Halperin*, F. Villegas*, S. Daren*, S. Steiner*, and S. Ellman. Dept. Psychol., CCNY, New York, N. Y. 10031.

REM sleep deprivation (RD) lowers thresholds for lateral hypothalamic (LH) intracranial self-stimulation (ICSS). D-amphetamine also lowers thresholds for LH ICSS. D-amphetamine raises thresholds for stimulus bound eating (SBE) electrically elicited from LH ICSS sites. This study investigated the effect of RD on SBE thresholds.

Six rats, maintained on an 1-12, d-12 lighting schedule were stereotaxically implanted with a bipolar electrode aimed at the LH, EEG screws and an EMG electrode. SBE thresholds, using 60 Hz. stimulation in a modified method of limits, were obtained either three hours into the dark period or 10 1/2 hours into the light period. After determination of stable SBE thresholds, the experimental paradigm consisted of two days of adaptation (A), five days of baseline (BL), five days of RD and five days of recovery (R). Animals were housed in sawdust during A, BL and R conditions. RD was achieved by maintaining animals on a small platform surrounded by water. Each animal was also tested in a large platform (LP) control condition; conditions were counterbalanced across animals.

All platform conditions significantly increased SBE thresholds over BL levels, however during RD, thresholds were significantly higher than during LP. All thresholds returned to BL levels during R. Increases in SBE thresholds occurred during both lighting conditions.

The effects of RD on both ICSS and SBE parallel the effects that result from administration of d-amphetamine. We interpret these results as implicating catecholamines as a common mechanism of action for RD and d-amphetamine.

1497 DECREASED CARDIORESPIRATORY COUPLING IN INFANTS AT RISK FOR THE SUDDEN INFANT DEATH SYNDROME. R.M. Harper, D.O.Walter, B. Leake, T. Hoppenbrowers*, M.B. Sterman, and J. Hodgman*. Sepulveda VAH, Dept. of Anatomy, UCLA and County USC Medical Center, Los Angeles, CA.

Seven normal infants and seven infants at risk for Sudden Infant Death Syndrome (SIDS) were instrumented with ECG, expired CO_2, EEG, EOG and somatic activity electrodes and recorded for 12 hr periods at 1 week and 1,2,3,4 and 6 mos. of age. The degree of cardiac variability that was due to respiration was assessed by calculating the coherence between cardiac rate and respiratory activity at the median respiratory rate for each minute. Coherence is analogous to a squared coefficient of correlation between respiratory activity and heart variability.

Successive minutes of each 12 hr recording were classified as quiet sleep (QS), active sleep, waking or indeterminate states by trained observers. Coherence values for each minute of the 12 hr record were sorted by sleep state, and average values for each sleep period were obtained for the entire recording. Effects of age, state and risk were assessed using analysis of variance and Duncan multiple range test procedures. In both normal and risk infants, cardiorespiratory coupling was higher in QS than in active sleep or waking. Coherence values in QS also dropped from the newborn period to 1 month of age, and then rose to the 6 month age period.

Coherence was lower for infants at risk for Sudden Infant Death than for normal infants in QS and in waking over all ages. This failure of regulation of cardiac rate variability by respiratory effort in the SIDS risk group may indicate a dysfunction of receptors sensitive to intrathoracic pressure change, or an abnormality in autonomic efferent activity to the heart.

1498 THE EFFECT OF METHYSERGIDE ON 5-HYDROXYINDOLE ACETIC AND HOMOVANILLIC ACIDS IN THE CISTERNAL CEREBROSPINAL FLUID OF CATS. H. Jackman and M. Radulovacki. Dept. Pharmacol., Univ. Ill. Med. Ctr., Chicago, IL 60612.

We have reported that methysergide maleate (ME), a competitive blocker of 5-hydroxytryptamine (5-HT) receptors, delays sleep onset and disrupts sleep patterns in cats when administered at a dose of 0.5 mg/kg. This disturbance of sleep in cats caused by ME lends support to the suggested requirement of a properly functioning 5-HT system involved in the mechanisms of endogenous sleep. Since 5-HT and dopamine (DA) have been implicated in the mediation of sleep and wakefulness, respectfully, we wanted to measure the metabolism of these monoamines by determining the concentrations of their major metabolites 5-hydroxyindole acetic acid (5-HIAA) and homovanillic acid (HVA) in cerebrospinal fluid (CSF) after 0.5 mg/kg ME. Five cats were implanted with cannulas to the cisterna magna (Radulovacki, 1974). Control injections of Ringer's solution, ip, were administered for three days and 1-ml samples of CSF were collected at two-hour intervals starting at 9 A.M. and ending at 5 P.M. On the fourth day, 0.5 mg/kg ME, ip, was administered at 10 A.M. and CSF samples were collected as in controls. The amine metabolites were assayed fluorometrically by the methods of Korf and Valkenburgh-Sikkema (1969) and Sato (1965). Our results are as follows:

	5-HIAA ng/ml CSF±S.E.		HVA ng/ml CSF±S.E.	
Sample	Control	0.5 mg/kg ME	Control	0.5 mg/kg ME
9:00	97 ± 14	122 ± 23	75 ± 10	86 ± 21
11:00	*100 ± 14*	*114 ± 25*	*108 ± 18*	*150 ± 36*
1:00	104 ± 13	127 ± 22	99 ± 10	116 ± 19
3:00	94 ± 12	108 ± 14	99 ± 12	96 ± 27
5:00	107 ± 12	129 ± 25	89 ± 14	109 ± 20

Our data show no significant differences in the 5-HIAA or the HVA concentrations between the control and ME-treated cats. Therefore, suppression of sleep by ME is accomplished without affecting the turnover of central 5-HT and DA. We have interpreted the effects of ME on sleep as reflecting the blockade of central 5-HT receptors. In light of this and our present findings, increased wakefulness could be mediated by a normally functioning DA system while the 5-HT system shows no compensatory mechanism on receptor blockade with ME.

1499 AN EXPERIMENTAL STUDY OF HYPOTHALAMIC AREAS AND CONNECTIONS RELATED TO SLEEP. F. Cleveland Kinney* (SPON: Elizabeth C. Crosby). Dept. Anat., Sch. Med. and Dent., Univ. Alabama in Birmingham, Birmingham, AL 35294

It is well documented that bilateral lesions located in caudal hypothalamic areas, and/or lesions at the midbrain diencephalic junction, result in narcolepsy and catalepsy in cat, monkey and man. However, the specific areas of the hypothalamus concerned have not been clearly delineated. In this study, bilateral, electrolytic stereotaxic lesions of the hypothalamus involving primarily the ventromedial nucleus and the posterior hypothalamic area resulted in prolonged sleep, or narcolepsy, for eight days and continual hypothermia in one cat and sleep for three days in another cat. During wakeful periods, circling behavior was observed in those animals in which the lesions extended into the overlying ventral thalamus. In a third cat, bilateral electrolytic stereotaxic lesions placed slightly caudal to the posterior hypothalamic area and which incidentally involved the basilar artery resulted in coma and decerebrate rigidity. Coma, resulting from this lesion of the mesencephalic diencephalic junction differed from those responses from the above mentioned hypothalamic lesions. Also, this animal was unresponsive to pain and lacked a corneal reflex following surgery. Behavioral changes following the placement of bilateral lesions slightly rostral to and overlapping the posterior hypothalamus were observed in one cat. This cat was generally unresponsive to its environment; it was slow to move and appeared to be somewhat obtunded. Another cat underwent surgery during which the fornix was partially interrupted bilaterally. This partial bilateral interruption of the fornix failed to produce sleep. The results from the stereotaxic lesions placed in the hypothalamus were contrasted with partial and complete lesions of the fornix and the hippocampal areas at different levels.

The Nauta technique for impregnating degenerated axons with silver was used to follow the degenerated pathways. Degenerated axons were traced to their terminations and their connections will be discussed.

1500 CIRCADIAN DISRUPTIONS OF SLEEP IN MICE: CAN THE SLEEP RHYTHM DISSOCIATE FROM THE ACTIVITY RHYTHM? Merrill M. Mitler*, Fred A. Vincent*, and William C. Dement. Sleep Disorders Center, Stanford U. Sch. Med., Stanford, CA 94305

Chronically implanted C57BL/10J (N=11) and BALB/cJ (N=2) mice were continuously monitored by running-wheel sensor for activity and by 96-hour polygraphic recordings for Wakefulness, NREM, and REM sleep. Forty-nine recordings from a two-year period were used to describe the temporal distribution of activity and sleep in these M. musculus strains. Daily (under LD) and circadian (under DD and LL) peaks in NREM sleep and REM sleep tended to coincide temporally. Daily and circadian peaks in Wakefulness and Wheel running also tended to coincide temporally. The segregation between NREM and REM sleep on the one hand and Wakefulness and Wheel running on the other hand was never complete -- sleep was often interspersed throughout the active phase and Wakefulness, throughout the inactive phase. The most striking phenomena were breakdowns of this inter-relationship between sleep and activity. Such breakdowns were characterized by a damped, relatively arrhythmic sleep rhythm coexisting with a well-defined, highly rhythmic activity rhythm. No environmental conditions could have accounted for such sleep rhythm disturbances. Yet, within mice over time, some recordings showed disruptions and others did not. Based on recent lesion work with the suprachiasmatic nucleus, one explanation of the phenomena is that the activity and the sleep rhythms have separate, dissociable suprachiasmatic pacemakers. Thus damping of the sleep rhythm may result from a phase relationship between the two pacemakers such that the peak-trough pattern in the sleep rhythm was blocked by competing activity.

A program on a PDP11T34 computer operating with RSX-11M has been devised to monitor continuously and on-line all four variables (Wakefulness, NREM sleep, REM sleep, and Wheel running) so that longterm interrelationships among the rhythms can be evaluated in association with any disruption in sleep rhythms. The program makes decisions using a conditionally adaptive, template matching algorithm. For each 10 seconds, digitized electrocorticographic data are used in conjunction with yes-no information from a wheel running detector. Handling more than one animal at a time is possible, since the configuration uses 15% of CPU time per mouse.

1501 RETROGRADE TRANSPORT STUDIES OF RELATIONS BETWEEN RAPHE NUCLEI AND LOCUS COERULEUS. Peter J.Morgane, William B.Forbes and Daniel A.Pasquier (SPON: W.L.McFarland). Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

In order to elucidate the possible circuitry linking the raphe nuclei with the dorso-lateral pontine tegmentum, we carried out retrograde transport studies of horseradish peroxidase (HRP).

In the rat,HRP solution(Sigma type VI;30 to 50% in saline) was injected through an 80-100 micron diameter micropipette into the dorsal raphe nucleus(DR)or the locus coeruleus(LC).An injection volume of 0.05 microliters was used.In 20 rats the injection was placed in the DR;in 12 of these the HRP was restricted to the target nucleus.In four other rats,HRP injections were made specifically in the main part of the LC.In control animals HRP injections were made in the cerebellar cortex,the oculomotor complex or the colliculus superior.Also,HRPinjections in the DR after suction of the cerebellar cortex were made.In addition,injections of 0.1 microliter of a similar HRP solution were made in the cat LC,through a one microliter Hamilton microsyringe.As it has been already described for the cat(Pasquier & Reinoso,Brain Res.120: 540,1977)brains were removed,cut in 40 micron sections,processed in diamino-benzidine,and mounted on the same day.Sections were left overnight at 37°C,then lightly counterstained with cresyl violet,cover-slipped,and studied under bright field and dark field illumination.

In the rat,after HRP injections in the DR labeled neurons were consistently found in the parabrachialis nuclei,primarily in the dorsal one.However,labeled neurons in the LC were not found,even when HRP injections placed in the DR diffused slightly in the central gray around DR.The same result was obtained after injections performed along the rostral-caudal axis of the DR.

In the rat and the cat,on the other hand,HRP injections in the LC showed labeled neurons in the DR.These labeled neurons seemed to be localized mainly in the rostral part of the DR.Labeling of DR neurons following small or large HRP injections in the cerebellar cortex was not found.

In summary,our data demonstrated that a direct DR connection to the LC exists,which is not reciprocated.Therefore,these studies support the view that the DR relates directly to the LC and could,thereby,exert influence on PGO spike release via these connections.Failure to demonstrate a LC to DR direct connection, in this material,does not favor the view that LC activity is associated with direct inhibition of the dorsal raphe nucleus.

1502 SLEEP STATE EFFECTS UPON RESPIRATION FOLLOWING VAGOTOMY AND CORD TRANSECTIONS IN THE CAT. A. Netick*, A. S. Foutz, and W. C. Dement. Department of Psychology, California State University, Hayward, CA 94542 and Department of Psychiatry, Stanford University School of Medicine, Stanford, CA 94305.

Breathing in the cat, slow and regular during NREM (non-rapid eye movement) sleep, speeds and becomes irregular during REM sleep. To determine whether this effect of state is dependent upon peripheral mechanisms, a series of 8 cats was prepared with standard electrode arrays for determining sleep stage. In addition, a tracheostomy in each cat permitted the insertion of a cannula attached to a pneumotachograph for recording respiration, and head-bolts imbedded in acrylic skull cap were used to restrain atraumatically the cats during recording sessions. Experiments were tape recorded; extensive samples of breathing under REM and NREM sleep were later digitized and analyzed.

Four of the cats were prepared for chronic recording by exteriorizing the cervical vagoaortic-sympathetic trunk in loops of skin; the nerve was inactivated by circulating cold alcohol through copper radiators around the skin loops. The remaining 4 cats were prepared semichronically with cord transections at T1; these cats later sustained bilateral vagotomies.

Inactivation of the vagi eliminated neither the relative speeding nor irregularity of breathing during REM sleep. Instead, the effect was exaggerated since the typical slowing of the vagotomy primarily affected breathing during NREM and not during REM. Following the cord transection eliminating intercostal breathing as well as peripheral feedback from the thoracic area, the state effect persisted as it did when this lesion was combined with the bilateral vagotomy.

It may be concluded that the effect of REM sleep on the frequency and regularity of breathing cannot be ascribed to afference mediated by the vagal nerves, nor to innervation of intercostal muscles, nor to intercostal to phrenic reflexes. This finding suggests an independent central origin for the effect of state upon breathing in the cat.

1503 OXOTREMORINE-INDUCED TYROSINE HYDROXYLASE ACTIVATION AND PARADOXICAL SLEEP IN THE RAT. P. Ramm* and H. Taub* (SPON. M.W. Donald). Queen's Univ., Kingston, Ont. K7L 3N6. Oxotremorine, a cholinersic agonist which is believed to cause prolonged elevation of tyrosine hydroxylase (TH) activity in the region containing the locus coeruleus (LC) (Lewander et al.; Nature 258: 440, 1975), was administered (1.5 mg./ks.) to seven rats. Sleep-wake activity was monitored (22 hr./day) for 15 days subsequent to a single injection of oxotremorine. This time period included the period of TH induction previously reported. Assays of brainstem TH activity confirmed enhanced activity 72 hrs. after oxotremorine administration. Minor alterations in sleep-wake activity occured during the period of enhanced TH activity, however no quantitative changes in paradoxical sleep (PS) were observed. These data are inconsistent with theories suggesting that: (a) noradrenersic neurons of the LC are directly responsible for executive regulation of PS, and (b) PS functions to maintain synaptic availability of catecholamines. These data suggest that, if a noradrenersic arousal system is present, it does not substantively affect electrocortical arousal during PS.

1504 ACTIVITY OF HUMAN HIPPOCAMPAL FORMATION AND AMYGDALA NEURONS DURING SLEEP. Luigi Ravagnati*, Eric Halgren, Thomas L. Babb, and Paul H. Crandall*. Dept. Surg./Neurol., Sch. Med., UCLA, Los Angeles, CA 90024.

Fine wire microelectrodes were bilaterally implanted in the hippocampus (HC), hippocampal gyrus (HCG), and basolateral amygdala (AM) of 17 psychomotor epileptics for diagnostic purposes. Action potentials from a single or a few neurons (termed a "unit") were recorded during a single 4-8 hr. nocturnal session including wakefulness (AW) and natural sleep. Sleep stages were scored according to standard EOG, EMG and EEG criteria. Visual inspection of the entire sleep study, and computer analysis of representative epochs, yielded the following conclusions: 1) Of the 107 units recorded during AW and different stages of sleep, 81% showed significantly ($p<.01$) different firing rates in different periods. 2) 69% of the 74 units recorded during a complete sleep cycle showed a significant change in firing rate at both the transition from AW to slow-wave sleep (SWS), and from SWS to REM sleep. In 80% of these responsive units, the change in firing rate at the AW→SWS transition was opposite to that at SWS→REM (Fig. 1). 3) HC neurons characteristically increased their firing rate during SWS and decreased it during REM, whereas most HCG neurons, the principle input of the HC, had the opposite pattern (Fig. 2). 4) Interval histograms and autocorrelograms generally did not change between sleep stages. However, some units did show a preponderance of shorter intervals during non-REM sleep, especially in ST3 and ST4, indicating a more 'clumped' or 'bursting' pattern of firing during these periods. 5) EEG spike-wave complexes characteristic of epileptic activity, if present, were greatest during non-REM sleep, and were suppressed during REM sleep, usually to levels below AW. Most units did not appear to change their firing in relation to epileptic spikes. Changes in firing rate that may possibly have been due to changes in the rate of epileptic EEG spikes are excluded from the above analyses.

We interpret our results as suggesting that the tonic levels of HC firing are not controlled by the HCG. They may instead be due to activity in septal or monoaminergic afferents. In all structures, firing rates during REM resembled those during AW rather than SWS. (Supported by the Italian CNR, by USPHS Grant NS 02808 and by the Ralph Smith Foundation)

1505 SLEEP IN AGED RODENTS. R. Rosenberg*, H. Zepelin* and A. Rechtschaffen* (SPON: B. E. Jones). Univ. Chicago, Chicago, IL 60637.

In humans, decreases in the amplitude of EEG delta activity and Stage 4 sleep begin in adolescence and continue throughout the life span. Increased awakenings at the end of the night and daytime naps result in a decrease in the day/night difference in amount of sleep in aged humans. EEG amplitude and diurnal rhythms of sleep in young and old F-344 rats and C57BL/6 mice were compared to determine if changes which occur with age in humans are present in rodents. Polygraph recordings of rat EEG and EMG were automatically scored for sleep stage; mouse recordings were visually scored. Resetting integrators were used to quantify unfiltered and prefiltered EEG amplitude (at 2-4, 6-8, 12-15 and 20-40 Hz for rats; at 2-4, 4-8, 8-16 and 16-32 Hz for mice). Zero-crossing wavelength detectors were used to count the number of delta (2-4 Hz) waves reaching a criterion height level (80 μv for rats, 25 and 168 μv for mice).

No significant age-related loss of EEG activity in any stage or frequency band was found in aged rats. In contrast, old mice showed a nonsignificant tendency toward lower EEG amplitude in all frequency bands and significantly fewer ($p<.05$) 168 μv criterion delta waves. Some loss in amplitude occurred in all stages in aged mice.

The diurnal distribution of NREM sleep and the diurnal distribution of delta activity within sleep (i.e., in young rodents there is more delta activity within sleep which occurs in the light part of the cycle) did not change in amplitude with age in mice. Aged rats, however, showed significant decreases ($p<.05$) in both the amplitude of the sleep rhythm and of the diurnal rhythm of delta activity within sleep as compared with young rats. Sleep bouts were also significantly shorter ($p<.05$) in old rats.

The results indicate that old mice are similar to humans in demonstrating an age-related decrease in EEG slow wave activity whereas old rats are similar in demonstrating decreased amplitude of diurnal sleep rhythms. The fact that sleep EEG amplitude in rodents may remain stable while diurnal rhythms change, and vice versa, indicates that different mechanisms govern these parameters. The loss of diurnal rhythms following lesion of the suprachiasmatic nucleus in rats suggests that the attenuation of diurnal rhythms in aged humans may be associated with some impairment of this nucleus. It has been suggested that the age-related loss of cortical neurons in humans may be responsible for the decline in delta activity amplitude. Since the neuronal population in both rats and mice is reportedly stable throughout life, the difference between the two rodent species reported here is evidence inconsistent with this hypothesis.

1506 EFFECT OF SLEEP DEPRIVATION ON LYSOSOMAL ENZYME ACTIVITY. Martin J. Skoczylas and Arabinda K. Sinha, Dept. Physiology, CMDNJ-Rutgers Med. Sch., Piscataway, N.J. 08854

In order to test the hypothesis that catabolism of nervous tissue increases during sleep deprivation, male adult Golden Syrian hamsters were hand-deprived of sleep (6, 12, & 18 hours) and the specific activities of three lysosomal enzymes, cathepsin D, β-N-acetylglucosaminidase, and acid phosphatase, were assayed in 0.32 M sucrose homogenates of cerebral cortex, pons and medulla and the rest of the brain, "midbrain". All animals were killed at about noon. By the 18th hour, the mean (12 animals in each group) specific activity of cathepsin D decreased by 25%, 23% and 21% of the control, respectively, in the cortex, "midbrain" and pons and medulla. The mean β-N-acetylglucosaminidase specific activity decreased only in cortex (22% at 18th hour), while the mean acid phosphatase specific activity decreased only in the "midbrain" (21% at 18th hour). The experiment was repeated by sleep depriving the animals by a mechanical device. The results were very similar to hand deprivation. These decreases in total specific activity following sleep deprivation may reflect an overutilization of the pools of these enzymes, whereby, their degradative rates exceed their rates of synthesis. The possibility of an increase in the concentration of inhibitors to the enzymes assayed is currently under investigation. (supported by an institutional GRS grant and ONR N00014-77-C-0332).

1507 EYE MOVEMENTS AND BLINKING IN SCHIZOPHRENIA: NEUROPHYSIOLOGIC CONSEQUENCES AND POTENTIAL FUNCTIONS OF BLINKING AND REM. J. R. Stevens, A. Livermore*, K. Wetzel* and S. Rosenblum* Depts. of Neurology, Psychiatry and Psychology, University of of Oregon Health Sciences Center, Portland, OR 97201.

Striking abnormalities in spontaneous blinking and lateral eye movement have been observed on clinical examination and recorded by telemetry from unmedicated patients with schizophrenia. These include unwinking stare, rapid rhythmic blinking, spontaneous rhythmic saccades and searching ("checking") movements. Systemic administration of dextroamphetamine (1 mg/kg) and apomorphine (0.5 mg/kg), threshold doses for behavioral response, and instillation of the GABA blocking agent bicuculline in the ventral tegmental area of the cat are associated with similar changes in eye movement. Spontaneous blinking has a relatively constant rate in all mammals which is independent of heat, humidity or the integrity of the afferent innervation of lids and cornea. Blinking during waking and REMs during sleep expose the peripheral retina to periodic brief pulses of light which provide a series of impulses, the number of which is directly proportional to the duration of waking and paradoxical sleep cycles. There is evidence that the alternating slow and paradoxical phases of sleep are associated with cyclic changes in release of hypothalamic-hypophyseal factors which regulate a number of metabolic and endocrine cycles, and that light conducted over direct pathways from retina to hypothalamus and mesencephalon contribute to regulation of these cycles. Experimental and field data will be presented which are consistent with the relationship between REM and blinking in a number of species, and which suggest that these ocular events excite oculo-endocrine pathways which regulate biologic activity in relation to the photoperiod.

1508 SEX DIFFERENCES IN THE ONTOGENY OF SLEEP APNEA DURING THE FIRST YEAR OF LIFE. Evelyn B. Thoman, Margaret P. Freese*, Patricia T. Becker*, Christine Acebo*, Victor N. Miano*, and William D. Tynan*, Department of Biobehavioral Sciences, Univ. of Conn., Storrs, CT 06268.

Respiration and behavioral sleep states were recorded for 15 male and 13 female infants over the first year of life. The first observation was made during an interfeeding period in the hospital at 2 days of age; then observations were made in the home during a 7-hour period whenever the infants were put down to nap, on weeks 2, 3, 4, and 5; and finally, observations were made in the home during the first two hours of overnight sleep at 3, 6, and 12 months of age. From the analog recordings of respiration, all apneic episodes, or respiratory pauses, of two seconds or longer were measured. Analyses of these data were made for active and quiet sleep states separately.

During active sleep, female infants had higher frequencies of apneic episodes and greater total duration of apnea during observations at all ages through 6 months of age; during quiet sleep females had greater frequency and duration of apnea through 3 months of age. The two sexes did not differ with respect to the mean length of apneic episodes in either sleep state. However, females had longer single apneic episodes in both sleep states throughout the first year.

The two sexes also differed in their predictability of apnea levels. Female infants were predictable at all ages from one observation to another throughout the first year of life. For the male infants, there were significant correlations within the first 5 weeks and between 6 months and 12 months; however, the correlations from 5 weeks through 6 months were not significant.

These results indicate a differential ontogeny of apnea in male and female infants which is most prominent during the same age period that SIDS incidence is highest. The females in this study had higher levels of apnea and more predictable apnea than the males through 6 months of age. We also know that males are more susceptible to SIDS, thus suggesting that their lower levels of apnea and/or their unpredictability may be associated with their greater risk for SIDS. Other recent evidence supports this position.

1509 AN IN VIVO MANIFESTATION OF TEMPORARY DECREASE OF INHIBITIONS IN VISUAL OR AUDITORY NEURON SYSTEMS. Clara Torda. Mt.Sinai Sch.Med & N.Y.Center for Psychoanalytic Training, N.Y.,N.Y.,10029.

It has been observed that selective inhibitions of inhibitory pathways of different sensory modalities may occur during differential cooling of thalamus. Evoked potential studies revealed that these periods of inhibition concur with increased amplitudes of peaks of the evoked potential of the same sensory modality. It is also known that the various states of consciousnes differently affect the peak amplitudes of visual and auditory evoked potentials. The amplitude of various peaks of the N_1-N_4 wave complex of the auditory evoked potentials are smallest during the fast wave sleep(the period of visual dreams). On the other hand, the amplitude of various peaks of visual evoked potentials are equal or larger than during wakefulness. It occurred, therefore, to study the nature of dream content and the nature of concurrent sensory evoked potentials. Ten adult volunteers (both sexes) participated in the experiments, several nights each. Preliminary experiments were first performed during several nights consisting of: a) recording visual and auditory evoked potentials during the various sleep phases; and b) recording of dreams during fast wave sleep. Evoked potentials were recorded by means of silver disk surface electrodes on a Grass polygraph and were fed into a compiuter of Average Transients (Mnemotron CAT 400). During other experimental nights the subjects were awakened by a taped instruct of increasing sound-intensity, stating: "please, tell out loud what goes through your mind right now", repeated until the subject awakened. The verbal reports were taped and the contents were evaluated by two independent judges. When awakened during fast wave sleep, most subjects reported dreams with visual content, and two subjects were found who reported dreams of auditory modality. Concurrent records of auditory evoked potentials revealed that during dreaming with auditory content the auditory evoked potentials resembled records obtained from states of wakefulness, during dreaming with visual content the auditory peaks had much smaller amplitudes. Also, when subjects habitually dreaming in imagery were awakened during sleep periods with auditory evoked potentials of high amplitudes, if they reported dreams, they were of auditory content. Comparison of these results with several types of control measurements led to the conclusions that: I) Individual variations occur in the incidence of interrelationships of inhibitory and excitatory processes of a sensory modality; and II) Changes of the ratio of excitatory and inhibitory processes within one sensory modality may affect the sensory mode of the dream content.

SOMATOSENSORY SYSTEMS

1510 PRIMARY AND NONPRIMARY SPINAL AFFERENTS TO THE GRACILE - Z NUCLEAR COMPLEX IN GALAGO. B. C. Albright* (SPON: D. E. Haines). Department of Anatomy, Medical School, University of North Dakota, Grand Forks, North Dakota 58201.

Individual dorsal rhizotomies were made unilaterally at representative spinal segments in seventeen bushbabies. The dorsal quadrant of the lateral funiculus was transected unilaterally at high cervical levels in two additional specimens. The medullae were sectioned in either transverse or horizontal planes and stained with either cresyl violet or Fink-Heimer methods.

The caudal pole of nucleus Z is present at levels through the obex. At this level, it is recognized as a small compact cell group which is contiguous with the ventrolateral border of the gracile nucleus. Rostrally nucleus Z shifts medially and is present along the ventromedial border of the nucleus gracilis. Rostral to the obex, the gracile nucleus decreases in size, becomes more diffuse and ends about 0.5 mm rostral to the obex. Rostral to nucleus gracilis, nucleus Z shifts dorsolaterally and terminates dorsal to the caudal portion of the spinal vestibular nucleus. Nucleus Z has two distinct longitudinal cytoarchitectural regions. At levels where both gracile and Z nuclei are present, their borders are contiguous and nucleus Z is composed of a compacted arrangement of small round and ovoid cells. Rostral to the gracile nucleus, Z is characterized by a diffuse arrangement of small cells of various multipolar shapes.

Lesions of the lateral funiculus produced dense localized preterminal debris throughout both the compact and diffuse regions of nucleus Z. Sparse contralateral debris was present in both the gracile and caudal Z nuclei. Just caudal to the obex, lateral funiculus lesions produced dense localized degeneration in the base of the gracile nucleus and sparse to moderate diffuse debris in dorsal areas. Sparse to moderate diffuse degeneration was present in the gracile nucleus at rostral pole levels. Dorsal root lesions at coccygeal, sacral and low to mid-thoracic levels resulted in moderate to sparse degeneration within the gracile nucleus rostral to the obex. Of these, sparse degeneration from coccygeal and sacral lesions was present in the medial part of the nucleus Z compact cell region. Dorsal rhizotomies at C_2, C_6, C_7 and T_1 segments produced moderate to sparse degeneration within overlapping fields in the ventrolateral part of the caudal Z nucleus. No primary afferent preterminal debris was present in the diffuse cell region of nucleus Z.

1511 EFFECTS OF EARLY WHISKER DAMAGE ON THE THALAMUS OF THE MOUSE: NEGATIVE EVIDENCE FOR "COMPETITION" IN THE SOMATOSENSORY SYSTEM. J.R. Anderson* and T.A. Woolsey. Dept. Anat. & Neurobiol., Washington U. Med. Sch., St. Louis, MO 63110.

In mice, damage to the vibrissae in the first week of life leads to alterations in the normal cytoarchitectonic patterns of barrels to which they project in SmI cortex. These patterns are precisely correlated with abnormal arrangements of thalamocortical projections to the barrels. The recent description of "barreloids" in the arcuate division of VB in the mouse, prompted us to look for cytoarchitectonic changes in the thalamus after whisker damage. In particular we were interested in the possibility that the thalamus - like the cortex - would show an altered cytoarchitecture and whether there was any evidence in VB which would suggest a "competition" for cortical space in the somatosensory system.

Barreloids are best demonstrated in VB of adult mice when the dorsum of the hemisphere is rolled 30° laterally and its anterior aspect elevated 2° with respect to the horizontal plane. Serial sections were taken through the thalami of the same hemispheres described by Woolsey & Wann '76 (vibrissa row C damaged on PND's 1-5,7,10,etc.) at 50 μm and stained with thionin. Each section containing VB was photographed. An optimal section in the series was identified and all neurons in 80 μm wide traverses across VB, perpendicular to the barreloid rows, were drawn under oil at a final magnification of 2200. The cross-sectional areas of over 3000 VB neurons were measured with the aid of a small computer.

The results are: 1) Early vibrissal damage alters the normal cytoarchitectonic arrangement of barreloids in the contralateral thalamus. 2) In appearance and time course the thalamic pattern parallels similar changes in the cortex: there is no apparent abnormality in animals lesioned on PND-7 or afterward and barreloids in rows adjacent to the areas associated with the damaged row C whiskers are larger. 3) The normal distribution of VB neuron sizes reveals two sharp peaks: the smaller neurons (15%) averaging 25 μm^2; the larger neurons (85%) averaging 85 μm^2. 4) A careful comparison of neuronal sizes across VB, especially in the altered zones associated with row C, shows no significant differences in mean neuronal sizes or overall size distributions.

We conclude that there are close parallels in the pattern and time course of thalamic and cortical cytoarchitectonic alterations in response to damage of peripheral sense organs and that competition as a mechanism to explain the altered thalamocortical projections in mice with early vibrissal damage can be ruled out. (Supported by NIH Grant NS 10244)

1512 RAPHE-SPINAL NEURONS: RESPONSES TO SYSTEMIC AND INTRACEREBRAL OPIATES. Stuart D. Anderson* and Howard L. Fields. Dept. Neurol. and Physiol., Sch. Med., UCSF, San Francisco, CA 94143.

In decerebrate or chloralose-anesthetized cats, dye-filled glass micropipettes were used to record single neurons in nucleus raphe-magnus (NRM) of the medulla (Taber et al., J. Comp. Neurol. 114:161, 1960). Bipolar stimulating electrodes were placed over the dorsolateral funiculus of the cervical spinal cord. NRM neurons were identified as projecting to spinal cord by their fixed latency antidromic spike elicited from one DLF electrode which collided with an orthodiomically conducted spike.

Fifty-nine neurons located with NRM were identified as raphe-spinal. The conduction velocities of these neurons ranged from 12^{5} to 60^{7} m/sec, the mean was $30^{5} \pm 11^{8}$ m/sec.

Raphe-spinal neurons were tested with brief trains of stimuli through electrodes implanted in the periaqueductal-periventricular gray regions. Of 18 raphe-spinal neurons tested, 14 were excited and 4 unaffected. Most raphe-spinal neurons had receptive fields similar to those reported for unselected cells in NRM (Brain Res. 123:363, 1977; Exp. Neurol. 53:304, 1976). Raphe-spinal cells usually respond to noxious or innocuous mechanical stimuli or to noxious heating of the skin or to auditory stimuli. Of 41 raphe-spinal neurons tested, 31 showed increased activity to mechanical or thermal stimuli in the noxious range.

The effect of opiate injected systemically or directly into midbrain on the activity of 13 raphe-spinal neurons was studied. Naloxone-reversible excitation was produced by systemic opiate (≤ 2.2 mg/kg morphine sulfate) in 3 neurons and by direct midbrain injection (≤ 15 μg etorphine or morphine) in 3 other neurons. Three of five neurons with naloxone-reversible opiate-induced discharge acceleration were also excited by noxious peripheral stimuli.

These results are consistent with the hypothesis that NRM is part of an endogenous pain-suppression system which mediates opiate analgesia by inhibiting spinal pain-transmission neurons (Mayer and Price, Pain 2:379, 1976).

1513 EFFECT OF IONTOPHORESES OF MORPHINE AND NALOXONE IN THE PERIAQUEDUCTAL GRAY ON THE ACTIVITY OF THE CELLS IN THE NUCLEUS RAPHE MAGNUS. Michael M. Behbehani. University of Cincinnati, College of Medicine, Dept. of Physiology, Cincinnati, Ohio 45267 USA.

The experiments reported here were designed to determine whether direct injections of morphine or naloxone in the periaqueductal gray (PAG) can alter the activity of the cells in nucleus raphe magnus (RM). Rats were anesthetized with ether and after cannulation of the femoral vein were maintained under urethane and α-chloralose anesthesia. A twin electrode consisting of 200mM naloxone hydrochloride and 50mM morphine sulfate was inserted in the PAG and another twin electrode consisting of a recording electrode and a 0.5M sodium-L-glutamate electrode was inserted in the RM. After isolation of a stable single unit in the RM, its response to either morphine or naloxone iontophoresed in the PAG was examined. The activity of those cells in RM which had very slow or no spontaneous activity was increased by iontophoresis of glutamate in the area surrounding the recording electrode. Morphine increased the spontaneous or glutamate-induced activity in 40% of the cells, an effect which was reversible by naloxone. Injection of naloxone before morphine decreased the firing rate of these cells and this effect was reversible by morphine. In approximately 20% of the cells, the opposite phenomenon was true. Both morphine and naloxone effects were detectable within one minute after their injection in the PAG. The morphine effect outlasted the injection period whereas the naloxone effect stopped within a few seconds after the naloxone injection was stopped. Some cells responded similarly to both morphine and naloxone and the remainder of the cells were not affected by either drug.

1514 ELECTRICAL AND THERMAL SENSITIVITY OF PERIPHERAL NERVE FIBERS. Spencer L. BeMent. Bioelectrical Sciences Laboratory, University of Michigan, Ann Arbor, MI 48109

Glass capillary microelectrodes were used to record from single primary afferent fibers in the superficial radial nerve of anesthetized cats maintained at 36-38° core temperature. The nerve was stimulated with bipolar hook electrodes 40-70 mm from the recording site and with natural stimulation of the forepaw receptors. The temperature of the mineral oil or saline-filled well connecting the stimulating and recording sites was carefully controlled with heating wires embedded in the paw holder. The conduction velocity was obtained from the latency of each single fiber response to supramaximal stimulation. The electrical stimulus was a short duration (20-50 μsec) constant current pulse. The pulse amplitude was obtained with a current probe. The data were taken at well temperatures from 28 to 36°C and corrected to specific temperatures with a Q_{10} value of 1.8 (Paintal, J. Physiol. 180:20, 1965).

The stimulating current for threshold stimulation of 45 fibers in one nerve was essentially constant within statistical variation for fibers with conduction velocities between 60 and 90 m/sec whereas it increased monotonically with decreasing conduction velocity for fibers with conduction velocities between 25 and 35 m/sec. No fibers were recorded with conduction velocities in the 35-60 m/sec range in this nerve. The threshold stimulation results for fibers with conduction velocities greater than 60 m/sec are at variance with the popular view that the larger the fiber diameter the less the current required to stimulate.

The conduction velocity histogram from 178 fibers in six nerves corrected to 37°C exhibited peaks at 25-30 and 60-65 m/sec; no fibers were found that conducted between 40 and 50 m/sec. However at 28°C the histogram peaks were at 15-20 and 45-50 m/sec; the faster fiber peak then appeared within the conduction velocity region where no fibers were found at 37°C. Therefore, the temperature of the nerve segment between the stimulating and the recording sites must be taken into account to avoid thermal smearing of conduction velocity determinations, even when the core temperature of the animal is maintained relatively constant. This fact is particulary important in studies where receptor types are related to conduction velocity (e.g. Bromberg and Whitehorn, Brain Res. 78:157, 1974; Burgess et al., J. Neurophysiol. 38:833, 1968)

The single fiber action potential duration was found to increase with decreasing conduction velocity in agreement with results (Paintal, J. Physiol. 184:791, 1966) for individual fibers recorded from filaments of cat saphenous nerve.

1515 MAGNITUDE ESTIMATES OF SPATIAL SUMMATION FOR CONDUCTED COOL STIMULI. Sherry L. Berg* and Dan R. Kenshalo. Dept. Psychology, Florida State University, Tallahassee, Florida 32306.

The psychophysical method of magnitude estimation was used to measure spatial summation of cool stimuli in five human observers. Contact thermal stimuli were presented to the right dorsal forearm after the site had been preadapted to 32.6°C. Twelve rates of temperature change ranging from 0.1° to 2°C/sec were administered for a 3 sec duration producing twelve corresponding logrithmically spaced cooling shifts from 0.3° to 6°C. Five stimulating surfaces (1,2,4,7.5 and 18cm^2) were introduced using all twelve intensity levels so that spatial summation for thermal cooling could be assessed.

The uniform shape and identical slopes of the power functions obtained for each of the five stimulating areas for the given intensity range suggests a unitary sensorineural mechanism underlying magnitude estimates of cooling. Additionally, the shallow slopes ($\beta = 1$) and the relatively restricted range of displacement for the five identical areal functions demonstrates that, in general, the absolute spatial summation at and above threshold for the cool sensation is less than that observed for the warming sense. 1516 PROJECTIONS FROM THE FIRST AND SECOND SOMATIC SENSORY CORTEX, THE MOTOR CORTEX AND THE CEREBELLUM TO THE POSTERIOR GROUP OF NUCLEI IN THE THALAMUS OF THE CAT. K. J. Berkley and D. C. Mash*. Dept. Psychol., Fla. St. Univ., Tallahassee, FL 32306.

The distribution within the posterior group of terminals from these various afferent sources was studied using a differential labeling strategy in which both autoradiographic and degeneration tracing methods were employed to label two different afferent pathways simultaneously in the same cat. This strategy allows one to make direct comparisons between the terminal distributions of the two afferent pathways under investigation.

In agreement with the results of other investigators, it was found that the first and second somatic sensory cortices projected to those portions of the medial division of the posterior group (POm) that also receive input from the gracile, cuneate, trigeminal and lateral cervical nuclei as well as from the spinothalamic tract. Although these projections appear to overlap completely with each other, the densest projections from the second somatic sensory cortex tend to be located more laterally than the densest projections from the first somatic sensory cortex.

In addition to the somatic sensory cortical projections and the projections from the other sources named above, POm also appears to receive inputs from the cerebellum and the motor cortex. These inputs are modest, tend to occur in not-necessarily-overlapping patches, are more likely to be found at the rostral and caudal poles of POm, and are consistently observable with both autoradiographic and degeneration labeling methods.

This highly convergent pattern of connectivity within POm is similar to the pattern that has been observed in the rostrally adjacent thin region that lies between the n. ventralis posterolateralis and the n. ventralis lateralis. This similarity suggests that these two regions may form one continuous zone that receives input from a wide variety of afferent sources with different functional characteristics and covers the caudal, dorsal, medial and rostral borders of the VPL and VPM somatic sensory thalamic nuclei.

1517 THERMAL STIMULATION OF THE CORNEA IN HUMANS. R.W. Beuerman and D.L. Tanelian.* Div. of Ophthalmology, Stanford Univ., Stanford, CA 94305

There is at present disagreement as to whether or not touch or temperature sensations can be evoked from stimulation of the human cornea in the absence of irritation or pain. In the present experiments, a device has been developed which allows precise control of the stimulation parameters. The subject was seated with the head supported while looking downward so that the eye was immersed in the stimulation chamber containing slowly circulating sterile saline at 33°C. Stimulation was by a saline jet (250 μm diameter) emerging from a nozzle at the bottom of the chamber 2-3 mm from the eye. The jet was switched rapidly from the adapting temperature (33°C) to the stimulus temperature (28° C-45°C) for a 2 sec. period. The rise time of the stimulus pulse was 375 msec, and the reproducibility of a stimulus temperature was ±0.05°C. The jet pressure was about 5 cm H_2O, which was below mechanical threshold for all tissues examined in this study.

When temperature pulses were applied to the upper eyelid in four trained subjects, only verbal responses of temperature sensation were obtained; there were no reports of irritation or pain. Using the same subjects, the experiment was repeated with the eye open so that the jet would impinge on the center of the cornea. All subjects reported sensations of irritation or pain as well as those of temperature. Irritation was initially reported at 35°C, while pain was not felt until 42°C. The sensations of irritation or pain were brief; a clinical examination found that the cornea had not been injured. Since it was found by visualizing the jet fluid with fluorescein that the lid margins were also contacted by the stimulus, additional experiments were designed to determine which sensations were evoked by thermal stimulation of the cornea. In the first experiment a specially designed hard contact lens covered the entire cornea; in the second the cornea was anesthetized while the lids retained normal sensation; and in the third experiment the cornea was mechanically isolated from the lid margins by a soft rubber cup which contacted the eye posterior to the cornea. In the first two experiments, the threshold for temperature sensations were similar to those previously determined while irritation was not reported. In the last experiment irritation was sensed at 36°C and pain at 42°C; temperature sensation was absent. It is concluded that although thermal stimuli are adequate stimuli for corneal receptors, only sensations of irritation or pain are evoked and that this sensory pathway may only have a nociceptive function.

1518 STRESS-PRODUCED ANALGESIA AND MORPHINE-PRODUCED ANALGESIA: LACK OF CROSS-TOLERANCE. Richard J. Bodnar, Dennis D. Kelly, Solomon S. Steiner*, and Murray Glusman. New York State Psychiatric Institute and City College of New York, N.Y.

Rats subjected to acute stressors such as a forced cold-water swim or repeated footshock demonstrate increased nociceptive thresholds. Repeated exposure to the same stressful situation results in adaptation in much the same way that repeated administration of a constant dose of morphine results in tolerance. The present study investigated the possibility of cross-tolerance between stress-produced analgesia and morphine-produced analgesia. Ten separate groups of six rats each were tested using the flinch-jump procedure 30 min after the following experimental manipulations. In the first group, each rat was subjected to a single cold-water swim at 2°C for 3.5 min; subsequent flinch-jump thresholds indicated that the animals developed profound analgesia. In the second, third, and fourth groups, the rats were given a single injection of morphine at one of three dose levels: 15, 10 or 5 mg/kg. All three dose levels produced analgesia; the analgesia caused by the acute cold-water swim was most comparable to that produced by 10 mg/kg of morphine. The fifth and sixth groups were subjected to either a daily cold-water swim or a daily injection of morphine (10 mg/kg) for 14 consecutive days. The return of flinch-jump thresholds to base-line levels at the end of the 14 day period indicated that adaptation or tolerance had developed to both procedures. In the seventh group, the animals were subjected to cold-water swims for 13 days and then injected with morphine (10 mg/kg) on the 14th day; subsequent flinch-jump thresholds demonstrated profound analgesia rather than adaptation or tolerance. Similar results were found in an 8th group tested for reverse cross-tolerance in which chronic morphine administration was followed by an acute cold-water swim. The remaining warm-water swim and placebo control groups confirmed these results. (Supported by NIMH Grant #13579, and by New York State Health Research Council Grant #365.)

1519 SIMILAR THALAMIC PROJECTIONS OF THE ROSTRAL AND CAUDAL PARTS OF THE DORSAL COLUMN NUCLEI IN THE RAT. A.C. Bonduki* (SPON: J. I. Johnson, Jr.). Departments of Psychology and Biophysics, and Neurosciences Program, Michigan State University, East Lansing, MI 48824.

In order to determine if rostral and caudal portions of the dorsal column nuclei have different projections to the thalamus, lesions were made in the gracile and cuneate nuclei of the rat. The lesions were restricted to regions rostral to, or caudal to, the obex. Following survivals of two to seven days, the animals were perfused and the brains were processed according to the Fink-Heimer method for anterograde degeneration. Degenerating terminals were present in the ventrobasal complex pars externa, the anterior pretectal nucleus, the medial division of the medial geniculate nucleus, the ventral portion of the zona incerta, and nucleus angularis (M. Rose: Mém. Acad. Pol. Sci. Lett., Cracovie, sér. B, 1935, 1-108; W. R. Mehler: Ann. N.Y. Acad. Sci., 1969, 167, 424-468) which occupies a small region between the ventrobasal complex and the central lateral nucleus and appears as a dorsolateral extension of the latter. Terminal degeneration was not observed in any of these nuclei following exposure of the medulla without a lesion (sham operations), or following eye removals, although in the latter case degeneration was present in the nuclei of the visual pathway. This pattern of terminal degeneration in the thalamus was identical for rostral and caudal lesions. The results differ from those of Lund and Webster in the rat (J. Comp. Neurol., 1967, 130, 301-312), but are in agreement with the findings of Boivie in the cat (Brain Res., 1971, 28, 459-490) and RoBards and Watkins in the opossum (Neurosci. Abstr., 1975, 1, 215). In addition, terminal degeneration in the ventral tier of the dorsal thalamus resulting from spinal hemisections and anterolateral cordotomies (at C_3) was located rostral to that resulting from dorsal column nuclei lesions, probably in the ventrolateral nucleus.

1520 CAT HINDLIMB DERMATOMES WITH SINGLE-UNIT RECORDING. Paul B. Brown and Herman R. Koerber*, Physiology & Biophysics Dept., West Virginia University Medical Center, Morgantown, WV 26506.

Dermatomes of dorsal roots L_4 - S_2 were determined by recording from dorsal root ganglion cells with myelinated afferents responding to light touch, using stainless steel microelectrodes.

RESULTS: The dermatomes determined with this method were smaller than those reported by previous authors. They displayed less overlap of adjacent dermatomes. Dermatomal trajectories were similar to those previously reported. Dermatomes were more similar to the corresponding dorsal horn dermatomes than are those of previous reports.

Individual receptive field sizes vary inversely with distance from toes; receptive field shapes (length/width ratios) show little variation as a function of position, averaging 1.76, substantially less than dorsal horn cells. Computed innervation density is greatest at the toes.

CONCLUSIONS: (1) previously reported dermatomes, determined using whole-root recordings, are probably inaccurate; (2) dorsal horn dermatomes differ significantly from dorsal root dermatomes, predominantly in being larger (convergence); (3) skin stretch during development probably affects dorsal horn cell receptive field shape more than primary afferent receptive field shape; and (4) previous assumptions of maximum innervation density on foot (especially toes) are tentatively confirmed by these data.

This research was supported by SUPHS Grant Number 2 R01 NS12061-03.

1521 ROSTRALLY AND CAUDALLY PROJECTING NEURONS IN THE DORSAL COLUMN NUCLEI OF THE DOMESTIC CAT. M. B. Bromberg and A. L. Towe. Dept. Physiology & Biophysics, U.W. Sch. Med., Seattle, WA 98195

In the course of a population study of the cuneate nucleus and adjacent tissue in chloralose-anesthetized domestic cats, a few neurons with unusual properties were encountered. The hunting stimulus was a brief shock to the dorsal funiculus at C3, ipsilateral to the site of recording. Stimulating electrodes were also placed in the central footpad of each paw, in caudal nucleus VP-L of the thalamus, and across the lateral tip of the cruciate sulcus of each cerebral hemisphere. A few neurons were apparently driven antidromically from the dorsal funiculus electrode, and some of these were also driven antidromically from the thalamus. Among some 1700 neurons examined (most, retrospectively), only one percent could be convincingly identified as projecting caudally, with about half of these also projecting rostrally to the thalamus. Collision tests were performed on only a few of these, toward the end of the study. C3 antidromic latency ranged from 0.6 to 2.3 msec (the latter neuron satisfying the collision test); VP-L antidromic latency ranged from 1.0 to 1.6 msec. Spike splitting usually appeared at iterative stimulus rates above 200-500 per second. About half of the neurons that projected both caudally and rostrally could not be influenced by cerebral stimulation, whereas 80% of those that projected only caudally could be excited from both cerebral stimulus sites. The remaining neurons were either excited from both cortical sites, were inhibited from both, or were excited from the contralateral and inhibited from the ipsilateral cortical sites. Three-fourths of the "caudal-rostral projection" neurons were hair-sensitive, with small excitatory receptive fields typical of cuneate and gracile neurons; the "caudal projection" neurons showed no such selectivity. Fully three-fourths of these neurons were isolated along the lateral margin of the cuneate nucleus (about 2.5 mm lateral to the midline); they were isolated 0.5 to 2.5 mm below the dorsal surface. They frequently could be recorded over a long distance (0.1-0.2 mm), and had large, low-frequency spikes. C3 antidromic threshold was usually much greater than C3 orthodromic threshold, suggesting that the axons were deep in the dorsal funiculus or in the dorsolateral funiculus.

(Supported by NS-396 and NS-5136.)

1522 RESPONSES OF PRIMARY AFFERENTS AND DORSAL HORN NEURONS TO VAGINAL PROBING IN CATS. Mary C. Bushnell*, Michael J. Iadarola and Donald D. Price (SPON: D. J. Mayer). The American Univ. and Georgetown Univ., Wash., DC 20016 and NIDR, NIH, Bethesda, MD.

We have studied mechanisms of neural afterresponses evoked in spinal cord neurons by natural stimulation of external genitalia of female cats. Both primary afferents and dorsal horn neurons were studied in anesthetized or unanesthetized spinalized cats, respectively. Each cell was tested for afterresponses using electrical and natural mechanical stimulation. The latter included Von Frey hairs and a calibrated vaginal probe.

Several types of primary afferents responded to vaginal stimulation. One type, similar to field receptors of glabrous skin, responded to Von Frey hairs of less than 1 gm applied to the vaginal mucosa at the clitoral region. These cells showed no activity during maintained pressure and little or no response during stimulator retraction. Another type of neuron discharged only during deep vaginal-cervical probing (insertion greater than 2.5 cm) and continued to respond for the duration of the stimulus. Primary afferents with receptive fields adjacent to the vaginal mucosa often discharged when the vagina was probed. None of the primary afferents that responded to vaginal probing exhibited afterresponses to any stimulus.

S_2 dorsal horn neurons responding to vaginal probing included: (1) tactile neurons that had input from low threshold mechanoreceptive afferents, (2) wide dynamic range neurons (WDR) that had input from low threshold afferents and nociceptive afferents, and (3) nociceptive specific neurons (NS) that had nearly exclusive input from nociceptive afferents. Many neurons of all classes projected to the level of the spinocervical nucleus. None of the tactile neurons responded with afterresponses to any mechanical or electrical stimulation of the vaginal region, and the NS neurons responded with afterresponses only to distinctly noxious stimuli. WDR neurons responded with increasingly greater frequencies as the force applied to the vaginal probe was increased from 30 to 110 gm/12.5 mm^2, and 75% of these neurons responded with distinct afterresponses following the termination of vaginal probing. It appears that these tactile-evoked afterresponses of WDR neurons cannot be attributed to afterresponses of primary afferents or to descending control but are produced by mechanisms within the spinal cord. These data lend support to the conclusion of Price et al. (Neurosci. Absts., 1977) that input over WDR neurons may mediate non-noxious aftersensations.

1523 REACTION TIME TO FIRST PAIN IN HUMAN SUBJECTS. James N. Campbell, Robert H. LaMotte. Dept. Physiology, Sch. Med., The Johns Hopkins Univ., Baltimore, Md. 21205.

The monkey hand is innervated by units sensitive to gentle warming that conduct in the C fiber range. Higher temperature stimuli activate both C fiber and A-delta fibers, the latter presumably subserving the sensation of "first" pain. It was predicted on this basis that the reaction time to heat stimuli of increasing intensity would decline sharply as the stimulus temperature approached the threshold for first pain. To test this hypothesis we measured the reaction time (RT) to radiant heat stimuli applied either to the thenar eminence of the hand or the volar forearm in three human subjects. The subject was instructed to release a key as soon as the first sensation occured whether it was warmth or pain. A CO_2 infrared laser under control via a radiometer provided a step increase in skin temperature to a constant level ($\pm$ 0.1°C) over a 7.5mm diameter spot. Stimuli were of 2s duration, and were followed by passive cooling to a base temperature maintained at 38°C. Runs consisted of 40 presentations of the same intensity that ranged in value from 39 to 51°C. Eight loci, on either the thenar eminence or distal volar forearm, were stimulated in rotating sequence, and at random intervals, with a mean rise time to the desired temperature between 200 and 250msec for each stimulus value. The mean inter-trial interval was 25s, and the mean interval for stimuli delivered to the same locus was 200s. When stimuli were delivered to the thenar eminence, the first sensation was typically that of warmth, and the median RT declined exponentially with increasing stimulus temperature to an asymptote of 520-1000msec for the three subjects. For stimuli delivered to the forearm, RT declined in a similar manner in all 3 subjects to an asymptote of 750msec for temperatures of 42 to 44°C. For these stimuli the first sensation perceived was warmth. With further increases in stimulus temperature the median RT declined exponentially to a new asymptote of 400msec, and the first sensation perceived was that of pain. RT's as short as 400msec require that primary afferents conducting faster than 4m/s be activated. It is therefore likely that A-delta fibers are active in the region associated with the threshold for first pain. The response latency measure for stimuli delivered to the volar forearm may provide a measure of the first pain threshold in non-human primates, and may in addition provide a measure of the first pain threshold independent of subjective judgements in human subjects.

1524 SINGLE REPRESENTATION OF THE HAND IN SOMATIC SENSORY CORTEX (SI) OF PROSIMIAN, GALAGO CRASSICAUDATUS. Mary Carlson* & Carol Welt (SPON: Ruth Bleier). New England Reg Primate Res Ctr, Southboro, MA 01772 & Central Wisconsin Center, Madison, WI 53704.

Following the finding of multiple projections of the hand to the primary somatic sensory cortex (SI) of the rhesus monkey, we began studies of the pattern of input from the hand to the cortex of a prosimian, Galago crassicaudatus. Although an earlier study of SI in a prosimian (Nycticebus coucang), had described but one hand projection responding to low threshold (LT) cutaneous stimulation, we felt that examination of another prosimian was warranted in view of the new findings on the differentiation in simian cortex.

Using microelectrodes, we mapped SI in galago in extremely fine detail (over 100 punctures in 4 sq. mm) and found only one area responding to LT cutaneous stimulation of the hand. However, within this single area we found that the glabrous and hairy surfaces of the hand project separately to the rostral and caudal divisions of the area in two distinct somatotopically organized patterns. The serial pattern of representation of the two surfaces of the hand is reminiscent of the pattern of representation of the entire hand in the rhesus, but is in contrast to the mirror image rerepresentation of the hand and foot in Aotus trivirgatus, a new world simian. The topographic organization of neurons responding to manipulation of joints was studied in chronically prepared unanesthetized animals. Joint afferents projected to neurons that were intermingled with those responding to LT cutaneous stimulation in both the rostral and caudal divisions of the hand area. The segregation of glabrous and hairy input seen in anesthetized recording sessions was also evident in the waking animal. Galago lacks a central sulcus and the two sagittal sulci that intersect SI do not correspond to the rostral and caudal boundaries of the area. Instead, in horizontal flattened sections they form a continuous cell sparse line, or incipient sulcus, dividing the hand and face areas. The results of these studies confirm the existence of only one hand area in prosimians, and further suggest that the multiple projections of the hand in simians may have evolved by selective migration of submodality types (i.e. cutaneous, joint, etc.) with the maintenance of somatotopic organization.

1525 RESPONSES OF CATS TO THERMAL PULSES. K. L. Casey, G. P. Frommer, T. J. Morrow* and R. G. Voss*. Depts. Physiol. and Neurol., Univ. Mich., Ann Arbor, MI 48109.

Pain research would benefit by the use of humane, quantitative tests of unlearned responses of animals to controlled natural stimuli. Accordingly, we have developed a semi-automated method for quantifying three behavioral responses of cats to thermal pulses delivered to each hindlimb. The method assumes that noxious stimuli should elicit vocalization, movement and interruption of an ongoing behavior at significantly higher probabilities than innocuous stimuli.

Restrained cats are trained to approach an illuminated food cup into which liquified liver is delivered when the cat's head breaks a photocell contact. A programmable integrated circuit controls the feeding schedule, timing, location and intensity of thermal stimuli, and activates 3 response latency counters. Stimuli are delivered by water-cooled contact thermodes; resting temperature is 38°C. In these experiments, pulse duration and rate of onset is 5 sec and 37.5°C/sec, respectively; fall time is about twice rise time. Pulse amplitudes are 43, 50, and 53°C. For 22 of the 43 15-sec food-available periods, a stimulus is initiated by food approach (contingent); 10 stimuli are non-contingent. Interstimulus interval ranges from 15 to 72 sec, and the stimulus sequence is based on a random order of intensity and laterality. Sensors for each response (movement, vocalization, and interruption of food approach) stop digital counters and register response latency. Any response can be selected to abort (escape) a stimulus.

Response probabilities of 4 normal cats to 43°C stimuli are not significantly different (χ^2 test) from those to blank trials in any response category. Three cats each gave significant responses in one of 3 different categories when pulses were 50°C. All cats, however, show highly significant food approach interrupt probabilities to 53°C pulses compared with blank trials; 3 cats also responded with movement and 2 with vocalization. These responses were maintained above control values for 3 months. Movements and vocalizations were significantly more frequent when stimuli were non-contingent. Mean interrupt latencies range from 2.72±1.17 sec to 2.34±1.42 sec and are not significantly different for movement or vocalization. A significant number of interrupt and movement responses occur within 1.0-1.5 sec, shortly after or even before final stimulus temperature is attained.

The results are consistent with thermal nociceptive thresholds determined by other methods (Rice and Kenshalo, J. Appl. Physiol. 17:1009, 1962), but suggest that a thermal rate sensitive or rate dependent process, rather than thermal displacement, initiates the behaviors monitored in this study. (Supported by NIH Grants NS12015, NS12581, and MH55989.)

1526 SOMATOSENSORY EVOKED POTENTIALS RECORDED DIRECTLY FROM HUMAN SMI CORTICAL AREA AND THALAMUS. Gastone G. Celesia. Dept. Neuro, St. Louis Univ. and Veterans Administration Hospitals, St. Louis, Missouri 63104, USA.

Recordings from the thalamus were carried out in 5 patients undergoing stereotaxic thalamotomy for treatment of Parkinson's tremor. Recordings from the exposed cortex were carried out in 4 patients undergoing temporal lobectomy for partial complex seizures.

Somatosensory evoked potentials (SEP) to median nerve stimulation recorded from VPL consisted of monophasic or diphasic potentials with mean onset latency of 13.8 msec. The major deflection was usually positive, with mean peak latency of 18.09 msec. Thalamic SEP to popliteal nerve stimulation had onset latency of 17.05 msec and peak latency of 23.3 msec.

More complex SEP to median nerve stimulation were obtained from the cortex. They consisted of two major positive waves P_1 and P_2. The mean onset latency of P_1 was 20.8 msec, the peak latency 28.4 msec. The mean peak latency of N_1 was 37.7 and of P_2 57.04 msec. SEP were recorded over both the precentral and postcentral gyri suggesting that somatosensory information converges to the motor cortex probably to be used for the integration of critical motor activity.

1527 CENTRIFUGAL CONTROL OF NOCICEPTION: AUTOANALGESIC MECHANISMS. W. T. Chance, A. C. White*, G. M. Krynock*, and J. A. Rosecrans. Dept. Pharmacol., Med. Col. Va., Richmond, Va. 23298.

Our previous reports (Proc. Soc. Neurosci., 2, 919, 1976; Fed. Proc., 36, 395, 1977) have indicated that lesion-induced hyperemotionality and conditioned fear elicit antinociception as measured by the rat tail-flick procedure. We now report the results of several experiments suggesting that these decreases in pain sensitivity are due to influences descending from higher levels in the CNS. In each of the following experiments antinociception was elicited by classically conditioning fear to the environmental stimuli associated with the tail-flick procedure. Acquisition of autoanalgesia was studied by shocking (15 sec/day; 0.8 ma) 30 albino rats 10 sec after the determination of their tail-flick latencies, while control rats (n = 20) were handled similarly but were never shocked. Although their initial responses did not differ, significant antinociception was observed in the conditioned group (4.5 vs 3.1 sec) on the 2nd test day. Furthermore, their response latencies continued to increase across the first 7 days (5.6 vs 3.4 sec; day 7). Pretreatment (30 min) with diazepam (2.5 mg/kg; i.p.) or naltrexone (1 mg/kg; i.p.) on day 8 did not reduce the antinociception (n = 10/gp). After 3 more conditioning days, the spinal cords of conditioned (n = 8) and control (n = 3) rats were severed at the T_3 level by cautery. Sham surgeries were performed on an additional 9 conditioned and 4 control rats. Assessment of antinociception on the following day revealed a significant (33%) decrease in latencies of the transected-conditioned group, while the transected control group showed a net increase in tail-flick response times.

The relationship of autoanalgesia to endogenous opiate peptides was investigated by assaying (centrifugation-liquid scintillation) binding of labeled opiates to whole brain homogenate of conditioned and control rats. In these studies binding of ^{3}H-NLeu-enkephalin and ^{3}H-etorphine was significantly reduced in conditioned rats. Furthermore, the correlation between binding and tail-flick latencies in the control rats was significant in the negative direction ($r = -0.87$; $n = 9$). Degradation of endogenous peptides by preincubation at 37° C effectively abolished the difference between groups, suggesting receptor occupation by an endogenous ligand responsible for initial differences in binding. Additional data suggesting the central nature of autoanalgesic mechanisms are preliminary experiments showing that lesions of the raphe magnus decrease antinociception in fear-conditioned rats. Since this lesion has also been reported to reduce both morphine- and methadone-induced analgesia (Fed. Proc., 36, 1024, 1977), similar centrifugal mechanisms may subserve these analgesic effects. (DA 00296-03).

1528 CELLS LOCATED IN SOMATOSENSORY CORTEX OF THE CAT SPECIFICALLY *SENSITIVE TO SKIN TEMPERATURE*. Allen B. Chatt and Dan R. Kenshalo. Dept.of Psychology, Florida State University, Tallahassee, Florida 32306.

113 cells were isolated in primary sensorimotor cortex of 20 paralyzed, unanesthetized chronic cats with 1μ, isonel coated tungsten microelectrodes. The responses of approximately 28% of the 46 cells isolated in the facial projection area were altered by alterations in skin temperature applied to their receptive fields (RF). Approximately 90% (9 of 11) of these mimicked cutaneous cold receptors in that they responded with an increase in activity to cooling stimuli. The higher level of activity was maintained until the stimulus was removed at which time the units demonstrated a decrease in activity which was on occasion followed by a rise in activity to near pre-warming levels. This level of activity then slowly decreased to pre-cooling levels. None of these units responded readily to mechanical stimuli. All RF's were large and irregularly shaped; most were contralateral to the site of stimulation, but two cells had bilateral RF's which appeared to be symmetrical and continuous across the midline. Each of these cortical temperature cells was somatotopically arranged with penetrations yielding temperature units lying near penetrations where HF and pressure sensitive units were found with similar spatial skin arrangements. Some evidence of a vertical organization of these cells was found in that 67% of the specifically sensitive cells and 46% of all thermally activated cells encountered were found in multi-cell perpendicular penetrations of cortex. Spatial convergence was a notable feature of these cells in that a large area stimulus was needed on most cells to convincingly activate the cell. Adaptation to a repeated cold stimulus was observed on a few cells. All cells were spontaneously active at skin temperatures normal for an animal under these experimental conditions. On a few cells, prior warming of the suspected RF was needed before the cell would respond to a cold stimulus. Steady state (SS) activity varied monotonically over adapting temperatures (AT) with a negative thermometer function and hysteresis was observed in the SS activity of all cells over AT. Bursting was evident at both low and high AT, but the types of bursting varied. Bursting at low AT was characterized by short interburst intervals and at high AT by long interburst intervals. The remaining cells in facial projection area responding to temperature were not submodality specific but responded to severe heating of the RF and high threshold mechanical stimuli. No units were found that mimicked cutaneous warm receptors. No units were found in forelimb projection area that were specifically sensitive to temperature although two units were found with ventral forepaw RF's that responded to severe heating and pinch. (NIH Grant NS 02992)

1529 SPATIAL SUMMATION RESPONSES OF THE CENTRAL NERVOUS SYSTEM TO UNMYELINATED AFFERENT ACTIVATION. Jin Mo Chung and Robert D. Wurster. Dept. of Physiology, Stritch School of Medicine, Loyola University of Chicago, Maywood, IL 60153.

Although temporal summation from unmyelinated afferent fibers is known to be frequently required to activate central nervous system responses, characteristics of spatial summation have not been clearly described. The possibility of spatial summation of the central nervous system to unmyelinated afferent fibers was tested using the somatosympathetic C reflex.

Adult cats were anesthetized and vagotomized, and the carotid sinuses were bilaterally denervated. Sympathetic nerve activity was recorded from the cervical sympathetic trunk while stimulating afferent nerves in the hindlimb. At a slow repetition rate, single shock stimulation of both A and C afferent fibers of a hindlimb nerve elicited a sympathetic A reflex. When trains of three pulses were given, an additional longer delayed C reflex component appeared. This sympathetic C reflex disappeared if the stimulus strength was lowered below the threshold of the afferent C fibers. These results confirm the notion that temporal summation is required to elicit the somatosympathetic C reflex. Instead of a train of pulses to one nerve, if single pulses were delivered in succession to three different ipsilateral hindlimb nerves, the somatosympathetic C reflex was also elicited. This result suggests that the somatosympathetic C reflex can be elicited by spatial summation of unmyelinated afferent fibers. Furthermore, the somatosympathetic C reflex could be also elicited by combined stimulation of ipsilateral and contralateral hindlimb nerves, suggesting bilateral spatial summation.

The somatosympathetic C reflex is known to demonstrate a recruitment phenomenon. That is, the size of the reflex progressively increases with repeated stimuli to unmyelinated afferent fibers. The recruitment phenomenon was observed during both temporal and spatial summation.

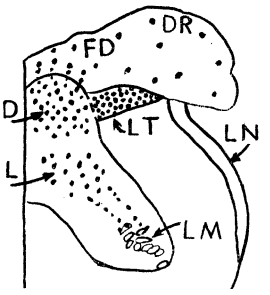
It is concluded that the central nervous system can be activated by spatial summation of unmyelinated afferent fibers as shown in the somatosympathetic C reflex. This spatial summation can be observed with bilateral afferent inputs and displays a recruitment phenomenon. (Supported by NIH Grant HL 08682.)

1530 DORSAL ROOT PROJECTIONS TO LISSAUER'S TRACT AND THE VENTRAL HORN OF THE FROG SPINAL CORD. W.L.R. Cruce, E.A. Neale, L.M. Bowers*, J.H. Neale, J.L. Barker, and B. Alexander*. Neurobiology Program N.E. Ohio Univ. Coll. Med., Rootstown, OH 44272; NIH, Bethesda, MD 20014; Anat. Dept., Howard U. Coll. Med., Washington, DC 20059.

Bullfrog (Rana catesbiana) spinal cord was removed with intact roots and maintained in a perfusing chamber at 18°C for 36 to 48 hr. Cords were viable (DR-VR reflex present) for at least 24 hr. Dorsal root ganglion (DRG) 10 was isolated through a silicone grease barrier and incubated for up to 24 hr in 500 uCi of ^{3}H-leucine in 0.5 ml Ringers. The cord was perfused with oxygenated frog Ringers containing 1mM unlabeled leucine and 20 ug/ml cycloheximide. Cords were fixed and processed for autoradiography. After 6-25wk exposure, autoradiograms were developed and stained.

Silver grains over dorsal root (DR) and dorsal funiculus (FD) fibers were sparse compared to those over spinal gray. The most dense concentration of grains was found over a region of neuropil which lay lateral to the dorsal horn. This region, which has been called Lissauer's Tract (LT) can be seen to contain fine fibers in Bodian-stained tissue and sparse myelinated profiles in osmium-stained material. In the EM, LT contains a few small diameter (0.5-2.5u) dendrites and myelinated axons as well as many fine (0.1-0.5u) profiles of axons and dendrites. Profiles of synaptic boutons are also present in about the same density as found in the dorsal horn (2-15 per 150u^2).

The second most dense region of silver grains lay over the dorsal field (D) of Ebbesson (comparable to laminae I-IV of mammals). The third greatest density lay over the lateral field (L) of Ebbesson (lam. V-VI). A clear space separated the grains over D from those over L. From the ventral edge of L, grains were distributed sparsely, though above background, all the way to the dorsal edge of the lateral motoneuron (LM) group. Frequently these silver grains were arranged in rows, suggestive of fibers. Often grains were seen gathered around the cell borders of the most dorsally situated motoneurons.



We conclude that dorsal root fibers terminate heavily in LT in the frog. Our results confirm Székely's recent demonstration (using $CoCl_2$ tracing) that dorsal root fibers can reach the somas of ventral horn motoneurons.

1531 POSITION SENSE: THE EFFECTS OF MUSCLE CONTRACTION. A. D'Almeida* & W.Z. Rymer. Dept. Neurosurg., Upstate Med. Ctr., Syr., N.Y. 13210

Muscle stretch receptors appear to influence the perception of joint position (1)(2), although the nature and importance of their contribution remain uncertain. The discharge rate of spindle receptors may be greatly increased by fusimotor action even at constant muscle length, allowing the existence of non-unique relations between length and discharge rate. Since isometric muscular contraction is accompanied by increased fusimotor activation (3), the occurrence of errors of perception of joint position under these conditions would support a significant spindle receptor contribution to positional sensation.

We examined the relation between muscle force and perceived steady-state joint position, using the proximal I-P joint of the right index finger in seven subjects. The finger was attached to an electromagnetic puller, capable of providing 20° of angular deflection under either positional or force servo-control. Perceived finger position was reproduced by active positioning of the left index finger, symmetrically mounted and attached to a length transducer. Measured variables were joint rotation on each side, and force output on the right side. Vision was excluded.

When the right index was moved passively, with constant speed, subjects were able to reproduce its final position with considerable accuracy. However, when subjects were required to produce an isometric contraction on achieving the final position, gross errors of perception occurred. These positional errors were directly proportional to the force being exerted by the subject, in a relation of the form: positional error = AF + C; F is force (g), A,C = constants. The mean value for A is .015°/g with a range of .007°/g to .023°/g and the value of C falls in the proximity of the actual displacement, as expected. When passive positioning of the left finger was reproduced by the right, working against isotonic or spring-like loads, no consistent errors of perception appeared.

The occurrence of marked positional errors with isometric contraction is evidence supporting a major contribution by spindle receptors to joint position sense, since their discharge rates increase approximately in proportion to the amount of force exerted (3). Limited human data (3), however, show that under isotonic conditions, there may be less force-dependent variation in spindle receptor discharge rate, perhaps accounting for the greater positional accuracy. Contributions from tendon organs or capsular receptors cannot of course be excluded by our findings.

1532 BEHAVIORAL MODULATION OF TRIGEMINAL BRAIN STEM NEURONAL ACTIVITY IN AWAKE RHESUS MONKEY. R.Dubner, R.L.Hayes, S.L.Berg*, and T.P. Medlin*. Neurobiol. & Anesth. Br., NIDR, NIH, Bethesda, MD 20014

Unit activity was recorded in trigeminal nucleus caudalis and subjacent lateral reticular formation in monkeys trained in a reaction time task to discriminate warming and noxious heat stimuli applied to the face (Hayes et al., Neurosci. Absts., 1977). Neuronal activity was correlated with the following behavioral events: 1) panel light onset indicating that a new trial could be initiated; 2) panel press initiating onset of innocuous (37°-43°C) and noxious (45°-49°C) thermal stimuli; 3) termination of thermal stimuli, and 4) panel release. Three classes of neurons have been studied. Receptive fields were limited to the ipsilateral face and often were confined to the trigeminal maxillary division. Nociceptive neurons exhibited responses correlated with onset and termination of thermal stimuli. Thresholds often were below 40°C, but stimulus-response functions were positively-accelerating in the noxious heat range. A preceding noxious heat stimulus suppressed thermal responses. Behaviorally non-relevant thermal stimuli evoked longer latency responses which sometimes were reduced in magnitude, whereas responses to particularly relevant stimuli were potentiated. Phasic polysensory neurons had flatter stimulus-response functions than nociceptive neurons and responses also were suppressed by preceding noxious heat stimuli. They had phasic response components which correlated with panel light onset and panel press. Behaviorally non-relevant thermal stimuli evoked weaker responses in the innocuous range; responses in the noxious range were delayed in onset but of similar magnitude. Thus, stimulus-response functions produced by non-relevant stimuli were similar in shape to those of nociceptive neurons. Tonic polysensory neurons exhibited maintained discharges throughout the panel press period which ceased when the monkey escaped noxious thermal stimuli or detected the termination of innocuous warming stimuli. Response magnitude sometimes increased during panel press and often high-frequency discharges preceded panel release. Unit firing was enhanced by behavioral relevance of thermal stimuli and the appropriateness of the motor response. Response magnitude was independent of thermal stimulus intensity except for increased responses to 47° and 49°C noxious heat stimuli. Preceding noxious heat stimuli did not suppress thermal responses. Panel light onset produced either an increase or a decrease in activity. These data suggest that (1) nociceptive neurons provide information about the intensity of noxious heat stimuli, (2) phasic polysensory neurons signal the presence of behaviorally significant stimuli, and (3) tonic polysensory neurons are associated with the execution of motor behaviors evoked by salient sensory stimuli.

1533 LONG SPINAL PATHWAYS MODIFYING FORELIMB MECHANOSENSORY NEURONS. R. W. Dykes and D. G. Tanji*. Dept. Physiology and Biophysics, Dalhousie University, Halifax, N.S., B3H 4H7

In decerbrate cats, glass-coated tungsten microelectrodes were driven into the cervical spinal cord. Electrical stimuli were applied to the ipsilateral and contralateral sciatic nerves during a search for units that responded to natural stimulation of the forelimb. The sciatic nerves were left in continuity so that hindlimb receptive fields could be identified. Afferent fibers and postsynaptic cells were identified by standard criteria. 50 μ thionin-stained sections of the spinal cord were used to locate electrolytic lesions placed at the end of electrode tracks and to reconstruct the penetrations. It was observed that some postsynaptic units of the cervical spinal cord received excitatory and inhibitory influences following sciatic nerve stimulation. These long spinal effects from the lower limbs were produced by large as well as small fibers. Some of the units studied responded to low threshold cutaneous stimuli on the lower limbs. Others responded to noxious cutaneous stimuli. Several neurons were observed with inhibitory receptive fields on the forelimb which could be excited by hindlimb stimulation. Others displayed excitation from the contralateral forelimb as well as from the hindlimbs. Both ipsilateral and contralateral effects were evident in the data obtained from hindlimb stimulation, however ipsilateral effects were more common. The latencies and temporal distribution of impulses resulting from hindlimb stimulation suggested that both large and small myelinated fibers converged on the same cervical neurons. Although modification of cervical motor neuron activity by sensory input from the lumbar spinal cord has been reported previously, long spinal pathways which modify cervical somatosensory neurons have not been reported. These observations suggest that integration of long spinal reflexes may occur by alterations in afferent information as well as by modification of the final common path. Further, if supraspinal influences can also modify these same neurons they have properties comparable to the α-motor neurons of the ventral horn.

1534 THE ORGANIZATION OF TRIGEMINO-THALAMIC NEURONS AS DETERMINED BY HORSERADISH PEROXIDASE RETROGRADE LABELLING. Takanori Fukushima*, Jack D. Grabow and Frederick W. L. Kerr. Mayo Foundation, Rochester, MN 55901.

Following injection of 30% horseradish peroxidase (Sigma VI) into the n.V.P.M. of 20 rats in doses ranging from 0.1 to 1.6 µl the distribution of labelled neurons in the trigeminal nuclear complex was determined using the diaminobenzidene method and compared with the distribution in other nuclei.

The organization of trigeminal projection neurons was much more complex than anticipated. In the main sensory nucleus and in n. oralis, the great majority of medium sized and many small neurons were labelled, while the largest neurons never contained H.R.P. In subnucleus interpolaris at the level of the facial nucleus, only a few small neurons were labelled, whereas in the caudal part the large stellate and polygonal neurons were strongly labelled together with a moderate number of small neurons.

Subnucleus caudalis showed yet another distinctive pattern: marginal neurons were frequently labelled, especially at the dorsomedial aspect of the nucleus. Considerable numbers of medium sized and small neurons in the s. gelatinosa were labelled, but none were marked in the nucleus proprius.

These highly distinctive and changing neuronal patterns correlate well with the original subdivision of the nucleus by Olszewski '50. The physiological role of the different nuclear groups is inferred from the similarity of patterns in main sensory and oralis to lemniscal nuclei, the non labelling of rostral interpolaris with projection to the cerebellum and of subnucleus caudalis, to the dorsal horn of the spinal cord. Caudal interpolaris is difficult to categorize, but may be comparable to lamina V of the dorsal horn. (Supported by NS 5995 from the National Institutes of Health.)

1535 AFFERENT AND EFFERENT COMPONENTS OF THE FACIAL NERVE IN THE BULLFROG: AN EXPERIMENTAL STUDY USING COBALT IONTOPHORESIS. Peter M. Fuller, Department of Anatomy, University of Louisville, Health Sciences Center, Louisville, Kentucky 40201.

Using adult bullfrogs (Rana catesbeiana) cobalt chloride was applied to the cut end of the seventh cranial nerve in 25 animals to dtermine the afferent and efferent components of the nerve. Following the cobalt treatment (Fuller and Prior, '75) the brains were fixed, embedded in egg yolk and serial sections cut at 33 microns. Alternate sections were stained for either cobalt or with a Nissl stain. In addition, a series of frog brains were processed with the rapid Golgi-Cox method in an attempt to further delineate the areas of termination of the afferent fibers and the origin of the efferent fibers.

There are three distinct components to the facial nerve in the bullfrog. The first is the motor component which arrises from the motor nucleus, situated medial and slightly caudal to the trigeminal motor nucleus. The cells of the facial motor nucleus are large and fusiform in shape. The motor fibers pass laterally from the nucleus and exit in close proximity to the afferent vestibular fibers of the eighth nerve. The second component of the facial nerve is sensory, and projects almost entirely to fasciculus solitarius. The fibers enter the fasciculus solitarius and are confined to the dorsal and dorsal-lateral portion of solitarius. Followed caudally, the number of fibers gradually diminishes as they terminate on the nucleus of solitarius. Fibers can be traced caudally to the first spinal segment. There are also a limited number of sensory fibers which enter the descending spinal tract of V. The third component of the facial nerve is proprioceptive. The large cells of the mesencephalic nucleus of V, located in the rostral third of the tectum, fill as a result of the cobalt iontophoresis. The fibers pass around the lateral edge of the tectum and then descend toward the ventral surface of the brainstem. Continuing caudally, the fibers pass lateral to nucleus isthmi and the cerebellar nucleus, and then exit with the remaining fibers of the facial nerve.

The motor and sensory components of the facial nerve have been reported previously in a variety of vertebrates, however, the proprioceptive component of the facial nerve is an entirely new finding.

1536 AFFERENTS TO BRAINSTEM NUCLEI (BRAINSTEM RAPHE, n. RETICULARIS PONTIS CAUDALIS AND n. GIGANTOCELLULARIS) IN THE RAT AS DEMONSTRATED BY MICROIONTOPHORETICALLY APPLIED HORSERADISH PEROXIDASE. Dorothy W. Gallager and Agu Pert. Adult Psychiatry Branch, NIMH and Dept. Psychiat., Yale U. Sch. Med., Bethesda, MD 20014.

Recently much attention has centered on the brainstem raphe nuclei (BR) (including the n. raphe magnus, n. raphe obscurus, and n. raphe pallidus) especially the raphe magnus as a possible relay center for mediating analgesia and inhibiting spinal pain transmission by opiates. However, at present only relatively massive degeneration studies have been used to define the afferent pathways to this region. The present study describes afferents of the brainstem nuclear groups including the BR and two adjacent nuclei, the n. gigantocellularis (nGC) and the n. reticularis pontis caudalis (nRPC) as determined by the horseradish peroxidase (HRP) retrograde transport method. HRP was applied microiontophoretically, resulting in a very localized (0.3 - 0.8 mm dia.), highly concentrated deposit of the enzyme (2.2 ±0.3 µg as determined in vitro). The most striking difference between the afferent projections to the BR and the two adjacent nuclei as determined by this method is that afferents to the BR originate principally from structures rostral to the pons. In contrast, afferents to the two adjacent nuclei (nGC and nRPC) appear to originate primarily within or caudal to the pons-medulla. Afferents to the BR include: lateral and dorsal mesencephalic central gray (excluding the dorsal raphe area), dorsal and ventral tegmentum, deep layers of the superior colliculus, medial vestibular nucleus (VIIIM), and a few cells from the ventromedial part of the prefrontal cortex. Afferents from the nGC include: dorsal and ventral tegmentum, deep layers of the superior colliculus, VIIIM, scattered afferents from the dorsal part of the mesencephalic central gray and throughout the lateral and ventral horn, and the dorsal horn deep to Rexed lamina V in the cervical spinal cord. Afferents from the nRPC include the dorsal and ventral tegmentum, VIIIM, n. pontis oralis, and deep layers of the superior colliculus. In addition, evidence for interconnections between all the adjacent reticular nuclei (BR, nGC and nRPC) was found.

Such afferent projections are compatible with the notion that the brainstem raphe nuclei may serve as a connection within the brainstem for a descending system while the nGC may be a brainstem terminus for a spinal ascending system.

1537 COMPARISON OF MECHANORESPONSIVE PROPERTIES OF FIRST AND SECOND-ORDER VIBRISSAE-ACTIVATED TRIGEMINAL NEURONS. John M. Gibson, Wen-Deo Tang*, and Wally Welker, Dept. of Neurophysiology, University of Wisconsin, Madison, Wisconsin 53706.

Different nuclei of the trigeminal complex are thought to exhibit distinct functional and projectional features. We are testing the hypothesis of subnuclear specialization by examining, with quantitative methods, single-unit stimulus-response (S-R) transactions in the rat's sensory vibrissae system. Having established a baseline of coding properties in the primary afferent population (Gibson, et al., Neurosci. Abstr., 1976), we began our study of second-order trigeminal neurons in Nucleus Oralis.

Vibrissae-activated single-unit responses were recorded from barbiturate-anesthetized albino rats. Mechanical stimuli consisted of quantitatively-controlled deflections of single mystacial vibrissae, using a standardized battery of waveforms in which stimulus parameters were varied systematically.

The S-R profiles of second-order units exhibited many similarities to those of first-order units: (1) A broad spectrum of properties was observed. (2) Thresholds (angular displacement and velocity) had a range approaching three orders of magnitude. (3) Adaptation rates were continuously distributed. (4) In response to a standard step deflection (approx. 7^{o}), about half the units fired for more than 200 msec. (i.e., were more "slowly-adapting"). (5) Adaptation rate varied with stimulus amplitude.

However, striking differences between first and second-order S-R profiles were noted: (1) Nearly half the second-order units had multiple-vibrissae receptive fields (half of which included a patch of fur), whereas no first-order unit responded to movement of more than one vibrissa. (2) The median angular displacement threshold of medullary units was about 0.2^{o}, one-fifth the first-order value; over three-fourths of the second-order units were more sensitive than the median first-order unit. (3) The median angular velocity threshold was about 3^{o}/sec., versus 100^{o}/sec. at first order; almost 90% of the second-order units had velocity thresholds below the first-order median.

By means of objective, quantitative methods, and without recourse to the usual dicotomous categorizations, we have defined differences between first and second-order S-R transactions which we infer to reflect selective information processing by one subnucleus of the trigeminal complex. Our findings also emphasize the necessity of appreciating the diverse spectrum of multi-dimensional features which characterize a population of mechanosensory neurons. Future studies will examine these relationships in other trigeminal nuclear regions.

1538 EM STUDIES OF DEGENERATIVE CHANGES IN THE AXONAL ENDINGS OF PRIMARY TRIGEMINAL NEURONS AND IN POSTSYNAPTIC NEURONS IN LAYERS I, II AND III OF NUCLEUS CAUDALIS FOLLOWING TOOTH PULP EXTIRPATIONS. Stephen Gobel and Joan M. Binck*. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20014.

The pulp chambers of teeth are innervated by hundreds of primary trigeminal neurons with either small myelinated (Aδ) or unmyelinated (C) axons. These neurons respond to a variety of noxious and thermal stimuli. Extirpation of tooth pulps results in amputation of the receptors of these primary trigeminal neurons and the subsequent filling of the pulp chambers with an inert material precludes the possibility of their regeneration. In order to determine the consequences of this procedure, a series of experiments in adult cats was conducted in which the tooth pulps of all mandibular teeth on one side were removed and the pulp chambers filled with dental cement. After survival times of 14, 30 and 60 days, degenerative changes are found in the axons of primary trigeminal neurons in the spinal tract and in their axonal endings in layers I, II and III of nucleus caudalis. The sequence of degenerative changes in the primary axonal endings in layer I differs from that in the primary endings in layers II and III. The axoplasm in layer I endings blackens and the endings are rapidly engulfed by glial cells. Degenerating primary endings in layers II and III, on the other hand, are not engulfed by glial cells but degenerate in situ over a more protracted period of time. They lose almost all of their synaptic vesicles and shrink in size but their axoplasm does not blacken.

In addition, neurons in layers I, II and III which receive synaptic input from the primary neurons innervating tooth pulps also degenerate. Transynaptic degenerative changes include a loss of organelles in cell bodies and dendrites, formation of large cavities in dendrites, breakdown of neurotubules in dendrites, a blackening of dendritic cytoplasm and withdrawal of spine heads from the glomeruli.

These experiments demonstrate that layers I, II and III of nucleus caudalis are major sites of termination of primary trigeminal neurons innervating tooth pulps. It is possible that the massive disruption in the synaptic circuitry of trigeminal pain pathways resulting from the loss of primary input from either tooth pulp extirpation or tooth extraction may be an important factor in some orofacial neuralgias.

1539 AIRJET STIMULATION OF HAIR RECEPTIVE FIELD ELEMENTS. M.D. Goldfinger and V.E. Amassian. Dept. of Physiology, SUNY Downstate Medical Center, Brooklyn, N.Y. 11203.

During continuous airjet stimulation of cat forelimb hairs, a primary afferent axon recorded by a glass-insulated tungsten microelectrode in the cuneate fasciculus yields maintained activity which, except at brief interspike intervals, approximates a random process (Goldfinger & Amassian (1976) Neurosci. Abst. II:911).

Previous investigators have shown that the parent hair afferent axon may be activated by stimulation of any one of the innervated receptive field hairs. Using airjet stimulation, we compared the responses of the parent axon during whole field and single hair stimulation - other hairs in the receptive field being pressed down with masking tape. The mean discharge rates with single hair stimulation always were a fraction of those obtained during whole field stimulation and often drifted. The single hair evoked discharge pattern also approximated a random process: ie, except at very short intervals, the interspike intervals were exponentially distributed, the expectation density function was flat, and the joint interval scatter plot indicated independence of successive intervals.

Because of spike train instability with single hair stimulation, spike trains must be compared from the onset of the airjet. Under this constraint, separate stimulation of two individual hairs of the same receptive field yielded considerable differences in parent axonal discharge rates (e.g. 95. & 122./sec; 80. & 114./sec; 66. & 98./sec; 25. & 82./sec, where each pair is from a different parent axon). The corresponding ratios of single hair: whole field discharge rates were: 1:2.6, 1:2.0; 1:2.7, 1:1.9, 1:3.4, 1:2.3; 1:9.9, 1:3.0. However, the number of guard hairs innervated by a parent axon is 4-9 in rabbit ear (Miller & Weddell (1966) J. Physiol. 187:291-305) and 10-20 in cat hindlimb (Brown & Iggo (1967) J. Physiol. 193:707-732), implying a less than linear summation in the whole field response to airjet stimulation. Simultaneously stimulating two hairs yielded a higher discharge rate than that during stimulation of either separately, but the observed rate was less than, equaled, or exceeded the algebraic sum of the separate rates. Simultaneously stimulating two hairs yielded a discharge rate lower than that with whole field stimulation.

In conclusion, the maximum whole field response to airjet stimulation does not appear to be explicable by the activity of a single 'dominant' hair within the field, but rather suggests a non-linear summation, at the axonal branch points, of activity derived from a number of hairs.

1540 THRESHOLD AND SUPRATHRESHOLD SENSATIONS PRODUCED BY ELECTRICAL TOOTHPULP STIMULI AND THEIR MODIFICATION BY FENTANYL, A NARCOTIC ANALGESIC. Richard H. Gracely*, Patricia A. McGrath*, Marc W. Heft* and Ronald Dubner (SPON: Charlene D. Jarvis). Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20014.

Sensations produced by toothpulp stimulation were examined in a series of experiments in which subjects (1) determined sensory detection and pain thresholds at different stimulation frequencies, (2) scaled the sensory intensity and unpleasantness of suprathreshold noxious stimuli and (3) rated electrical stimuli before and after the administration of fentanyl, a short acting narcotic analgesic. Electrical stimuli were 1-sec trains of monopolar, monophasic, cathodal, 1-msec duration, constant current pulses delivered to the labial surface and incisal ledge of upper incisor teeth. All subjects reported detection thresholds that were significantly lower than pain thresholds at all frequencies studied (Method of Limits). Mean pain thresholds varied nonmonotonically with frequency, decreasing from 26 μA at 5 Hz to 20 μA at 100 Hz, and increasing to 25 μA at 500 Hz. Sensory detection thresholds did not change with frequency (mean=8 μA, 5-500 Hz).

Forty subjects scaled the intensity and unpleasantness of pain produced by toothpulp stimuli by choosing words from randomized lists of either sensory (i.e. weak, moderate, intense) or affective (i.e. annoying, unpleasant, distressing) verbal descriptors validated in a previous study (Gracely et al., Neuroscience Abstracts 2:937, 1976). In addition to 100 Hz electrical stimuli, the subjects also rated sensations produced by a natural noxious cold stimulus (ethyl chloride spray) applied to exposed dentin. Responses to the controlled electrical stimuli produced reliable psychophysical functions linear in log-log coordinates (r=.99). These functions predicted the sensory intensity and affective verbal descriptor responses made directly to the natural stimuli, based on direct matches (Method of Constant Stimuli) between the electrical and noxious cold stimuli. In a final experiment, 32 subjects rated 100 Hz electrical toothpulp stimuli between pain threshold and pain tolerance before and after the I.V. administration of 0.05 mg fentanyl. Fentanyl significantly reduced the magnitude of the sensory intensity verbal descriptor responses, while the affective verbal descriptor responses were unaltered.

These series of experiments show that (1) detectable toothpulp stimuli do not necessarily produce pain even at frequencies up to 500 Hz, (2) pain scales developed with electrical toothpulp stimuli have validity in the evaluation of natural noxious stimuli, and (3) a narcotic analgesic drug reduced the perceived sensory intensity of noxious toothpulp stimuli rather than altering the affective aspect of the pain experienced.

1541 SPATIAL SUMMATION IN THE THERMOSENSORY SYSTEMS OF THE HUMAN AND THE MONKEY. Joel D. Greenspan* and Dan R. Kenshalo, Dept. of Psychology, Florida State University, Tallahassee, Fla. 32306

Three human observers were tested for their ability to detect warm and cool stimuli applied to their left palm. Four areas of stimulation were used--7, 4, 2, and 1 cm^2. For each area, the observers' sensitivity to four intensities of warming and cooling were assessed using a yes-no signal detection procedure. In addition, one monkey with prior experience in the same paradigm was given identical tasks with the exception that the monkey was also tested with a 0.5 cm^2 area of stimulation.

The human data for both warming and cooling indicated some degree of spatial summation under all conditions. That is, as the area of the stimulus was increased, the stimulus intensity decreased in order to maintain the same degree of detectability. The function which relates stimulus area and intensity for a given level of detectability is described by the formula:

$$I = kA^b,$$

where A is the area and I is the intensity of the stimulation. This is the same type of function that has been obtained by using classical psychophysical methods. For warming stimuli, an increase in area was found to increase detectability more for readily detected intensities than for those intensities less readily detected. A similar phenomenon was not found when cool stimuli were used. A change in area of a cool stimulus produced the same relative effect regardless of the detectability of the stimulus initially.

The monkey area-intensity function can be described by the same formula as that for humans. However, while the humans showed spatial summation over areas up to 7 cm^2, spatial summation in the monkey appeared to be limited to less than 2 cm^2. Possible variations in innervation density of the palms of these species may account for this difference.

1542 RESPONSES OF JOINT AFFERENT NEURONS TO CONTROLLED DEFORMATIONS OF ISOLATED JOINT CAPSULE. Peter Grigg Dept. of Physiology, University of Massachusetts Medical School, Worcester, Mass. 01605, USA.

Recordings were made of afferents in cat medial articular nerve, innervating a section of knee capsule which was surgically removed from the cat and studied in vitro. Responses of afferents were studied in relation to applied stresses and strains. The capsullar material consisted of a small (1.0 x 0.5 cm) sheet which could be loaded either along its long axis (in-plane loading) or normal to the sheet (transverse loading). Most afferents could not be activated with pure in-plane loading. Those which were activated had high (over 50g) thresholds. All afferents studied, however, were readily activated using a combination of in-plane and transverse loadings. Under these conditions, most afferents had low thresholds for activation (transverse loads of 5g or less) and when activated were slowly adapting. Discharge in afferents appeared to be related to a multi-dimensional stress state in capsullar material, since for most afferents studied, responses were not a unique function of either in-plane or transverse loads. Supported by NIH grant NS- 10783.

1543 A (^{14}C)-2-DEOXYGLUCOSE METABOLIC MAPPING STUDY OF THE RAT POSTEROMEDIAL BARREL SUBFIELD. Peter J. Hand, Richard R. Miselis, and Martin Reivich. Depts. Animal Biology and Neurol., Sch. Vet.Med. and Med. and Inst. Neurol. Sci., U. of Pa., Phila., PA 19104.

The relationship of mystacial vibrissae with the posteromedial barrel subfield (PMBSF) of the first somatic sensory cortex (SI) was studied in six adult rats using the recently developed (^{14}C)-2-deoxyglucose (2DG) metabolic mapping technique (Kennedy et al. Proc. Natnl. Acad. Sci., 73: 4230-4234, 1976). Following selective clipping, various combinations of vibrissae were hyperstimulated with a hand-held brush to evoke neural activity, increase metabolic activity, and thus uptake of 2DG in neurons of PMBSF of unanesthetized, restrained rats. After ten minutes stimulation, 50 uCi of 2DG was pulse injected intracardially via a chronic catheter and vibrissae stimulated an additional thirty minutes. Rats were sacrificed by an intravenous injection of saturated KCL, brains removed rapidly and frozen in a Freon-dry ice mixture, and neural tissue prepared according to Kennedy et al. Stroking of all five rows of mystacial vibrissae resulted in increased 2DG uptake in the five rows of barrels of contralateral PMBSF. Stimulation of vibrissal rows A,B,D,E densely labeled all rows, excepting C. Conversely, vibrissal row C stroking heavily labeled row C. When a single vibrissa (No. 3, row C) was stroked, a remarkably discrete oval-shaped column of dense labeling, 400-um in diameter was observed within barrel 3, row C. The column, although extending throughout cortical laminae I-VI, was densest within layer IV. The heaviest uptake appeared within the barrel core with less dense labeling in its "wall". All barrels surrounding No. 3, row C exhibited less dense 2DG uptake than adjacent cortical regions (a negative image outlining PMBSF). Stimulation of two vibrissae (Nos. 2 & 4, row C) resulted in two discrete columns of labeling within the appropriate barrels of PMBSF. In addition, certain brainstem and thalamic nuclei were examined for 2DG uptake. Dense labeling was observed in ipsilateral principal (PV) and spinal (N.tr.sp.V) trigeminal nuclear complexes and the contralateral thalamic ventrobasal complex (VB). In all cases, dense uptake was conspicuously absent from subnucleus interpolaris of N.tr.sp.V, but was present in subnuclei caudalis and oralis. When comparing the effects of total vibrissal and row C stroking, the areal extent of labeling was similar in N.tr.sp.V, but densities were not. In contrast, their densities were similar, but areal extents not in PV and VB. In conclusion, these findings demonstrate: 1) the relationship of mystacial vibrissae with the barrels of PMBSF, VB, PV and N.tr.sp.V, 2) the basic columnar organization of SI, and 3) the value of the 2DG technique in mapping somatosensory connectivity. (Supported by Grant NS06716).

1544 COMPARISON BETWEEN NEURONAL SAMPLES FROM PERICRUCIATE AND PRECORONAL CEREBRAL CORTEX OF CHLORALOSE- and BARBITURATE-ANESTHETIZED CATS. G.W. Harding*, R.M. Stogsdill*, and A.L. Towe (SPON: M.D. Mann). Dept. Physiol. & Biophys. (SJ-40), Univ. of Wash. Sch. of Med., Seattle, WA 98195.

Single neuron samples from the sigmoid gyri of chloralose-anesthetized cats differ from those of barbiturate-anesthetized cats primarily in having many more wide-field neurons. The fate of these neurons was studied by comparing samples from four cerebral sites in barbiturate cats with a reference sample from comparable sites in chloralose cats. Standard procedures were followed, with the exception that the entire experiment was automated—including single neuron isolation and tracking. Recording in forepaw cortex and using a supramaximal shock to the central footpad of the contralateral forepaw as a hunting stimulus, 435 excitable neurons were obtained. Sufficient information was obtained on 374 of these for use in this analysis. The average number of excitable neurons per electrode penetration at a given site serves as an index of overall excitability within that site. In comparison with chloralose, excitability under barbiturate was near normal in precoronal tissue (field 3b), but was markedly reduced in pericruciate tissue (field 4). The neurons were partitioned into sets: sa, sb, and m (small-, bilateral, and wide-field, respectively), and compared with the same sets in a reference chloralose sample of 3390 neurons. The table shows the proportions observed relative to those expected, by sets, at each recording site.

Set/Site	Precruciate	Postcruciate	Midsigmoid	Precoronal
sa	0.27	0.62	1.11	0.94
sb	0.17	0.42	2.67	2.88
m	0.005	0.03	0	0.96

Both the distributions in depth and the response properties of the sa and sb neurons under barbiturate were similar to those under chloralose (with somewhat shorter response latencies), rather than being an amalgum of sa, sb, and m neuron properties. Thus, the excitability of m neurons is nearly zero under barbiturate (because of sample size, the 0.96 value in precoronal tissue may be spurious); the m neurons are not converted into sa or sb neurons under barbiturate anesthesia. Further, though the excitability of sa neurons is the same, and that of sb neurons greater, in barbiturate than in chloralose for precoronal (field 3b) and midsigmoid (field 3a) tissue, it drops significantly in pericruciate (field 4) tissue, especially at the more anterior site. Evidently, barbiturate selectively depresses and/or chloralose enhances the projection pathway(s) into pericruciate tissue. (Supported by NS00396 and NS05136)

1545 DIFFERENTIAL EFFECTS OF A NARCOTIC AND A MINOR TRANQUILIZER ON DETECTION AND DISCRIMINATION OF THERMAL STIMULI BY RHESUS MONKEY. R.L. Hayes, R.D. Harris, P.J. Wolskee* and R. Dubner. Neurobiol. and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20014.

Two water-restricted rhesus monkeys were trained to detect the termination of innocuous heat pulses delivered via a feedback-controlled contact thermode (1 cm diam.) applied to the upper hairy lip. Adapted skin temperature was 35°C. A panel was illuminated to signal the beginning of each trial. Monkeys depressed the lighted panel to initiate innocuous heat pulses (39°, 41°, 43°C) of randomly varying durations (2-8 sec). Panel releases of less than 2 sec (reaction times or RTs) after the termination of these stimuli were rewarded by water (0.5 cc). Additional heat pulses of a constant duration (20 sec) were presented quasirandomly in which the temperature increase reached the noxious range (45°, 47°, 49°, 51°C). Release of the panel at the termination of noxious stimuli was not rewarded by water. However, early releases terminated heat pulses on these trials, thereby allowing the monkeys to escape noxious heat stimuli. Thus the task assessed RTs indicating the detection of the termination of innocuous heat stimuli or the discrimination of the onset of higher stimulus intensities shifting into the noxious range. The effects of both the narcotic, morphine sulfate, and diazepam, a minor tranquilizer and muscle relaxant, were assessed at intramuscular doses of 0.5, 0.75 and 1.0 mg/kg. The highest dose produced some behavioral toxicity with both drugs. Diazepam significantly increased the RTs for the detection of the termination of all innocuous stimuli at every dose tested. The effect was dose dependent but not related to the magnitude (ΔT) of the innocuous temperature shift, thus suggesting a non-specific, drug-produced increase in RTs. Morphine did not significantly affect RTs to innocuous stimuli at any ΔT. Analysis of drug effects on the discrimination of the onset of noxious stimuli was done using RTs corrected by each drug dose for the non-specific increase in RTs observed for innocuous ΔTs. Diazepam did not significantly affect RTs to the onset of any noxious stimuli. Morphine had a dose dependent effect on RTs to noxious stimuli. A 0.5 mg/kg dose reliably increased RTs to 45°C; 0.75 mg/kg increased RTs to 45° and 47°C; 1.0 mg/kg, in spite of some behavioral toxicity, increased RTs to 47°C. Thus, at the doses tested, morphine but not diazepam affected discrimination of the magnitude of temperature shifts into the noxious range. These results suggest that: (1) Drug-produced changes in emotionality are not sufficient to influence discrimination performance in this task since diazepam, a putative anxiety reducing agent in animals and humans, produced only non-specific effects, and (2) narcotics can affect a sensory-discriminative component of responses to noxious temperature shifts.

1546 MODULATION OF AFFERENT SIGNALS IN THE SOMATOSENSORY SYSTEM BY PRIOR INPUT. C.L. Hinman*, J.S. Kroin*, R.J. Sclabassi*, H.A. Risch* (SPON: J.S. Buchwald). Brain Res. Inst., UCLA, Los Angeles, CA, 90024.

Nonlinear interactions resulting from a series of peripheral stimulations with inter-stimulus intervals of less than 500 msec have been found to occur among responses in the somatosensory system of cat and man. A characterization of cat somatosensory responses to trains of interactive peripheral stimuli was accomplished by the mathematical method of functional power series analysis. A random train of impulses having an exponential distribution of inter-stimulus intervals was delivered to the superficial radial nerve. A set of system kernels was then calculated from responses evoked in the contralateral cuneate nucleus (DCN), in the nucleus ventralis posterolateralis (VPL), and at somatosensory S1 cortex in order to describe nonlinear interactions occurring at those locations. Theoretically, first-order kernels provide the characteristic response of the system to a unitary impulse, and second-order kernels approximate the nonlinearity in the response due to pairs of interacting impulses. Experimental results confirmed the theoretical predictions and also reflected the nonlinearity derived from 2-pulse recovery cycle experiments. Concerning the source of such nonlinear interactions in the somatosensory system, ablation of S1 cortex altered specific aspects of the kernels from both DCN and VPL, indicating that one possible method by which prior input normally modulates afferent signals at those loci is by the activation of cortical feedback loops at latencies of less than 5 msec and 15 msec, respectively. (Supported by USPHS Grants NS-02501, NS-11443, and by Grant 516 C from the National Multiple Sclerosis Society).

1547 *THE EFFECTS OF L-DOPA ON THE RESPONSIVENESS OF DORSAL HORN INTERNEURONS TO MECHANICAL SKIN STIMULATION.* *Charles J. Hodge and Charles Woods**.

Single cell recordings were made from 50 lumbar dorsal horn interneurons in both intact and spinal cats. The responses of the cells to skin or hair displacement were measured before and after the intravenous injection of L-DOPA in amounts ranging from 5 to 100 mgm/kgm. Following low doses of L-DOPA (less than 25 mgm/kgm) an increase in responsiveness was consistently found. This was manifest by an increase in the average number of spikes per stimulus, frequent increases in receptive field size and at times an increase in spontaneous activity. Some cells showed a change in the modalities of skin stimulation to which they would respond. Neither the sensory characteristics of the cell in the control state nor its laminar location, as determined by marking with fast green, had a significant influence on the changes in responsiveness seen after L-DOPA. Larger doses of L-DOPA caused significant inhibition with characteristics suggesting a separate mechanism, possibly serotonin release in the spinal cord. Results were similar in spinal and intact animals. The results support the hypothesis that L-DOPA causes sensory alterations in part, at least, by affecting sensory transmission at the segmental level.

1548 TACTILE DISCRIMINATION DURING NEGLECT FOLLOWING UNILATERAL LESIONS IN LATERAL HYPOTHALAMUS OF RATS. Lee Hoyman*, G. Daniel Weese*, and Gabriel P. Frommer. Dept. Psychol., Indiana U., Bloomington, IN 47401

Marshall et al. (Science, 1971, 174, 523-525; J. Comp. Physiol. Psychol., 1974, 86, 375-395) showed that rats fail to orient towards tactile stimuli contralateral to unilateral lesions in lateral hypothalamus (LH). To determine if such neglect is associated with deficits in detecting tactile stimuli, we compared orienting responses with learned responses guided by lateralized somatic discriminative stimuli (S_d). We found that rats that failed to orient to tactile stimuli contralateral to the LH lesion could still use such stimuli as S_d to guide learned responses, but they could not make responses contralateral to it.

Female hooded rats were anesthetized, blinded, and implanted with a lesioning electrode in LH, verified terminally from frozen sections. They were trained in a small, clear plastic restraining box with openings on either side through which tactile S_d ($\geq$ ½g) could be delivered. Three 1.3 cm dia. holes, one in the front wall and one each near the front of the side walls, were equipped with photocells to detect nose-poke approach responses which required only head movements to make. Correct approaches were rewarded with access to sugar water. Each rat mastered (96% correct) one of three tasks: 1) approach whichever side hole was on the same side as S_d; 2) approach whichever side hole was on the side opposite S_d; 3) approach front hole whenever either side was touched (Go No Go). The LH lesion was then made electrolytically through the implanted electrode. Sixteen of 22 rats showed contralateral neglect for at least two days. Those trained on Task 1 or 2 showed severe deficits, but only on trials on which responses contralateral to the lesions would have been correct. Task 2 was critical: all six rats responded correctly to S_d contralateral to the LH lesion (because responses were directed ipsilateral to the lesion), but made many errors of commission to S_d ipsilateral to the lesion but few of omission (showing they detected the stimuli but turned incorrectly to the ipsilateral hole). The four rats in Task 3 (Go No Go) showed a small, transient increase in false alarms and in latency to respond to stimuli ipsilateral to the lesion, perhaps due to exaggerated competing orienting responses to them.

These data show that rats exhibiting neglect on the orienting response measure could detect somatic stimuli contralateral to LH lesions. The data suggest that neglect following LH lesions is based on the failure of tactile stimuli to acquire control of responses contralateral to the lesion. (Supported by PHS grants MH 26973 and S05 RR 7031)

1549 FUNCTION AND MORPHOLOGY OF HORSERADISH PEROXIDASE IDENTIFIED CELLS IN RAT SmI "BARREL" CORTEX. Von Ayre Jennings* and John R. Bartlett. Center for Brain Research, University of Rochester, Rochester, New York 14642.

Under urethane anesthesia over 200 units located in the "barrel region" of rat SmI cortex have thus far been classified in terms of their responses to controlled manipulations of contralateral vibrissae and a number of these have been identified by ionophoretically injecting horseradish peroxidase (HRP) intracellularly. In many, but not all cases, a unit responded to manipulation of more than one vibrissa. Commonly seen were: 1) "on-phasic" units giving a burst of discharges at only the onset of vibrissa movement, 2) "on-off phasic" units similar to 1) but discharging at both the onset and end of movement, 3) "tonic" units whose discharge was maintained at an elevated level during maintained displacement of a vibrissa, 4) "tap" units responding only to very fast (>150°/sec) vibrissa movement and 5) "whisking" units whose discharge rate increased during the spontaneous vibrissae movements seen during light but sufficient anesthesia. In some cases of the latter, the unit's activity was inhibited if the moving vibrissa contacted a stationary object. Where more than one vibrissa affected a unit, three interactive effects were seen; summation, where movement of two vibrissae was more effective than one (1+1>1), a lack of summation where the effect of two vibrissae equaled that of either one (1+1=1) and "absolute" summation where a unit discharged only if both vibrissae were moved (0+0=1). Thus far no cases of inhibition have been seen.

Recording and HRP injection is via 0.1-0.5μ, 300-500 megohm pipettes whose tips are beveled using a unique piezo-electric device. The HRP is dissolved in a Tris-HCl buffered KCl solution. Cells from the above categories have been identified as pyramidal and both spiney and smooth stellate types. Although about 10% of the units studied are now being successfully labeled with HRP, the total number so far identified is still too low to allow a meaningful comparison of morphology with response classification. (Supported by NIMH Grant #MH 05456).

1550 TACTILE SPATIAL DISCRIMINATION ON THE PALM: PSYCHOPHYSICS AND PERIPHERAL NEURAL CODING. K.O. Johnson, J.R. Phillips*, and I. Darian-Smith. Dept. Physiol., Univ. Melbourne, Melbourne, Victoria. Australia

The sense of touch in the glabrous skin of the hand, like the visual sense, is primarily concerned with spatial information. A further similarity to visual function is that this tactile sensation is based on three receptor types each having different sensitivity curves across the spectrum of mechanical frequencies. The aim of the work reported here was to isolate and analyze the characteristics of spatial discrimination subserved by one of these receptor populations, the slowly adapting Merkel receptors. The following data describe studies in which we have tried to define the human capacity to discriminate stationary spatial patterns and in which we have mapped the spatial profiles of peripheral neural activity evoked by various stationary patterns in M. nemestrina.

In our psychophysical studies we have attempted to define the tactual acuity for stationary stimuli in a way that will allow us to place constraints on the possible mechanisms of spatial processing. We have used three types of spatial stimuli:

1. Modified Landolt C test. Subjects were asked to discriminate between a radius with a gap and one without. The minimum gap that was discriminated reliably (75% correct) was 0.7 mm.
2. Grating orientation test. Two square wave gratings were applied successively to a subject's finger tip, the first with the gratings parallel to the finger and the second parallel or orthogonal to the first. Gaps as small as 0.8 mm allowed reliable discrimination (75% correct).
3. Letter recognition. Subjects were asked to name letters of the alphabet when they were applied to the finger tip. After brief exposure to the task subjects readily recognized letters that were 8.0x6.0 mm; preliminary experiments suggest that the threshold is lower.

The measures of acuity reported here relate to one another in a way similar to the corresponding measures of visual acuity.

The spatial profile of discharge in the slowly adapting fiber population reconstructed from studies of single fibers can be characterized by four observations: (a) the dynamic component of the response is much more widespread than the static component, (b) the static component decays by half within 0.5 mm of an edge or a point, (c) slowly adapting receptors are primarily sensitive to shear stresses in the skin and (d) the response properties are much less variable than those of quickly adapting receptors or Pacinian corpuscles. The shear sensitivity results in edge enhancement in the discharge profile; the discharge at the edge of a flat stimulus is three times that in the flat region.

1551 THE ACTION OF IONTOPHORETICALLY APPLIED SEROTONIN ON SPINOTHALAMIC TRACT NEURONS IN THE PRIMATE. D.R. Kenshalo, Jr.,* L.M. Jordan, R.F. Martin, L.H. Haber, and W.D. Willis. The Marine Biomedical Institute and Depts. of Physiology & Biophysics and Anatomy, Univ. Texas Med. Br., Galveston, TX 77550 and Dept. of Physiology, Univ. of Manitoba, Winnipeg, Canada R3E OW3.

Stimulation in the region of the raphe magnus nucleus results in an inhibition of activity of spinothalamic tract neurons. The cells in the raphe nuclei are known to contain serotonin, which has a depressant action on many dorsal horn interneurons in the cat. If serotonin has a depressant action on primate spinothalamic tract neurons, this would suggest a direct inhibitory pathway from the brainstem onto neurons believed to signal pain.

Spinothalamic tract neurons were identified in the lumbosacral and sacral spinal cord of monkeys. Iontophoretic application of serotonin onto 31 cells resulted in a depression of activity in 19 of these. The depression of activity was progressive rather than immediate, which suggested a buildup of the drug was necessary. In contrast, when current effects were encountered, the effects were always of immediate onset. The depression of activity continued after serotonin application was terminated, whereas current effects terminated immediately. In five cells, pulses of glutamate were interacted with the depressant action of serotonin. Glutamate produced an excitation which was partially blocked by application of serotonin in all cases. A separate population of spinothalamic tract cells, which responded to receptors in deep tissue but not to cutaneous receptors, were powerfully excited by serotonin. A total of five cells of this type were encountered, and in each case the excitation was slow of onset and lasted well beyond the application of the drug.

In those cases in which a depressant action of serotonin on units responding to cutaneous stimuli could not be demonstrated, it was possible that the microelectrode array was too far away from the cell to allow a buildup of an effective concentration of the drug. The interference with the action of glutamate excitation by serotonin suggests that serotonin has a direct effect on the postsynaptic membrane of these spinothalamic tract neurons. If this is the case, the possibility that raphe-spinal cells form a direct inhibitory path to spinothalamic cells becomes a reasonable hypothesis.

This work is supported by NIH grant 09743 and the Canadian M.R.C., NS 05698 to DRK, and NS 05087 to LHH.

1552 SOMATOTOPIC ORGANIZATION OF THE BRACHIAL CORD OF CAT. H. Richard Koerber*, and Paul B. Brown. (SPON: W.E. Gladfelter). Dept. of Physiology and Biophysics, West Virginia University Medical Center, Morgantown, West Virginia 26506.

Spinal cord segments C_4-T_2, the segments receiving forelimb cutaneous input, were characterized in adult cats of both sexes by recording from single units with stainless steel microelectrodes.

The dorsal horn dermatomes correspond closely to the dermatomes of the corresponding dorsal roots, with the exceptions that C_4 and C_5 dorsal horn dermatomes contain input from the forelimbs which is not part of their dorsal root inputs, and dorsal horn dermatomes are larger than the dermatomes of their dorsal roots.

Cells with receptive field centers on the proximal limb were generally located in the lateral dorsal horn and cells with distal receptive fields tended to be located more medially.

The dermatomal trajectory courses from the shoulder, down the anterior surface of the forelimb, across the ventral forepaw and up the posterior surface of the limb onto the thorax, with shifting overlap, and little receptive field overlap between the preaxial and postaxial limb.

As is the case is other nuclear regions of the CNS, the relative area devoted to projections from the forepaw is disproportionately large relative to the area devoted to cutaneous regions of similar size which are located more proximally on the limb. The areas of greatest representation density are the ventral forepaw and both the medial and lateral aspects of the wrist. There is a secondary focus of representation density at shoulder and axilla, corresponding to the secondary focus at the perineum in the lumbosacral maps of the hindlimb. Receptive fields were larger and more elongated on the leg than on the foot.

We conclude that the organization of forelimb dorsal horn projections to the cervical enlargement in the cat spinal cord obeys similar organizational rules to those previously observed in the projections of hindlimbs to the lumbosacral enlargement.

1553 PRIMATE PARESTHESIAS: SPECIFIC AND NONSPECIFIC ASCENDING SPINAL MECHANISMS. M. Levitt and J. H. Levitt, Dept. Physiol. Pharmacol., Bowman Gray Sch. Med., Winston-Salem, N.C. 27103

We have described objective evidence of disturbing lumbosacral paresthesias in monkeys consequent to thoracic contralateral anterolateral cordotomy or hemisection (Fed. Proc. 36:538, 1977). The laterality does not suggest release from descending inhibition as a cause. A chronic irritative focus at the surgical site was deemed unlikely, since paresthesias were unchanged after subsequent surgical repetition, 4 segments rostrally. Paresthesias of cordotomy were similar to those resulting from total limb de-afferentation, or an upper lumbar syrinx (African Green monkey); suggesting a common, though unknown, neural mechanism. Others have concluded that interruption of the "spinothalamic system" is a primary cause of central pain in humans (Cassinari & Pagni, Central Pain, 1969). A remaining nonspecific ascending system was postulated to be essential. The paresthesias in monkeys after thoracic cordotomy were found to be independent of peripheral input (L_4-S_2 roots) from the affected dermatomes, or (with supramaximal cordotomy) of conduction via other paucisynaptic sensory tracts; however, they appeared to be dependent upon diffusely located homolateral mechanisms. Indeed, thoracic AL cordotomy or hemisection did not prevent the occurrence of bilateral paresthesias after second-stage bilateral L_4-S_2 posterior rhizotomies; or after second-stage hemisection on the other side and two segments away. These findings suggested that the paresthesias of cordotomy or rhizotomy might have been sustained by bilaterally, diffuse, polysynaptic spinal mechanisms. The paresthesias resulting from thoracic cordotomy were greatly attenuated, but not abolished after complete L_1-$_3$ spinal transection, 3-12 months later in 4 monkeys. Post-transection survival times ranged from 14-54 days, during which similar signs of paresthesias were detected in the leg contralateral to the cordotomy or hemisection. In one of these cases, a unilateral lumbar sympathectomy was then performed, which failed to stop the paresthesias. These findings suggest that the paresthesias of thoracic AL cordotomy are caused by the generation of chronic abnormal discharges of a somatotopically organized neuronal pool at a brain (diencephalic?) level; and the manifestation of the paresthesias is dependent upon central excitability states which are determined by nonspecific neural influences acting upon the discharging pool, and in part arising at caudal spinal levels. The report of C.N. Liu (Anat. Rec. 178:403, 1974) suggested that the ascending nonspecific influences can be modified by prior bulbar pyramidotomy. (Supported by USPHS Grant NS 11921).

1554 CENTRAL TERMINATION OF IDENTIFIED CUTANEOUS AFFERENT UNITS WITH FINE MYELINATED FIBERS. A.R. Light* and E.R. Perl. Dept. Physiol., Univ. North Carolina, Chapel Hill, NC 27514.

In anesthesized cats and macaque monkeys, the spinal cord distribution and synaptic termination of single, physiologically characterized primary afferent neurons was determined. The emphasis was on slowly-conducting myelinated fibers, but elements with conduction velocities ranging from 7.5 to over 70 M/sec were studied so that the projection pattern of the fine myelinated fibers could be compared with that of the coarse myelinated fibers. Unitary recordings were made from intact dorsal roots using micropipette electrodes filled with horseradish peroxidase (HRP). After the functional characteristics of a unit were determined by examining its response to natural stimulation of the skin, HRP was iontophoretically introduced into the fiber by a modification of the technique reported by Light and Durkovic (J.Exp. Neurol.53: 857, 1976). The single fibers stained by the reaction product of HRP could be traced into the spinal cord for several mm with main branches, extensive arborization of fine collaterals, and presumed synaptic thickenings clearly visible. The three dimensional distribution of thses fibers was reconstructed using an interactive, computer-based graphics system. Fourteen (14) neurons identified as high threshold mechanoreceptors, i.e. mechanical nociceptors (HTM), which had conduction velocities between 7.5 and 40 M/sec were found to have many synaptic enlargements in the dorsal horn marginal zone (lamina 1 of cat), and a few enlargements in the substantia gelatinosa (lamina 2 of cat). In addition, at least the more rapidly conducting and more sensitive of the HTM fibers also had a branch with synaptic enlargements in the medial and central portions of the nucleus proprius (lamina 5 of cat). D-hair afferent units (conducting between 11 and 20 M/sec) had a different termination pattern with a few synaptic enlargements in the marginal zone and a predominant distribution of terminals in the nucleus proprius (laminae 4 and 5 of cat). Other myelinated fiber receptors (G-1 and G-2 hair follicle, Type I and II slowly adapting cutaneous, field, and Group Ia and II muscle) each exhibited a characteristic pattern of terminations. However, none of these primary afferent types had en passant or terminal enlargements in the marginal or SGR zones. These data suggest that activation of marginal zone neurons by HTM reported for cat (Christensen and Perl, J. Neurophysiol. 29:293, 1970) and for monkey (Kumazawa and Perl, in Sensory Functions of the Skin. Y. Zotterman, Ed., Pergamon, Oxford, 1976) is probably monosynaptic and similar direct connections exist to certain neurons in the neck of the dorsal horn.

1555 THE UNIT ACTIVITY OF SOMATOSENSORY AFFERENTS FROM CAT HINDLIMB DURING NORMAL WALKING. Gerald E. Loeb and Jacques Duysens. Laboratory of Neural Control, NINCDS, NIH, Bethesda, MD 20014.

The activity of individual somatosensory afferents from cat hindlimb during normal walking has been studied using a new method of implanting "floating" wire microelectrodes in the dorsal root ganglia (Neurosci. Abst. #782, 1976). 67 units from 11 cats have been so studied and subsequently characterized by physiological tests under anesthesia. The entire range of myelinated and unmyelinated afferents (0.8 to 108 m/sec) appears to be sampled by this technique, yielding the following preliminary observations:

Of 18 hair receptors (40 to 94 m/sec), almost all had highly repeatable firing patterns during walking even when their fields were not contacted by objects (e.g. on dorsum of foot or lateral hip).

14 light touch receptors (27 to 87 m/sec) were generally inactive unless their receptive fields contacted an external object. Skin stretch sensitivity appeared to modulate or initiate activity in some but not all of 4 stretch sensitive units.

11 spindle primaries (70 to 105 m/sec) and 4 spindle secondaries (43 to 57 m/sec) generally responded to passive stretch and to an apparently variable alpha-gamma coactivation. Some units had only one activity peak during passive stretch. Others had an additional peak during active muscle contraction. This latter activity could reach frequencies above that of the passive stretch peak but usually showed a pause during maximum shortening rate of the muscle. In our scattered sample, the only systematic difference between primaries and secondaries appeared to be higher peak firing rate in some but not all primary endings.

4 Golgi tendon organs had activity closely correlated with EMG activity and, presumably, active tension of their muscles, with very little passive stretch response during gait or manipulation.

5 knee joint receptors (46 to 75 m/sec) had very complex and variable activity patterns not simply related to joint angle, and possibly influenced by joint loading and/or capsular muscle tension. Units with similar responses to manipulation could have very different activity during walking.

There were 10 units of undetermined modality, often with complex bursting and/or long periodic cycles of spontaneous activity usually not modulated by gait. One unit was modulated by blood pressure changes, but others have been unresponsive to a variety of thermal, noxious, and visceral stimuli, and may represent the poorly understood classes of free endings and/or sympathetic afferents.

1556 INHIBITION IN SUBMODALITY CHANNELS INFLUENCING SI CORTICAL MECHANORECEPTIVE NEURONS. J. Martin* and W.A. Spencer* (SPON: K.R. Weiss). Div. Neurobiol., Dept. Physiol., Coll. Phys. and Surg., Columbia U., New York, N.Y. 10032

Afferent inhibition of unit responses evoked in primary somatosensory cortex is believed to participate in spatial and temporal contrast mechanisms operating within a given submodality channel of the primary projection pathway. But the identification, with stimuli selective for different peripheral mechanoreceptors, of central segregation of mechanoreceptive channels suggests an additional function: inhibition might arbitrate competing claims of different mechanoreceptive submodalities by being distributed from one submodality channel onto another.

In the present study single unit discharge patterns of quickly adapting SI cortical neurons in cats lightly anesthetized with Na Thiopental were examined to assess inhibition generated by sinusoidal mechanical stimuli delivered to their peripheral receptive fields. Cells responding to displacement of hairs were found to be tuned to low frequency skin indentations (flutter). Cortical units believed to be driven by Pacinian afferents (PC cells) were shown to be tuned to higher frequency stimuli (vibration) and to have receptive fields located deep to the skin. Anesthetic conditions allowed surgical decoupling of stimuli to skin and deeper tissue to achieve optimal selectivity. Several experimental conditions were examined using three different stimuli to various loci on the cat contralateral forelimb. Hair and PC cell test responses to effective single sinusoids at receptive field centers were paired with steady skin indentation, flutter or vibration conditioning stimuli delivered to nearby loci, and usually presented 15 ms. before the test stimulus.

Suppression of the test evoked single unit response of quickly adapting cortical cells was regularly observed when the conditioning stimulus was limited to the submodality of the cell under investigation. Little or no suppression was observed when the conditioning stimulus selectively activated submodality channels other than that driving the cell. Thus, a 20 Hz flutter stimulus strongly inhibited the test response of hair cells but not PC cells, and a 200 Hz vibration had exactly the opposite effect. A steady skin indentation inhibited the test response of some PC cells to a limited extent; yet, under no circumstance so far examined did this form of stimulation inhibit the test response of hair cells.

Our data thus tend to minimize the effects of cross-submodality inhibition. They accord with recent psychophysical inferences (Zambelli et al., 1976) that afferent inhibition is primarily important in shaping information concerning stimulus locus and distribution within a given submodality channel.

1557 PROJECTIONS FROM THE SPINAL CORD AND THE GRACILE, CUNEATE, TRIGEMINAL AND LATERAL CERVICAL NUCLEI TO THE POSTERIOR GROUP OF NUCLEI IN THE THALAMUS OF THE CAT. D. C. Mash* and K. J. Berkley. (SPON: Judith Tunkl Blumsack). Dept. Psychol., Fla. St. Univ., Tallahassee, FL 32306.

The distribution within the posterior group of terminals from these various afferent sources was studied using a differential labeling strategy in which both autoradiographic and degeneration tracing methods were employed to label two different afferent pathways simultaneously in the same cat. This strategy allows one to make direct comparisons between the terminal distributions of the two afferent pathways under investigation.

It was found that there was considerable overlap between the projections of all of these pathways throughout most of their combined zone of termination in the medial division of the posterior group (POm). Within this highly convergent termination zone, however, certain differences were observed. Terminals from the trigeminal n. tended to be more heavily distributed further caudally and medially within POm than those from the n. cuneatus, while n. cuneatus terminals in turn tended to be more heavily distributed further medially and caudally than those from the n. gracilis. Although the projections from the lateral cervical n. extended throughout most of the region in POm that received gracile, cuneate and trigeminal fibers, its terminals were more heavily distributed laterally within this zone. Projections from the spinothalamic tract, on the other hand, tended to be more concentrated in the medial portions of this zone. In individual experiments, it was often observed that fibers from each of the two pathways under investigation did not necessarily appear to terminate on precisely the same group of cells; they appeared instead to terminate on neighboring cells within the same small region.

These results provide an anatomical basis for the results of electrophysiological experiments which show that the response properties of cells in the somatic sensory portions of the posterior group vary over a wide range and that cells with different response properties tend to be spatially commingled rather than separated in this region.

1558 THE RELATIONSHIP OF CYTOARCHITECTURE AND DENDRITIC MORPHOLOGY TO AFFERENT INPUT WITHIN THE THALAMIC VENTRAL TIER NUCLEI OF THE RAT. J.P. McAllister*, D.M. Fekete*, J. Wells and D.K. Ryugo (SPON: J.S. Schwaber). Dept. Anat., Univ. Vermont, Burlington, VT 05401.

The present report addresses the relationship between the pattern and type of afferent input to the thalamic ventral tier nuclei and the unique morphological properties of the corresponding recipient target tissue. In Fink-Heimer preparations, lesions of the dorsal column nuclei (DCN) produce heavy contralateral degeneration in the lateral and anterolateral portions of the ventral posterior nucleus (VPL) as well as sparse degeneration in the central intralaminar nucleus (CIN). The primary terminal field in VPL contains fusiform neurons whose somata and tufted dendrites form a series of lamellae oriented parallel to the incoming lemniscal fibers. The secondary terminal field is marked by fine degenerating fibers and large neurons with multipolar, unbranched radiating dendrites. Spinal cord (SC) hemisections produce a primary terminal field in the ipsilateral rostral VPL, overlapping slightly with the most anterolateral region of DCN projections, and a secondary bilateral field in CIN. These degeneration patterns essentially confirm the observations of Lund and Webster (JCN, 1967a,b). The deep nuclei of the cerebellum (Cb) project contralaterally to the ventral medial (VM), ventral lateral (VL), central lateral (CL) and paracentral (Pc) nuclei, as well as to CIN. Some of the degenerating fibers recross the midline in the thalamic commissure to terminate in the central medial (CM) and Pc nuclei. The primary targets of Cb projections, VM and VL, are characterized by a mixed population of round, fusiform and multipolar neurons whose moderately branched dendrites are distinct from those in the adjacent regions. These Cb projections resemble those of the opossum (Walsh and Ebner, JCN, 1973).

These observations reveal that projections from SC, DCN and Cb exhibit a dual termination pattern within the dorsal thalamus. Each of these thalamic afferent systems projects to a primary target receiving a segregated input, and to a secondary target receiving multiple inputs. Finally, these target areas each have morphological characteristics which tend to complement the type and pattern of afferent input.

1559 CHANGES IN THE PARAMETERS OF SIGNAL DETECTION THEORY PRODUCED BY SUGGESTION AND TRANSCUTANEOUS ELECTRICAL STIMULATION. Douglas B. McCreery* and James R. Bloedel. Dept. Neurosurg., Med. Sch. Univ. Minnesota, Minneapolis, MN 55455.

Experiments were performed to assess the effect of transcutaneous electrical stimulation on the perception of non-noxious and noxious thermal stimuli using an adaptation of signal detection theory. Normal human subjects were divided into two general groups, one in which the thermal stimuli were applied during electrical stimulation of forearm nerves and a sham stimulation group in which the electrical stimulation was not applied even though the subjects were told it was. This paradigm permitted both an analysis of as well as a control for the subjective factors related to suggestion which may affect the perception of non-noxious and noxious thermal stimuli. All results were tested statistically to a significance of $p=.05$ using an analysis of variance. In addition, the experiment was repeated using two different paradigms of stimulation to ensure that the results were not likely to be paradigm specific. In previous investigations utilizing SDT in the study of experimental pain, it has often been assumed that changes in criterion without concomitant changes in discriminability reflect only changes in response bias rather than actual changes in perception. The present study indicates that in a paradigm in which the experimentor does not have explicit control of the perceptual variables, this assumption is not generally valid. Specifically, we found that a change in discriminability occurred during sham electrical stimulation, thus demonstrating that this factor could be affected by suggestion. Secondly, during actual electrical stimulation, changes in criterion without accompanying changes in discriminability were observed which were interpreted as reflecting an actual analgesia rather than changes merely in response bias, namely a change in the subject's verbal description of what was actually perceived.

1560 BODY REPRESENTATION IN S-I CORTEX OF CAT: RELATION TO CYTOARCHITECTURE. T.M. McKenna*, D. A. Dreyer & B. L. Whitsel. Dept. of Physiol., Sch. Med. and Dent. Res. Cent., University of North Carolina, Chapel Hill, North Carolina 27514.

While the body representation in somatosensory area I (S-I) of the monkey cerebral cortex has been described in a way that permits analysis of the transformations between the peripheral sensory receptor sheet and its cortical representation, existing accounts of the cat S-I body representation lack the resolution required to perform such an analysis. As a consequence, the rules governing the mapping of the body onto the S-I cortex in these two species cannot be directly compared. With this objective in mind, we performed extracellular recordings from single neurons in the S-I cortex of unanesthetized cats. The receptive field (RF) and submodality of each neuron was determined using light punctate mechanical stimulation of the skin, hair movement, limb movement or pressure applied to deep tissues. Neurons were sampled in cytoarchitectural areas 2, 1, 3b, 3a and 4; all penetrations were histologically verified. A map of the connectivity and submodality distribution of the cat S-I cortex was obtained by plotting the data from each penetration in relation to cortical cytoarchitecture. This relationship is depicted in two ways: (1) with the gyri as they appear normally and (2) with the sulci "opened" and the cortex unfolded onto a plane. It is shown that in many respects, the connectivity and submodality distribution of the S-I map in both cat and monkey are similar. Although it frequently was observed that penetrations advanced across cytoarchitectonic boundaries did not exhibit a transition in submodality, neurons responding selectively to deep stimuli were found in greatest numbers in areas 3a and 2 and cutaneous neurons occurred in greatest numbers in areas 3b and 1. In all penetrations that crossed cell columns, a continuous sequence of RFs was observed. This not only occurred when a penetration crossed cytoarchitectural boundaries but also when it remained within a single cytoarchitectural field. The extensive cortical zones devoted to the representation of cutaneous forepaw and hindpaw mechanoreceptors each extended continuously from area 2 into area 4. Discrete RFs on the wrist or ankle were represented at multiple points around the forepaw and hindpaw regions and it appears that, as in the monkey, the distal fore- and hindlimb representations are continuously bounded by cell columns receiving input from the wrist and ankle, respectively. Observations obtained in this study lead us to conclude that, despite the many obvious differences between monkey and cat, the rules which govern those aspects of somatosensory cortical organization revealed by RF and submodality mapping appear to be identical in the two species. Supported, in part, by NIH grants NS10865, DE02668 and RR05333.

1561 SENSITIZATION OF A-DELTA NOCICEPTIVE AFFERENTS TO NOXIOUS RADIANT HEAT DELIVERED TO THE MONKEY HAND. Richard A. Meyer* James N. Campbell, and Robert H. LaMotte. Dept. Physiol., Sch. Med., The Johns Hopkins Univ., Baltimore, Md. 21205.

A group of A-delta nociceptive afferents (ADN) that innervated the hairy or glabrous skin of the monkey hand developed enhanced responsivity (sensitization) to noxious radiant heat delivered to their receptive fields. Thirty-seven ADN's (28 glabrous and 9 hairy units) with a median conduction velocity of 32 m/s, a mean receptive field area of 42.8 mm^2, and a mean mechanical threshold to nylon monofilaments of 3.89 bars were studied by the method of single unit recording. A CO_2 infrared laser under radiometer feedback control provided a step increase in skin temperature to a constant level ($\pm$ 0.1°C) over a 7.5mm diameter spot with rise rates greater than 30°/sec. Approximately half of these high threshold mechanosensitive afferents did not respond to the first presentation of 53°C, applied for 3 sec. However, with each presentation of this stimulus the number of impulses evoked progressively increased from 0 to 5 on the first trial to a mean plateau level of 58 impulses during subsequent trials. There was also a progressive decrease in response latency and the development of an afterdischarge which typically lasted several seconds after termination of the stimulus. Spontaneous activity between stimulus presentations developed in about half the units studied. Heat thresholds were tested 5 to 30 minutes after sensitization and were found to be significantly lowered - occasionally as low as 38°C. Also, the rate of discharge evoked by heat stimuli increased monotonically with increasing stimulus temperature. The dynamic response properties of these units were compared with those of 58 polymodal nociceptive C fibers (CPN) innervating the monkey hand. These CPN's had a mean conduction velocity of 0.8 m/s, a mean receptive field area of 18.9 mm^2, and a mean mechanical threshold of 5.95 bars. In contrast to the ADN's, the CPN's typically showed a decline in response to successive thermal stimuli, an increase in response latency, and an increase in heat threshold. Of 17 CPN units studied with repeated 53°C stimuli, only 3 developed signs of sensitization. These results suggest that the ADN's contribute to the increased magnitude of pain evoked by heat stimulation following a first degree burn.

1562 ACTIONS OF SOMATOSTATIN AND METHIONINE-ENKEPHALIN ON CAT DORSAL HORN NEURONES ACTIVATED BY NOXIOUS STIMULI. Vjekoslav Miletic*, Mark S. Kovacs* and Mirjana Randic. Iowa State University of Science and Technology, Ames, Ia. 50011.

Using the indirect immunofluorescence technique Hökfelt et al. (Neuroscience, 1:131, 1976) have demonstrated the occurrence of somatostatin-positive fibres in the superficial laminae of the dorsal horn, with the highest concentration observed in the lamina II of the rat spinal cord. The physiological role of somatostatin-positive fibres is at present unclear. Since it is known that this region contains neurones principally excited by an input in nociceptor afferent fibres, it was of interest to study the central effects of somatostatin by applying it microelectrophoretically to dorsal horn nocioceptive and other types of neurones at the level of Rexed's laminae I-VII. In addition, we have tested sensitivity of nocioceptive neurones in the laminae I-III to methionine-enkephalin. It is known that this area contains both, opiate receptors and enkephalins.

We have found that: 1) Somatostatin causes a depression of almost all tested dorsal horn neurones in laminae I-III, activated either by noxious mechanical and/or thermal stimulation or by a volley in Aδ or C fibres. In addition, the wide dynamic-range cells located in lamina V, activated by both non-noxious and noxious cutaneous stimuli, were moderately depressed by somatostatin. Occasionally biphasic responses were seen in lamina V-type cells. 2) Somatostatin depressed responses of nocioceptive neurons to adequate stimulation. 3) In contrast, the majority of units activated by low-threshold mechanical and electrical stimuli located in laminae I-V were unaffected by somatostatin. 4) Infrequent excitatory effects of somatostatin were observed in lamina VII. The characteristics of the depressant response to somatostatin were as follows: relatively rapid onset and recovery, depression of rate of firing was frequently accompanied with the increase in spike amplitude, graded decrease in excitability with increased current and absence of similar response during application of the control positive current.

The predominant effect of methionine-enkephalin in nocioceptive units was depression of spontaneous and evoked neuronal firing rate. A few units activated by low-threshold mechanical stimuli seem to be insensitive to methionine-enkephalin.

Our results demonstrating the depressant effect of somatostatin upon the majority of tested spinal nocioceptive neurones seem to suggest that somatostatin-containing neurones may exert an attenuating influence upon the incoming pain information. In addition, we have shown that methionine-enkephalin has a potent depressant action on the excitability of nocioceptive neurones located at the level of Rexed's laminae I-II. (Supported by PHS Grant NS12972-01 and Iowa State University Research Foundation).

1563 IDENTIFICATION OF CORNEAL AFFERENT CELLS IN THE TRIGEMINAL GANGLION OF THE CAT USING HORSERADISH PEROXIDASE. Charles Morgan, Irving Nadelhaft, William C. de Groat. Depts. of Neurosurg. and Pharmacol., Univ. of Pittsburgh School of Medicine and Veterans Administration Hospital, Pittsburgh, Pa., 15261.

Afferent fibers from the cornea travel through the trigeminal nerve into the brain stem. It has been generally assumed that the cell bodies of these fibers are located in the trigeminal ganglion; however, this has never been definitely established.

In the present study corneal afferent cells have been positively identified in the ophthalmic region of the trigeminal ganglia of seven cats. The basic procedure involved scoring the cornea of one eye with a knife, applying horseradish peroxidase (HRP) to both eyes, and then covering both eyes with contact lenses. The cats were anesthetized with dial urethane throughout the whole procedure including the 30-36 hours allowed for transport of the HRP to the ganglion cells. Frozen sections, 42 u thick, were processed in diaminobenzidene or benzidene after being mounted on glass slides. Cells were identified under dark field illumination.

In the control eyes the HRP had contact with the intact cornea, sclera, conjunctiva, and eyelids, yet no cells were labelled in the ipsilateral ganglia. On the basis of this it seems reasonable to conclude that HRP was only taken up by the nerve endings of the damaged cornea and not by the intact cornea or surrounding mucous membranes. The number of cells labelled was roughly proportional to the amount of area damaged. A 9 mm diameter circular area of damage commonly led to labelling of 75 to 100 cells, whereas scoring the entire cornea (approx. 5 times greater area) resulted in 691 labelled cells in one cat. Cells were distributed randomly only within the medial portion of the ganglion in an area 3 mm long, 1 mm wide and 1.9 mm thick extending from dorsal to ventral surfaces. Scoring medial or lateral portions of cornea did not result in any obvious shift in the random distribution of labelled cells within the ganglion and suggests there is no topographical organization to this system at this level. The labelled cells were typical monopolar sensory ganglion cells ranging from 20 to 50 microns in diameter.

Within the limits of this experiment we conclude that corneal afferents are carried in the trigeminal nerve and have their cell bodies randomly distributed throughout the medial portion (ophthalmic area) of the trigeminal ganglion in a non-topographic manner. We find that the nerve endings in intact corneal tissue do not take up HRP but must be damaged for this to occur. The number of cells labelled is proportional to the damage.

1564 THE EFFECT OF CHRONIC TRACTOTOMY UPON THE RESPONSE PATTERNS OF SENSORY NEURONS IN ROSTRAL TRIGEMINAL NUCLEI. Samuel G. Nord and Ronald F. Young. Departments of Neurology and Neurosurgery Upstate Medical Center, Syracuse, NY 13210.

The results of previous electrophysiologic investigations of tooth pulp projections to the trigeminal sensory complex have led to the proposal that the firing patterns of cells in rostral nuclei of the complex are influenced by activity evoked in cells of the nucleus caudalis. Specifically, it has been proposed that the responses of the rostral cells to pulpal stimuli include late components which originate in the caudalis neurons. These late components have been presumed to relate to the identification of a stimulus as noxious. The present investigation examines the potential contribution of caudalis neurons to the firing patterns of the rostral trigeminal cells in experiments with chronically tractotomized animals. Adult cats were subjected to unilateral trigeminal tractotomy at the level of the obex. Four to six weeks later each animal was lightly anesthetized (Pentobarbitol) and paralyzed (Gallamine) and was studied in acute experiments. Unit activity was recorded from neurons in the trigeminal nuclei oralis and principalis on both the tractotomized and unoperated (control) sides of each preparation. Recording sites and completeness of tractotomies were verified histologically. Response patterns exhibited by cells on each side of the brainstem varied considerably. For example, single, maximally effective, pulpal stimuli evoked between one and twenty spikes in neurons located on each side. These spikes were arranged in brief bursts, in prolonged continuous trains or in multiple component discharges. Mechanical stimulation was also effective in activating many of the neurons. Again, brief, prolonged and multiple component responses were recorded. Differences in response patterns on the two sides were not detected in either the exclusively pulpal or the polymodal neurons. Thus, the results of our experiments indicate that late discharge components, whether in response to pulpal or to mechanical stimuli, may not originate in nucleus caudalis. Furthermore, our data lend no support to the hypothesis that prolonged or multiple component neuronal activity in rostral trigeminal nuclei is exclusively related to noxious pulpal stimulation.

1565 ANALGESIC EFFECTIVENESS OF BRAIN STIMULATION IN PRIMATES ON ESCAPE BEHAVIOR TO TOOTH PULP STIMULATION. T. D. Oleson, D. B. Kirkpatrick*, and S. J. Goodman. Dept. of Surg./Neurosurg., Sch. Med., UCLA - Harbor General Hospital Campus, Torrance, CA 90509

Nine adult Rhesus monkeys (Macaca mulatta) were implanted with bipolar stimulating electrodes in the upper canines and in various regions of the brain. In four monkeys, silver disc stimulating electrodes were placed under the infraorbital neocortex. The remaining five monkeys were implanted with four electrode-track arrays aimed for midline sites in the diencephalon, mesencephalon, cerebellum, and medulla oblongata. All monkeys were trained to press a lever to terminate 5 Hz, 0.5 msec, square wave, shock pulses delivered to the tooth; current intensities were varied between 0.25 ma and 5.0 ma. These animals were also given a shock titration schedule whereby the current intensity was increased in 0.25 ma steps every 5 sec unless the monkey pressed the lever to reduce the current one step for each bar press. After current levels eliciting reliable escape and titration behaviors were established, 20 Hz, 0.5 msec, biphasic, square waves were delivered to the various brain sites for 60 sec. Electrical stimulation of the diencephalic nucleus anterior medialis, the lateral hypothalamus, the preoptic area, and the septal nucleus all elicited large and prolonged increasesin both escape and titration behavior to tooth pulp stimulation. At current intensities (1.0 ma to 3.0 ma) which elicited little to no side effects, shock thresholds were increased by over 300% and often did not return to control levels until 3 hours following the termination of brain stimulation. Only a moderate and brief elevation of shock threshold was observed during orbital cortex stimulation, and this effect was often accompanied by nonaversive but behaviorally distracting lateral eye gazes. Unlike previous reports in rats and cats, the midbrain central gray, the dorsal raphe nucleus, and the nucleus raphe magnus were not optimal sites for obtaining stimulation - produced analgesia in primates. When elevations in shock threshold occurred following electrical activation of these brain areas, they were always accompanied by aversive behaviors. Stimulation of the cerebellum resulted in similar negative findings. Naloxone (2 mg/kg) did not block the analgesic effectiveness of any brain site. This data thus points to the importance of the rostral, midline diencephalon for reducing escape responses to tooth pulp stimulation. Electrical activation of these same diencephalic areas also inhibited behavioral responses to foot shock and tail pinch, attesting to the generality of the antinociceptive effect of brain stimulation.

1566 RESPONSES OF BULBAR RETICULAR NEURONES TO REPEATED CUTANEOUS STIMULATION. J.A. Pearson* and W.M. Smith* (SPON: J.P.J. Pinel). Dept. of Physiology, University of British Columbia, Vancouver, B.C., Canada V6T 1W5.

In previous experiments designed to elucidate the neuronal basis of flexor reflex habituation, several types of spinal interneurones were encountered whose activity changed as a consequence of stimulus repetition. The type which was of particular interest was spontaneously active and was inhibited by cutaneous stimulation. The period of inhibition progressively lengthened with each successive trial. This build-up of inhibition could not be demonstrated in rats whose spinal cords had been transected at the mid-thoracic level. Furthermore, Haber and Wagman (1974) have shown that repeated stimulation of the nucleus reticularis gigantocellularis (NGC) also caused a progressive inhibition of spinal interneurones. It is suggested therefore, that NGC might be necessary for the demonstration of inhibitory build-up of spinal interneurones to repeated cutaneous stimulation.

In the present experiments the responses of neurones in the medullary and pontine reticular formation were studied. Rats were anaesthetized with urethane (1.5 g/kg). Unitary activity of reticular neurones was recorded using glass microelectrodes containing pontamine sky blue (4% in 1M NaCl). Recording sites were marked by ejection of the dye from the recording electrode. Peripheral cutaneous stimuli were delivered through a pair of 30 gauge needles inserted into the skin of a hind paw.

The activity of 35 neurones, which were situated either in the NGC or the nucleus reticularis pontis caudalis (NPC) and activated by cutaneous stimulation, was studied in detail. The threshold for activation of these cells was high (10-15V., 0.5 msec) and the response occurred after a long latency (20-50 msec). Weak natural stimuli (hair movement, touch) were ineffective and strong pinch or pin prick were required. On repeated stimulation, the responses of 14/35 cells remained constant in latency and duration. In the remaining 21 cells, the duration of the evoked discharge progressively increased with repeated trials and often persisted for several seconds after the stimulation ceased. The rate of build-up of activity was directly related to both the intensity and the frequency of stimulation. Eight of these 21 cells could be antidromically activated by stimulation (via concentric bipolar electrodes) of the lumbar cord.

In summary, repeated cutaneous stimulation causes a progressive increase in the activity of reticular neurones whose axons project to the lumbar cord. It is tentatively suggested that this response pattern may be partially responsible for the development of inhibition of spinal interneurones.
(Supported by the Medical Research Council of Canada.)

1567 PROCESSING OF CUTANEOUS TEMPERATURE INFORMATION IN CAT MEDULLA, D.A. Poulos, E.L. Auen*, J.T. Molt and H. Hirata*, Div. of Neurosurgery and Dept. of Physiology, Albany Medical College, Albany, N.Y. 12208

We have studied further the response properties of one population of thermoreceptive afferents identified in the spinal trigeminal nucleus of urethane anesthetized cats whose peripheral receptive fields appear to be limited to the glabrous surfaces of the nose and lips (Molt, J.T. and Poulos, D.A. (1976) Neurosci. Abstr. Vol. II p 945). The units were considered to be specific cold afferents; however, their response characteristics differed somewhat from the usual description of trigeminal cold receptors. Unlike the "typical" cold receptors we found that give dynamic rate increases to rapid cooling steps of 2-20° below a 35°C standard temperature, the units studied did not increase their activity above the preceding 35°C firing level and indeed more often showed a transient (2-3 sec) rate decrease to rapid cooling. Like "typical" cold receptors, the units did respond to rapid warming steps of 2-10° above the standard 35°C with transient rate decreases and surprisingly, showed dynamic rate increases when returned (cooled) to 35°C from all warmer stimulus temperatures. Due to the latter observation we re-examined the behavior of this unit type to rapid cooling below a warmer standard temperature of 43°C. When rapid cooling steps of 2-28° were applied below the warmer 43°C standard temperature the units behaved like typical cold receptors in that dynamic rate increases always occurred. The dependency of the type of dynamic response to cooling seen in these units on starting temperature cannot be attributed to differences in primary afferent input. All primary afferent cold fibers thus far described invariably show rate increases upon rapid cooling. Nor can the differences we observed be attributed to an overall shift in the range of thermal sensitivity of the cells since their static temperature response profiles tested over a wide range of temperatures held constant (45-13°C) are indistinguishable from those of typical thermoreceptors. We conclude that a form of neural processing occurs within the marginal zone of the spinal trigeminal nucleus where these cells are found intermingled with the population of typical thermoreceptors. Since their peripheral receptive fields appear to be limited to glabrous skin, the cells we have described may play some special and thus far unrecognized role in the central processing of thermal information.

1568 NEURAL REPRESENTATION OF TACTILE-EVOKED AFTERSENSATIONS BY SPINOTHALAMIC TRACT NEURONS. D. D. Price, R. L. Hayes, M. A. Ruda, and R. Dubner. Neurobiology and Anesthesiology Br., NIDR/NIH, Bethesda, MD 20014.

Long duration aftersensations can be evoked by brief tactile stimuli. They outlast the duration of the stimulus and arrival of primary afferent input by several seconds and often minutes. They are often aversive and can be immediately terminated by rubbing the stimulated area. The possible involvement of the spinothalamic tract in this phenomenon was investigated by analysis of tactile-evoked responses of 45 spinothalamic tract neurons and of 20 presumed interneurons of L-7 of rhesus monkeys. They were maintained on 66 percent nitrous oxide and 34 percent oxygen and their carotid arteries were bilaterally ligated. Each cell was tested for afterresponses to a variety of natural stimuli as well as electrical stimulation of receptive fields. A mechanical stimulus used to test all neurons consisted of moving a camel hair brush 5 cm in 5 sec along the major axis of receptive fields. As in previous studies, we found neurons that had input from low threshold mechanoreceptive afferents (tactile neurons), neurons that had input from low threshold afferents and nociceptive afferents (wide dynamic range neurons, WDR), and neurons that had nearly exclusive input from nociceptive afferents (nociceptive specific neurons, NS). None of 20 tactile neurons responded with afterresponses to the camel hair brush stimulus, to noxious heat, or to intense electrical stimulation. Four of these were spinothalamic neurons. In contrast, 13 of 18 WDR spinothalamic neurons responded with distinct afterresponses (20-56 sec duration) to the standard camel hair brush stimulus. These afterresponses could be abruptly terminated by firmly rubbing the stimulated area. The locations of neurons exhibiting this response were in dorsal horn laminae I, IV, and V. Only noxious stimuli evoked afterresponses in NS neurons. Thus, input over WDR neurons may be necessary for tactile-evoked aftersensations in primates.

1569 SOMATOTOPIC ORGANIZATION OF THE DORSAL HORN IN CATS WITH PARTIAL LUMBOSACRAL DEAFFERENTATIONS. Lillian M. Pubols and Michael E. Goldberger. Dept. Anat., Med. Coll. of Pa., Phila., Pa. 19129.

The receptive fields of dorsal horn neurons at the L6 spinal cord segment in cats are organized such that the proximal hindlimb is represented laterally; the distal hindlimb, medially (Brown & Fuchs, J. Neurophysiol. 39:1, 1975). The L6 dermatome does not extend as far proximally as the receptive fields of the most laterally placed dorsal horn neurons (Kuhn, J. Neurophysiol. 16:169, 1953). Therefore, these neurons are thought to be innervated by roots other than L6. In view of recent evidence that the receptive field characteristics of dorsal horn neurons may be altered following partial deafferentation (Basbaum & Wall, Brain Res. 116:181, 1976), a study of the somatotopic organization of the L6 dorsal horn of L6-spared, lumbosacral deafferented cats was undertaken.

Unilateral lumbosacral dorsal rhizotomies were performed extradurally. Microelectrodes were used to map the tactile input to dorsal horn neurons at L6 in methoxyflurane anesthetized cats. Four animals in which all roots caudal to T12 were sectioned, sparing L6, were studied, one each at survival times of 12 hours, 2, 9 and 30 days. The results from these animals were compared with maps from two animals having both the L6 and L7 roots intact at 2 day survivals, and with published data from normal animals.

In animals having a single root spared receptive fields were exclusively on the lower leg and foot. The lateral foot, including digit 5, was not represented. All but one of the responsive loci were located in the medial 2/3 of the dorsal horn. In animals with two roots spared there were significantly more responsive loci per active electrode penetration than in the one root animals. This difference was seen throughout the mediolateral extent of the dorsal horn. The somatotopic map of two root animals was similar to that of one root animals, but extended to the lateral border of the dorsal horn. In two root animals some neurons with large, multiple receptive fields, which always included an area adjacent to the dorsal midline, were seen. These neurons tended to be located close to the border of the lateral white column.

Thus, in both types of deafferented preparations the somatotopic map of the L6 dorsal horn is consistent with that of intact animals. The L7 root supplies the lateral one-third of the dorsal horn, as well as the medial 2/3 also innervated by L6.

1570 RESPONSES TO SOMATIC STIMULATION IN N. PARAFASCICULARIS (Pf) AND IN THE POSTERIOR GROUP OF NUCLEI (PO) IN THE UNANESTHETIZED CAT. W. W. Pugh* and I. H. Wagman. Department of Animal Physiology, University of California, Davis, California 95616.

Single unit electrical activity was recorded from immobilized cats by means of chronically implanted chambers. Attachment of the head to the stereotaxic frame by an adapter permitted painless fixation while maintaining stability. 213 units (75 in PO and 70 in Pf were confirmed histologically) were analyzed. Stimuli used were electric to skin as well as adequate ranging from hair movement to strong pinch of skin and deep tissue. Responses of the two nuclei differed as follows: (1) *Receptive field (RF) size and symmetry.* 39% of PO cells had bilateral receptive fields covering most of the body surface. The remaining RFs were contralateral ranging from one limb (23%) to less than 2 cm^2 (38%). 90% of Pf units had bilateral RFs which involved either most of the body surface or both extremities. A few cells (10%) had contralateral receptive fields which were also quite large. No somatotopical organization was noted for either nucleus. (2) *Latency of response.* Following threshold electric skin stimulation, units in PO responded with a bimodal distribution of latencies. 63% of cells responded with an average latency of 20 ± 4.9 msec; the remainder had an average latency of 36 ± 3.2 msec. Similarly 62% of Pf units had an average latency of 20 ± 3.6 msec. but the others had latencies varying from 40 to 800 msec. (3) *Modality and dynamic range.* The PO group had 20% audio input of which nearly half also responded to somatic stimuli. No cells in Pf were excited by auditory stimulation. Responses in both PO and Pf were obtained by adequate stimulation: hair displacement, touch, brisk tap, skin and deep tissue mechanical stimuli, joint rotation. However, 60% of PO cells responded to low threshold somatic stimuli while 10% of Pf units responded similarly. Brisk tap affected 5% of PO and 62% of Pf cells. Intense mechanical stimulation including extremes of joint movement excited 15% of PO and 37% of Pf cells. Two-thirds of the former and one-half of the latter had wide dynamic ranges, i.e., they responded to low intensity stimuli or tap as well. (4) *Inhibition.* Under the conditions of the experiment only a few PO cells were inhibited, usually by light mechanical displacement of skin or hair movement in or near the excitatory RF. In contrast, a small number of Pf cells also showed inhibition, but only by intense stimulation such as extreme flexion/extension of joints or strong pinch to skin or deep tissue. In summary, in the unanesthetized cat Pf is more likely to be excited by poorly localized tap, articular or intense deep tissue and skin stimulation while the PO group responds more often to more localized light cutaneous input. (Supported in part by NIH grants RR00169 and AM16716).

1571 THALAMIC NEURONS PROJECTING TO THE SECOND SOMESTHETIC *AREA (SII)* OF THE CORTEX OF THE VIRGINIA OPOSSUM. Martine J. Robards and Ford F. Ebner. Neuroscience Sect., Div. Bio. & Med., Brown Univ., Providence, R. I., 02912.

Large and small iontophoretic injections of horseradish peroxidase (HRP) were placed in electrophysiologically identified regions of the SII cortex of halothane-anaesthetized opossums. After varying survival intervals (mode: 48 hours), the animals were sacrificed, and sections through thalamus were reacted with diaminobenzidine and peroxide in a phosphate buffer.

Receptive fields of units in SII were found to be large and predominantly bilateral (although not necessarily symmetric)in both forelimb and hindlimb representation areas. When low impedance micropipettes (500 KΩ) were used, click-evoked potentials could be recorded in SII, but with higher impedance micropipettes (2 MΩ), which readily recorded somesthetic unit activity, no units were found in SII which could be driven with a click stimulus.

HRP injections in electrophysiologically localized forelimb regions filled a large number of neurons throughout the middle third of the ventrobasal complex (VB), the classical forelimb area. In addition, clusters of cells in the magnocellular medial geniculate (MG_{mc}), lateral and medial parts of the posterior group, ventromedial nucleus, and the central intralaminar nucleus were filled.

HRP injections in electrophysiologically localized hindlimb regions filled a large number of neurons in the lateral third of VB (classical hindlimb area), as well as cells in the other nuclei listed above. However, while the distribution of filled cells in VB was different after fore- and hindlimb SII injections, no similar distinction between the two types of injections could be made in the other thalamic nuclei.

Cases which showed filled cells in VB always filled cells in the other nuclei, and vice versa. Hindlimb injections in SII tended to produce a relatively greater number of filled cells in the non-VB thalamic nuclei, especially in MG_{mc}. Since the hindlimb representation abuts on the auditory cortex, and since we saw an occasional filled cell in the ventral (or principal) nucleus of the medial geniculate in hindlimb SII injection cases, we cannot be certain that the injection did not spread into the adjacent fringe of auditory cortex. Alternatively, hindlimb SII may receive a relatively greater input from non-VB nuclei than does forelimb SII.

No evidence, either anatomical or electrophysiological, was found to support a division of SII of opossum into the "place-modality-specific" and "place-modality-nonspecific" subdivisions as reported for cat. (Supported by USPHS #NS13031.)

1572 SYMPATHETIC INFLUENCE ON RESPONSES OF FROG CUTANEOUS RECEPTORS. William J. Roberts and Anne L. Calof*, Neurological Sciences Institute, Good Samaritan Hospital, Portland, Oregon 97209.

Localized sympathetic dysfunction and pain are often coincident in patients; however, there is no accepted explanation of the function of the sympathetic nervous system in chronic or acute pain except in certain syndromes. These experiments have been designed to investigate the possible modulation of nociception by sympathetic actions on receptors. The initial work has focused upon low-threshold mechanoreceptors, which are thought to be involved in nociception through their inhibitory actions on unmyelinated fibers in the spinal cord.

Unitary activity in afferent fibers was recorded from filaments of the cutaneous branch of the peroneal nerve in Rana pipiens. Afferent units were first characterized as to their preferred (adequate) stimulus. Calibrated mechanical stimuli, consisting of step changes in force, were then applied to the skin with a solenoid device. Spike threshold and adaptation rate were thus measured.

Effects of sympathetic stimulation were consistent for receptors of a given type, adaptation rate and mechanical threshold. Fast adapting compression receptors with very low thresholds (< 70 mg force from a 3 mm dia. probe) were inhibited, showing threshold increases on the order of 25%. This inhibition was maintained during low frequency (5/sec) sympathetic stimulation. Fast-adapting compression receptors having higher thresholds (80-300 mg) were briefly facilitated, but this facilitation did not persist with maintained sympathetic stimulation. Slowly adapting compression receptors were also briefly facilitated by sympathetic stimulation. "Stroke" receptors showed a prolonged facilitation which differed from the facilitation of compression receptors in that it did persist with maintained sympathetic stimulation. No consistent sympathetic influence on myelinated prick receptors has been observed. The effects described above are the predominant effects observed; some units showed a brief facilitation-inhibition sequence. C-fiber nociceptors have not yet been tested.

These results indicate that sympathetic modulation of mechanoreceptor sensitivity is consistently observed in frog skin with an intact blood supply. There are transient effects, lasting several seconds, and maintained effects; both are consistent for each class of receptor as defined above. Prediction of the role of the sympathetic system in nociception requires, in addition to these data, knowledge of which classes of low threshold receptors influence nociception centrally, and information about sympathetic actions on non-myelinated afferents.

1573 BRAINSTEM UNIT RESPONSES TO TACTILE, NOCICEPTIVE AND GENITAL STIMULI IN FEMALE SQUIRREL MONKEYS. James D. Rose. Depts. Psychiat. and Anat., Sch. Med., Emory Univ., Atlanta, GA 30322.

There is much current interest in mechanisms of somatic sensation and pain in primates, but research has focussed on the spinal cord, thalamus and neocortex. Contemporary views of the sensory properties of reticular neurons are based largely on data from cats and rodents. The present work provides information on the sensory responses of brainstem reticular neurons in the monkey. In 13 female squirrel monkeys anesthetized with a chloralose-urethane mixture and paralyzed with gallamine triethiodide, 317 brainstem single units were tested for responsiveness to the following stimuli: tactile stimulation of the face, limbs, tail, trunk and external genitalia; vaginal and rectal probing; and nociceptive stimuli including foot pinch, needle pricks and localized heat. Tactile, genital and nociceptive stimuli elicited responses in 68, 69 and 64% of the units, respectively. Responsive neurons were located in the reticular formation, extending from the caudal medulla to the posterior thalamus and in non-reticular (e.g. tectum) regions as well. The unit responses consisted primarily of simple accelerative, and less often decelerative, changes in firing. Most of the cells responded to more than one form of stimulation. Units responding to tactile stimuli had extensive, usually bilateral peripheral receptive fields. Responses to vaginal stimuli were usually simple accelerations of firing which, in some instances, were enhanced by probe contact with the cervix. Responses to a foot pinch were most pronounced at pinch intensities which were well above the threshold for flexion responses in lightly-anesthetized unparalyzed monkeys. These nociceptive responses displayed little or no linear correlation with pinch force. In contrast to the good responsiveness of brainstem units to pinch stimuli, they were quite unaffected by needle pricks and thermal stimulation. In 6 of the monkeys, the effect of estradiol administration on the responsiveness of midbrain and pontine units was examined. The proportion of cells responding to vaginal probing was increased by estradiol, and similar to results reported for the cat by Rose (Brain Res. 97: 79, 1975; Exp. Neurol. 49: 639, 1975) the number of units responsive to tactile stimuli was increased as well, but the hormone had no effect on unit responsiveness to nociceptive stimuli. Results in the monkey differed from those in the cat in that genital tract stimulation didn't elicit a complex array of unit response patterns, no units responded exclusively to genital stimulation and estrogenization did not enlarge tactile receptive fields of monkey brainstem units. Supported by NIH Grant NS12260.

1574 DIRECT COMPARISON OF HUMAN AND MONKEY TEMPERATURE SENSITIVITY. Andrew J. Rózsa, Helen H. Molinari, and Dan R. Kenshalo. Department of Psychology, Florida State University, Tallahassee, Fla. 32306.

The thermal sensitivities of three human subjects and two rhesus monkeys have been examined using a signal detection "yes-no" procedure. The experimental paradigm used for the two species was identical except for a difference in the actual reward for correct responses. The stimuli were presented to 7 cm^2 areas on the subjects' palms from a number of adapting temperatures between 28° and 40°C.

At each adapting temperature the warm and cool stimulus intensities required to produce a constant level of sensitivity were calculated. The stimulus intensity required to produce a constant warm sensation level decreased when the adapting temperature was increased. The stimulus intensity required to produce a constant cool sensation level decreased when the adapting temperature was decreased. Since identical procedures were used for both species, direct comparisons of monkey and human thermal sensitivity can be made. Equivalent stimulus intensities produced identical warm and cool sensation levels in both species. The changes in thermal sensitivity with adapting temperature were also remarkably similar. Thus, the differences, if any, between human and monkey thermal sensitivities appear to be minimal.

These data indicate that the thermosensory neural mechanisms of the rhesus monkey can, in fact, be used as an adequate model for the human temperature sensing system.

1575 EM AUTORADIOGRAPHIC LOCALIZATION OF INDOLEAMINERGIC AXONAL ENDINGS IN TRIGEMINAL NUCLEUS CAUDALIS. M.A. Ruda and S. Gobel. Neurobiology & Anesthesiology Br., NIDR, NIH, Bethesda, Md. 20014

Anatomical and physiological studies have demonstrated a descending inhibitory pathway to nociceptive neurons in nucleus caudalis (CAUD) and the dorsal horn of the spinal cord. This pathway is thought to be serotonergic. The purpose of these experiments was to locate and characterize serotonergic axonal endings in CAUD which might inhibit the firing of neurons in trigeminal pain pathways.

Tritiated serotonin ([^{3}H]5HT), at a concentration of 10^{-5}-10^{-6}M, was topically applied for a period of 1 hr. onto CAUD of adult cats pretreated with a monoamine oxidase inhibitor to block the catabolism of serotonin and anesthetized with sodium pentobarbital. Our approach relies on the ability of neurons which normally utilize serotonin as a neurotransmitter to take up [^{3}H]5HT at their axonal endings. Following a survival time of 30 min-1 hr., the cats were perfused with 1% glutaraldehyde and 1% paraformaldehyde in a phosphate buffer. CAUD was then processed for light and EM autoradiography. Light microscopic analysis of 1μm sections demonstrated a specific laminar distribution of [^{3}H]5HT. Layer I was heavily labelled while layer II was moderately labelled. Grain density in layer III and the magnocellular layer was not above background level.

In EM autoradiographs, two major categories of morphologically distinguishable axonal endings were found to contain [^{3}H]5HT: dome-shaped endings and scalloped endings. Most of the dome-shaped endings were located in layer I. These endings formed single synapses, predominantly on small caliber dendritic shafts. The most heavily labelled group of dome-shape endings contained small, highly flattened, agranular vesicles and a few dense core vesicles. A second group contained small round or oval agranular vesicles and a few dense core vesicles. In contrast, the scalloped endings were found predominantly in layer II. These endings formed multiple synaptic contacts with several small caliber dendritic shafts and spines. They contained round or oval agranular vesicles and an occasional dense core vesicle.

Since our Golgi and HRP studies have shown that most of the dendrites in layer I are derived from layer I projection neurons, these experiments indicate a direct axodendritic serotonergic input to layer I projection neurons. In addition, serotonergic inputs to layer II synapse on dendrites of interneurons which modulate the transfer of input from primary axonal endings in layers II and III to the projection neurons in layer I. These inputs to layers I and II may represent descending pathways for the modulation of layer I nociceptive neurons by one or more serotonergic cell groups.

1576 CELLULAR CONDENSATIONS IN SENSORIMOTOR NEOCORTEX OF THE OPOSSUM (Didelphis virginiana). S.T. Sakai* and W.L. Weller (SPON: L.I. O'Kelly) Dept. of Psychology and Neuroscience Program, Michigan State University, East Lansing, MI. 48824 and Dept. of Anatomy, University of Tasmania, Hobart, Tasmania 7001.

Discrete cytoarchitectonic units termed barrels have been reported in SmI cortex of the mouse (Woolsey and Van der Loos, Brain Research, 17: 205, 1970). The brains of several mammals have since been examined in order to determine whether similar cellular condensations occur in the SmI face area (Woolsey, Welker and Schwartz, J. Comp. Neurol., 164: 79, 1975). The present study investigated tangential sections of the opossum sensorimotor cortex. Because cellular condensations may be more readily visualized in young animals, brains were obtained from 30, 40, 58, 70 day and adult opossums. The tissue was fixed in aldehydes and embedded in celloidin. Fifty μm tangential sections were stained in thionin. Cellular condensations were observed in layer IV in the 30, 40, 58, 70 day and adult opossum sensorimotor cortex. These condensations were oriented perpendicular to the pial surface and appeared as cell-dense circular or ellipsoidal rings containing fewer cells in the hollow. A septum of relatively fewer cells separated adjacent cell rings. The diameter of the cell ring ranged from 85 to 150 μm. The number of cellular aggregates ranged from 128 in the 30 day old opossum to 616 in the adult opossum. Three major groups of cellular aggregates appeared to be present in the rostromedial, rostrolateral and caudal areas of the sensorimotor cortex. Furthermore, these major groups appear to be connected by bridges of sparse cellular aggregates.

Because previous work indicated that the barrels of the posteriomedial barrel subfield in the rat functionally correspond to the mystacial vibrissae representation (Welker, Brain Research, 26: 259, 1971), it is interesting to note that the spatial distribution of the cellular condensations does not appear to be confined to the facial representation as outlined electrophysiologically by Pubols, Pubols, DiPette and Sheely (J. Comp. Neurol., 165: 229, 1976). Furthermore, the number of cellular condensations (128-616) far exceeds the number of vibrissae present in the opossum (46-56) as reported by Lyne (Proc. Zoo. Soc., 133: 79, 1969). Possibly some groups of cellular condensations correspond to other peripheral structures. However, the functional correlate is yet to be investigated.

(Supported by NIMH fellowship 1 F31 MH05390-01 and NIH research grant NS 05982)

1577 SPINAL TRIGEMINAL TRACT IN DOGS: AN ELECTROPHYSIOLOGICAL STUDY. Richard J. Schneider, Fred Nelson*, Henry Wiener* and Abdul L. Itani*. Dept. Surg., Div. Neurosurg. U. Md. Med. Sch., Balt., Md. 21201.

Insulated tungsten microelectrodes with electrolytically sharpened tips (1-20μ) were used to record evoked potentials from single cells and nerve fibers in the descending trigeminal tract and nucleus. Physiological stimuli (light touch, pinprick) were employed to initiate these potentials, while their conduction velocity was measured with electrical stimulation. Histology of several brainstems in this series was done.

The initial question we were asking was whether the representation of the head in the spinal trigeminal tract and nucleus conformed to the Dejerine onion-skin pattern. This pattern was deduced clinically from the distribution of sensory loss on the head following spinal trigeminal tractotomy for intractable pain in human patients. It centers on the nose and lips and expands in circles of increasing radius in lamellar fashion to include the rest of the head. This differs from the pattern of representation described for the three divisions of the trigeminal nerve: mandibular, maxillary and opthalmic. In the latter, a zone of innervation corresponding to a particular rostro-caudal division should be spared by a tractotomy at different levels. In addition, physiological characteristics of the cells and fibers were sought.

In dogs, the divisional pattern of representation was seen to exist in the descending tract. A submodality segregation (hair, skin, pressure) may also exist. Latencies to electrical stimulation indicated conduction velocities in the Group II range. The majority of units conducted in this range while only a few would fall into the conduction velocity group associated with "C" fibers and noxious stimuli.

1578 CHARACTERISTICS OF SOMATIC RECEPTIVE FIELDS OF NEURONS IN POSTCRUCIATE CEREBRAL CORTEX IN AWAKE-RESTRAINED AND TWO ANESTHETIC CONDITIONS IN THE SAME CAT. J.C. Slimp and A.L. Towe. Dept. Physiol. & Biophys. (SJ-40), Univ. of Wash. Sch. of Med., Seattle, WA 98195.

Evidently the characteristics of somatic input to the cerebral cortex differ under different anesthetic conditions. To examine these characteristics and compare them with the unanesthetized condition, a cat was prepared for chronic extracellular recording. The location, size and modality of somatic receptive fields of postcruciate cerebral neurons were studied under three conditions: unanesthetized (542 neurons), chloralose anesthesia (84 neurons) and sodium pentobarbital anesthesia (142 neurons), over a seven-month period. Of 64 sites sampled in the unanesthetized condition over a 20 mm^2 area, 17 were shared in common with the two anesthetic conditions. Half of the neurons in barbiturate, one-fourth in unanesthetized and one-eighth in chloralose, though tonically active, were unresponsive to somatic stimulation. Of the responsive neurons, the percentage distributions by modalities for the 17 common sites are shown in the table below, along with that for the 64 sites (in parentheses) for the unanesthetized condition.

Modality/Condition	Pentobarbital	Unanesthetized	Chloralose
Touch	61	35 (38)	67
Hair	10	13 (13)	25
MTJ	24	27 (23)	8
Joint only	4	24 (26)	0

Although the locations of the receptive fields did not differ markedly among the three conditions, the sizes differed in several respects. Receptive fields in chloralose were larger and those in barbiturate were smaller than in the unanesthetized condition. All of those in barbiturate, nine-tenths of those in unanesthetized and three-fourths of those in chloralose were less than a tenth of the body surface in area. Bilateral receptive fields were not found in barbiturate, though they made up 3% of the unanesthetized and 21% of the chloralose samples. In the unanesthetized condition, the size of the excitatory receptive field and the degree of responsiveness of the neuron changed with the state of alertness and/or simultaneous stimulation outside the excitatory receptive field on one-seventh of the neurons. Thus, the response characteristics of individual cerebral neurons and the statistical properties of samples of cerebral neurons vary with the experimental conditions. Even in unanesthetized preparations, attention must be paid to the posture and state of alertness of the animal.

1579 BIPHASIC ALTERATIONS OF NOCICEPTIVE THRESHOLDS INDUCED BY FOOD DEPRIVATION. Angela Spiaggia*, Richard J. Bodnar, Dennis D. Kelly, Mary Ellen McManus*, and Murray Glusman. New York State Psychiatric Institute, New York, N.Y. 10032.

An abrupt shift to a starvation diet is a severe stressor which prompts a variety of physiological reactions and behavioral adaptations, such as increased ACTH secretions, accelerated motor activity and pronounced adjunctive behaviors. The present study investigated whether food deprivation like other stressors would alter respondent nociceptive thresholds. The flinch-jump thresholds of 16 rats were tested in twice daily sessions for three baseline, three food deprivation, and two recovery days. Weight, food intake, water intake and activity were also monitored. All rats were maintained on a 14 hour on/10 off light-dark cycle. For eight rats deprivation was scheduled to begin at the end of the dark cycle, while the other eight began at the end of the light cycle. After 12 hours, on the first day of deprivation, jump thresholds were significantly higher than normal, while after 72 hours on the third day of deprivation, jump thresholds were significantly lower than baseline. These biphasic changes in jump thresholds were most marked in rats tested at the end of their dark cycle. Although baseline food intake, water intake and activity were also greater at the end of the dark cycle than at the end of the light cycle, the biphasic alterations in nociceptive thresholds during food deprivation could not be predicted by changes in these variables. These data demonstrate that food deprivation can cause orderly alterations in nociceptive thresholds which are sensitive to circadian rhythms but which are independent of such factors as water intake, activity and weight. Viewed in the context of other studies of stress-produced analgesia, it seems likely that an abrupt shift to a starvation diet may trigger a series of neurochemical events which, in the short term, produced analgesia, but which, over a longer period, render the organism hyperalgesic. (Supported by NIMH Grant #13579 and by New York State Health Research Council Grant #365.)

1580 THE REPRESENTATION OF THE BODY SURFACE IN SmII OF THE GREY SQUIRREL. M. Sur*, R. J. Nelson and J. H. Kaas, Depts. of Elect. Engineering, Anatomy, and Psychology, Vanderbilt Univ., Nashville, TN 37240.

The region of the Second Somatosensory Representation, SmII, was mapped with microelectrodes in seven (7) adult grey squirrels, Sciurus carolinensis. Detailed results led to the following conclusions. (1) SmII is located immediately caudal to the representation of the head in SmI (for the organization of SmI, see Nelson and Sur, Anat. Rec. 187: 666, 1977), in an architectonic field previously described as P1 (Kaas et al., J. Comp. Neur. 145: 273, 1972). (2) The contralateral body surface is systematically represented with SmII with the head and face most medial, adjoining the supra-orbital region of SmI. The neck, arm, trunk, leg, and tail are progressively more lateral within SmII. Thus, the head-to-tail progression in SmII is basically medio-lateral rather than rostro-caudal as has been reported for other mammals. (3) The dorsum of the trunk is represented along the caudal margin of SmII and the ventrum is more rostral. (4) Although receptive fields on the glabrous skin of the hand or foot were large and included parts of the arm or the leg, it was possible to conclude that the representation of the hand and foot are located in the rostral parts of the arm and leg region of SmII. Thus, the orientation of the body surface within SmII differs from that usually described, but is similar to that reported for the cat by Haight (Brain Res. 44: 483, 1972).

In each experiment, the rostral border of SmII was defined by extending rows of recording sites into SmI. Similarly, parts of the lateral and caudal border of SmII were delimited by recording sites activated by auditory stimuli. Electrode penetrations were considered to be within SmII when they conformed to a second systematic representation of the contralateral body surface and were related to a body part which was also represented more rostrally, in SmI. Using similar light cutaneous stimulation, receptive fields for comparable body parts were usually significantly larger for recording sites within SmII than for those in SmI. Under recording conditions of urethane anesthesia, receptive fields were predominantly confined to the contralateral body surface. However, a few receptive fields were bilateral and these were continuous across the midline.

1581 REINNERVATION OF GLABROUS SKIN FOLLOWING NERVE CRUSH - A SINGLE FIBER STUDY IN BABOONS. J.K. Terzis* and R.W. Dykes, (Spon: J.C. Fentress,) Department of Physiology and Biophysics, Dalhousie University, Halifax, N.S., Canada, B3H 4H7.

The left ulnar nerve was crushed at the level of the wrist in five female baboons (Papio anubis) using sterile surgical techniques. The contralateral unoperated ulnar nerve served as the control. The animals were allowed to survive from one to five months. At monthly intervals the functional properties of the regenerating mechanoreceptive afferent fibers reinnervating the glabrous skin on the ulnar side of the previously denervated hand were investigated and compared to fibers from the control side. The electrophysiological techniques employed in this study included electrical stimulation of the ulnar nerve at the wrist, above the level of the crush, along with single fiber dissection of ulnar nerve at the mid-arm level. This arrangement allowed rapid isolation and identification of a large number of single fibers. Once the latency of the afferent fiber was recorded, the hand was searched for its receptive field. Once identified, this was demarcated under magnification and drawn on enlarged photographs of the hand. Areas of highest sensitivity were outlined. The response characteristics of the normal mechanoreceptive fibers innervating the glabrous skin were used as a standard for comparison to data from afferent fibers reinnervating the contralateral hand. More than 800 single fibers were isolated from the ulnar nerve in approximately equal numbers from the normal and from the injured nerves. The results demonstrated that on the side of the injury, (i) conduction velocities of the nerve fibers which had been separated from their end organs were significantly slower than the controls, (ii) receptive field size and shape, and areas of highest sensitivity, were abnormal in recently reinnervated receptive fields, (iii) the response threshold and stimulus-response relation were altered, and (iv) there was a slow progression of reinnervation with time occuring in a proximo-distal direction. These results can explain some of the observations concerning altered sensibility in the hand following blunt peripheral nerve injuries.

1582 DIFFERENTIAL SENSITIVITY TO VARIOUS SENSORY STIMULI IN INTACT AND SPINAL HIBERNATING GROUND SQUIRRELS. Delphi M. Toth. Dept. Anat., Univ. of New Mexico Sch. Med., Albuquerque, NM 87131.

In hibernating mammals, conduction in peripheral nerves persists at body temperatures as low as 1°C. In contrast, nerves of non-hibernators cease to conduct at temperatures below 25°C. Hibernating animals, therefore, have the potential to perceive sensory input. Though various authors have briefly mentioned hibernators being disturbed by a variety of isolated stimuli during experiments concerning other aspects of hibernation, no systematic attempt has been made, to date, to determine to which sensory modalities hibernating animals are able to respond and to what degree they are sensitive to specific stimuli within different modalities. Thus, in the present series of experiments, responsiveness to a variety of modalities of sensory stimulation was compared in intact and spinal hibernating Citellus lateralis. Spinal hibernators were prepared by transection of the cord at the level of C_1 during hibernation and were maintained in the cold with artificial respiration. Modalities of stimulation included tactile, thermal, nociceptive, vibratory, proprioceptive, auditory, alimentary and olfactory. Indices of response included occurrence of at least one burst of muscle action potentials, increases in heart rate, respiratory rate and thoracic temperature, occurrence of visible movement, and initiation of an evoked arousal. The occurrence of bursts of muscle action potentials appeared to be the most sensitive index of responsiveness. In all instances this was also the first response of the hibernator following stimulation.

Intact and spinal hibernating ground squirrels alike were most responsive to tactile and nociceptive stimulation, as well as to locally applied vibration. Intact hibernators were strikingly more responsive than spinal hibernators to lowering of the ambient temperature and vibration of the testing chamber. Neither intact nor spinal animals responded to warming or cooling of a small area of the skin, or to the proprioceptive stimulus of tilting the cage. In modalities for which the spinal hibernators were not tested, intact hibernators were unresponsive to auditory stimulation and most responsive to alimentary stimulation. Smelling salts and ether were effective olfactory stimuli but extracts of vanilla and anise were not.

In summary, the hibernator will respond, to varying degrees, to a diversity of peripheral sensory stimuli. It is also evident that the various measures of responsiveness are not equally sensitive as indices of subtle changes in the hibernator's level of arousal.

1583 ORGANIZATION OF POSTCRUCIATE NEURONS WITH RESPECT TO SOMATIC MODALITY AND RECEPTIVE FIELD IN AN AWAKE-RESTRAINED CAT. A.L. Towe and J.C. Slimp. Dept. Physiol. & Biophys. (SJ-40), Univ. of Wash. Sch. of Med., Seattle, WA 98195.

Observations from barbiturate preparations form the primary basis for our ideas about cerebral organization. How well these ideas apply to the unanesthetized condition was examined in a cat equipped for chronic extracellular recording by studying the location, size and modality of the somatic receptive fields of neurons within a 20 mm^2 circular area of postcruciate tissue over a seven-month period. In a sample of 542 neurons obtained from 64 parallel electrode tracks (3 with no neurons and 3 with only one), only 391 were responsive to somatic stimulation. Some topographic organization was evident, with neurons having trunk receptive fields located caudomedially and those having forelimb fields located laterally. However, there was extensive overlap and mixing of fields and modalities in all tracks in which more than two neurons were isolated. In the extreme case, neurons with hindlimb receptive fields were occasionally found intermingled with neurons having receptive fields on the wrist, paw, and/or digits of the contralateral forelimb. Often, two or more neurons were recorded simultaneously; in terms of a superficial vs. deep modality partition, the probability of finding mixed modalities was one-fourth, whereas the probability of finding non-overlapping receptive fields between neurons of the same modality was one-third. For sequentially recorded pairs of neurons isolated at increasing distances apart, the probabilities slowly changed in the direction of increasing disorder. As shown in the following table, the changes were slight.

Separation in mm	Modality similarity			Receptive field overlap*		
	Superfic.	Deep	Mixed	Complete	Partial	No
0	.31	.43	.25	.53	.18	.29
0.25	.32	.29	.39	.44	.32	.24
70.4	.29	.29	.43	.25	.25	.50

*Overlap calculated for pairs of the same modality

When calculated in terms of four submodalities (touch, hair, MTJ, and joint only), the probability that a neuron showing one modality will be followed by another of the same modality was slightly higher than chance, suggesting a minor degree of submodality ordering in depth. Consistent with the idea of topographic organization, receptive field location showed greater ordering in depth. However, the data do not show the high degree of spatial organization with respect to location, size and modality of neuronal receptive fields that one is led to expect from previous studies on anesthetized preparations.

1584 COMPARISONS OF PUNCTATE, EDGE AND SURFACE STIMULATION OF SLOWLY ADAPTING SOMATOSENSORY AFFERENTS OF CATS. Charles J. Vierck, Jr. Dept. Physiol., Sch. Med., Univ. of North Carolina, Chapel Hill, N.C. 27514, on sabbatical leave from the Dept. Neuroscience, Univ. of Fla., Col. Med., Gainesville, Fla. 32610.

Action potentials of single peripheral afferents were isolated by dissection of the posterior femoral cutaneous nerve or of dorsal roots supplied by this nerve. Units were characterized in terms of adaptation rate, regularity of discharge, temperature sensitivity, responsivity to skin stretch and receptive field (RF) configuration. Afferent fibers from types I and II slowly adapting (SA) mechanoreceptors were selected for stimulation with a servo-controlled stimulator that reliably delivered indentations of 0.09, 0.4 or 0.8 mm. For each of these intensities, the number of action potentials elicited from 0 to 0.1 or from 1.0 to 1.5 sec after stimulus onset was related to the configuration of the stimulus probe in an unequivocal fashion. For all units of both types, a point stimulus centered on the small uniform RF of a type II unit or on a type I dome produced the highest rate of discharge, and indentation by a flat surface over the entire RF produced the lowest rates. For the flat surface probe similar low rates of discharge were produced by 0.09 and 0.8 mm indentations. In contrast, the rate at 0.8 mm was more than double that produced by 0.09 mm when the point stimulus was used. At all intensities and for both sampling periods, stimulation of a dome or a type II receptor by a probe which placed an edge on the RF elicited discharge frequencies that were intermediate to those obtained with the point and the flat surface. These results suggest that the SA units respond best to local deformations. This could provide a peripheral selectivity for edge as well as point detection. Supported by Grants NS 10321 and NS11132 from NINCDS.

1585 THE EFFECT OF DORSAL COLUMN STIMULATION ON THE NOCICEPTIVE RESPONSE OF DORSAL HORN CELLS. Zsuzsanna Wiesenfeld, Ulf Lindblom,* and Daniel N. Tapper. Dept. Physical Biology and Section of Physiology, New York State College of Veterinary Medicine, Cornell University, Ithaca, NY 14853

Single dorsal horn cells with nociceptive input were studied in urethane anaesthetized flaxedilized cats. The cats were spinalized at L_1 and the cells were recorded in S_1 segment. Most cells were located in Rexed's laminae IV and V; a few were in the marginal lamina I. The majority of the cells received convergent input from low threshold mechanoreceptors as well as nociceptors responding to noxious heat. The effect of single and repetitive electrical stimulation of the ipsilateral dorsal columns on the activity of these cells was examined. The antidromic response of the afferents contributing to the dorsal columns was monitored by recording from the posterior femoral cutaneous nerve. The intensity of the dorsal column stimuli used was typically twice the threshold required to activate the largest diameter fibers.

A single shock to the dorsal columns usually caused short latency orthodromic activation of the cells, followed by inhibition lasting about 100 msec. The orthodromic activation was not, however, necessary, for the inhibition to occur. The stronger the cell was discharging, the shorter was the duration of the inhibition. Prolonged repetitive stimulation at 3Hz had no effect on the cells' ongoing activity or responsiveness to mechanical or painful stimulation. Repetitive stimulation for 3 or 6 minutes at 50Hz had no effect on about 2/3 of the cells. The rest of the cells were less responsive for up to 30 minutes after the cessation of stimulation. These results may indicate that the population of dorsal horn cells receiving nociceptive input is heterogeneous and various subclasses may have different functions in various types of pain.

1586 ALTERATIONS IN THE NEUROPIL OF THE THALAMIC VENTRAL TIER NUCLEI IN THE RAT FOLLOWING LESIONS IN THEIR PRINCIPAL AFFERENT INPUTS.
J. Wells and L.N. Tripp*. Dept. Anat., Univ. Vermont, Burlington, VT 05401.

Based on the delineation of the ventral tier nuclei by McAllister, et al. (this vol.), electron micrographs of the neuropil of the ventral posterior (VPL) and ventral lateral (VL) groups of nuclei were analyzed for population density and volume proportion of synaptic terminals. Because of the relative simplicity of the neuropil of VPL and VL in the rat, synaptic terminals can be grouped into three general categories: 1. small terminals with round vesicles and asymmetric densities (type S); 2. large terminals with round vesicles, asymmetric densities and often a partial glial capsule (type L) and 3. terminals of widely varying sizes that contain flat or pleomorphic vesicles (type F). Alterations in the normal neuropil were determined following lesions of the dorsal column nuclei (DCN), the deep cerebellar nuclei (Cb) and the sensory-motor cortex which are the principal afferent inputs to these thalamic nuclei.

Eighty percent of VPL terminals were type S, 10% were type F and slightly less than 10% type L. The volume of type S and type L terminals was approximately equal. Some type S terminals were of cortical origin and synapsed on small dendrites. The type L terminals were primarily largely of DCN origin and synapsed on proximal dendrites and cell bodies. These observations confirm the results of others. Some type L terminals did not degenerate following nearly complete DCN lesions, and only 20-25% of the type S terminals degenerated following extensive cortical lesions.

Although the population density of terminals is approximately equal in VPL and VL, VL contains many more type F terminals and fewer type L terminals. Cerebellar lesions cause about half of the type F terminals (7-10% of the total number of terminals) in VL to degenerate. Thus, the majority of synapses in both VPL and VL seem to originate from sources other than their principal afferent inputs. We will attempt to correlate these data with a similar analysis of the central intralaminar nucleus currently in progress.

1587 PHYSIOLOGICAL ORGANIZATION OF THE RAT CORTICAL BARREL FIELD FOLLOWING NEONATAL VIBRISSAL DAMAGE.
Carol Welt, Res. Dept., Central Wisconsin Center for the Developmentally Disabled, Madison, WI 53704.

Normal anatomical arrangements of cortical barrels are disrupted by neonatal damage to the mystacial vibrissae in mice and rats. The present experiments were carried out to determine if modified physiological projections accompany these morphological alterations. Vibrissal follicles in rows B and D or row C alone were cauterized in rat pups on the day of birth. When these animals were at least 120 days old the contralateral cortical barrel field was extensively mapped under urethane anesthesia with tungsten microelectrodes. All brains were sectioned tangentially, parallel to the layer IV barrelfield.

Vibrissae did not regrow in 75% of the cauterized follicles. The gaps left on the face by the missing vibrissae were occupied by down hairs. In many cases there were no corresponding gaps between the cortical projections from the intact vibrissal rows. Thus, when row C was missing the projections from row B were contiguous to those from row D. Sometimes there were narrow silent zones where the missing vibrissae would normally project. Most of the vibrissae which regrew in cauterized follicles did not activate any cortical neurons. Cortical areas that did receive projections from such regrown vibrissae were much smaller than normal. Cortical areas for the intact vibrissae adjacent to cauterized follicles increased in size, but these increases were not equal to the size of the normal projection area for the cauterized row.

Nissl-stained sections of these brains showed that in all cases there were five rows of morphologically distinct barrels. Cauterization of vibrissal follicles in one or more rows did not eliminate the corresponding row(s) of cortical barrels. These barrel rows may be reduced in size, but there does not appear to be a significant expansion of the barrels for the intact vibrissae into the territory of barrels for cauterized vibrissae. These experiments show that the increases in the cortical projection areas for intact vibrissae do not result primarily from increases in the size of their morphologically defined barrels. Rather, these results suggest that subsequent to neonatal vibrissal damage in rats, some of the cortical neurons in the corresponding barrels may become activated by projections from adjacent vibrissae.

1588 NATURAL LOSS OF MILK TEETH CAUSES DEGENERATION IN BRAIN STEM.
Lesnick E. Westrum, Departments of Neurological Surgery and of Biological Structure, Univ. of Washington, Seattle, Washington 98195 USA

Contrary to usual notions, recent studies show that degeneration of central processes occurs after lesions to their peripheral branches and preliminary results reported here indicate further that central degeneration may occur as a natural process. Tooth pulp extirpations in adult cats result in transganglionic axonal degeneration in the spinal trigeminal nucleus (Westrum et al., 1976 Brain Res., 101:137). Therefore since resorption of deciduous teeth causes degeneration of the peripheral axons innervating the teeth (Karlsson et al., 1974 J. Dent. Res., 53: 1428) then exfoliation of milk teeth might be expected to produce transganglionic degeneration in the brain stem trigeminal nuclei. Thus far 8 young cats between 3-9 months of age, and at various stages of exfoliation of deciduous and eruption of permanent teeth, are being used to study the possible degeneration patterns in the brain stem. Animals are perfused with buffered formalin and frozen sections are made in the transverse plane throughout the brain stem to include the entire trigeminal nuclear complex. Serial sections (1 in 12) were stained with reduced silver methods for degenerating axons and terminals (Nauta-Gygax and Fink-Heimer). By 6 months of age, when the milk teeth are actively exfoliating, axonal degeneration can be seen bilaterally in the spinal trigeminal nucleus. The distribution is principally in the ventral part of pars interpolaris and adjacent rostral pars caudalis, near the level of obex and may be more dense on one side than the other. Rostrally pars oralis and the main sensory nuclei are free of degeneration. The amount of degenerative material is reduced and eventually disappears in older animals. The pattern and distribution of the degeneration is similar to that observed in adult cats, 11-14 days after total unilateral pulpectomies that likewise decreases in amount with time. The results show that transganglionic degeneration of central sensory processes does occur in brain stem as an apparent consequence of the natural process of tooth replacement (resorption, exfoliation and eruption) and that the CNS representation for at least part of the innervation of the milk teeth may be similar to that of mature tooth pulps. Also remodelling or reinnervation by the central sensory processes may be occurring along with the changes in peripheral innervation during tooth replacement especially since the degeneration disappears after exfoliation and reappears in the same area following pulpectomies in adults. (Aided by NIH Grants NS09678 and NS04053. The author also acknowledges the technical assistance of Bruce F. Miller, Ph.D.).

1589 PERSISTENCE OF MOTION SENSE AFTER JOINT RECEPTOR BLOCK
W.J. Williams, R.W. Bossemeyer*, E. Kokmen
Bioelectrical Sciences Laboratory and Department of Neurology University of Michigan, Ann Arbor, MI 48109

Joint receptors have been considered to be the primary and possibly exclusive mediators of position and motion sense until recently. Recent reports have forced a reconsideration of this view and drawn attention to the possible role of muscle receptors as well. In the past, claims have been made that occlusion of the blood supply to the hand or anesthetic block of the finger joint abolished position and motion sense in the joint. We have devised a procedure that permits motion sense threshold to be continuously monitored for long periods of time so that the effects of occlusion or anesthesia could be followed during various phases of the altered condition. The finger joint (metacarpophalangeal joint of the index finger) was articulated sinusoidally (at 0.5 Hz in most cases). The intensity (amplitude) of the sinusoidal stimulus was slowly increased until the subject felt the motion, whereupon the closure of a switch by the subject caused the intensity of the stimulus to decrease. When the subject no longer felt the motion the switch was opened and the stimulus intensity again increased. This is similar in principle to the von Békésy audiometric technique.

When the upper arm cuff and wrist cuff were inflated (250 mmHg) the motion sense threshold gradually increased from the normal value of about 1° to a point where motion sense was completely lost. When the arm cuff was removed and the wrist cuff was left in place, motion sense returned as reflected by a threshold of about 3°. Blood flow was monitored by use of plethysmographic techniques, insuring complete blockage of flow to the hand. Pin pricks, von Frey hairs, blunt objects and tuning forks were used to assess the degree of loss of sensation in the hand. Motion sense returned even when the hand remained completely anesthetic after removal of the upper arm cuff.

Similar differences between normal and digital nerve block conditions were observed. In this case the first interphalangeal joint was used. 8-10ml 2% Xylocaine was injected to create a ring block proximal to the joint. Again, sensory assessment insured loss of sensation in the vicinity of the joint after nerve block.

These results are taken as support of the hypothesis that joint receptors are not the exclusive mediators of motion sense. Receptors in muscle or tendons must contribute as well.

Supported by USPHS Grant NS 08470

1590 THE THALAMOCORTICAL SYSTEM OF THE RAT SOMATIC SENSORY CORTEX: ORGANIZATION, DEVELOPMENT, AND CONNECTIONAL SPECIFICITY.
S.P. Wise. Dept. Anat. and Neurobiol., Washington Univ. Sch. of Med., St. Louis, Mo. 63110

Autoradiographic and axonal degeneration fiber tracing studies demonstrate that thalamocortical fibers entering the first somatic sensory cortex (SI) of the adult rat are: (i) distributed mainly to layers VI, IV, and I; (ii) found exclusively in those parts of SI which contain dense aggregates of layer IV granule cells, not in the surrounding and intervening, less granular (but commissurally connected) parts; (iii) distributed in column-like clusters, 250-450 μm in width, throughout the entire extent of the granular aggregates in layer IV and in the subjacent parts of layer VI.

Thalamocortical fibers reach the presumptive layer IV early in cortical development, towards the end of the third postnatal day. The adoption of a generally mature pattern of distribution occurs before layer IV becomes clearly distinguishable from the supragranular layers, before the granule cell aggregates appear, and about 3-4 days before the commissural fibers reach the less granular parts of SI.

The potential interaction between developing commissural and thalamocortical fiber systems was examined by removal on the first or second postnatal day of either the commissural system (by hemidecortication or commissurotomy) or the thalamocortical system (by thalamotomy). In neither case did the laminar or spatial organization of the remaining afferent fiber system show any abnormality when examined experimentally in the mature animal. These findings suggest that both the thalamocortical and commissural fibers specifically form connections with a certain cell class at a particular depth in the cortex, even in the absence of the terminals of a nearby afferent fiber system. The connectional specificity seen in the neocortex contrasts markedly with the plasticity of afferent connections in the allocortex.

In the absence of thalamic input, the cortex shows a slight (13%) reduction in the combined thickness of the granular and supragranular layers. The granule cell aggregates develop to the same horizontal extent as in the normal. Within them, however, subsidiary groupings, such as the "barrels", fail to acquire their definitive form, indicating that only this finer aspect of cortical cytoarchitecture is dependent upon thalamic connectivity.

(Supported by grants NS10526 and EY00092 from the N.I.H.)

1591 RESPONSE PROPERTIES OF SUBSTANTIA GELATINOSA NEURONES IN THE CAT.
Tony L. Yaksh, Patrick D. Wall* and Eugene G. Merrill*. Dept. of Anatomy, University College London, England.

The substantia gelatinosa rolandi (SG) contains many small cells and is penetrated by primary afferents as well as the dendrites of more deeply lying cells. This region may function as an important link in the primary afferent pathway. Yet, the uniformly small size of the cells has made it difficult to record their response properties. With the use, however, of glass coated, platinum-plated, tungsten microelectrodes, we have been able to record reliably the responses of 308 cells located in the SG of the cat. Animals were rendered decerebrate, or decerebrate-spinal while body and cord temperature, blood pressure and arterial pO_2 were monitored and maintained throughout the experiment. Two search procedures were used: 1) the electrode was inserted and spontaneously active (SA) cells were examined (161 cells); 2) penetrations were made while the adjacent Lissauer tract (LT) was stimulated at 1 Hz. In this latter procedure, 56 cells were antidromically driven (followed with a fixed latency of 0.5 - 3 msec) while 91 cells were orthodromically driven (variable latency of 2 - 5 msec and failed to follow at 2 - 10Hz). As the general response properties of cells obtained by either procedure were similar, it appears likely that either approach was sampling from the same cell population. Three unusual types of cell were observed. 1) Small field cells. These units had RFs up to 1.5 cm^2. Often clusters of these cells having small overlapping fields could be noted. We excluded the liklihood that these cells were afferent fibres by virtue of their SA, variable latency upon electrical stimulation of the RF and their inability to follow high frequency stimulation. Penetration through these cell clusters often revealed deeper cells with larger RFs which encompassed the RF of the more dorsal cells. 2) Habituating cells with variable RF field size. 43 units showed marked habituation. In the extreme, a single brush failed to elicit a second response if tested in less than 5 - 10 sec. In several units, the RF appeared to have a variable portion which showed marked transient habituation and a second portion which showed little habituation. 3) Prolonged discharge cells. We observed 56 cells in which a single brush produced stable discharges lasting for several seconds to several minutes. Barbiturates blocked the prolonged discharge. The great majority of cells responded to brush or brush touch and pressure but 59 cells required heavy pressure or pinch of their RF before responding. No cells were detected which responded only to unmyelinated afferents.

1592 IDENTIFICATION OF UNMYELINATED FIBERS IN THE TRIGEMINAL MOTOR ROOT OF HUMAN AND CAT.
Ronald F. Young and Richard T. Stevens*. Dept. of Neurosurgery, Upstate Medical Center, Syracuse, NY 13210

Recent work has focused on the fiber spectrum of spinal ventral roots in various animals. Particular interest has been paid to the identification of unmyelinated fibers since the ventral spinal roots are considered to be primarily motor in function while unmyelinated or C fibers are commonly thought of as being sensory in nature. Specifically, unmyelinated fibers have long been related to the perception of pain. Although unmyelinated fibers have been identified in significant numbers in spinal ventral roots at different segmental levels, there as yet has been no similar analysis of the fiber spectrum of the trigeminal motor root.

In this study, trigeminal motor roots from cat and human autopsy material were fixed and embedded for electron microscopy. Whole root fiber counts of myelinated fibers were obtained by light microscopy of thick sections. Electron microscopy was employed to obtain fiber ratios of myelinated and unmyelinated fibers. The spectrum of fiber diameters in each individual root was determined by the use of a computerized digitizer. Using this method each fiber to be measured was traced with a stylus. This value was automatically entered into a computer for calculation of fiber diameter, computation of histograms and statistical analysis when desired.

The results reveal the presence of unmyelinated fibers in the trigeminal motor root of both species. Such fibers have not previously been reported. A considerable variation in the ratio of myelinated to unmyelinated fibers exists between animals but consistent ratios are present within each species. In the human trigeminal motor root unmyelinated fibers comprise approximately 24% of the total fiber population while in the cat trigeminal motor root the unmyelinated fibers comprise approximately 11%. These results are similar to those reported for spinal ventral roots.

Classical physiological concepts consider the spinal ventral roots and trigeminal motor root to relate exclusively to motor function. The finding of unmyelinated fibers in spinal ventral roots and our confirmation of their presence in the trigeminal motor root has cast considerable doubt on this hypothesis. The findings suggest a partial sensory function for "motor" roots. The occasional failure of trigeminal sensory rhizotomy to provide effective relief of facial pain and the relatively frequent later recurrence of pain will be discussed in relation to the unmyelinated fibers demonstrated in the trigeminal motor root.

SPINAL CORD

1593 DISTRIBUTION OF ^{3}H NOREPINEPHRINE AFTER LOCAL INJECTION OF ^{3}H DOPAMINE PRECURSOR INTO THE SPINAL CORD OF THE CAT. John L. Alderman, Jewell L. Osterholm, John D. Irvin, Lucas J. Martinez*. Dept. Neurosurgery, Thomas Jefferson Medical College, Phila., Pa. 19107.

Although radiolabelled neurotransmitter precursor loading of the brain for turnover and metabolism studies can be attained through intraventracular injection with relative ease, precursor loading of the spinal cord through comparable routes (cisternal or lumbar) is much less efficient. To circumvent this problem for spinal norepinephrine (NE) studies ^{3}HDA (10uci/10ul) was injected stereotaxically into the medullary portion of the thoracic (T8) cord at the rate of 1ul per minute. After 60 minutes the injected cord region was removed, divided into grey and white matter and cut into 2mm subsections along the cord axis. The ^{3}HNE and ^{3}HDA precursor was then isolated and separated by conventional methods and estimated by liquid scintillation spectrophotometry. Endogenous NE levels for calculation of the specific activity (SA) were determined radioenzymatically. While only 11% of the total cord ^{3}HDA and 12% of ^{3}HNE was found in the white matter compared to 89% and 88% for the grey, the specific activity of ^{3}HNE in the two regions were 40 and 60% respectively, because of the greater endogenous NE concentrations found in the grey. By 60 minutes, ^{3}HDA, was 31% converted to its ^{3}HNE product in the white, and 40% in the grey. Thirty-six percent of the total radioactivity (^{3}HNE + ^{3}HDA) was confined to the first 2mm of injection, and the remainder descended logarithmically for at least another 8mm above and below the injection site. The data suggests that the thoracic axons take up and metabolize endogenously administered precursor nearly as efficiently as the nerve endings. Furthermore, local injections of ^{3}HDA precursor appears to be the route of choice for the study of ^{3}HNE turnover and metabolism in the spinal cord.

1594 THE DORSOLATERAL FUNICULUS OF THE SPINAL CORD: A MAJOR ROUTE FOR DESCENDING BRAINSTEM CONTROL. Allan I. Basbaum and Howard L. Fields, Depts. Anat. and Neurol., UCSF, San Francisco, CA. 94143.

Previous anatomical studies have emphasized that ventral spinal pathways are the predominant locus of brainstem-spinal axons. Recent autoradiographic analysis (Basbaum et al, PNAS, 1976), however, has demonstrated a significant medullospinal projection in the dorsolateral funiculus (DLF). To more precisely determine which brainstem cell groups contribute axons to dorsal vs. ventral spinal pathways, the present study was undertaken.

The thoracic and lumbosacral cord was exposed in barbiturate-anesthetized cats. Large bilateral injections (40μl) of a 50% solution of horseradish peroxidase (HRP) were placed in the L6-L7 lumbar spinal segment. At the same time, partial spinal cord lesions were made at upper thoracic levels. The lesions resulted in selective interruption of retrograde transport of HRP from the lumbar cord to the brainstem and thus delineated the pathways by which brainstem neurons project to the spinal cord. The spinal lesions included: unilateral DLF; bilateral DLF; dorsal hemisection; ventral hemisection; lateral hemisection plus contralateral section of the ventral and ventrolateral funiculus. In the latter, the dorsal columns were sectioned bilaterally, thus isolating one DLF. Retrograde transport of HRP was demonstrated with hydrogen peroxide and o-dianisidine according to the technique of de Olmos.

Cell bodies with axons in the ventral and ventrolateral funiculi are located in the medial and lateral vestibular nuclei. Scattered cells were also found in medullary reticularis paragigantocellularis, gigantocellularis, pontis caudalis and oralis. Raphe pallidus and obscurus project primarily via ventral pathways as do a few cells in the locus caeruleus.

The most striking observation was the large numbers and wide distribution of brainstem neurons contributing axons to the DLF. These include cells in the ipsilateral hypothalamus, Edinger-Westphal nucleus, and large numbers in subcaeruleus and reticularis magnocellularis (lateral to the raphe magnus). Paragigantocellularis, locus caeruleus, parabrachialis, retroambiguus and the solitary nucleus also send axons in the DLF, some of which course in the contralateral DLF. Numerous cells in the raphe magnus, but far less in raphe pallidus contribute axons to the DLF. Cells of the red nucleus (pars magnocellularis and parvocellularis) and a discrete paralemniscal region of the pontine reticular formation send axons exclusively in the contralateral DLF. These data underscore the importance of the dorsolateral funiculus in transmitting a profound and diverse source of brainstem modulation of spinal neurons. Supported by NS-70777, 11529, 05272, 11614.

1595 ROLE OF DORSAL RADICULAR ARTERIES IN RECOVERY OF FUNCTION AFTER DEAFFERENTATION. A.J. Berman, A. Marty* & A.S. Rothman*. Veterans' Administration Hospital, Bronx, N.Y.

Although considerable purposive movement remains after section of the dorsal roots serving the forelimbs in the monkey, there is much variation between animals in their postoperative status. Not only are there differences in rate and degree of recovery of movement sequences with the affected forelimbs but, in addition, some animals develop weakness of the hindlimbs while others do not. The hindleg weakness, when it occurs, may appear immediately after surgery or may develop slowly during the postoperative period.

It has been reported that preservation of the radicular vessels embedded within the root fibers results in more rapid recovery of function than when they are sectioned during dorsal rhizotomy. The present study was undertaken to test whether either the degree and rate of recovery of forelimb function or the maintenance of hindlimb function was related to the degree of interference with the dorsal radicular blood supply to the cord during surgery. Fourteen M. mulatta were subjected to bilateral dorsal rhizotomy C2-T3. In seven cases, the dorsal radicular arteries were spared while in the other animals the vessels were sectioned with the roots. This phase of the surgery was performed under 16 and 25 power magnification.

Weakness of the hindlimbs occurred in two of the seven animals in which the vessels were sacrificed but was not present in any of those in which the vessels were spared. As far as forelimb function was concerned, however, no differences between groups were noted.

All animals were perfused with micropaque solution at the time of sacrifice and x-ray examination of the vasculature of the spinal cord was performed. Those animals which developed weakness of their lower extremities were found on histological examination to have degeneration in the pyramidal tracts.

Results of this study indicate that sacrificing the dorsal radicular arteries during C2-T3 dorsal rhizotomy does not contribute to the degree of neurological deficit in the forelimbs consequent to the deafferentation, but may result in long tract involvement, thus affecting function well below the level of the lesion.

1596 EFFECT OF PARACHLOROPHENYLALANINE ON BLOOD FLOW IN THE TRAUMATIZED SPINAL CORD. Robert A. Brodner and Robert H. Roth. Sect. Neurosurg., Dept. Surg. and Dept. Neuropharm., Yale Sch. Med., New Haven, Conn. 06510.

In recent studies (Br Res 118: 348, 1976) we have demonstrated a significant correlation between elevated cerebrospinal fluid (CSF) serotonin and reduced intramedullary blood flow following experimental spinal cord injury. In an effort to increase post-traumatic spinal cord perfusion and, thereby, inhibit ischemic changes, serotonin was depleted by pretreatment with parachlorophenylalanine (PCPA), a serotonin antagonist, and the resultant effect upon intramedullary blood flow was studied.

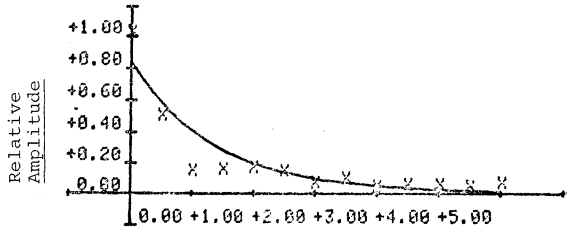
Thirty adult cats were pretreated 48 hours prior to the experiment with PCPA (400mg/kg) and then their thoracic spinal cords were contused with a 500gm-cm force. Control animals were traumatized at the same injury level, but received no PCPA. At various time intervals up to 1 hour after trauma, CSF serotonin concentrations were assayed and the intramedullary blood flow patterns were studied by the thioflavine S fluorescent technique.

A statistically significant decrease in CSF serotonin was noted in all the PCPA treated cats as compared to the untreated controls. The post-traumatic reduction in spinal cord blood flow seen in the control group was reversed in the treated animals to a state of normal perfusion.

In this study, prevention of the post-traumatic rise in CSF serotonin by PCPA has been correlated with improved microcirculatory dynamics within the traumatized spinal cord, demonstrating that the decreased blood flow and attendant ischemia associated with spinal cord injury may be amenable to pharmacological therapy.

1597 TRANSMITTER TURNOVER IN THE MONOSYNAPTIC SPINAL PATHWAY OF MAN. A.A. Buerger and B. Sherman*. Depts. of Physical Med. & Rehabilitation and Physiology, California Coll. of Med., Univ. of California, Irvine, CA 92717.

In an attempt to determine the rates of release and replenishment of the transmitter involved in the monosynaptic spinal reflex, we have studied the exponential decay of the H reflex and the M reflex in the gastrocnemius-soleus of man due to trains of 16 stimuli. Trains were delivered at rates ranging from 0.25 Hz to 5 Hz and the areas under the M and H responses were calculated. At any one frequency for four trains the average area of each of the 16 M and H responses was calculated and exponential decay curves were fitted to the 16 averaged areas. (See example below):



The rate of decay of the H reflex (as well as the rate of decay of the ratio between the H and M reflexes) increase with the frequency of the stimulus train. This decay probably is due to homosynaptic depression and the parameters of the exponential curve can therefore be used to calculate the rate of transmitter turnover in the monosynaptic spinal pathway of man. We have done this, using the methods of Esplin et al (e.g. J. Neurophysiol. 40:95-105, 1977). An analysis of the available data suggests that both release and replenishment of the transmitter for this monosynaptic reflex are linearly related to stimulus frequency and that, at comparable frequencies of stimulation, the values we have calculated for humans are of the same order of magnitude as those which have been obtained in other vertebrates.

1598 NONLINEAR ANALYSIS OF DORSAL HORN CELLS. Arthur D. Craig, Jr. and Daniel Tapper, Dept. of Physical Biol. and Section of Physiol., N.Y.S. Coll. Vet. Med., Cornell Univ., Ithaca, NY 14850

In order to overcome limitations in the use of the Poisson impulse train variant of the Wiener nonlinear analysis method, due in part to axonal refractory periods, a new technique has been devised for the dynamic analysis of neural pulse-input/pulse-output (nonlinear) systems. By utilizing an input pulse train which is a Bernoulli series of (geometrically distributed) intervals, it has been shown that a nonlinear system may be modeled by a set of orthogonal functionals similar to the Poisson-Charlier functionals, and whose kernels may be estimated by cross-correlation. Following implementation on a PDP-11/05-GT40, the technique has been applied in the spinal cat, using input trains of varied mean and modulus. Input pulses are used to electrically elicit action potentials in single afferent fibers innervating Type I cutaneous receptors (Haarscheiben, HS). Responses of monosynaptically connected lamina IV-V dorsal horn cells (DHC) are recorded extracellularly, and digitilized as interval sequences. The HS-DHC system kernel estimates are presently computed up to the second order, and the model responses to single pulses (linear kernel) and pulse pairs of several interstimulus intervals plotted. The latter compare favorably to PST's generated by the classical condition-test paradigm. Inspection of model output suggests dynamic system dependence on mean input pulse rate, as well as other indications of third or higher order system characteristics. For example, the inhibitory period often observed following the monosynaptic response can deepen and occur with shorter latency as the input mean is increased, even to the point of occluding any preceding facillitatory period. Examples of late facilitation (15-100 msec) have also been observed for close pulse pairs, where the classical two-pulse PST gave little indication of such a phenomenon. Compared to the classical paradigm, this technique acquires more information characterizing a neural system in less time, and, further, is readily adapted to multi-input and cascaded systems. Nonlinear system models will be used to generate generalized models of DHC operation.

1599 COMPENSATORY CHANGES IN MOUSE SCIATIC NERVE FOLLOWING CONTRALATERAL NERVE DAMAGE. Richard A. Gerren*, Douglas E. Groswald*, and Marvin W. Luttges. Aero. Eng. Sciences, Univ. of Colorado, Boulder, CO 80309.

Neurophysiological and neurochemical analyses were used to study the changes in mouse sciatic nerves as a consequence of damage to the contralateral sciatic nerve. Sodium dodecyl sulfate-polyacrylamide gel electrophoresis separations of whole sciatic nerve proteins revealed transient changes in relative protein concentrations of the undamaged nerves. Such changes occur within one week after damage to the contralateral nerves. During the same time period electrically-elicited responses in the undamaged nerves differ from responses of control nerves tested in mice which had sustained no nerve damage. The experimental nerves exhibit considerable changes in relative refractoriness when tested with paired electrical stimuli of variable interstimulus intervals. Spinal influences are implicated in these altered response characteristics since removal of such influences by proximal nerve sectioning results in loss of the effect. Transpinal alterations in excitability and electrophoretic alterations in protein composition are both consistent with compensatory spinal changes induced by contralateral nerve damage.

1600 PROJECTIONS AND ORIGINS OF THE SPINOTHALAMIC TRACT IN THE RAT. Glenn J. Giesler, Jr., Allan I. Basbaum and Daniel Menétrey*. Dept. Psych., UCLA, Los Angeles, CA 90024 and Depts. Anat. and Physiol., UCSF, San Francisco, CA 94143.

In an earlier study (Giesler et al., Brain Res. 118: 320, 1976), antidromically identified spinothalamic tract (STT) neurons in the rat were found to be widely distributed throughout the dorsal horn and intermediate gray zone of the lumbar enlargement. Interestingly, it appeared that STT cells located within the intermediate zone with non-cutaneous receptive fields tended to be activated only from midline thalamic structures. At the same time, STT neurons encountered within the dorsal horn having response properties characteristic of that area were activated uniformly from lateral thalamus. To pursue this apparent dichotomy of thalamic afferents, we have used the retrograde transport of horseradish peroxidase (HRP) to assess projections and origins of the STT.

Injections of .05 to 0.1μl were made in various thalamic areas. Retrograde labeling of STT neurons was examined following treatment with either diaminobenzidine or o-dianisidine (J. de Olmos) reaction techniques.

HRP injections into the intralaminar group produced labeling which was restricted to the intermediate zone and ventral horn at all spinal levels. STT cells were found bilaterally only in upper cervical segments. A discrete grouping of neurons was located in the ventromedial aspect of the dorsal horn in segments L3-6. A similar but less dense pattern of labeling throughout the cord was achieved following injections into more anterior medial thalamic areas (medial dorsal n., central lateral n.).

Injections filling the ventral posterior lateral n. produced a strikingly different distribution of STT neurons. In upper cervical segments, particularly dense groups of cells were found in the caudal extension of the dorsal column nucei. Many neurons were also found within the lateral white matter which appear on cellular morphological grounds to be the lateral cervical n. Less dense labeling was produced in C1-3 in the ventral horns bilaterally. In the cervical enlargement and thoracic cord, HRP-positive cells were found almost exclusively in the dorsal horn. Labeling in the lumbar cord was also encountered within the dorsal horn, including the ventromedial area of L3-6 identical to that labeled by medial thalamic injections.

Together with our earlier findings, these data suggest that in the rat the STT carries cutaneous and non-cutaneous somatic information separately in pathways having different cells of origin and terminal projections.

1601 THE FILUM TERMINALE OF THE FROG SPINAL CORD: GABA UPTAKE BY A NON-TRANSFORMED GLIAL PREPARATION. S. Glusman, M. Pacheco* and B. Haber, Depts. of Physiology and Cell Biology, Centro de Investigacion del IPN, Mexico, and the Marine Biomedical Institute, University of Texas Medical Branch, Galveston, Texas 77550.

In the tadpole, the tail is innervated by motor neurons present in the terminal segments of the spinal cord. During development leading to metamorphosis, the tail is resorbed, and the majority of the neuronal elements involved in its innervation degenerate. The resulting structure after metamorphosis is the frog filum terminale (FT); this is that portion of the spinal cord which extends caudally beyond the level of the last spinal root. The frog FT has been shown to consist of a few motor neurons, some descending fibers, relatively few ependymal cells and to a large extent glia. The glia are the predominant cell type in the FT, and have astrocytic like morphology. We have studied the regional distribution of GABA uptake in the frog spinal cord, in comparison to the filum terminale, as well as in the spinal cord of the developing tadpole. AOAA (10^{-4}M) was included in the incubation medium, and better than 95% of intracellular radioactivity is present as GABA. The uptake of GABA in the frog spinal cord is mediated by a saturable, high affinity, Na^+ dependent mechanism. As one proceeds caudally beyond the level of the last spinal root, the velocity of the GABA uptake increases markedly, and in the caudal portion of the FT it is three times higher than in any other portion of the frog cord. A similarly increased uptake in the FT is also observed for glycine, taurine and ß-alanine. In the tadpole during early stages of development, GABA uptake is similar in all segments of the spinal cord. However, during the later stages of development, GABA uptake in the most caudal portion of the tadpole cord increases dramatically, and approaches the rates seen in the FT of the adult frog. Frog FT segments incubated with ^{3}H-GABA ($2X10^{-7}$M) were fixed in 2.5% glutaraldehyde in 0.1M cacodylate buffer, and sections were prepared for light and electron microscope radioautography. The radioautographic studies clearly show extensive labelling of the glial cells, as well as labelling of the ependymal cells. The latter however represent only a very small percentage of the overall FT cellular population. In summary, the frog FT represents a unique non-transformed glial preparation which can be used to advantage to study the accumulation of neuroactive amino acids and other properties of normal glia.

1602 THE EFFECTS OF PROGRESSIVE HYPERCAPNEA ON SPONTANEOUS POLYNEURONAL ACTIVITY IN THE CHICKEN EMBRYO SPINAL CORD. T. J. Gonya* and B. T. Stokes (SPON: E. K. Michal). The Ohio State University, Columbus, Ohio 43210.

Neurogenesis of the motor neuropil in the chicken embryo is characterized by peak frequency in multiunit spontaneous activity (bursts) at about day 13, which subsequently decline until day 19 of development. Several lines of evidence have suggested that the emergence of active inhibitory neural circuits is responsible for this modulaton of polyneuronal activity. The effects of changes in respiratory gases (PO_2, PCO_2) on spontaneous neural activity in lumbosacral spinal cord have been investigated late in chick development (14 to 19 days). Polyneuronal burst frequency was monitored while five minute pulses of altered gaseous environments were applied to the embryonic environment. The effect of an initial CO_2 pulse has been studied and reported previously. 3,1, or .5% CO_2 has been shown to depress activity at 14 and 16 days. However, in 19 day old embryos, .5% CO_2 actually enhances burst activity; while 1 and 3% CO_2 pulses will still inhibit ongoing activity.

In addition to the above, data has now been collected on the effects of multiple hypercapneic episodes on burst activity. Consequtive pulses of 3, 1, or .5% CO_2 appear to produce less of an effect on polyneuronal discharges when compared to an initial pulse. Low doses of CO_2 may transiently increase neural activity between pulse periods (.5% CO_2 was seen to enhance activity during a second pulse). However, with one exception, burst frequency was seen to decline significantly throughout subsequent interpulse periods.

The data suggest that hypercapnea does influence the polyneuronal activity patterns recorded in chicken embryo spinal cord. The response is clearly dependent on concentration and age of the ambryo, and may be related to the blood gas changes which occur throughout normal development.

1603 SPINAL PROJECTIONS FROM THE DORSOLATERAL PONS-LOCUS COERULEUS AND ADJACENT RETICULAR FORMATION-A LIGHT AND ELECTRON MICROSCOPIC STUDY. G.E. Goode, J.W. Atkinson*, G.F. Martin and K.A. Crutcher, Dept. Anat., Sch. Med., The Ohio State University, Columbus, Ohio, 43210.

Following horseradish peroxidase injections into lumbar, thoracic or cervical spinal cord, reaction product can be localized in neurons of the rostral pons, specifically, the locus coeruleus and locus coeruleus pars alpha and in the adjacent reticular formation of the North American opossum. As in other mammals the catecholamine content of these neurons can be made to fluoresce. Autoradiographic labelling was plotted in the spinal cord following injections of [^{3}H] amino acids that cover the locus coeruleus, locus coeruleus pars alpha and adjacent reticular formation. In cervical segments, label was found over axons in the white matter. These labelled axons form a continuous peripheral band that arches from the dorsolateral fasciculus to the ventral median fissure. These axons were separated from the external limiting membrane by unlabelled axons. Terminal label was found along the reticulated periphery of the gray matter and overlapped the location of fluorescent varicosities seen in the spinal cord. A similar pattern of degenerating axons was found in cervical and lumbar cord two days after stereotaxic lesions which destroyed part of locus coeruleus or an area just medial to the nucleus. A band of degenerating myelinated axons (3-15µ in diameter) extended from the anterolateral quadrant, around the periphery of the ventral funiculus and well into the septomarginal white matter. Degenerating terminals could not be found in spinal gray following survival times of 48 hours, although degenerating axons and preterminal fragments were identified. Degenerating terminals have thus far been identified on intermediate and distal dendritic shafts in the marginal neuropil of the ventral horn as early as 20 hours after rostral pontine lesions. Rapid degeneration of myelinated axons in cervical and lumbar spinal cord following brainstem lesions has not been generally recognized.

1604 EXPERIMENTAL SPINAL CORD TRAUMA: PATHOPHYSIOLOGY OF THE ACUTE STAGE. Patricia A. Grady, Otis R. Blaumanis*, John T. Lucas*, S. Kumar Jirge* and Erland Nelson. Dept. of Neurol., Sch. Med., Univ. of Maryland, Baltimore, Md. 21201.

The pathophysiology of acute experimental spinal cord injury was studied in mongrel dogs lightly anesthetized with nitrous oxide in oxygen. The spinal cord was exposed by laminectomy and traumatized at the C_2 level by dropping a weight (600-1200 gm. cm. impact). Blood pressure, heart rate and respiratory rate were monitored during the experiments. Animals were maintained on a respirator following the trauma. Dogs were perfused through the heart with 2.5% buffered glutaraldehyde immediately, and at one, two and six hours after injury. Spinal cords were removed and prepared for light, transmission (TEM) and scanning electron microscopy (SEM).

Apnea and bradycardia occurred immediately after spinal cord injury. An increase in systolic and diastolic blood pressure which occurred within seconds persisted for several minutes.

Gross observation revealed moderate to severe hemorrhage on the dorsal surface of the cord as well as in the underlying gray matter at the site of injury. This hemorrhage was usually not apparent or minimal when animals were perfused immediately after the injury. Correlative SEM demonstrated thrombus formation in dorsal and anterior spinal arteries. Patchy endothelial desquamation with platelet aggregates as well as frank thrombosis were observed. Consistent hemorrhagic non-perfusion was observed in areas of gray matter underlying the site of injury. Thrombi were also observed in intraparenchymal vessels.

These observations suggest that the cardiovascular and respiratory responses described occur as a direct result of the initial impact to the spinal cord and that thrombi and vascular occlusion occur secondary to direct injury to blood vessels. Vascular injury may play a primary role in the pathogenesis of traumatic myelopathy.

1605 GLUCOCORTICOID EFFECTS ON SPINAL CORD FUNCTION. Edward D. Hall, Thomas Baker and Walter F. Riker, Jr. Dept. Pharmacol., Cornell University Medical College, New York, N.Y. 10021.

The effects of intensive glucocorticoid dosing on segmental spinal cord function in cats have been studied. Adult cats were treated with triamcinolone (8 mg/kg) intramuscularly once daily for seven days. On the first post-treatment day segmental spinal reflexes in the lumbar cord were examined. Under halothane, a tracheotomy was performed and the spinal cord transected at C1. Anesthesia was terminated and positive pressure ventilation with room air begun. A dorsal laminectomy exposed segments L4 to S2. The popliteal fossa of one leg was dissected to expose peripheral nerves for stimulation. All reflex responses were recorded at ventral root L7. Complete neuromuscular paralysis was maintained with gallamine.

As a result of the triamcinolone pre-treatment, polysynaptic discharge was significantly enhanced. Single monosynaptic (2N) transmission at 0.2 Hz was increased, but not significantly. Paired stimuli disclosed that the rate of 2N recovery after single impulse transmission was greatly improved in glucocorticoid animals. Consistent with this was the fact that the 2N pathway in treated preparations was better able to maintain repetitive transmission at 50 Hz. 2N Post-tetanic potentiation was enhanced, and was seen at conditioning frequencies which barely evoked PTP in untreated animals. Direct and recurrent post-synaptic inhibitory mechanisms were not affected, but presynaptic inhibition was greatly increased. Consistent with this increase was an increase in the amplitude of the dorsal root potential V.

The intravenous administration of a single large 90 mg/kg dose of the water-soluble glucocorticoid methyl prednisolone brought about a striking elevation in the amplitude of the 2N response. This occurred within 20 seconds after injection, with no effect on polysynaptic discharge. Increased spindle discharge as a contributing factor was ruled out. Low doses of Na pentobarbital (2.5 to 10.0 mg/kg) prevented the 2N increase.

These results reflect a direct action of glucocorticoid on the primary afferent terminals improving excitability and transmitter release. These effects may in part explain the reported benefits of glucocorticoid treatment in acute spinal cord injury (Ducker, T.B. and Hamit, H.F., J. Neurosurg. 39 (1969) 693-697).

1606 EFFECTS OF INHIBITION ON FIRING RATES OF HOMONYMOUS MOTONEURONS OF DIFFERENT TYPES. Dale A. Harris and Elwood Henneman. Dept. Physiology, Harvard Medical School, Boston, Mass. 02115.

Single motor axons from plantaris or medial gastrocnemius motoneurons were isolated in ventral root filaments of decerebrate cats. After collection of 10-12 units, their critical firing levels (CFLs) were measured one after the other in a short time. Pairs of units of similar size as judged by their CFLs were placed on separate recording electrodes and their responses to repetitive shocks applied to the muscle nerve were compared simultaneously. The rates of each unit were determined by averaging during the first second of discharge following the onset of stimulation. By varying the intensity or frequency of repetitive stimuli, the two units could be made to respond with a wide range of firing rates. It was found that the ratio of the rates of the two simultaneously recorded units was approximately constant over the entire range of measured rates. Next, with the excitatory input maintained at a constant level that elicited maximal firing rates, stimuli were applied to the nerve of an ipsilateral antagonistic muscle to produce graded inhibition of the firing rates of the test units. As wide a range of inhibited response rates as possible was obtained by varying the parameters of the inhibitory input. Ideally, this range of inhibited rates was comparable to that obtained by varying the excitatory input alone. It was found that the ratio of the rates of inhibited pairs were not always constant over the entire range of measured rates. Detailed inspection of the data showed that, in general, the ratio of rates of pairs of motoneurons of similar size (CFL) and firing rate (ratio appro. = 1) remained constant when the degree of excitation or inhibition was varied, indicating that the cells were receiving inputs of comparable effectiveness. However, although the ratio of rates of units of similar size (CFL) but radically different rates (ratio approx. = 2) remained constant when excitation was varied, the ratio changed considerably when inhibition was varied, indicating that the units were not equally affected by the inhibition. Further tests revealed other differences between units of equal size, which depended on the similarity or dissimilarity of their firing rates. All results were in agreement with previous findings indicating that there are at least two types of motoneurons in a single pool having different physiological response characteristics.

Supported by a grant from the National Institutes of Health to Dr. E. Henneman and a Muscular Dystrophy Fellowship to Dr. D. Harris.

1607 DELAYED 'OFF-RESPONSES' IN THE SUBSTANTIA GELATINOSA. Ian Hentall. Dept. of Biology and Research Lab. of Electronics, M.I.T., Cambridge, MA 02139.

Platinum-tipped, metal microelectrodes registered, in the substantia gelatinosa of unanesthetized spinal cats, single units (34) which responded to gentle mechanical stimuli with a 5-20 sec. burst of impulses, 50-100 msec after withdrawal of the stimuli, but which were mainly silent before and during stimulation. A second touch during bursts inhibited firing, with the onset time indicating that this effect came from Aα-fibers. Noxious thermal and mechanical stimuli were initially ineffective, although, over a period of some minutes, a regular background activity (1-5 impulses/sec.) developed following such stimulation. In units possessing this activity, a noxious stimulus increased the firing rate during its application and produced a nearly silent period in about the first sec. following its removal.

Cutaneous electrical pulses delivered every second, a repetition period exceeding burst length, enabled an average-response histogram to be constructed which showed that the process giving rise to the initial delay resembled in time course the negative dorsal root potential (DRP). This process is regarded as an extension of Aα inhibition. Based on these data, a direct synaptic effect upon the afferent telodendron from the inhibitory process in these units' dendrites is suggested as one cause of the negative DRP.

1608 SPONTANEOUS ANTIDROMIC ACTIVITY IN SENSORY AFFERENTS. S. G. Kamerling and E. G. Anderson. Univ. Ill. Med. Ctr., Chicago, IL 60612.

Recent studies from this laboratory have demonstrated the occurrence of spontaneous, antidromic action potentials traveling in the dorsal roots of unanesthetized spinal cats (Repkin et al., Brain Res. 117: 147, 1976). The present studies show that this activity, termed the dorsal root discharge (DRD), occurs in a select population of fibers. Although the DRD was observed in S1 dorsal roots, in cutaneous nerves, and in peripheral muscle nerves (flexors and extensors) of de-efferented spinal cats, it seems confined to larger diameter afferent fibers. Conduction velocities of single-action potentials of the DRD were estimated from the time taken for such potentials to travel between two pairs of bipolar hook electrodes which supported the nerve. Spike conduction velocities were distributed among three groups with means of 38 ± 1.3, 72 ± 1.7, and 96 ± 2.4 meters/sec (± S.E.M.), respectively. These values correspond to Group I or Group II afferents. The majority of fibers showed conduction velocities within the second group.

These data indicate that antidromic activity can be detected in selected populations of sensory afferents, even under conditions of minimal surgical intervention. The physiological significance of this activity is not yet apparent, but we have observed it to be markedly decreased by small doses of pentobarbital (2 mg/kg, iv) and profoundly facilitated by GABA (100 mg/kg, iv). This latter effect is presumed to result from the GABA-induced depolarization of primary afferents. Since previous studies have shown that the DRD was not depressed by bicuculline or semicarbazide, the DRD apparently reflects non-GABA-mediated, tonic primary afferent depolarization. (Supported by USPHS Grant NS 12649.)

1609 *LOCALIZED UPTAKE OF ^{14}C 2-DEOXYGLUCOSE IN CAT SPINAL CORD AND DORSAL COLUMN NUCLEI IN RESPONSE TO SCIATIC NERVE STIMULATION.* John S. Kauer and William B. Stewart*. Depts. of Neurosurgery and Physiology, *Yale Univ. Sch. of Med.*, New Haven, Conn. 06510.

2-deoxyglucose(2DG) has been successfully used to map increased metabolic rate related to neuronal activity in various CNS structures in response to physiological stimulation(Kennedy et al., Science.187:850,1975; Sharp, Br. Res. 100:46,1976; Sharp et al., Br. Res. 98:596,1975; Sokoloff, in Brain Work, 1975 p385). It has also been used to demonstrate increased activity in the dorsal horn of rat lumbar spinal cord(SC) with electrical stimulation of the sciatic nerve(Kennedy, ibid.,1975). These latter results are of particular interest because they suggest that 2DG uptake can reflect neuronal activity elicited by artificial(electrical)stimulation. In addition, the uptake patterns are consistent with known projections of the sciatic nerve demonstrated with other methods(Sprague and Ha, Prog.Br. Res.11:210,1964). The present study was designed to examine further the activity produced by sciatic nerve stimulation in the cat, since the larger spinal cord of this animal permits a more precise correlation of 2DG uptake with the anatomy of the SC. Uptake patterns were examined in unanaesthetized control cats and in anaesthetized cats in which the sciatic nerve was stimulated. The autoradiographs of the activity patterns were compared with Nissl stains of the tissue from which they were taken in order to establish the location of the radioactive label.

The SCs in the control cats show the central gray matter to have a greater level of baseline uptake than the surrounding white matter. In those animals in which the sciatic was stimulated with brief shocks at 10 Hz or more, there was localized uptake in the ipsilateral dorsal horn in lumbar segments 5-7 and in the ipsilateral nucleus gracilis. Animals stimulated at 2 Hz showed no stimulus-related uptake. In those sections showing maximal uptake, the activity was localized to Rexed's laminae 3-5, with less uptake in laminae 1 and 2. In sections rostral and caudal to the level of maximum uptake, the activity was limited to a strip extending across laminae 3-6 on the medial margin of the dorsal horn. The recordings of the compound action potential proximal to the stimulation site indicated that the large fibers composing this nerve were maximally activated. There was no apparent A delta or C fiber activation. In those sections showing ipsilateral dorsal horn activity, there was no obvious contralateral uptake nor increased focal uptake in the ipsilateral ventral horn, although motoneurons in this region were presumably activated antidromically. These patterns of uptake, localized to the dorsal horn and dorsal column nuclei, are consistent with activation of and 2DG uptake in the synaptic terminals of large afferent fibers.

1610 *POST-TETANIC POTENTIATION AND DEPRESSION OF RENSHAW CELL DISCHARGES.* K. Krnjević and D. Lekić*[1]. Dept. of *Anaesthesia Research, McGill Univ., Montreal H3G 1Y6.*

In cats under Dial anaesthesia, tetanic stimulation of a lower lumbar ventral root (at frequencies of 50-500 c/s, for 5-20 s) evokes after a variable early period of depression, a very prolonged potentiation (PTP) of Renshaw cell discharges in response to single shock stimulation of ventral root. This is seen as an increase in the number of spikes per discharge (reaching a maximum of +20-50 % after tetani at 200-300/s) rather than a rise in the peak frequency of firing - indeed this was usually reduced. As elsewhere the magnitude and duration of PTP are a function of frequency and duration of tetanus. The PTP can last for > 3 min and is occasionally followed by a late phase of depression. There is a comparable PTP of the spontaneous firing of Renshaw cells. On the other hand, tests of Renshaw cell responsiveness to ACh show a very pronounced post-tetanic depression that may block all responses for 10-20 s, complete recovery being delayed for 1-2 min after a 10 s tetanus at 100-200/s. This post-synaptic change, which is evident after tetanic stimulations at frequencies as low as 10/s, must contribute to the overt early post-tetanic depression of firing, and probably significantly limits the maximum observable PTP. It cannot be mainly caused by desensitization to ACh, since discharges evoked by aspartic acid are also markedly diminished after a tetanus. It is not clear whether this reflects a general, non-specific post-activity depression, or a prolonged reciprocal inhibition of Renshaw cells. The former seems to be indicated by the marked reduction in spontaneous firing that immediately follows strong excitation with ACh: the absence of subsequent potentiation of spontaneous firing shows that PTP is a presynaptic phenomenon, as previously found at other junctions.

1611 THE EFFECT OF OSMOTIC PRESSURE ON REFLEX ACTIVITY IN THE ISOLATED FROG SPINAL CORD. D. A. Lake and C. D. Barnes. Dept. of Physiology, Texas Tech Univ. Sch. Med., Lubbock, Tx. 79409.

Furshpan (J. PHYSIOL. 134: 689, 1956) reported that with an increase in the osmotic pressure of the external fluid there was an increase in MEPP frequency but no change in the size or quantal content of evoked EPPs in the isolated frog nerve-muscle preparation. The present study was done to determine if osmotic agents had a similar lack of effect on evoked activity in the central nervous system. Spinal cords of Rana Pipiens were isolated and superfused with a modified glucose-Ringers solution (NaCl, 100 mM; KCl, 2.5 mM; Na_2HPO_4, 2.5 mM; NaH_2PO_4, 0.45 mM; $CaCl_2$, 1.9 mM; $NaHCO_3$, 12 mM; and glucose, 2.8 mM) aerated with a 95% O_2-5% CO_2 gas mixture (pH 7.4). The tenth dorsal root (DR 10) was supramaximally stimulated and ventral root reflexes (VRR) were recorded in VR 10 and VR 9. Increasing the osmotic pressure of bathing medium with mannitol produced a concentration-related depression of bath intra- and intersegmental VRR. The VRR depression was only partially reversible at all concentrations of mannitol added. This response will be further characterized by the use of other agents (urea, glucose, glyerol) which are known to penetrate the cell membrane at various rates.

1612 RHOMBENCEPHALIC CELLS OF ORIGIN OF DESCENDING SPINAL SYSTEMS IN THE ATLANTIC STINGRAY. R.B. Leonard and W.D. Willis. Marine Biomedical Inst. and Depts. of Anatomy and Physiology & Biophy., University of Texas Medical Branch, Galveston, Texas 77550

There have been few experimental studies of the cells of origin of descending spinal cord pathways in non-mammalian vertebrates. We have begun to investigate these systems in the stingray using the retrograde transport of horseradish peroxidase (HRP) to avoid the problems in recognizing chromatolytic reactions in these animals, particularly in small neurons. HRP was injected into the spinal gray using a microelectrode. The approach was through the dorsal columns to minimize direct injury to fibers to caudal spinal levels, and 0.2 µl was slowly injected in each of several tracks. Initial animals received multiple bilateral injections, while subsequent animals received more restricted unilateral injections with a contralateral hemisection rostral to the injection site. In addition, current experiments are examining the possibility of a somatotopic organization within these systems. Following injections at caudal pectoral fin cord levels, labelled cells are found within the spinal cord and continuing through the spino-medullary transition zone dorso-lateral to the central canal. These appear to be long propriospinal neurons continuing into the caudal reticular formation. A distinct group of neurons replaces the somatic motor column as it becomes smaller throughout this zone. In addition a few labelled cells are located dorsal to the central canal where the solitary complex joins on the midline. There is an extensive projection from the raphe beginning at medullary levels and continuing rostrally past the inferior olive. Some raphe cells are located ventrally between the olives, but the majority are situated dorsally. Additional cells are located adjacent to the raphe through most of this region. Another group of cells are located dorso-lateral to the rostral pole of the olive and continue rostrally a short distance. There are scattered cells among the VIth nerve rootlets which increase rostrally as a distinct group ventral and slightly medial to motor V. Scattered cells are among the rootlets of the anterior lateral line-vestibular nerve complex as well as within the rostral pole of the posterior lateral line lobe. We assume most or all of these are vestibulo-spinal neurons. Another group of relatively small cells is located laterally at the level of the cerebellar peduncles. The descending systems from the caudal brainstem in the stingray appear similar to those described in mammals. However, we have refrained from assuming homologies of many of these groups until more is known about the organization of and afferents to each group. Supported by NS 11255, NS 05434 and a grant from the Muscular Dystrophy Association of America.

1613 MONOSYNAPTIC REFLEX CONNECTIONS OF EXTERNAL URINARY AND EXTERNAL ANAL SPHINCTER MOTONEURONS. Robert Mackel* (SPON: B.W. Peterson) Rockefeller Univ., New York, N.Y. 10021.

The striated muscles of the pelvic floor which are directly related to the continence aspect of micturition and defecation are the external urethral and external anal sphincters (EUS, EAS). The most important source of motor supply to the two external sphincters is derived from the deep branches of the mixed somatic pudendal nerve.

To study the properties of motoneurons supplying the sphincter muscles experiments were performed on male cats anesthetized with chloralose, using intracellular recording techniques. The pudendal nerve branches to the EUS and to the EAS were dissected out and mounted separately for antidromic and orthodromic stimulation. The motoneurons which were identified antidromically and localized by dye injection were found to be intermingled in the S2, S3 segments of the spinal cord. The conduction velocity of the EUS and EAS motor axons ranged between 50-70 m/sec.

Monosynaptic connections to EUS and EAS motoneurons were demonstrated upon stimulation of the S_2-S_3 dorsal roots and upon stimulation of the same nerve branch which contained the motor axon. The central latencies (central conduction time plus synaptic delay) as measured from the arrival of the afferent volley at the cord dorsum to the beginning of the EPSP ranged between 0.6 and 0.9 msecs. Such short latency EPSPs were observed in 13 out of 17 cells with dorsal root stimulation and in 13 out of 25 cells with stimulation of the nerve branch containing the motor axon. The monosynaptic response could in each case be evoked at low threshold and only from the homonymous nerve branch.

These results support the observations of Garry et al. (1959) and Bishop et al. (1956) who observed a significant increase in tonic EMG-activity and a powerful contraction upon distension of the EUS and EAS in the cat. The results of the present experiments suggest that a monosynaptic reflex similar to that present in other somatic muscles contributes to the stretch-evoked contraction of the EUS and EAS. Such reflexes in the EUS and EAS presumably play a direct role in preventing the emptying of the bladder or the rectum. Preliminary results show that EUS and EAS motoneurons also receive direct inputs from descending spinal pathways.

1614 DIFFERENTIAL PROJECTIONS OF CAT MEDULLARY RAPHE NUCLEI IN SPINAL CORD WHITE MATTER. Richard F. Martin, Larry M. Jordan and William D. Willis. Marine Biomedical Institute, Dept. Physiol. & Biophy. and Anat., Univ. Texas Med. Br., Galveston, TX. 77550 and Dept. Physiol., Univ. Mannitoba, Winnipeg, Canada.

Serotonin terminals found in the spinal cord gray matter have been attributed to descending projections of the medullary raphe nuclei. Although some previous studies in the cat indicate that fibers from the nucleus raphe magnus course in the dorsolateral fasciculus, it was uncertain what the origin is of the many 5HT axons projecting in ventromedial and a ventrolateral fasciculi. This study shows that fibers coursing in these regions arise from the nuclei raphe pallidus and obscurus.

Neurons of medullary raphe nuclei of the cat were retrogradely labelled following injections of horseradish peroxidase (HRP) into the lumbar enlargement (L6). A 50% solution of HRP (1.0-5.0 µl) was injected bilaterally into the spinal cord gray matter of anesthetized animals using a glass micropipette. Partial cordotomies were performed in these animals at the time of injection to restrict transport of HRP to those axons projecting in the spared white matter. The cordotomies were performed at T12-L1, a level separated from the HRP injection site by four to five segments to avoid HRP uptake from cut axons.

In three cats in which dorsolateral cordotomies were performed, a large percentage of neurons of both nucleus raphe pallidus and nucleus raphe obscurus were labelled following HRP injection. No neurons in the rostral half of nucleus raphe magnus were labelled in these animals. In two cats in which ventral cord sections were performed, HRP labelled occurred in large percentage of neurons in the rostral half of nucleus raphe magnus. A reduced number of labelled cells were found in nucleus raphe pallidus or nucleus raphe obscurus in these animals.

This work was supported by NIH grant NS 09743.

1615 PROPERTIES OF SYNAPTIC LINKAGE FROM "DISTANT" AFFERENTS ONTO DORSAL HORN NEURONS. L.M. Mendell, E.M. Sassoon*and P.D. Wall* Cerebral Functions Group, University College London, Gower St. London, U.K.

These experiments were prompted by recent findings that dorsal horn neurons in lumbar segments of cat spinal cord (e.g. L7) can be driven by electrical stimulation of a distant dorsal root (e.g. L3 or L4), but not by natural stimulation of skin supplied by these roots. We placed 9 pairs of 25 gauge needles in the skin of the limb and the flank for electrical stimulation of the skin ($A\beta$-δ strength), and studied the responses of dorsal horn neurons in the L7 segment with cutaneous receptive fields. Extracellular recordings in decerebrate-spinal preparations revealed that the probability of a unit responding to stimulation of the flank (innervated by L3 or L4) increased as the receptive field was more proximal (i.e. "hip" units responded with a higher probability than "toe" units). Generally, the repetitive discharge was weaker and more variable in response to flank stimulation than to stimulation within the receptive field on the limb. These differences were less evident when the natural receptive field was proximal (i.e. on the leg or hip). Intracellular recording with citrate electrodes in both decerebrate-low spinal and anesthetized-low spinal preparations revealed that an even larger proportion of L7 neurons was excited, often subliminally, by flank stimulation. Each cell responded (probably monosynaptically) with a short latency to stimulation within the receptive field even at high frequencies (e.g. 50 Hz). In contrast, the response to flank stimulation usually had a long latency (>10 msec) and was generally erratic even at 1 Hz although in some cells EPSPs followed at 1 Hz or even (in a very small minority) at 10-50 Hz. Increased ability to follow high stimulation frequencies was associated with shorter response latencies (as short as 4 msec) and with more proximal natural receptive fields (leg or hip). In some cells stimulation of the flank yielded IPSPs or EPSP-IPSP sequences which exhibited no set order from cell to cell (i.e. IPSPs could precede, follow or overlap EPSPs). We conclude that a small minority of EPSPs from distant afferents could be monosynaptic but that the projection is primarily polysynaptic. However, the possibility of low efficacy monosynaptic projection failing to follow at 1 or 10 Hz cannot be discounted. Either way, the inability for the response to follow at high frequencies indicates that input from the flank cannot undergo significant temporal summation. This, coupled with the relatively weak input, probably explains why natural stimulation of the flank fails to drive cells in L7. (Supported by NIH, MRC and a Josiah Macy, Jr. Foundation Faculty Scholar Award (L.M.)).

1616 DECENERATION AND EARLY NEURONAL OUTGROWTH FOLLOWING SPINAL CORD TRANSECTION IN XENOPUS LAEVIS TADPOLES. Mary Ellen Michel* and Paul J. Reier. Dept. Anatomy, University of Maryland School of Medicine, Baltimore, MD 21201

Whereas only limited neuronal regeneration appears to occur in the mammalian CNS, several nonmammalian vertebrete species posssess a remarkable capacity for structural and functional recovery following CNS injury. In order to characterize some of the cellular mechanisms underlying such regenerative ability, degeneration and early neuronal outgrowth were examined in transected spinal cords of Stage 54 tadpoles. Following complete cord section at lumbar levels, animals were sacrificed between 1 and 14 days; specimens obtained immediately adjacent to the cut ends as well as from the intervening lesion zone were examined by electron microscopy. Within 2 days numerous swollen axons and distended myelin sheaths were present, and by 5 days Wallerian degeneration was extensive. Very little cellular debris and only a few degenerating fibers were still present adjacent to or within the lesion zone by 14 days. Major cyst formation and glial-connective tissue scarring did not occur during this degenerative period. Concurrent with the massive degenerative changes noted at 5 days was an early outgrowth of fibers into the lesion zone from both rostral and caudal ends. The number of these processes increased dramatically between 5 and 10 days. At 14 days the majority of neuronal profiles in the lesion zone were organized into fascicles surrounded by either cytoplasmic processes or a single basal lamina. Many of the cells associated with these bundles exhibited cytological features similar to those of immature glia found within the normal Xenopus spinal cord. Other cells were derived from the surrounding meninges. Most of the fibers within the initial caudal cord segment were organized into smaller fascicles surrounded by ependymoglial processes. The early post-transection period in this system is thus characterized by rapid degeneration, debris removal and early onset of regeneration without the formation of cysts or glial-connective tissue scars. Furthermore, the presence of cellular sheaths around fascicles of neurites may provide a permissive structural framework for neuronal outgrowth. 1617 RESPONSES OF VENTRAL HORN CELLS IN THE CAT LUMBAR SPINAL CORD TO CUTANEOUS STIMULATION. Helen H.Molinari and Dan R. Kenshalo. Dept. Psychol., Fla. State Univ., Tallahassee, Fla. 32306

The responses to cutaneous stimulation of cells located in the ventral horn (laminae VII and VIII) of the cat lumbar spinal cord were compared with those of dorsal horn cells (laminae I-VI). Tungsten microelectrodes were used to search the spinal cords of cats anesthetized with chloralose and paralyzed with gallamine triethiodide. Units were classified by stimulating the hindlimbs with hair movement, tactile stimulation with von Frey hairs, thermal stimulation, and noxious stimulation with smooth and serrated forceps, and determining the type of stimulus that produced the largest response. To avoid stimulation of deep receptors, the noxious pinch stimuli were presented while the skin was pulled away from the underlying tissue.

The vast majority of units in the ventral horn responded maximally to noxious stimulation, whereas units were found in the dorsal horn which responded to hair movement, to touch, or to noxious stimuli. Of the ventral horn cells, about half responded only to pinch, while the others responded to pinch and strong tactile stimuli or to pinch and heat.

The nociceptors in the ventral horn tended to have larger receptive fields than the dorsal horn nociceptive, hair, or tactile units. However, there was considerable variability in the sizes of the receptive fields of the ventral horn cells. One unit responded to stimulation of 2 cm^2 of the ipsilateral foot, while another responded to stimulation of any spot on the lateral surface of either hindlimb. Most of the ventral horn cells (75%) had their receptive fields confined to a single area on the ipsilateral or contralateral hindlimb and thus carried relatively localized noxious information. The remaining ventral horn units were activated by pinch over large areas of either hindlimb and provided non-localized information about the impingement of nociceptive stimuli on virtually any part of these limbs. The receptive fields of dorsal horn cells were confined to the ipsilateral hindlimb or back.

1618 TRAUMA INDUCED CHANGES IN THE SPONTANEOUS ELECTRICAL ACTIVITY IN THE SPINAL CORD OF THE CAT. J.T. Molt, D.A. Poulos and R.S. Bourke, Div. of Neurosurgery and Dept. of Physiology, Albany Medical College, Albany, N.Y. 12208

Hemorrhagic necrosis resulting from blunt trauma to the spinal cord is a progressive destructive process which first consumes gray and then white matter. As the lesion develops, descending modulation of spinal cord neurons caudal to the injury site is interrupted resulting in changes in various potentials which can be recorded from the cord. One such potential is the spontaneous spinal electrogram (SEG). The SEG as recorded from the dorsal spinal gray matter of the cat consists of low voltage background activity (25 μV) upon which occur spontaneous, random, monophasic, larger voltage (50-200 μV) potentials termed negative sharp waves (NSWs) which are 20-40 msec in duration and are recorded as negative going to an indifferent electrode. Recent evidence indicates that the NSWs may be generated spontaneously by the same neurons from which the negative components of the cord dorsum potential can be evoked. It has been demonstrated that generation of NSWs is inhibited by both segmental and supraspinal input. To test the hypothesis that the SEG may be a sensitive indicator of the degree of destruction resulting from a traumatic insult to the cord, groups of anesthetic-free, decerebrate cats were subjected to either a 500 gm-cm, a 250 gm-cm or a 100 gm-cm injury by dropping a 50 gm weight 10, 5, or 2 cm respectively onto the exposed dura of the cord. The percent change in the number of NSWs recorded from the exposed surface of the cord 3 cm caudal to the injury site was plotted as a function of time over a 6 hr period following injury. The slope of the least squares linear regression line correlated positively with the severity of injury measured with a strain gauge at the time of the injury (impulse) and later confirmed histologically (see Table, * indicates significance at 5% level, n = 10).

	r (correlation coefficient)
slope vs impulse	.70 *
slope vs white matter lesion	.74 *
slope vs gray matter lesion	.32
slope vs total lesion	.71 *

These results indicate that the SEG may serve as a sensitive indicator of the degree of spinal cord injury (especially to white matter) and may be useful in the assessment of various treatment modalities used to reverse the effects of trauma. Supported by NIH grant NS 13042.

1619 SPINAL CORD REGENERATION IN RATS FOLLOWING IMMUNOLOGICAL SUPPRESSION AND INDUCED TOLERANCE TO CNS ANTIGENS. Kevin R. Nelson*, Earl R. Feringa and H. Lee Vahlsing*. Depts. Neurol. and Path., VA Hosp. and U. of Mich. Med. Ctr., Ann Arbor, MI 48105.

The purpose of this investigation was to determine if an immune response to central nervous system (CNS) antigens plays a role in preventing the regeneration of long descending motor axons within the spinal cord of the rat.

Forty inbred, isogeneic female rats were divided into three study groups. In an attempt to induce tolerance to CNS antigens, 2 groups (11 animals each) received a 75 mg injection of isogeneic spinal cord emulsified in saline on day 1 of life, and then once a week until the spinal cord was transected at 6 weeks of age. In addition, one of these two groups was given cyclophosphamide, 75 mg/kg, 48 hours after spinal cord transection, for immunosuppression. The third group (18 animals) also had spinal cord transections at 6 weeks of age and served as untreated controls.

Three months were allowed for neural fibers to regenerate. Two methods were used in all animals to detect regeneration. First, the spinal cord was stimulated proximal to the transection site, and signals picked up from dorsal and ventral rootlets distal to the transection. For each animal, 128 such stimulus response curves were averaged by a computer and results evaluated in a blind fashion for possible axonal transmission across the transection site. Evidence for transmission across the transection was found in none of the controls, in 2 receiving spinal cord injections alone ($p=.042$), and in 2 receiving spinal cord and cyclophosphamide injections ($p=.042$).

The second evaluation method utilized anterograde axonal transport of tritiated proline which had been injected into the sensory-motor cortex 21 days before the animals were sacrificed. Identical measured lengths of spinal cord taken from above and below the transection site were solubilized and placed in scintillation fluid. The number of disintegrations per minute (dpm) for each segment was recorded and the value dpm distal/dpm proximal was calculated for each animal. The mean value for the group receiving spinal cord injections alone was .066 and did not differ significantly from the control mean of .069 ($p=.392$). However, the mean of .127 for the group receiving spinal cord injections and cyclophosphamide did differ significantly from controls ($p=.037$).

The electrophysiological evidence suggests that animals made tolerant to brain antigens have an improved ability to regenerate intraspinal axons. The radioisotope study indicates that more tritiated proline was transported to the distal spinal cord segment in tolerant animals which were also treated with cyclophosphamide. This drug may act as an additional immunosuppressant or by another unidentified mechanism.

1620 INCREASE IN Ia-MOTONEURON PROJECTION FOLLOWING SPINAL CORD TRANSECTION. S.G. Nelson and L.M. Mendell. Duke University Medical Center, Durham, N.C. 27710

Individual averaged EPSPs produced by single medial gastrocnemius (MG) Ia fibers in MG motoneurons become significantly larger on the average following spinal cord transection at T13 or L5. These conclusions were obtained by comparing data from spinal anesthetized (Nembutal, 35 mg/kg) cats to those from intact anesthetized cats using the spike triggered averaging technique (Mendell and Henneman, J. Neurophysiol., 34:171, 1971). These amplitude increases were observed following acute transection at either level, but chronically only after the L5 transection. The time course of the increase following L5 transection suggests two separate processes since the initial EPSP amplitude increase was attenuated 5 days after transection and a secondary increase began at about 2 weeks. Following transection at T13, there was an immediate marked increase in average EPSP amplitude, followed by a gradual decline to normal levels over a period of 2-3 weeks. Some variability between animals was observed, presumably resulting from as yet undetermined differences in lesions and/or variability in the projection of Ia fibers (Type X and Type Y, Scott and Mendell, J. Neurophysiol. 39:679, 1976). Increases in mean amplitude were marked by a virtual disappearance of small EPSPs (< 100 μV) and also by the appearance of large (400-1200 μV) brief EPSPs rarely seen in intact animals. The mechanism underlying this EPSP enlargement could be presynaptic (e.g., tonic presynaptic disinhibition) or postsynaptic, although our data indicate no generalized changes in the latter (e.g., motoneuron resistance). Another possibility is a structural change in the Ia-motoneuron synapse (e.g., collateral sprouting of Ia fibers). Consistent with this, single Ia fibers evoked EPSPs in a larger proportion of homonymous and heteronymous motoneurons than normal, particularly in L5 transected preparations. Since normal EPSPs smaller than 15 μV were not resolved, this increase in projection frequency may in some cases have been due to increases in mean EPSP amplitude resulting in fewer small ones being missed. However, higher projection frequencies were occasionally seen in preparations chronically transected at L5 when the Ia fiber produced EPSPs of normal amplitude. The sprouting hypothesis could also account for increased mean EPSP amplitudes following chronic L5 transection (which substantially denervates triceps surae motoneurons) compared to no increase following chronic T13 transection (which produces much less denervation of triceps surae motoneurons). Other mechanisms (e.g., denervation supersensitivity) may also contribute to this phenomenon. (Supported by NS 34680, NS 08411, GM 00929).

1621 RELEASE OF ACETYLCHOLINESTERASE BY CULTURED SPINAL CORD CELLS. T. H. Oh, J. Y. Chyu* and S. R. Max. Depts. Anatomy, Neurology and Pediatrics, Univ. of Maryland Sch. of Med., Baltimore, Md. 21201.

The release of acetylcholinesterase (AChE) from neurons was studied using cultured chick embryo spinal cord cells. Cells dissociated from 12-day-old chick embryo spinal cords were grown in culture for 10-12 days. Numerous well differentiated spinal neurons were found after 7-10 days in culture. AChE activity per dish increased by 60 fold from days 2 to 12. AChE was released into the surrounding media by the cells when they were incubated either in the standard culture medium or the serum-free medium. AChE release was significantly reduced when protein synthesis and microtubules were disrupted by cycloheximide and colchicine, respectively. Histochemical localization of AChE indicated that the synthesis and release of AChE are attributable to neurons. Cultured chick embryo brain and neuroblastoma cells also released AChE into the media. These results are discussed with regard to possible physiological roles for AChE secretion from neurons. Supported by grants from NSF (BNS 76-15370), NIH (NS 11342), Bressler Fund and MDAA.

1622 MORPHOLOGY OF ENDINGS OF PRIMARY AFFERENT COLLATERALS TO THE SPINAL CORD SELECTIVELY STAINED BY ANTEROGRADE MOVEMENT OF HRP Eric Proshansky* and M. David Egger. Dept. Anat., CMDNJ-Rutgers Med. Sch., Piscataway, N.J. 08854.

Analysis of dorsal root axons selectively stained by uniform filling with HRP indicates that this technique can effectively demonstrate, in the adult cat, each of the distinct types of dorsal root collateral described by Cajal and later workers using the Golgi method in fetal and neonatal material. Adult cats were sacrificed after immersion of severed dorsal rootlets for 24 hr in a 40-60% solution of HRP in distilled water. Spinal cord sections processed by the diaminobenzidine technique showed an abundance of dorsal root collaterals homogeneously filled with HRP. Axons or terminals examined in the light microscope showed no evidence of anterograde degeneration. (In animals sacrificed at 48 and 72 hr after rootlet transection, many axons were both swollen and constricted and numerous fragments of HRP-filled material, presumably disrupted axons, were visible.) The study of L5-S1 dorsal root collaterals in 24 hr material indicated that fibers to laminae I-III include both thin axons (<1 μm) entering by way of Lissauer's tract, and thicker fibers entering by way of the dorsal column. These latter fibers enter lamina III from its ventral surface, forming the classically described "flame-shaped" endings within lamina III and the ventral portions of lamina II. In laminae IV-VI, moderately thick (1.5-2.0 μm) collaterals form extensively ramified terminal arborizations having clusters of terminal knobs. The terminal fields of these fibers are distributed across the laminar boundaries and over wide mediolateral portions of the dorsal horn (200-400 μm). Collaterals were also stained within the intermediate region and ventral horn. One group of these fibers formed a dense, circumscribed terminal field laterally adjacent to the central canal. The thickest (4-5 μm) dorsal root collaterals were observed to enter and terminate within the ventral horn. These collaterals, which are likely to be derived from Ia fibers, begin to branch after passing through the dorsal horn, and divide repeatedly within the ventral horn. Terminal knobs 3-5 μm in size are formed at the ends of the branches or, commonly, on long, extremely thin side-collaterals. The terminals of these fibers are distributed throughout much of the ventral gray matter.

The ability to stain previously recognized varieties of dorsal root collaterals in large numbers by HRP filling suggests that this technique will now permit the detailed morphological description of primary afferents in the adult spinal cord.

(Supported by USPHS grant NS 12261.)

1623 THE SYNAPTIC ORGANIZATION OF THE DORSAL HORN OF THE MONKEY SPINAL CORD: A QUANTITATIVE ELECTRON MICROSCOPIC STUDY. Henry J. Ralston, III. Department of Anatomy, Univ. of California School of Medicine, San Francisco, CA. 94143.

In order to determine the contribution of various synaptic types to the population of synapses in the monkey dorsal horn, the fine structure of the horn has been examined in specimens obtained from normal animals and from 8 animals surviving 18 hours to 32 days following labeling of dorsal root fibers, the labeling obtained by extradural dorsal rhizotomy of 3 consecutive dorsal roots of one side, and by the injection of 100μC of H^3 leucine into each of the corresponding dorsal root ganglia of the opposite side. Specimens were processed for conventional electron microscopy (EM) and EM autoradiography (ARG). Vertically oriented sections running from dorsal column white matter through the base of lamina IV (about 800μ total) were scanned, and counts were made of synaptic and other profiles contained in consecutive 50μ regions of the total 800μ length of section. For ARG, both the radioactive and non-radioactive sides of the cord were processed, to check for background silver grains.

The distribution of the several synaptic types varied significantly from lamina I to lamina IV. Of the more than 6000 synaptic profiles classified, round-vesicle (R) synapses accounted for 51%, flat vesicled (F)-36%, and dense-cored (D) vesicled-8%. In laminae I, II and the upper zone of III, R's were about 55-65% of the total, and F's only 13-25%; deeper in III and IV, the number of F's equalled or exceeded those of R's. D's constituted 25% of the total in I, 15% in upper II, and 5% or less at deeper levels. Following rhizotomy, degenerating synapses were first recognized at 2 days survival, reached maximum numbers at 4-5 days, and were uncommon at survival periods greater than 10 days. The number of degenerating synapses totaled from all animals in any lamina never exceeded 6% of the total of normal synaptic profiles: in I-5%; II-6%; III-6%; IV-3%. The ARG results of the distribution of grains seen with fast transport times demonstrated a maximum of 31% of grains found over synaptic profiles, the remainder principally overlying myelinated and non-myelinated axons; thus, fast-transport ARG is not primarily a marker of synapses in the cord. Of the labeled profiles, R's accounted for 10% in I, 22% in II, 28% in III, and 9% in IV; D's were 6% in I; 5% in upper II, and unlabeled at deeper levels; F's were not labeled above background.

Dorsal root axons thus appear to synapse in about equal numbers in laminae II & III, and in lesser numbers in I & IV; they may be classed principally as R's or D's, and participate chiefly in axodendritic and axoaxonal synapses. (Supported by NS-11614 from NIH).

1624 REFLEX INTERACTIONS OF MUSCLES CONTROLLING HEAD POSITION. Samuel Rapoport* (SPON: V.J. Wilson). Rockefeller Univ., New York, N.Y. 10021.

Neural control of limb movement is characterized by a pattern of reciprocal innervation between antagonistic muscles, with supraspinal centers exerting some of their effects by modulating reflex interactions. The present investigation was conducted to explore whether a similar mechanism is involved in the control of head position.

In the cat, sternomastoid and cleidomastoid (SCM) flex the head and rotate it to the opposite side. The ipsilateral biventer and complexus (BC) extend the head and rotate it to the ipsilateral side. Thus SCM and BC are functionally antagonistic muscle groups. The synaptic effects of SCM and BC afferents upon motoneurons of these muscles were studied using intracellular recording. In most cases, cells were polarized to enhance inhibitory effects not apparent at the resting potential. Motoneurons were identified by antidromic stimulation of the muscle nerves. 13 cats were utilized, 10 anesthetized with chloralose, 2 with pentathol, and one decerebrate.

Stimulation of a muscle's own afferents, at strengths near threshold for the afferent volley, produces Ia EPSPs in these motoneurons at a mean latency of 0.8 msec, s.d.=0.5 n=49 (all measurements herein are from positive peak of the incoming volley). When the afferents to the antagonist muscle are stimulated at strengths higher than 1.5 x threshold of the lowest threshold fibers, both EPSPs and IPSPs occur. In SCM mean IPSP latency is 8.7 msec (n=10, range 4.8-12.5) and mean EPSP latency is 2.7 msec (n=10, range 1.5-7.6). In BC mean IPSP latency is 3.8 msec (n=17, range 1.6-7.0), and mean EPSP latency is 2.5 msec (n=4, range 1.2-3.7). The latency measurements of the observed IPSPs, and the stimulus strengths required to elicit them, suggest that, in contradistinction to limb motoneurons, there is no disynaptic Ia inhibition between the antagonists BC and SCM (n=56).

These data, together with the well organized monosynaptic projections to BC motoneurons from brainstem centers, suggest that segmental networks are less important in the control of head position than in the control of limb movements. Rather, the pattern of activity providing control of head position may be imposed upon motoneurons by supraspinal centers.

Supported in part by N.I.H. Grant NS 02619.

625 VISCERO-SOMATIC CONVERGENCE IN THE LATERAL CERVICAL NUCLEUS OF THE CAT. Don Rigamonti, Georgetown Medical School, Dept. of Anatomy, Washington, D.C. 20007.

The spino-cervico-thalamic tract is generally considered a major pathway transmitting signals of an exteroceptive nature to the cerebral cortex. Recently, we reported that the tract carries information from visceral structures. This was suggested by a single unit analysis of the lateral cervical nucleus (LCN), a major relay nucleus for the pathway. Further experiments were conducted to determine if there was convergence of signals from somatic and visceral structures in the LCN.

Alpha-chloralose anesthetized adult cats were operated having pairs of electrodes attached to the splanchnic nerve and thoracic sympathetic chain to deliver graded stimuli and record the resultant neurogram, respectively. Blood gasses and core temperature were monitored and maintained within acceptable physiological ranges. Histological reconstruction of frozen sections stained for Nissl substance allowed reconstruction of spinal cord and midbrain, recording and stimulating, sites. The ipsilateral LCN was searched with micropipettes filled with an electrolyte-dye solution. A hunting stimulus was applied to the contralateral midbrain by an electrode grid and antidromic responses were amplified, displayed and photographed using standard techniques. Units responding to midbrain stimulation were classified as tract cells or neurons intrinsic to the nuclear complex based on the antidromic response. Subsequently, neurons were tested for input from the splanchnic nerve and natural stimulation of hair, joints and deep structures.

Extracellular recordings in the LCN indicate the presence of both tract and intrinsic neurons. We have also confirmed earlier reports suggesting input to the LCN from high threshold myelinated afferents of the splanchnic nerve. The majority of units also exhibited convergence of input from somatic structures. The most effective stimuli were hair movement and pressure applied to deeper structures of the ipsilateral forelimb, trunk and hindlimb. Thus it appears that the tract of Morin serves to integrate exteroceptive as well as interoceptive information.

1626 INTRACELLULAR ASPECTS OF THE SCHIFF-SHERRINGTON PHENOMENON. J. C. Schadt and C. D. Barnes. Dept. Physiol., Sch. Med., Texas Tech Univ., Lubbock, TX 79409.

The intracellular aspects of the Schiff-Sherrington phenomenon were studied in decerebrate cats. Forelimb motoneurons were identified by antidromic activation from the deep radial, median, or ulnar nerves. Reversible post-brachial spinal cord transection was produced by coldblock while simultaneously monitoring resting potential and input resistance of identified forelimb motoneurons. Motoneurons with axons in the radial nerve showed a decrease in membrane potential and a decrease in input resistance during coldblock. Median and ulnar motoneurons showed an increase in membrane potential and a decrease in input resistance. Several cells were encountered in the region of the motoneuron pool which could not be antidromically identified. The input resistance of these cells always decreased while the cells showed either increases or decreases in membrane potential. We conclude that the Schiff-Sherrington phenomenon is mediated thru facilitation of extensor and inhibition of flexor α-motoneurons.

1627 THE LOCALIZATION OF CORTICAL AND SUBCORTICAL NEURONS PROJECTING TO THE SPINAL CORD IN THE RAT. Jean M. Schoenen* and Valerie B. Domesick. Mailman Research Center, McLean Hospital, Belmont, MA 02178

The purpose of this study was to map the cortical fields which give rise to corticospinal fibers. In addition, neurons in several subcortical areas which project to the spinal cord were identified. Horseradish peroxidase (0.5-5µl of a 13% solution) was injected manually into cervical, thoracic, and lumbar segments of the spinal cord in 10 rats. Following a survival time of 24 hours, the brains were prepared according to the method of Graham and Karnovsky (1966). The labeled cortical neurons were mapped on a dorsal view of the cortex.

Labeled neurons in the cerebral cortex were small, medium, and large pyramidal cells, located exclusively in Layer V. These corticospinal neurons occupy a remarkably large field which extends laterally and caudally farther than previously indicated by various architectonic maps. Injections in the cervical spinal cord labeled neurons in a large field about 3.5mm wide, which begins rostrally in front of the genu of the corpus callosum, and extends caudally to a level just rostral to the splenium. A somatotopic arrangement of corticospinal neurons was evident: the field of neurons labeled by injections at sub-cervical levels did not extend as far rostrally and narrowed progressively in the medial direction. Thus, neurons labeled by lumbar injections were confined to a comparatively narrow medial strip of cortex. When projected upon Krieg's (1946) architectonic map, the field of corticospinal neurons included parts of areas 4 and 6 in the frontal cortex and areas 1, 3, and 7 in the parietal cortex. Two other, smaller fields of labeled cells were identified in the anterior medial cortex and in the lateral cortex just above the rhinal fissure.

Further labeled cells were identified at all levels of the brain stem. In the diencephalon, such cells appeared in the zona incerta and in the hypothalamus, namely the nuclei lateralis, perifornicalis, periventricularis and paraventricularis (parvocellular sector) hypothalami. In the midbrain, labeled cells were identified in the stratum griseum profundum of the superior colliculus, central gray, and the nuclei of Edinger-Westphal, interstitialis of Cajal, raphis dorsalis and ruber. At pontine levels, labeled cells were located in the nuclei tegmenti dorsalis lateralis, locus coeruleus, raphis magnus, and reticularis gigantocellularis . At medullary levels, labeled cells were found in the vestibular nuclei, the raphe region, the nucleus commissuralis, and the lateral reticular formation. That serotonin, noradrenalin or TRH are found in several of these subcortical cell groups may explain the presence of these substances in the spinal cord. 1628 THE EFFECT OF 5-HYDROXYTRYPTAMINE ON FROG MOTONEURONS. Brimmer R. Sherman*, Richard F. Thompson. Department of Psychobiology, UCI, Irvine, CA 92717.

An electrophysiological study was undertaken to elucidate the role of 5-hydroxytryptamine (5-HT) in the amphibian (Rana catesbeiana) spinal cord. Isolated spinal cords were hemisected and maintained in a chamber which had continually circulating amphibian Ringer's solution. The media was oxygenated and maintained at 9° ±1°C. 5-HT in various concentrations was applied to the cord by superfusing it with a Ringer's solution containing the drug.

The addition of 5-HT to the superfusate (10^{-3}-10^{-6} M) produced a transient increase of the lateral column elicited ventral root response (LC-VRR). This increase occurred 3-7 minutes after the application of the drug and was followed by a long lasting depression of the LC-VRR; however, the LC-VRR returned to the pre-drug level following a wash off period with normal media. 5-HT (10^{-3}-10^{-4} M) also produced a reversible depolarization of the motoneurons, as determined by a positive deflection of the ventral root potential, whether the cord was superfused with normal Ringer's or with Ringer's containing 20 mM $MgSO_4$. The LC elicited focal potential recorded from a micropipette in the motoneuron pool can easily be differentiated into pre and postsynaptic components. The presynaptic component corresponds to the orthodromic invasion by the action potential volley into the LC terminals, while the postsynaptic component corresponds to the synchronous discharge of the motoneurons. 5-HT (10^{-3}-10^{-5} M) produced a transient increase followed by a decrease of the postsynaptic component of the LC focal potential, while having no effect on the presynaptic component. The postsynaptic component of the response returned to normal following a wash off period with normal media.

The depolarization of amphibian motoneurons by 5-HT has previously been reported (Comp. Biochem. Physiol. 23:553, 1967); however, this could be produced by the action of 5-HT sensitive interneurons on motoneurons. This was tested by blocking synaptic transmission with high Mg^{++} concentrations. Motoneurons are depolarized by 5-HT in a high Mg^{++} media, indicating that 5-HT acts directly on the motoneurons. Possible implications of these findings will be discussed.

1629 ORIGINS OF THE LONG DESCENDING AND ASCENDING PROPRIOSPINAL PATHWAYS IN CAT AND MONKEY. Robert D. Skinner, Joe Dan Coulter and Allen B. Chatt. Dept. Anat., Univ. Arkansas Coll. Med., Little Rock, AR 72201; and Depts. Physiol. and Biophys., and Psychiat. and The Marine Biomedical Inst., Univ. Texas Med. Branch, Galveston, TX 77550.

The cell bodies of origin of the long descending and ascending propriospinal pathways have been localized in cat and monkey utilizing retrograde transport of the enzyme horseradish peroxidase (HRP). According to other investigators the method of chromatolysis has not been adequate to make this localization.

Injections of 1-5 µl of 50% or 70% HRP in saline were made in either the cervical or lumbar enlargements using a glass pipette of 50-100 µm diameter attached to a microsyringe. Penetrations went through the dorsal columns in order to injure as few axons as possible, and injections were made into the spinal gray matter. After 3 days the animals were perfused with 0.5% paraformaldehyde and 2.5% glutaraldehyde in phosphate buffer. The 50 µm sections were treated with standard procedures using diaminobenzidine to obtain a reaction product.

After injection into the lumbar enlargement, neurons containing the reaction product (labeled neurons) were found in the cervical enlargement mainly in laminae VII and VIII with a few cells in V, VI and X in both cat and monkey. The cat also had a few labeled neurons in I and IV.

After cervical injections labeled neurons were located in the lumbar enlargement mainly in laminae VII and VIII with some in I, IV, V, VI, and X in both cat and monkey. The monkey had more labeled cells in lamina I and the cat more in IV. The labeled neurons in lamina IV of the cat could be due to injury to axons of non-primary neurons during penetration through the dorsal columns.

1630 DORSAL ROOT PROJECTIONS TO THE LUMBAR SPINAL CORD IN THE CAT: A LIGHT AND ELECTRON MICROSCOPIC AUTORADIOGRAPHIC STUDY. R.L. Snyder* (SPON: S.B. Tieman). Dept. Anat., Sch. Med., UCSF, San Francisco, CA. 94143.

The projections of the primary afferents to the spinal cord of cats were examined with autoradiography following injections of up to 0.5 mCi tritiated leucine or lysine into single lumbar dorsal root ganglia. Light microscopy of coronal 1 µ plastic sections at the level of the entry of the labeled dorsal root revealed that the heaviest label was found in the marginal layer (ML) and the substantia gelatinosa (SG) of the dorsal horn regardless of the postoperative interval (3-11 days). More ventral portions of the spinal grey - the nucleus proprius (NP), intermediate grey (IG) and the ventral horn (VH) contained progressively less label. At successive levels rostral and caudal to the root entry, the label within the SG and NP decreased rapidly, while the label in the ML and the rest of the spinal grey decreased more slowly. Thus, two or three segments from the level of the root entry most of the label was found in the ML, IG, and Clarke's column (rostrally). SG at these levels contained little or no label. Lesions of Lissauer's tract (LT) prior to ganglion injection completely abolished the labeling of the ML rostral and caudal to the root entry. At the level of entry the amount of label in the ML was reduced, while the rest of the spinal grey was unaffected. Section of the entering large diameter dorsal root axons along the level of entry of the labeled root midway across the dorsal horn abolished the label in the IG and VH, but left the label in the dorsal horn intact. These results suggest that the axons of LT project primarily, if not exclusively, to the ML, and that some of the dorsal column large diameter axons project into dorsal horn, directly, while others curve around the medial portion of the dorsal horn and then recurve up into NP and SG as classically described.

Electron microscopic autoradiography at the level of the root entry demonstrated that the labeled terminals in the ML, SG, and NP represent morphologically distinct populations with some overlap. In the ML most labeled terminals contained large clear vesicles and numerous large dense cored vesicles. In the SG three terminal types were labeled: terminals similar to those labeled in ML; the "C" terminals (Gobel, 1974), which contained large clear vesicles and a dense matrix; and terminals which contained large clear vesicles and a pale matrix. Only this third terminal type was found labeled in the NP and Clarke's column. Since ML, SG and NP-Clarke's receive projections from different fiber types within the dorsal root with some overlap, these results suggest that each of the fiber types within the dorsal root terminates in a bouton that has a characteristic morphology.

1631 MULTIUNIT ACTIVITY PATTERNS IN THE BRACHIAL SPINAL CORD OF DYSTROPHIC CHICH EMBRYOS. B.T. Stokes. The Ohio State University, Columbus, Ohio 43210.

The frequency and content of polyneuronal burst discharges were examined in different regions of the cervical spinal cord (segments 14 and 15) of normal and dystrophic chick embryos from days 18 to 20 of incubation. On the dorso-ventral axis in a midlateral position, the pattern of change in burst frequency was quite different in normal and dystrophic embryos. Although bursts were encountered in each in approximately the same region and at about the same frequency, significant declines in frequency were encountered only in deeper regions of the spinal cord of dystrophic embryos. In normal embryos, bursts maintained their frequency independently of the position of the sampling electrode. Qualitative and quantitative analysis of individual burst content in these same regions has revealed that a significant decline in the number of spikes per burst is only found in the dystrophic cord in these same deep regions. Microelectrode marking techniques have revealed that this lower region consists mainly of lamina nine cells of the brachial motor columns. If the frequency and content declines in the dystrophic cord are associated with modifications in the motor outflow from this region, they may have relevance to the neurogenic etiology of muscular dystrophy.

1632 RESPONSE PROPERTIES OF LATERAL CERVICAL NUCLEUS CELLS IN THE RAT Gideon Urca, Glenn J. Giesler, Jr. and John C. Liebeskind. Dept. Psych., UCLA, Los Angeles, CA 90024.

Recent evidence (Giesler et al., this meeting) has demonstrated the existence of a scattered grouping of cells in the first three segments of the dorsolateral cervical cord. Their location in the dorsal area of the lateral columns, their projection to contralateral thalamus as verified by retrograde transport of HRP, and their morphology indicate that they may be the homologue of the lateral cervical nucleus (LCN) found in cat and monkey. In this study, an attempt was made to characterize the somatosensory inputs and projections of this nucleus by electrophysiological means. Unitary recordings were made in Urethane anesthesized paralyzed rats through micropipettes filled with Pontamine Sky Blue dye. Iontophoretic application of dye was performed at the conclusion of each successful recording tract. Histological examination showed all recorded cells to be within LCN. In the majority of experiments a comb of three bipolar stimulating electrodes was placed at the mesodiencephalic junction to test for thalamic projection using the antidromic activation technique. All cells encountered were tested for their responsiveness to hair movement, pressure, noxious pinch and graded electric shocks to the receptive field.

All cells recorded within the LCN responded to hair movement on at least a portion of the ipsilateral body surface. The vast majority of receptive fields covered more than one body quadrant and often extended to the contralateral side. The largest fields were found to cover the entire body surface including the head. In addition to their responsiveness to hair movement a large proportion of cells was also activated by mild pressure. In contrast to previous reports on the cat LCN, a number of cells were found to respond more vigorously to noxious pinch. Units responding only to nonnoxious stimuli reacted to electrical stimulation of their receptive fields with a low threshold, short duration burst of activity. Response latencies varied between 4 and 15 ms depending on the body region stimulated. In contrast, neurons that also responded to noxious stimuli produced additional late bursts of activity following intense electric shock. In the majority of cases antidromic testing revealed a projection to the contralateral thalamus.

The ability of these cells to code both noxious and nonnoxious stimuli, the remarkable convergence on them, and their direct access to the thalamus all suggest that the LCN has an important role in the perception of cutaneous stimuli in the rat.

1633 PROTEIN COMPOSITION OF THE SHORT TERM HEMISECTED RAT SPINAL CORD AND BRAIN SHOWN BY POLYACRYLAMIDE SDS SLAB GELS. Michael R. Wells*, Jerald J. Bernstein and Mary E. Bernstein*. Departments of Neuroscience and Opthalmology, University of Florida, Gainesville, Florida, 32610.

Proteins from rat spinal cord and brain were examined using SDS polyacrylamide slab gels at periods of 12 hours, 1, 3, 7 and 14 days after a left spinal cord hemisection at T2. Slab gels (0.75 mm) utilized were essentially the same as those described by Kelly and Luttges (J. Neurochem. 24:1077, 1975) consisting of a linear-exponential gradient from 8.75% to 18.75%. Male Long-Evans hooded rats were used throughout the study. Two hemisected, two sham (laminectomy and dura incisure) and one normal animal were used at each time interval. At the time of utilization animals were perfused with saline. Samples were taken from left and right somatomotor and occipital cortex, and in 4 mm segments from left and right halves of spinal cord extending up to 14 mm rostral and caudal from the site of spinal cord hemisection. Analysis was made by direct comparison of banding patterns on the gel by stain (Coomassie Blue) and densitometry. In brain, no differences in protein patterns or intensity were noted over postoperative time. In spinal cord, banding patterns at the site of lesion indicated increases in the staining intensity of bands in the regions of 10-20,000 molecular weight (MW), 70-75,000 MW, 80-85,000 MW, and 110-120,000 MW as early as 12 hours after hemisection. At sites distal to the lesion, both left and right (bilaterally) only bands in the regions of 70-75,000 MW and 80-85,000 MW showed increases in intensity, primarily the 70-75,000 MW region. This band comprised from 7-10% of the total protein in the area of the lesion. The rostrocaudal extent of the increased band at 70-75,000 MW reached a maximum between 12 hours and one day after hemisection and decreased over time. By 14 days postoperative, the major band was restricted to the site of hemisection and the cord contralateral to the lesion.

The bands of increased density after hemisection could be correlated with blood components. The major band at 70-75,000 MW corresponded to serum albumin, while the band from 10-20,000 MW may be attributed to hemoglobin. Other bands noted seemed associated with blood globulins or fragments. The penetration of blood proteins into spinal cord tissues was attributed to a breakdown of the blood brain barrier. The presence of high concentrations of such exogenous protein in spinal tissues may be associated with traumatic edema. (Supported by grant NS06164, NINCDS).

1634 SUBSTANTIA GELATINOSA UNIT ACTIVITY: NOCICEPTION AND NARCOTICS. George L. Wilcox and David J. Mayer. Dept. of Pharmacology, Univ. of Minn. Med. Sch., Minneapolis, MN 55455 and Dept. of Physiology, Med. College of Va., Richmond, VA 23298.

Presynaptic inhibition of primary afferent sensory fibers in the spinal cord dorsal horn may be an important mechanism of endogenous CNS pain modulation and of narcotic analgesia. The neurons of substantia gelationsa (SG) have been proposed as mediators of presynaptic inhibition in the dorsal horn. We designed experiments to test the hypotheses that SG mediates presynaptic inhibition and controls afferent impulses, and that morphine alters this inhibition. The investigation applied newly developed statistical/electrophysiological techniques to identify SG unit activity in the rat and to systematically study SG responses to noxious electrical stimulation of the footpad. Further studies tested morphine effects on this SG evoked activity.

The experiments were done acutely on chloralose anesthetized, paralyzed rats with the tibial nerve exposed and a laminectomy of lumbar segments two and three. Electrical stimuli were delivered subcutaneously to the plantar surface of the foot, and the tibial nerve compound action potential was monitored to verify Aβ-γ or Aδ stimulation. In some experiments, a $1mm^2$ area near the stimulating dipole was thermally damaged (50°C for 1 min) in an attempt to increase tonic levels of C fiber activity. Presynaptic inhibitory action (primary afferent depolarization, PAD) in the spinal cord was inferred from measurements of the bipolar dorsal root potential (DRP). SG activity was identified on the basis of spatial disparity of amplitude discriminated poststimulus time histograms (PSTH). Action potentials within a low amplitude window (40-100 μV) which occurred at only one of two closely spaced microelectrodes (5 μm tips, 50 μm separation) would most often have originated from neurons small and closely packed relative to the electrode separation. SG neurons uniquely fulfill these anatomical criteria; therefore, unit activity with maximum interelectrode disparity was ascribed to SG neurons. SG neurons so identified showed characteristically long activation (150 ms) after non-noxious stimuli and their peak activity correlated well with the peak of PAD. Stimuli exciting peripheral Aδ fibers and stimuli accompanied by adjacent tissue damage evoked qualitatively different SG responses and PAD time courses. Differences in SG PSTHs were not uniform, however, suggesting SG comprises a heterogeneous population with respect to nociception. Morphine depressed DRPs to nonoxious as well as noxious stimuli, and appeared to alter the temporal coherence of SG responses. (Supported in part by NIH grants, DE00116 and DA00576, and by grants from Univ. of Minn. Grad. Sch. and The Minnesota Medical Foundation.)

1635 METABOLIC AND FUNCTIONAL CHANGES OF SPINAL CORD IN EXPERIMENTAL ISCHEMIA. Shokei Yamada,* Delmar C. Sanders,* Gary E. Haugen,* and Dale E. Brown.* (SPON: M. Rosenthal) Section of Neurosurgery, Loma Linda University School of Medicine, Loma Linda, CA 92354.

Evidence increasingly suggests that human paraplegia is often the result of spinal cord ischemia. The causes of ischemia have been reported as occlusion of the anterior spinal artery, cord compression by a large intraspinal mass, temporary aortic clamping in repair of coarctation (0.5% incidence), etc. In this investigation the authors have adopted a non-invasive optical technique, to determine changes in the oxidative metabolism of cord mitochondria. Other parameters that were measured included oxygen availability by polarographic oximetry, spinal cord potentials in response to dorsal root stimulation.

Twenty cats were anesthetized with ketamine then intubated and given N_2O:O_2 anesthesia. The lumbosacral cord and nerve roots were exposed. Ischemia of the lower spinal cord was produced by either intraluminal occlusion of the thoracic aorta (Swan-Ganz Catheter) or application of a ligature around the proximal descending aorta. In both cases the femoral arterial blood pressure dropped to 0 mmHg on occlusion. A dual wavelength reflectance spectrophotometer was applied to the lumbosacral cord, and the relative reduction-oxidation (redox) level of cytochrome a,a_3 was measured during various durations of ischemia, ranging from 1 to 10 minutes. The polarographic electrode (25μ teflon coated platinum wire) was inserted into the gray matter through the dorsal column. A bipolar stimulator electrode was applied to the L_7 dorsal nerve root, and a monopolar electrode was applied to the dorso-lateral surface of the L_7 cord segment.

Aortic occlusion resulted in reduction of cytochrome a,a_3, decreased spinal cord oxygen availability, a rapid decrease in the interneuron potential within the first one minute and a minimal decrease in the posterior column potential for the same period. Within one minute after the occlusion for 1 to 5 minutes, the redox level of cytochrome a,a_3 and oxygen availability returned to the original level. But it took longer for the redox level to return to normal after prolonged occlusion. Longer the period of ischemia the slower the return of the interneuron potential to normal. There was little recovery of the interneuron potential noted after the ischemia lasted 10 minutes or longer.

The authors conclude that the ischemia of spinal cord results in depletion of ATP due to the lack of oxygen availability as well as complete reduction of the respiratory chain. The potential change in the interneuron indicates that the ion pump is no longer adequate to maintain the membrane potential because cytochrome a,a_3 were fully reduced.

SYNAPTIC TRANSMISSION

1636 RELEASE OF RADIOLABELED NEUROTRANSMITTERS FROM PURIFIED RAT BRAIN SYNAPTIC VESICLES. Suad Al-Zahid*, Larry J. Bearden* and Samuel T. Christian. Neurosciences Program, Med. Ctr., Univ. Ala. in Birmingham, Birmingham, Ala. 35294.

A flow dialysis system was utilized to study the release of radioactive neurotransmitters from preloaded synaptic vesicles in vitro. Loading of the vesicles was accomplished by incubating highly purified preparations of rat cerebral synaptic vesicles (100 ug protein/ml) with the transmitter to be studied for 10 minutes at 37°C in 5mM Tris-HCl buffer, pH 7.5, containing 156mM KCl, 5mM NaCl, 0.1mM ATP, 0.1mM $MgCl_2$ and 0.1mM EGTA. Preliminary results indicate that vesicular uptake of the putative neurotransmitter serotonin (5HT) is an active process which is efficient at an ATP concentration of 10^{-4}M.

The dialysis cell consisted of an upper chamber (with an injection port) separated from a lower chamber by a cellulose membrane with a M. W. cutoff of 12,000. Entrance and exit ports in the lower chamber permitted dialysis buffer (5mM Tris, pH 7.5, 156mM KCl, 5mM NaCl, 0.1mM ATP, 0.1mM $MgCl_2$, 0.1mM EGTA) to be pumped through the cell continuously. Effluent fractions were collected and subsequently analyzed for the presence of radioactivity. Using this system, the release of ^{3}H-5HT from synaptic vesicles was monitored continuously as components of the release mechanism (synaptic vesicles, synaptic membranes, ATP and cations) were injected sequentially into the upper chamber of the dialysis cell. After the injection of preloaded vesicles into the upper chamber, the rate of efflux of ^{3}H-5HT was allowed to reach a steady state. When vesicles were suspended in the Ca^{++} free dialysis buffer, the subsequent introduction of synaptosomal membranes did not bring about an increase in the rate of efflux of the labeled amine. However, when $2x10^{-6}$M Ca^{++} was titrated into the upper chamber, a rapid efflux of the amine was immediately observed. Deletion of ATP from the dialysis medium was found to abolish the Ca^{++} stimulated ^{3}H-5HT release. No increase in the rate of baseline efflux was observed when Ca^{++} was replaced by Mg^{++} at $2x10^{-6}$M. These experiments show that Ca^{++} and an energy source such as ATP must be present for the release of ^{3}H-5HT to occur. The flow dialysis system mimics the in vivo neurotransmitter release process, and has proven itself to be well suited for further studies of the neurotransmitter release mechanism.

1637 REDUCTION OF POST-TETANIC POTENTIATION BY HALOTHANE IN THE STELLATE GANGLION. Daryl Christ* (SPON: T.W. Schoultz). Dept. Pharmacology, University of Arkansas for Medical Sciences, Little Rock, AR 72201

Compound action potentials were recorded from the postganglionic nerve of the isolated hamster stellate ganglion. Repetitive stimulation (30 Hz for 5 sec) of the preganglionic nerve induced a period of post-tetanic potentiation (p.t.p.) when the ganglion was blocked by hexamethonium chloride (5×10^{-4}M). Halothane reduced the magnitude and duration of the p.t.p. in the presence of hexamethonium. It also reduced the amplitude of the pre-train compound action potential. When the ganglion was blocked with low concentrations of halothane (10-15 mg%) alone, the p.t.p. was very prominent, but it was smaller than the p.t.p. in hexamethonium alone. As the concentration of halothane was increased to 20 mg%, the duration of the p.t.p. was shortened. At 30 mg% halothane, the pre-train potential was completely obliterated, as well as the p.t.p. These results indicate that halothane depresses p.t.p. in the stellate ganglion of the hamster, although the concentrations necessary for this effect are rather large. The depression appears to be due to an effect on the underlying mechanisms of the p.t.p. and not simply due to the blocking action of halothane on the nicotinic effects of the neurotransmitter. (Supported by NIH Grant NS-10393.)

1638 SYNEXIN: A NEW PROTEIN FROM THE ADRENAL MEDULLA THAT MEDIATES CALCIUM DEPENDENT ASSOCIATION OF CHROMAFFIN GRANULES. C.E. Creutz*, C.J. Pazoles and H.B. Pollard (SPON: I. Hanbauer). NIH, Bethesda, MD 20014

Exocytosis of neurotransmitters, hormones and other cell secretory products is generally believed to require an increase in the intracellular free [Ca^{++}], although the mechanism of this Ca^{++} action remains unresolved. The main consequence of Ca^{++} action is thought to be the induction of close association or "fusion" of secretory vesicles with plasma membranes or in many cases, with other secretory vesicles. In order to investigate the biochemical details of this event, we have chosen to study the calcium dependent process of vesicle aggregation using chromaffin granules (CG's) from the adrenal medulla. The aggregation of CG's can be conveniently assayed by turbidity measurements of granule suspensions, and can be verified by light and electron microscopy.

We now report the discovery of a new protein from the adrenal medulla that mediates calcium induced aggregation of CG's. This protein is soluble, heat labile and trypsin sensitive, and can be partially purified by fractionation with ammonium sulfate precipitation and gel filtration. The activity of this protein is absolutely dependent upon a free [Ca^{++}] of at least 10^{-6} M, and under these conditions also binds to CG's. On SDS gels, ~70% of the protein with this activity migrates with an apparent M.W. ~44,000. Electron micrographs of CG aggregates formed by this protein reveal that the limiting membranes of the granules have fused with one another, leaving the individual granule cores separated by a pentilaminar membrane structure. These fusion sites are similar in appearance to the fusion sites seen in E.M. images of secreting cells.

We have named the CG aggregating protein "synexin," from the Greek synexis, which means "meeting". It is possible that synexin is the intracellular calcium receptor in exocytosis and that its role is to regulate membrane fusion.

1639 POSSIBLE ROLE OF SYNAPTIC VESICLE - ASSOCIATED PHOSPHOPROTEINS IN MEDIATING CALCIUM - DEPENDENT NEUROTRANSMITTER RELEASE. Robert J. DeLorenzo and Steven D. Freedman.* Dept. Neurology, Yale Univ. Sch. Med., New Haven, Ct. 06510

The anticonvulsant phenytoin (diphenylhydantoin, DPH) has been shown to inhibit several calcium-dependent release processes, including the release of neurotransmitter at the neuromuscular junction (Ann. Neurol. 1: 334, 1977), from brain slices (Arch. Neurol. 29: 239, 1973), and during posttetanic potentiation (Pharmacol. Exp. Ther. 156: 591, 1967). Previous investigations in this laboratory (BBRC 71: 590, 1976; J. Neurochem. 28: 21, 1977) have demonstrated that DPH and calcium have antagonistic actions on the level of phosphorylation of synaptosomal fraction proteins DPH-L and DPH-M, and presented the hypothesis that these antagonistic effects on protein phosphorylation may mediate the opposing actions of DPH and calcium on neurotransmitter release from the presynaptic nerve terminal.

Since synaptosome preparations are very heterogeneous, the current investigation was initiated to further test this hypothesis by determining the localization of phosphoproteins DPH-L and DPH-M in subfrations prepared from synaptosome preparations by standard density gradient techniques. The synaptosomal preparation was subfractionated into synaptic membrane, synaptosomal mitochondria, synaptosomal soluble, and synaptic vesicle enriched fractions. Each presynaptic nerve terminal preparation subfraction was incubated with [γ-^{32}P] ATP in the presence or absence of calcium and/or DPH and the incorporation of [^{32}P] phosphate into protein in each subfraction was quantitated as described in our previous investigations. Synaptosomal phosphoproteins DPH-L and DPH-M were enriched in highly purified synaptic vesicle fractions, while synaptic membrane and mitochondrial fractions had low levels of these phosphoproteins. DPH inhibited the calcium-dependent phosphorylation of these synaptic vesicle-associated phosphoproteins. The effects of DPH and calcium on the levels of phosphorylation of synaptic vesicle-associated proteins DPH-L and DPH-M were independent of ATP concentration over a wide range of concentrations.

The enrichment of proteins DPH-L and DPH-M in synaptic vesicle fractions suggests that these proteins are present within the presynaptic nerve terminal. These results confirm our initial hypothesis and further suggest that the antagonistic actions of calcium and DPH on neurotransmitter release may be mediated by the opposing actions of these agents on the phosphorylation of specific proteins localized in the presynaptic nerve terminal in association with the synaptic vesicles. Further studies on these synaptic vesicle phosphoproteins may help elucidate the molecular mechanism mediating calcium dependent neurotransmitter release.

1640 ENHANCEMENT OF SYNAPTIC RESPONSES TO STIMULATION OF THE PERFORANT PATH IS DEPENDENT ON THE NUMBER OF FIBERS ACTIVATED. R. M. Douglas and B. L. McNaughton (spon. G. V. Goddard), Department of Psychology, Dalhousie University, Halifax, Nova Scotia, Canada, B3H 4J1.

Long-lasting increases in synaptic efficacy (enhancement) have been observed at the perforant path-granule cell synapse of the hippocampus, but the amount of change has been quite variable. The present study shows that stimulus intensity is a critical factor in determining if, and how much, enhancement is produced by high-frequency stimulation. Small monosynaptic extracellular EPSP's were recorded in the dentate gyrus of rats anaesthetized with pentobarbital. The intensity of test stimuli was held constant while the intensity during the high-frequency trains was varied by changing either pulse width or current. A minimum intensity was needed to produce enhancement. The results from 15 preparations indicated that a stimulus intensity resulting in an EPSP (recorded from the region of maximal positive response in the hilus of 5.6 mV $\pm$ 1.3 (S.D.) was necessary before any enhancement was observed. Trains with intensities yielding larger EPSPs produced more enhancement. while the 5.6 mV EPSPs were close to population spike threshold, the generation of a large population spike by inserting one high-intensity pulse during a low-intensity train did not produce enhancement. Several observations suggest that this effect was due to the activation of more fibers by the high-intensity trains and not to more reliable firing of fibers. Fiber potentials followed equally well during low- and high-intensity trains. More importantly, the low-intensity trains were as effective as the high-intensity trains for producing the short-lasting augmentation-like and PTP-like increases described by McNaughton (this meeting). Furthermore, very long trains of low intensity produced no long-lasting effects, while high-intensity trains of far fewer pulses at much lower frequencies did. The data suggests that the amount of enhancement is proportional to the number of fibers (above an apparent minimum) activated by the high-frequency trains.

1641 THE MEMBRANE EFFECT OF DIBUTYRYL-GUANOSINE 3':5'-CYCLIC MONOPHOSPHATE ON SINGLE MAMMALIAN SYMPATHETIC NEURONS. N.J. Dun, K. Kaibara* and A.G. Karczmar. Loyola Univ. Stritch Sch. Med., Maywood, Il. 60153.

Acetylcholine (ACh) and dibutyryl-guanosine 3':5'-cyclic monophosphate (cGMP) were applied iontophoretically from double barreled micropipettes to the isolated rabbit superior cervical ganglion cells and the responses were recorded by means of intracellular microelectrode techniques. The proximity of the double barraled micropipette was estimated by the rise time of ACh potential (<30 msec) which was induced by a brief single current pulse. cGMP when applied by tetanic current pulses (30 Hz, 5 sec) consistently evoked a membrane depolarization of less than 10 mV in amplitude and 30-120 sec in duration. In many cells, a long after-hyperpolarization was observed following the membrane depolarization elicited by cGMP. The cGMP induced membrane depolarization was not blocked by superfusing the ganglion with d-tubocurarine (50 µM) which completely abolished the ACh potential and/or atropine (10 µM). Replacing Na ions from the superfusing solution with Tris-buffer which completely and reversibly abolished the ACh potential did not appreciably affect the cGMP induced membrane depolarization. Other ionic studies revealed that the electrogenesis of cGMP mediated membrane depolarization was complex and apparently different from the usual ACh potential generated by nicotinic receptors. (Supported by NS06455).

1642 ACTIVATION OF FROG MOTONEURONS BY STIMULATION OF CONTRALATERAL VENTRAL ROOTS. S. D. Erulkar and R. W. Soller*. Dept. Pharmacology, Univ. Penna. Sch. Med., Philadelphia, Pa. 19174.

It has been shown by electrophysiological techniques that lumbar motoneurons on the same side of the frog spinal cord are electrically coupled (Grinnell, J. Physiol. 182: 612, 1966). This coupling is thought to occur through motoneuronal dendrites which ramify within the dorsal horn. Using the Golgi method Liu and Chambers (The Interneuron, U. Calif. Press: 193, 1969) have shown the presence of medially oriented motoneuronal dendrites which cross the midline in the anterior commissure. In this study we demonstrate electrical interaction among motoneurons of both sides of segments 8 - 10 of the isolated frog (R. pipiens) spinal cord and suggest that this may occur through bundling of the medially directed dendrites.

Electrical stimulation of ventral roots 8, 9 or 10 on one side elicited responses in respective contralateral ventral roots; these responses were characterized by two components: a short latency (1-4 msec.) spike-like response followed by asynchronous activity which was sustained for 50 msec. The second component was abolished by substituting the normal Ringer's solution with one containing no calcium and 2 mM magnesium, suggesting that the asynchronous activity was due to synaptic activation, while the early response resulted from electrical interaction. It was unclear whether the synaptically evoked activity was a result of crossed recurrent pathways activated by motoneuronal collaterals or pathways activated secondarily to electrical stimulation.

Intracellular recordings from motoneurons in normal Ringer's solution confirmed the presence of both components of motoneuronal activation in response to contralateral ventral root stimulation. The responses with the shortest latencies were action potentials whose ascending phases rose directly from the baseline; in later responses, the action potentials were generated from EPSP's. In zero calcium Ringer's solution only short latency spikes were elicited. Furthermore, in many units the latencies of contralaterally evoked spikes were shorter than those of ipsilaterally evoked spikes.

Both electrical and synaptic interactions among motoneurons were transmitted through the anterior commissure, since cutting this structure abolished the cross-segmental interaction.

1643 EFFECTS OF POSTSYNAPTIC COBALT INJECTIONS ON VERTEBRATE ELECTRICAL AND CHEMICAL SYNAPTIC TRANSMISSION. Donald S. Faber, Charles Kaars*, and Steven J. Zottoli. Res. Inst. on Alcoholism, Buffalo, N.Y. 14203 and Depts. of Biology and Physiology, SUNYAB.

Iontophoretic injections of cobalt ions into the goldfish Mauthner cell (M-cell) have marked effects on mixed electrically and chemically mediated excitatory postsynaptic potentials (EPSPs) evoked by stimulation of the posterior branch of the VIIIth nerve. Intracellular recordings were obtained from the M-cell soma or lateral dendrite with cobalt-acetate microelectrodes and a second independently positioned KCl electrode. Using 2.5-50nA current pulses of 100-200 msec duration at intervals of 1.5 sec we have always observed an irreversible reduction or blockade of the electrotonic component of the mixed PSP. This decoupling occurs in the absence of any significant reduction in M-cell resting membrane potential, antidromic spike height, or input resistance. Cobalt also brings about a reversible reduction (20-50%) in the later chemical component of the mixed PSP. Selective stimulation of VIIIth nerve branches can produce chemically mediated EPSPs in the M-cell which are not associated with a shorter latency electrotonic PSP. In contrast to the observed reduction of the chemical component of the mixed responses, these exclusively chemical PSPs are not reduced by cobalt. Histological localization of the injected Co^{++} confirmed that it was restricted to the M-cell.

Politoff et al., (Brain Res. 76:343, 1974) found that Co^{++} crossed the electrotonic synapses connecting adjacent segments of the crayfish lateral giant axon when iontophoresed slowly and decoupled these synapses when iontophoresed rapidly. Our results indicate that intracellular Co^{++} can also decouple a vertebrate electrotonic synapse. The lack of an effect on the passive membrane properties of the M-cell indicates that Co^{++} - induced decoupling results from an increased junctional resistance. Nakajima (J. Comp. Neur. 156:375, 1974) has found that the presynaptic terminals electrotonically coupled to the M-cell lateral dendrite are morphologically mixed, i.e. they exhibit both gap junctions and the ultrastructural specializations commonly associated with chemical transmission. The observation that Co^{++} can reduce the chemical component of mixed PSPs while having no effect on purely chemically mediated PSPs suggests that Co^{++} crosses these gap junctions and exerts a presynaptic effect. The results are consistent with the hypothesis that synapses with the morphological correlates of both electrical and chemical transmission ordinarily function in both of these modes.

1644 INTRAVENTRICULAR ADMINISTRATION OF POTENT EXCITOTOXINS MAY YIELD CLUES TO LOCATION OF GLUTARECEPTIVE NEURONS. T. de Gubareff* and J.W. Olney, Washington Univ. Sch. Med., St. Louis, MO 63110.

Kainate (KA), N-methyl-DL-aspartate (NMA) and DL-homocysteate (HCA) are potent excitatory analogs of glutamate (GLU) which, when administered systemically, mimic GLU in destroying neurons in or near circumventricular organ (CVO) regions of brain (e.g., arcuate hypothalamic nucleus, subfornical organ, area postrema). They also destroy neurons locally when injected directly into various brain regions. The toxic action of these compounds appears to be selective for dendritic and somal, while sparing axonal portions of the neuron (Olney, et al., NS Abst., 1, 371, '75); however, it remains to be clarified whether or to what extent the toxic action is specific for functionally distinct populations of neurons. To explore this, we administered these agents into the lateral ventricle of adult rats in doses of 20 nmoles (KA), 150 nmoles (NMA) and 600 nmoles (HCA) and comprehensively examined the CNS for acute lesions. The spinal cord and brain stem were included since GLU is suspected of being an excitatory transmitter released at primary afferent sensory synapses (e.g., on spinal dorsal horn interneurons and neurons of gracile, cuneate and spinal trigeminal nuclei.

All KA-treated animals died within 1 hr after treatment; however, a widespread GLU-type dendritotoxic reaction was evident at the time of death which corresponded roughly in distribution with more circumscribed neuron-necrotizing lesions detected in NMA or HCA animals three hours following treatment. Major findings were that neurons in CVO regions tended to be spared while those in several non-CVO regions were selectively damaged. Neural elements upon which primary sensory afferent fibers synapse were particularly vulnerable as were stellate interneurons in the molecular layer of the cerebellar cortex and certain hippocampal interneurons.

We conclude: (1) that systemic administration of excitatory amino acids may be preferable to intraventricular administration for purposes of exploring the role(s) of arcuate or other CVO neurons in neuroendocrine function since excitatory amino acids may have greater access to CVO zones from blood than from the ventricle. (2) Excitatory amino acids given intraventricularly may be preferentially toxic to neural elements having glutamergic (or aspartergic?) synaptic input, although non-uniform and incomplete penetration of these compounds from ventricle into brain precludes obtaining more than a partial mapping of such elements. (3) Whether glutareceptive and aspareceptive elements can be identified separately by intraventricular application of potent analogs related structurally more to one or the other of these putative transmitters is an intriguing issue to be explored. Supported by USPH grants NS-09156, DA-00259 and RSD Award MH-38894 (JWO).

1645 FACILITATION OF CALCIUM-ACTIVATED OUTWARD CURRENT IN SKATE AMPULLAE OF LORENZINI. W.D. Huse*, D.C. Spray and M.V.L. Bennett, Dept. of Neuroscience, Albert Einstein College of Medicine, Bronx, New York 10461.

Voltage-clamped ampullae of Lorenzini exhibit two phases of active current generated by the receptor cells when stimulated by an appropriate command pulse. An early inward phase is carried by Ca, voltage-sensitive, and non-inactivating. A late outward phase (I_{out}) is voltage-insensitive, dependent on Ca influx, and presumably carried by potassium ions (cf. Clusin, Spray & Bennett, Nature, 256: 425, 1975; Clusin & Bennett, J. Gen. Physiol., 69: 145, 1977). I_{out} tail currents last about 0.6 sec, which may reflect time for reduction of intracellular free Ca. For several seconds after a Ca influx, activation of I_{out} requires less Ca influx, which suggests that residual Ca below the level required for I_{out} is removed gradually over this period. For pulses briefer than 0.2 sec a constant Ca influx is required for outward current activation (I_{out}), i.e. Ca removal is insignificant over this period, and brief pulses threshold for I_{out} can be used as a quantitative measure of residual Ca. Ca influxes subthreshold for I_{out} can also be quantitatively measured, but when I_{out} is activated the cells escape from the clamp and influx is no longer easily determined. For increasing pulses of constant duration that maximally activate g_{Ca}, but are too brief to activate I_{out}, facilitation decreases as the Ca equilibrium potential E_{Ca} is approached, i.e. less influx produces less facilitation. For a pulse exceeding the E_{Ca} there is still some facilitation ascribable to a Ca tail current after the pulse; this current is difficult to see directly because of capacitative transients. Below E_{Ca} longer pulses produce greater facilitation. Above E_{Ca} increasing pulse duration does not affect facilitation, which is consistent with the tail current explanation. Apparently the time course of facilitation is longer following prepulses that themselves activate the late current; the calcium influx under these conditions is much larger and removal mechanisms may be altered. Analysis of the time course of facilitation following Ca influxes of varying amounts should help to clarify the nature of Ca removal mechanisms in the receptor cells.

1646 PRESYNAPTIC RECEPTORS MAY REGULATE ACETYLCHOLINE RELEASE IN PARASYMPATHETIC GANGLIA. David A. Johnson*, Robert Beach*, Jesus Alanis and Guillermo Pilar. Physiology Section, Biological Sciences Group, University of Connecticut, Storrs, CT 06268.

In adrenergic systems, transmitter release is influenced by presynaptic receptors. Similar modulation has been suggested to exist in cholinergic systems (Polak, R.L., Br. J. Pharmac. 41: 600, 1971); however, the mechanism of action has not been shown. The present study demonstrates the presence of presynaptic ACh receptors in the avian ciliary ganglion and characterizes their role in the release of neurotransmitter.

Ganglia from 5-9 day-old White Leghorn chicks were prelabelled with 1μM ^{3}H-Ch at 37°C. ^{3}H-Ch taken up from the incubation medium was synthesized into ^{3}H-ACh. ^{3}H-Ch and ^{3}H-ACh were separated by liquid ion exchange following the conversion of ^{3}H-Ch to ^{3}H-PhCh by choline kinase. Tetraphenyl boron in acetonitrile: toluene fluor extracts ^{3}H-ACh (>85%) while the resultant ^{3}H-PhCh remains in the aqueous phase (>98%). Labelled ACh remaining in the ganglion at the conclusion of the experiment was determined by high voltage electrophoresis following extraction with acetic acid:ethanol.

In the presence of 35μM neostismine bromide, effluents were collected at 3 min intervals. ^{3}H-ACh was released by 3 min. 50 mM K^+ challenges or 3 min. preganglionic nerve stimulation at 20 Hz. This release was shown to be Ca^{++}-dependent. The ^{3}H-ACh released by electrical stimulation was less than that brought about by high K^+. More than 60% of all radioactivity collected during stimulation was identified as ^{3}H-ACh. Atropine (3.0×10^{-6} M), added to the bath, caused a significant increase in the level of ^{3}H-ACh released in response to stimulation by high K^+.

Transient ACh application (3.2×10^{-7} M), while recording intracellularly from presynaptic nerve terminals, elicited a 5-10 mV reduction in membrane potential accompanied by a decrease in membrane conductance. The presynaptic action potential amplitude was also reduced. Prolonged bath ACh application results in a decreased excitatory post-synaptic potential which is partially due to post-synaptic receptor desensitization. There was a decreased quantal content, measured by the coefficient of variation during this period, suggestive of a decrease in transmitter release.

This evidence supports the hypothesis that there are ACh receptors in preganglionic nerve terminals and they may be involved in modulation of transmitter release through a feedback mechanism via presynaptic depolarization.

1647 EFFECTS OF CADMIUM ON CALCIUM-DEPENDENT SYNAPTIC TRANSMISSION IN THE BULLFROG SYMPATHETIC GANGLION. T.E. Kober* and G.P. Cooper. Dept. Environ. Health, Col. Med., U. Cincinnati, Cincinnati, OH 45267.

In recent work (Nature 262: 704, 1976) with bullfrog sympathetic ganglia, we showed, using electrophysiological techniques, that lead blocks synaptic transmission presynaptically by competition with calcium and, using ^{45}Ca, that lead in fact does reduce the uptake of calcium by preganglionic nerve terminals. These experiments have now been replicated with cadmium.

The 9th or 10th sympathetic ganglion was removed from the bullfrog (Rana catesbeiana) along with several cm of the pre- and postganglionic nerves. The ganglion was placed in a chamber which allowed for the perfusion of the ganglion with normal or modified Ringer's solution. Supramaximal stimuli were applied at a rate of 1/sec. Control response was measured after 30 min in normal Ringer. Then the ganglion was perfused for 30 min with Ringer's solution containing lowered Ca, added Cd ($CdCl_2$), or both. The log of the ganglionic response amplitude was a positive linear function of the log of Ca concentration between 0.2 and 1.0 µM Ca. Cd shifted the response to the right with no appreciable change in slope, suggesting a competitive antagonism of Ca by Cd.

In other experiments the effects of Cd on the uptake of ^{45}Ca by presynaptic nerve terminals were examined. The method of Blaustein was used (Science 172: 391, 1971). ^{45}Ca was added to a bath containing a pair of ganglia. One member of the pair was stimulated supramaximally for 20 minutes at a rate of 6 stimuli/sec. The amount of ^{45}Ca taken into the ganglia was measured by conventional scintillation counting. Stimulation of the preganglionic nerve in control preparations resulted in a three-fold increase in ^{45}Ca uptake. However, 50µM Ca reduced ^{45}Ca uptake of stimulated ganglia by only 30% (the same concentration of Pb reduced the uptake by 91%).

The electrophysiological experiments suggest that Cd, like Pb, blocks synaptic transmission in the sympathetic ganglion by competitive antagonism of Ca-mediated transmitter release from presynaptic nerve terminals. However, Cd has appreciably less effect on the entry of ^{45}Ca into presynaptic nerve terminals. It is possible that Cd and Pb interfere with Ca at different cellular loci. (Supported by EPA contract #68-03-0429 and NIEHS grants #ES-00159 and #ES-01494).

1648 POSSIBLE ROLE OF cAMP IN MODULATION OF ENDOGENOUS ACTIVITY IN THE LOBSTER CARDIAC GANGLION. José R. Lemos* and Allan Berlind. Biology Department, Wesleyan University, Middletown, CT. 06457.

In the lobster, Homarus americanus, the pericardial organ releases a putative hormone which acts upon the heart. The hormone has been identified as a peptide (Berlind and Cooke, 1970) and the pericardial organ extract (XPO) when applied to the isolated cardiac ganglion increases both the frequency of bursts and the number of spikes (action potentials) within each burst.

5-hydroxytryptamine (5-HT), a putative neurotransmitter in the ganglion, increased the frequency of endogenous bursting but appeared to have no effect on the number of spikes per burst.

Both cAMP and its analogs, $N^6,O^{2'}$-dibutyryl cAMP and 8'-Bromo cAMP, mimicked the action of XPO when applied to the isolated ganglion. Dibutyryl cAMP produced significant increases in concentrations as low as 10^{-8}M. The effects of cAMP were linearly related to its applied concentration. Sodium butyrate (10^{-5}M) and 5' AMP (10^{-5}) decreased bursting frequency. Cinanserin (5×10^{-5}M), a 5HT antagonist, inhibited the endogenous activity of the ganglion.

A number of cyclic nucleotide phosphodiesterase inhibitors (PI): isobutyl methyl xanthine (10^{-5}), aminophylline (10^{-5}) and papaverine (10^{-4}) mimicked the effects of XPO. Preliminary results indicate that these PI elevate the levels of cAMP in the ganglion 4 to 5-fold. Furthermore, the PI's potentiate the effects of XPO. Evidence will be presented on the direct effect of XPO application on cAMP levels in the 9-neuron system and the localization of cAMP within that system.

The system affords an opportunity to determine the mechanism for modulation of activity in a small and relatively simple neuronal network.

1649 FUNCTIONAL AND ANATOMICAL STUDY OF SYNAPTIC TRANSMISSION IN CULTURE WITH PRESYNAPTIC HORSERADISH PEROXIDASE INJECTION. R.L. Macdonald, E.A. Neale and P.G. Nelson. BBBr., NICHD, NIH, Bethesda, Md. 20014.

Mammalian neurons derived from fetal mouse spinal cord and grown in dissociated cell culture have been used to investigate the relationship between morphology and function in central nervous system synapses. Evoked monosynaptic postsynaptic potentials (PSP's) were recorded during simultaneous intracellular recordings from pairs of synaptically connected neurons; after electrophysiological study, the presynaptic neurons were injected with horseradish peroxidase (HRP) by passing 0.5 sec positive pulses for 40-100 nA.min at 1/sec through the recording micropipette which was filled with a 4% solution of HRP (Sigma, Type VI) in Tris-HCl and 0.2 M KCl (pH 8.6). Following fixation and incubation for peroxidase activity, it was possible at the light and electron microscopic (EM) levels to determine the number and distribution of presynaptic terminals, thus allowing a direct comparison between individual PSPs and their corresponding terminals. Evoked monosynaptic inhibitory postsynaptic potentials (IPSPs) were observed less frequently than evoked monosynaptic excitatory postsynaptic potentials (EPSPs). IPSPs were monophasic with rapid rise and fall time and were easily reversed from hyperpolarizing to depolarizing by passing polarizing current through the recording microelectrode with reversal potentials being 10-20 mV hyperpolarized relative to the resting membrane potential. HRP injection revealed that although the somas of inhibitory neurons were usually small in size, the dendrites often manifested a complex morphology with numerous highly branched, entwined processes. These neurons preferentially distributed their synaptic terminals to somas and proximal dendrites of postsynaptic cells. EPSPs were variable in size (1-40 mV) and in time course. The excitatory neurons generally had large somas from which emerged several moderately branched, tapering dendrites. In one excitatory example, the EPSP was 3-4 mV and HRP injection revealed 28 synaptic terminals distributed along the soma and only 2 of the postsynaptic cell dendrites. EM reconstruction of 10 boutons revealed an average of 3-4 areas of synaptic specialization (presumed release sites) to yield a total number of 75-100 release sites. Assumption of a quantal size of 100-200 μV (based on previous experiments using coefficient of variation measurements) implies a quantal content of 15-40 and suggests a quantal content per terminal of about 1, with a release probability per release site of 0.2 to 0.3. The results suggest that in dissociated cell culture, spinal cord neurons retain significant specificity with respect to function and morphology.

1650 CHARACTERIZATION OF BRAIN STEM NEURONS IN CULTURES. Kenneth C. Marshall, Walter J. Hendelman and Boris Gimbarzevsky. Depts. of Physiology and Anatomy, University of Ottawa, Ottawa, Canada, K1N 9A9.

Cultures of cerebellum explanted from newborn mice into the Maximow chamber mature in an organotypic manner. Explants from the peduncular region typically contain three distinct groupings of neurons, a cortex region (Cx), one containing deep nuclear neurons (DN), and an area of brain stem neurons (BS). The identity of these BS cells has not been ascertained, but we have characterized them in morphological and electrophysiological studies in the whole explants described above, and in cultures which consisted exclusively of BS neurons. In living cultures, it is seen that the typical BS neurons are 20-25 μ diameter, often with granules around the periphery of the soma and are found in a compact cluster. In studies of such neurons injected with horseradish peroxidase, they are found to have stout, and very long dendrites bearing spine-like processes. The axons branch extensively and course to widespread regions of the cultures. Electrophysiological studies in which two BS neurons are recorded simultaneously by different electrodes have shown that excitatory synaptic connections are formed between these cells. Cross-correlation analysis of extracellular records demonstrated short-latency excitatory correlations. Intracellular records reveal EPSPs associated with iontophoretic activation of a second BS neuron. Electrical stimulation of the cortical region in these cultures may result in short latency EPSPs or antidromic activation. The EPSPs are thought to be the result of collateral activation from other antidromically excited BS neurons. Electron microscopic studies indicate an absence of synapses on the soma and proximal dendrites, but asymmetric synapses are formed on small post synaptic profiles by boutons containing round vesicles. These are also seen in cultures containing peduncular region alone, indicating the origin of the boutons from BS neurons. These studies will aid in the identification of the BS neurons, and may lead to a model system for study of a CNS excitatory transmitter.

1651 PHYSIOLOGICAL BASIS OF DEPOLARIZING AND HYPERPOLARIZING EVOKED POTENTIALS IN GIANT AXONS IN LAMPREY SPINAL CORD. Gary Matthews* and Warren O. Wickelgren. Dept. Physiol., Univ. of Colo. Med. Sch., Denver, CO 80262.

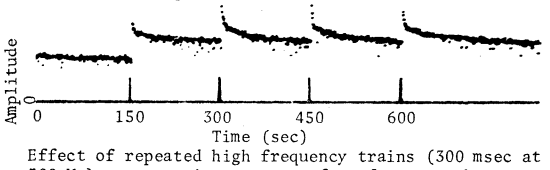
Intracellular recordings were made from the spinal axons of reticulospinal cells (Müller cells) in lamprey. Depolarizing and hyperpolarizing "synaptic-like" potentials were observed in response to stimulation of the spinal cord several cm distant. Their amplitudes were graded with the intensity of the stimulus to the spinal cord but never were larger than 10 mV at normal resting potential (-80 mV). The amplitude of the hyperpolarizing response was not affected by hyperpolarization with injected current, and no change in input resistance during the response could be detected. Therefore, it is proposed that the hyperpolarizing response is caused by the passive spread of inhibitory postsynaptic potentials from cells electrically coupled to Müller axons. The depolarizing response, on the other hand, grew in amplitude as an axon was hyperpolarized to -90 mV, but further hyperpolarization produced no additional increase in response size. Depolarization to -70 mV (which was the limit due to delayed rectification in the axon membrane and the limited current passing capabilities of the electrodes) nearly abolished the response, and the extrapolated "reversal potential" was -65 mV. The dependence of the size of the depolarizing response on axonal membrane potential suggested that it was caused by a conductance change, but the failure of the response to continue to grow with hyperpolarization beyond -90 mV was inconsistent with this interpretation. In fact, if it is recognized that the depolarizing response normally turns on some delayed rectification and thus "shorts" itself out to some extent, then the growth of the response during imposed hyperpolarization of the axon could be due to progressive reduction in the amount of delayed rectification produced by the depolarizing response. Further, it would be expected that the effect of hyperpolarization should saturate when the entire area of axon membrane at which the recording electrode looks has been hyperpolarized sufficiently to prevent the depolarizing response from turning on any delayed rectification. Quantitative analysis of the potential dependence of the response amplitude and the current-voltage characteristics of Müller axons was consistent with this interpretation. Thus, the depolarizing response in Müller axons is apparently also a result of passive spread to them of current from cells to which they are electrically coupled. This work suggests that depolarizing coupling potentials can show dependence on membrane potential and thus can mimic to some extent chemical synaptic potentials. (Supported by NIH grant NS 09661).

1652 DISSOCIATION OF SHORT- AND LONG-LASTING MODIFICATION OF SYNAPTIC EFFICACY AT THE TERMINALS OF THE PERFORANT PATH. B. L. McNaughton. Dept. of Psych., Dalhousie Univ., Halifax, N. S., Canada, B3H 4J1.

When brief trains of high-frequency electrical stimulation are delivered to the perforant pathway, the synaptic response recorded in the fascia dentata undergoes a prolonged increase which can last for weeks in chronically prepared animals. In anaesthetized preparations, the mechanism generating the long-lasting increase was observed to saturate with repeated stimulus trains. After saturation, however, short-lasting increases could be elicited repeatedly. The decay of these short-lasting effects is well fit by a sum of two exponentials whose time constants are similar to those reported by Magelby and Zengle (J.P. 257:449, 1976) for augmentation and post-tetanic potentiation at the neuromuscular junction. This suggests that the long-lasting effect is not PTP but some other process not found at the neuromuscular junction. In the absence of evidence to the contrary, the descriptive term enhancement will be used for the long-lasting process.

A stimulus intensity threshold exists below which only short-term effects but not enhancement can be elicited, regardless of train frequency or duration. It is thus possible to study the short-term effects in the absence of enhancement, during its development, and once the enhancement mechanism has been saturated. These studies indicate that enhancement multiplies the synaptic response by a constant which is independent of the presence or absence of the short-term processes. This is a necessary condition for the localization of the enhancement process to the post-synaptic cell. These studies also provide evidence that enhancement develops slowly, over a period of about 50 seconds following a brief high-frequency stimulus train.

A process resembling facilitation at the neuromuscular junction also occurs at these synapses. This process, which is observed when paired stimuli are delivered at intervals of between 20 to 50 msec, is markedly affected by the presence of the other short-term processes, but not by enhancement.



Effect of repeated high frequency trains (300 msec at 500 Hz) on synaptic response of perforant path. Test pulses at .5 Hz. Trains indicated by vertical bars.

1653 ACTION OF BACLOFEN ON CUNEATE TRANSMISSION. M. E. Morris, K. Krnjević, and S. Fox*. Department of Anaesthesia Research, McGill University, Montreal, Canada.

The antispastic agent Baclofen (*Lioresal*, β-(4-chlorophenyl)-γ-aminobutyric acid) has previously been shown to markedly depress the efficiency of transmission at the primary afferent synapses of the cuneate nucleus, while decreasing the excitability of the presynaptic terminals (Fox et al, 1976, Neurosci. Abs. I, 1003). In further studies multi-barrelled micro-pipettes have been used to record the extracellular activity of single cuneate neurones in unanaesthetized, decerebrate cats and for iontophoretic applications of Baclofen and the potential excitatory transmitters, glutamic acid and Substance P (sP). Outer barrels contained 1M Na-L-glutamate, 10mM sP (Beckman) in 20mM acetic acid, 1M NaCl, and 10-15mM dl-Baclofen (Ciba); the central recording barrel was filled with 3M NaCl. Iontophoretic application of Baclofen blocked rapidly but reversibly all forms of unit firing (spontaneous, or evoked by glutamate or sP) - probably by activating post-synaptic GABA receptors (Puil et al, 1975, Fed. Proc. 35, 307). In contrast, intravenous injections of Baclofen (0.1-10 mg/kg) had no consistent effects on such unit discharges or other excitatory effects of sP, and also did not depress the electrical excitability of the post-synaptic cuneo-thalamic cells (reflected in the α-wave of the medial lemniscal response to direct cuneate stimulation). At the same time afferent terminals became less excitable, as shown by a reduction in (i) the direct antidromic responses, (ii) the dorsal column reflex, and (iii) the enhancement normally evoked by a preceding afferent volley (although the associated inhibition of transmission was not diminished). From these results it appears that the block of transmission by Baclofen is unlikely to be mainly due to a specific antagonism of sP. The most significant site of action is probably presynaptic - either through block of impulse invasion into terminals, or interference with the storage and/or release of transmitter. Since post-tetanic potentiation is maintained or even enhanced, Baclofen cannot cause total depletion of transmitter stores. As previously postulated (Fox et al, 1976, Neurosci. Abs. I, 1003), the most probable mechanism of action is by interference with transmitter release (cf. also recent demonstration of evoked release of amino acids from cortical slices (Potashner, 1976, Fed. Proc. 36, 952)).

1654 A SPECIFIC EFFECT OF LOW DOSES OF SEROTONIN ON THE DECAY RATE OF POST TETANIC POTENTIATION. Susan A. Newlin*, Paul B. J. Woodson, Werner T. Schlapfer, and Samuel H. Barondes. Div. of Physiology and Pharmacology, Dept. of Medicine, and Dept. of Psychiatry, UCSD, La Jolla, CA 92093; and Psychiatry Research, VAH, San Diego, CA 92161.

Low doses of serotonin (10^{-8} M to 10^{-7} M) in the perfusion media cause an increase in the rate constant of decay (k) of post tetanic potentiation (PTP) at an identified synapse of Aplysia californica, without causing a change in the amplitude of PTP or in the size of an isolated EPSP. With higher doses of serotonin (10^{-5} M) effects on the amplitudes of PTP and on isolated EPSPs are also observed (Tremblay, et al., Brain Res. 109: 61, 1976).

The increase in k caused by serotonin (10^{-7} M) can be strongly antagonized by the serotonin antagonist, SQ 10,631 (10^{-4} M). Serotonin also causes a hyperpolarization of R15 at the hyperpolarized membrane potential we use. This post-synaptic effect is not blocked by SQ 10,631, but is blocked by LSD-25, BOL-148, and Methysergide.

Isobutlymethylxanthine (IBMX)(5×10^{-4} M) + serotonin(10^{-7} M) cause a greater increase in k than either agent alone. IBMX has been shown to inhibit phosphodiesterase in Aplysia (Treistman and Levitan, Nature 261: 62, 1976); and serotonin has been shown to increase cyclic AMP (Cedar and Schwartz, J. Gen. Physiol. 60: 570, 1972; Levitan, et al., J. Neurobiol. 5: 511, 1974) and activate a protein kinase in Aplysia (Levitan and Barondes, PNAS 71: 1145, 1974).

The low effective doses of serotonin and the antagonism of the serotonin effect by SQ 10,631 are consistent with a serotonin effect at a presynaptic receptor at RC1-R15. The effect of IBMX suggests that, as with other known actions of serotonin, a cyclic nucleotide may be involved. The data also suggest that the presynaptic receptor has different pharmacological properties than the serotonin receptors on R15.

1655 BIOLOGICAL PROPERTIES OF NON-NEUROTOXIC β-BUNGAROTOXIN. Ronald H. Ng* and Bruce D. Howard. (SPON: F.D. Marshall, Jr.) Dept. of Biological Chemistry, UCLA School of Medicine, Los Angeles, CA 90024.

β-Bungarotoxin is a presynaptically acting neurotoxin that inhibits the evoked release of acetylcholine from motor nerve terminals. The toxin also alters the storage of several transmitters and non-transmitter compounds in synaptosomes. Wernicke et al.[1] have proposed and given evidence that the effects of β-bungarotoxin on neuromuscular and brain synapses result from an interference with energy metabolism caused by a phospholipase A activity associated with the toxin. To investigate the enigma that β-bungarotoxin is neurotoxic while most other phospholipases are not, we examined whether neuronal membranes possess a specific phosphoglyceride substrate for β-bungarotoxin phospholipase A. If found, it may explain the following observations: (1) neuronal membranes are a better substrate than erythrocyte ghosts for β-bungarotoxin phospholipase A[1], and (2) brain membrane preparations contain a higher density of high affinity binding sites for the toxin than do membranes from liver or erythrocytes[2]. However, we found that the extent of different phospholipids hydrolyzed and the composition of fatty acids released from rat brain synaptosomes by β-bungarotoxin did not differ significantly from those affected by a non-neurotoxic phospholipase A from the same snake venom or that from V. russelli venom. β-Bungarotoxin appears to have 2 sites essential for its neurotoxicity: its phospholipase A catalytic site and a second site[3]. By chemically modifying this second site β-bungarotoxin can be converted into a non-neurotoxic phospholipase A. This conversion causes no change in its phospholipase A activity using synaptosomes as substrate. However, non-neurotoxic β-bungarotoxin has lost the native toxin's ability to inhibit GABA uptake into synaptosomes; the inhibition of GABA uptake is due to a toxin-induced depletion of energy stores[1]. These results suggest that the neurotoxicity of β-bungarotoxin cannot be attributed solely to its ability to hydrolyze phosphoglycerides. 1656 D AND L ISOMERS OF HOMOCYSTEIC ACID COMPARED FOR NEUROTOXICITY. J.W. Olney, T. de Gubareff,* and C.H. Misra. Washington Univ. Sch. Med., St. Louis, MO 63110.

In early microelectrophoretic experiments, Curtis and Watkins demonstrated that L-homocysteic acid (L-HCA) is about equal to glutamate (GLU) in neuroexcitatory potency, whereas D-HCA is substantially more powerful. More recent findings of Balcar and Johnston (J. Neurobiol., 3, 295, 1972) and Cox and Watkins (Brit. J. Pharm., 57, 433, 1976) suggest that L-HCA is taken up by both high and low affinity transport into brain slices whereas D-HCA is not taken up at all. GLU has neurotoxic properties which its several excitatory analogs, including DL-HCA mimic (Olney et al., Exp. Br. Res. 14, 61, 1971). Since rapid intracellular uptake by high affinity transport is the postulated mechanism by which the excitatory stimulus of GLU and its analogs is terminated, failure of D-HCA to be taken up (hence failure to be inactivated) may help explain its greater excitatory potency. Furthermore, if the excitotoxic hypothesis (Olney et al., NS Abst. 1, 371, 1975) is correct, that the excitatory and toxic activities of GLU-mimetic compounds are mediated by a common mechanism acting at a common receptor, it follows that D-HCA, being a more potent excitant than L-HCA, should also be a more potent toxin. If, on the other hand, the toxic activity of GLU-mimetics stems from an interference in intracellular metabolism as some have postulated, only the HCA isomer which is taken up intracellularly (L-HCA) should have appreciable toxic activity.

D-HCA and L-HCA were administered subcutaneously to 10 day-old mice at several doses and their relative neurotoxic potencies were assessed in terms of the severity of the hypothalamic lesion produced at a given dose. Each compound was also injected directly into the striatum of the adult rat and the size of the acute lesion induced by a given dose of each isomer was compared. By either subcutaneous or intrastriatal injection both isomers destroyed neurons but in each case D-HCA was the more powerful toxin. These findings strengthen the excitotoxic hypothesis and lend support to evidence from microelectrophoretic and ultrastructural studies suggesting that the receptor which mediates excitotoxic phenomena is on the external surface (dendritic or somal) of affected neurons. Although the premise that D-HCA is not transported intracellularly is based on indirect evidence (that D-HCA does not competitively inhibit active uptake of either L-GLU or L-HCA) it seems unlikely, in light of such evidence and all other available information, that either an intracellular uptake mechanism or an interference in intracellular metabolism underlies the excitotoxic activity of the HCA molecule (or of GLU and its other excitotoxic analogs since all members of the group are likely to have the same mechanism of excitotoxic action). Supported by USPH grants NS-09156, DA-00259 and RSD Award MH-38894 (JWO).

1657 THE EFFECT OF MITOCHONDRIAL UNCOUPLERS AND INHIBITORS ON EPINEPHRINE RELEASE FROM ADRENAL SECRETORY VESICLES. C.J. Pazoles, C.E. Creutz* and H.B. Pollard. NIH, Bethesda, MD 20014

Bovine adrenal chromaffin granules (CG) will release their contents when exposed to ATP, Mg and high concentrations of chloride salts (Hoffman et al. (1976) Arch. Biochem. Biophys. 176:375). Release is the result of an increase in the intragranular osmotic content and subsequent osmotic lysis of CGs (Pollard et al. (1976) JBC 251:4544). Recently we have shown that the osmotic content increase is due to an ATP stimulated influx of chloride ions through saturable anion transport sites in the granule membrane, and that anion transport blockers (SITS, probenecid, pyridoxal phosphate) inhibit release competitively with respect to external chloride ions (Pazoles and Pollard (1977) JBC, in press). However, the specific mechanism by which ATP promotes chloride transport is poorly understood. The CG possesses a Mg-ATPase and it has been suggested that this enzyme may play a role in release by pumping protons into the CG thus providing an electrical driving force for chloride uptake (Casey et al. (1976) Biochem. J. 158:583). The CG also possesses an electron transport chain which could be involved in the release reaction.

We have investigated the possible roles of ATPase and electron transport in the release reaction by studying the effects of mitochondrial uncouplers and inhibitors on release. The mitochondrial inhibitors oligomycin, antimycin-A and rotenone (all at 1.4 µg/ml) had no effect on release. Several uncouplers, however, were potent release inhibitors. These included TTFB (K_i = 0.15 µM), PCP (K_i = 2.5 µM), DNP (K_i = 30 µM), and FCCP. TFNB was not inhibitory. Kinetic analyses revealed that the uncouplers, like the anion transport blockers, inhibited release competitively with external chloride ions. We also found that the inhibitory uncouplers also stimulated the ATPase activity of CGs.

These results suggest that mitochondrial uncouplers, which are thought to act as proton ionophores, may actually inhibit release by interacting directly with the chloride transport site of the CG. These substances are, in fact, either anionic or strongly electronegative under the conditions employed. We conclude that although the stimulatory effect of uncouplers on the CG ATPase is consistent with its postulated proton pumping activity, this effect may be unrelated to the inhibition of CG release by these substances. Alternatively, it is possible that the ATPase and chloride transport sites are functionally coupled in a way which results in kinetic competition between uncouplers and chloride. Our results also indicate that the CG electron transport chain is either insensitive to mitochondrial electron transport inhibitors or is not involved in Mg-ATP-chloride induced release.

1658 ROLE OF PERMEANT ANIONS AND OSMOTIC LYSIS IN THE REGULATION OF EPINEPHRINE RELEASE FROM ISOLATED CHROMAFFIN GRANULES AND EXOCYTOSIS OF SEROTONIN FROM HUMAN PLATELETS. H.B. Pollard, C.J. Pazoles, C.E. Creutz and N.R. Shulman. NIH, Bethesda, MD 20014

Isolated chromaffin granules from bovine adrenal medulla release epinephrine when exposed to Mg^{2+}-ATP and high concentrations of permeant anions such as Cl^- (Hoffman, et al. (1976) Arch. Bioch. Biophys. 176:375). The release process depends on ATP-mediated, passive uptake of anions through an anion transport site and is competitively inhibited by impermeant, anion transport blocking agents, such as isethionate (Pollard et al. (1977) Prog. Clin. Biol. Res. 75:269), SITS (4-acetamido-4-isothiocyanostilbene -2-2'-disulfonic acid disodium), probenecid and others. The granule release event itself is due to osmotic lysis and was thus also suppressed by increased external osmotic strength (Pollard et al. (1976) JBC 251:4544). We have previously viewed this granule release reaction as a possible model for chemical events in exocytosis, and we now report that the anion transport blocking drugs also inhibited thrombin- and A23187-activated serotonin secretion from human platelets. The permeant anion of physiologic importance was hydroxyl ion rather than chloride, since serotonin release was unaffected by removal of Cl^- from the medium, and Dixon analysis (1/v vs [Inhibitor] at various pH's) showed the drugs to be competitive inhibitors with respect to OH^- concentration. K_i values were: suramin (0.9 µM); SITS (28 µM); pyridoxal phosphate (58 µM) and probenecid (335 µM). Serotonin secretion from platelets was also suppressed by increased osmotic strength of the medium, and the suppression curves, as a function of external osmotic strength, were identical for both the granule and platelet systems. We concluded that platelet secretion probably depended on anion transport and osmotic lysis analogous to those processes occurring in epinephrine release from granules, and that the general chemical and physical properties of the releasing chromaffin granule appeared to be conferred upon the secreting platelet. One explanation for this phenomenon could be that exocytosis in platelets occurs by serotonergic granules becoming "fused" or closely juxtaposed to the platelet plasma membrane, thereby allowing the granule's putative anion transport system access to OH^- ions in the external medium. The "fission" step of exocytosis might then occur as a consequence of osmotic lysis following anion entry into the vesicle interior. These findings may have fundamental importance for exocytosis in general, and could also lead to new clinical applications for anion transport blocking drugs.

1659 GABA AND NON-SYNAPTIC NEUROTRANSMISSION. E. Ramon-Moliner

Dept. Anat. & Cell Biol., Sch. Med., Univ. Sherbrooke, Sherbrooke, Quebec, Canada.

A selective action of GABA at synaptic sites appears quite likely (Takeuchi & Takeuchi, J. Physiol. 177:225,1965; Usherwood, Comp. Biochem. Physiol. 44A:663, 1973; Craelius, J. Physiol. 263:405, 1976). However, a second, extrasynaptic, type of action appears also likely. GABA acts on the 6th. abdominal segment of the crayfish, which lacks inhibitory innervation (Kufler & Edwards, J. Neurophysiol. 21:589, 1958). It depolarizes the posterior root ganglia (Nishi et al., Neuropharmacol. 13:215, 1974; De Groat, Brain Res. 38:429, 1972) in which no synapses of any kind are found (Andres, Z. Zellforsch. 55:1, 1961; Beaver et al., Arch. Path., 79:557, 1965; Pannese, Z. Zellforsch. 52:567, 1960; J. Comp. Neur. 132:331, 1968; Pannese et al., Brain Res. 46:215, 1972; J. Comp. Neur. 160:463, 1975). In the olfactory bulb, an inhibitory action of granule cells upon mitral and tufted neurons appears to be mediated by GABA (Nicoll, Brain Res. 35:137, 1971; McLennan, Brain Res. 29:177, 1971). These granule cells appear to be filled with vesicles of post-synaptic nature (Ramon-Moliner, Brain Res. 105:551, 1976) and devoid of efferent synapses (Ramon-Moliner, Brain Res., in press). GABA appears to be involved in presynaptic inhibition (Eccles et al., J. Physiol. Lon. 168:500, 1963; Davidoff, Science, 175:331, 1972) but axo-axonic synapses are very rarely observed in the spinal cord of frog (Glusman et al., Neurosci. Let. 2:137, 1976) or of the cat (Ramon-Moliner, unpublished observations). Therefore, a probable non-synaptic interaxonic modulation is involved in the mechanism of presynaptic inhibition and primary afferent depolarization, the latter being influenced by drugs that interfere with the GABA system (Barker and Nicoll, J. Physiol. Lon. 228:259, 1973; Davidoff, Exp. Neurol. 35:179, 1972). The possible involvement of glia should be considered: it is rich in GABA (Neal and Iversen, Nature, 235:217, 1972; Ljungdahl and Hökfelt, Brain Res. 62:587, 1973; Minchin and Iversen, J. Neurochem. 23:533, 1974; Iversen and Kelly, Biochem. Pharmacol. 24:933, 1975; Hammerstad and Lytle, J. Neurochem. 27:399, 1976) and it could release this transmitter as a result of the accumulation of extracellular potassium (Young et al., Brain Res. 63:479, 1973) following axonal depolarization.

1660 CATECHOLAMINE-STORING GRANULES FROM A CLONED CELL LINE. R. Victor Rebois* and Bruce D. Howard (SPON: S. Eiduson) UCLA Medical School, Los Angeles, CA 90024.

Greene and Tischler (PNAS 73:2424, 1976) have established a pheochromocytoma cell line (PC12) from rat adrenal medulla. These cells store catecholamines and exhibit a depolarization-induced, Ca^{2+}-dependent release of catecholamines (Trans. Amer. Soc. Neurochem. 8:161, 1976). We have found that these cells are a good source of catecholamine-containing storage granules. These granules are similar to chromaffin granules from normal adrenal medulla and to catecholamine-containing synaptic vesicles with respect to their mechanism of storage of catecholamines. Storage granules from PC12, like chromaffin granules and catecholamine-containing synaptic vesicles, accumulate catecholamines by an ATP-stimulated process. For these studies cells were removed from culture plates by washing with growth media, pelleted by centrifugation, and homogenized in a Teflon-glass tissue grinder. Storage granules were isolated by a series of centrifugation steps. The granules were preincubated for 5 min at 30° and then with 0.1 μM [^{3}H]dopamine (16 Ci/mmol) for an additional 5 min in a 10 mM phosphate buffer (pH 7.4) containing 0.32 M sucrose, 1 mM Mg^{2+} and 1 mM ATP. The accumulated dopamine was separated from the medium dopamine by passage through a small column of Sephadex G-25. Under these conditions, approximately 30 pmoles of dopamine were accumulated per mg of granule fraction protein. Dopamine uptake was stimulated by ATP and inhibited by 0.2 μM reserpine. The ATP-stimulated uptake was also inhibited by 1 μM S-13, an uncoupler that dissipates proton gradients, and by 40 μM dicyclohexylcarbodiimide (DCCD), which inhibits some Mg^{2+}-ATPases, but not by ouabain, which inhibits Na^+/K^+-ATPase activity. The granules contain a Mg^{2+}-ATPase activity that was inhibited by DCCD. These results indicate that catecholamine uptake by storage granules from PC12 cells is driven by a pH gradient that in turn is generated by a Mg^{2+}-ATPase activity associated with the granules. Thus, the energetics of catecholamine uptake by PC12 storage granules is similar to that of chromaffin granules from normal adrenal.

1661 LITHIUM: EFFECTS ON THE ELECTROGENIC SODIUM PUMP AND SLOW SYNAPTIC INHIBITION. Peter A. Smith* and Forrest F. Weight. Lab. Neuropharm., NIMH, Saint Elizabeths Hospital, Washington, D. C. 20032

The cellular mechanisms of the action of lithium in the nervous system is of interest because of its importance in treating certain types of mental illness. We tested the effect of lithium on the electrogenic sodium (Na) pump and the slow IPSP in bullfrog sympathetic ganglia using the sucrose gap technique. The administration of acetylcholine (ACh: 3 mM) produces a nicotinic depolarization followed by an after-hyperpolarization (AH) that results from the activation of the electrogenic Na pump. When Na in the Ringers solution was replaced by Li, the ACh depolarization still occured but the AH was abolished. Presumably Li is not extruded by the electrogenic Na pump, as has been found previously in other tissues. Li-Ringer also blocked the muscarinic slow IPSP and the hyperpolarizing response to agonists such as methacholine. We recently found that ouabain and K-free Ringer can effectively inhibit the electrogenic Na pump without blocking the slow IPSP (Nature 267 68, 1977), indicating that the slow IPSP is not generated by activation of the electrogenic Na pump. In view of this, we conclude that the effect of lithium on the slow IPSP is not a direct consequence of sodium pump inhibition.

1662 THE ROLE OF Mg^{2+}-ATPase AND A pH GRADIENT IN THE STORAGE OF CATECHOLAMINES IN SYNAPTIC VESICLES. Lawrence Toll* and Bruce D. Howard. UCLA Medical School, Los Angeles, CA 90024.

We have obtained evidence that a Mg^{2+}-ATPase situated on the membrane of catecholamine-storing synaptic vesicles is utilized in the loading of catecholamines into the vesicles. This ATPase appears to be a proton-translocating enzyme. Its activity generates a transmembrane pH gradient that in turn drives catecholamine transport. A similar mechanism can be invoked for the loading of catecholamines into adrenal chromaffin granules. For this study we have measured the in vitro, ATP-stimulated uptake of [^{3}H]norepinephrine (NE) by a fraction enriched in synaptic vesicles from rat brain. Both the uptake of NE and the Mg^{2+}-ATPase activity were inhibited by 40 μM dicyclohexylcarbodiimide (DCCD), 3 μM tributyltin and 100 μM 4-chloro-7-nitrobenzofurazan (Nbf-Cl), which are known also to inhibit proton-translocating ATPases from other sources. Catecholamine uptake was inhibited by 100 μM dinitrophenol (DNP), 4 μM FCCP and 1 μM S-13, which are known to make membranes permeable to protons. Johnson and Scarpa (J. General Phys. 68:601, 1976) and others have shown that the internal pH of chromaffin granules is approximately 5.5, indicating a transmembrane ΔpH of almost 2 units. They demonstrated that this proton gradient could be dissipated by the utilization of several cation ionophores. We have found that the ability of these ionophores to inhibit NE uptake by synaptic vesicles corresponds well with their reported ability to dissipate the pH gradient in chromaffin granules. FCCP at 0.4 μM and the K^+ ionophore valinomycin at 3 μg/ml individually had only a small effect on NE uptake or on the ΔpH, but acting together they greatly inhibited uptake and markedly altered the pH gradient. The Ca^{2+} ionophore A23187 was shown to dissipate the pH gradient only in the presence of Ca^{2+} or Mg^{2+}; A23187 was a more effective inhibitor of NE uptake in the presence of 1 mM Ca^{2+}, 1 mM Mg^{2+} than in the presence of 1 mM Mg^{2+}. Finally, nigericin, which catalyzes a K^+/H^+ exchange greatly inhibited NE uptake.

The effect of various compounds on NE efflux was studied by incubating [^{3}H]NE-loaded synaptic vesicles with the compounds. Compounds that inhibit uptake by acting at the ATPase had little or no effect on efflux. Also 0.2 μM reserpine, which inhibits NE uptake but does not affect the pH gradient, did not cause efflux. But, all the compounds that dissipated the transmembrane pH gradient also caused a significant efflux of NE from the vesicles. These results indicate that a pH gradient is indeed involved in the loading of NE into synaptic vesicles and in the maintenance of at least some of the freshly accumulated transmitter within the vesicles. It remains to be determined whether a membrane potential also is involved in the storage of NE in the vesicles.

1663 UNEXPECTED BIDIRECTIONAL CROSS TOLERANCE TO THE EFFECTS OF ETHANOL AND LOW TEMPERATURE ON THE RATE OF PTP DECAY AT AN IDENTIFIED SYNAPSE IN APLYSIA. M. Elaine Traynor*, Werner T. Schlapfer, Paul B. J. Woodson and Samuel H. Barondes. Depts. of Neurosciences and Psychiatry, UCSD, La Jolla, CA 92093, and Dept. of Psychiatry, VAH, San Diego, CA 92161.

The rate of decay of post-tetanic potentiation (PTP) at the identified synapse, RC1-R15 is accelerated by perfusion with 0.8 M ethanol (Nature 260: 797, 1976) and decelerated by reduction of the temperature (Nature 258: 623, 1975). There is a sharp transition in the temperature dependence of the rate of PTP decay in going from 12 to 10°C; such that the rate of PTP decay is more markedly affected over this interval than over neighboring intervals (Nature 258, op cit.). The effects of ethanol and low temperature both show adaptations that we refer to as "tolerance." Repeated exposure to ethanol results in a tolerant state in which ethanol no longer accelerates PTP decay (Science 193: 510, 1976). Likewise, keeping the preparation below 10°C for 4 or more hours leads to either a shift to a lower temperature, or a disappearance of the transition in the temperature dependence of the PTP decay rate, although PTP still decays more slowly at low temperatures (Nature 258: 623, 1975). Such a preparation is said to be temperature adapted.

We now report that preparations which are tolerant to ethanol do not exhibit a transition in the temperature dependence of the PTP decay rate; i.e. they appear to be temperature adapted (n = 4). Conversely, preparations which are temperature adapted are tolerant to the effect of ethanol in accelerating PTP decay rate (n = 7). Preparations which were treated in all ways similar to ethanol tolerant preparations, except for exposure to ethanol, showed a sharp transition in the PTP decay rate upon going from 12 to 10°C (n = 2). Preparations which were treated in all ways similar to temperature adapted preparations, except for exposure to temperatures below 15°C showed a marked acceleration of PTP decay rate by 0.8 M ethanol (n = 5).

The finding of bidirectional cross tolerance to treatments with opposite actions is unexpected. Further experiments, in progress, may help explain it.

Supported by VAH, San Diego, and a grant from the NIAAA.

1664 BENZODIAZEPINES MIMIC THE PRESYNAPTIC ACTION OF GABA ON A CHOLINERGIC SYNAPSE OF APLYSIA. J.-P. Tremblay and G. Grenon*. Lab. Neurobiol. Fac. Med. Laval Univ. Quebec, QUE. Canada.

The concept that benzodiazepines act through a GABAminergic mechanism has been recently developed by Costa et al., (Life Sci. 17, 167, 1975). Benzodiazepines have also been shown to affect brain acetylcholine level (Consolo et al., Eur. J. Pharmacol. 27, 266, 1974; Domino and Wilson, Psychopharm. 25, 291, 1972).

The effects of two water soluble benzodiazepines (flurazepam and RO-5-6901) have been studied on a monosynaptic, unitary and cholinergic synapse recorded in cell R15 of Aplysia after minimal stimulation of the right connective. Trains of 100 stimuli at 1/sec, followed by test pulses at interval ranging from 20 to 200 sec were given every 10 to 30 min (variable in different preparation). At this frequency, the size of the first few EPSPs decreases (synaptic depression), but with further stimulation the EPSP size increases to a sustained facilitated plateau (frequency facilitation). The train is followed by a period of post-tetanic potentiation (PTP) during which EPSPs are even larger than during the facilitated plateau.

Addition to the perfusate of a benzodiazepine (10^{-5} to 2×10^{-4} M) reduces the size of all EPSPs of a train. The EPSP size reach about 50% of their control value in 1 to 3 hrs depending on the drug concentration used. The benzodiazepines also reduce the synaptic depression and the PTP and increase frequency facilitation ratio (size of hundredth EPSP of a train divided by the size of the first EPSP of that train). The membrane potential was slightly depolarized (0 to 12 mV, N = 10) and there was a slight (0 to 20%) reduction of the membrane resistance.

The effects of the benzodiazepines were attributed to a presynaptic action since the slight changes in membrane resistance and potential of the postsynaptic cell could not account for the large reduction of EPSP size, and for the changes of synaptic depression, frequency facilitation and PTP. These effects of benzodiazepines are similar to those previously observed with GABA at this synapse (Tremblay and Plourdes, Can. J. Physiol. and Pharmacol., submitted) and they are probably due to a direct or indirect action on a presynaptic GABA receptor. Benzodiazepines have also been previously observed to reduce PTP of another cholinergic synapse in the bullfrog sympathetic ganglia (Suria, Neuropharm. 15, 11, 1976).

(Supported by grant MA-5977 of the Medical Research Council of Canada).

1665 MODULATION OF TRANSMITTER RELEASE AT AN INHIBITORY SYNAPSE IN THE C.N.S. OF THE LEECH. Bruce G. Wallace* and John Nicholls. Dept. of Neurobiology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

An inhibitory synapse that exhibits several unusual features has recently been described by Thompson and Stent (1976). In particular they observed that as the membrane potential of the presynaptic neuron became depolarized, each of its impulses gave rise to a larger inhibitory potential in the postsynaptic neuron. (This is the opposite of the conventional picture of presynaptic inhibition). We have now investigated the properties of this synapse in greater detail, measured the effect of presynaptic depolarization and hyperpolarization on the quantum content of synaptic potential and shown in addition that presynaptic inhibition at this synapse results from hyperpolarization of the terminals.

The synapse is situated in the third most anterior ganglion in the nerve cord, between an inhibitory interneuron and a motoneuron that supplies the heart. The relationship between the membrane potential in the presynaptic neuron and the amount of transmitter released by each impulse is steep. For example depolarizing the presynaptic cell body by 10 mV increases the size of the inhibitory potential recorded in the postsynaptic cell by a factor of about 6. This increase in release develops gradually over the course of about 0.5 sec after a step depolarizing change in membrane potential and decays slowly after a hyperpolarizing step. Unlike other synapses described in the leech, when the presynaptic cell is stimulated to give trains of impulses at various frequencies little facilitation or depression is apparent.

Presynaptic inhibition of release occurs by way of the homologous interneuron on the contralateral side of the ganglion. Its impulses produce inhibitory potentials on its homologue (i.e. the presynaptic interneuron). These hyperpolarizations reduce the sizes of inhibitory potentials recorded in the heart motoneuron. Recordings made from the interneurons on both sides of the animal show that both modulation of release and presynaptic inhibition occur as normal physiological events in generating the rhythmical activity of the motoneurons that supply the heart. Under normal circumstances, the interneurons fire out of phase with one another: thus the bursts in one cell inhibit the other and depress the amount of transmitter it releases.

Thompson, W. J. & Stent, G. S. (1976). J. Comp. Physiol. 111, 309-333.

1666 ENDOGENOUSLY GENERATED PTP AT AN IDENTIFIED SYNAPSE IN APLYSIA AND ITS MODULATION BY PERIPHERAL TONICITY SENSORS. Paul B. J. Woodson and Werner T. Schlapfer. Depts. of Psychiatry, UCSD, La Jolla, CA 92093 and VAH, San Diego, CA 92161.

Kupfermann and Weiss (J. Gen. Physiol. 67: 113, 1976) suggest that cell R15 of the abdominal ganglion of Aplysia releases a hormone which causes weight gain, probably through supression of water secretion. In the absence of synaptic input, R15 is a spontaneous burster (Strumwasser, J. Psychiatr. Res. 8: 237,1971). We now report that in both, an intact preparation (restrained unanesthetized animal with externalized abdominal ganglion), and a semi-intact prep (connected tentacular, circumeosophageal, abdominal, branchial, osphradial ganglia, anterior tentacles and osphradium), the bursting of R15 is strongly modulated by patterned bursts of the large EPSP which we call RC1-R15 (Brain Res. 109: 1, 1976). The membrane properties of R15 confer a tendency to fire in bursts during RC1-R15 maintained depolarization. In both preparations, the spontaneous firing of RC1-R15 may be tonically accelerated or decelerated by hyper- or hypotinic seawater, respectively, applied to the anterior tentacles. This sensory input does not habituate. Lifting the anterior tentacle out of the water, drying it off, leads to acceleration of the firing of RC1-R15. Scratching, poking or applying amino acids implicated in sexual or feeding behavior to the anterior tentacles do not affect RC1-R15 firing rate. The normally high spontaneous firing rate of RC1-R15 (intraburst frequency reaches 10/sec, with bursts a few seconds to many mins. apart) keeps the EPSP in a state of post-tetanic potentiation, which decays slowly when spontaneous firing is stopped by a sucrose gap on the right connective (presynaptic axon). In the blocked prep, electrical stimulation of the right connective reveals the decay of PTP. When PTP has decayed, the EPSP amplitude may be PTP'd either artificially by repetitive stimulation of the right connective (Brain Res., op. cit.) or by removal of the sucrose block.

We conclude that the efficacy of RC1-R15 reflects the tonicity of the environment both in its firing rate and in its amplitude because of the dependence of the PTP mechanism on the presynaptic firing rate. The PTP component of this synapse's efficacy appears to be regulated by presynaptic serotonin receptors (Newlin, et al., this volume) and by a heterosynaptic input (Brain Res. 109: 83, 1976).

1667 COMPARISON OF EXCITATION OF SINGLE CORTICAL NEURONS IN AWAKE CATS BY EXTRACELLULARLY AND INTRACELLULARLY DELIVERED CURRENT. C. D. Woody and E. Gruen*. UCLA Med. Center, Los Angeles, Ca. 90024.

Multiple barrel, glass microelectrodes were used to deliver current while recording intracellularly from neurons of the coronal peri-cruciate cortex. Baseline potential shifts on penetration averaged 45mV. The electrodes were separated vertically at the tips by 10-20μ to permit separate, simultaneous intracellular (IC) and extracellular (EC) recordings from the same unit. EC recordings did not have significant baseline shifts. After establishing absence of significant crosstalk between barrels, effects of constant current delivery via the IC and EC barrels were compared. Rectangular cathodal (+) current pulses of 10 msec duration were used to excite, sometimes with superimposed steady intracellular depolarizing or hyperpolarizing currents.

The preliminary studies, conducted in 28 neurons, gave consistent results. IC currents of 0.4 - 2.0nA produced repeated spike initiation during current application in all units. EC currents of 2-100nA promoted discharge in all but five neurons. Other details on neural excitation with weak EC currents are given elsewhere (Woody et al. J. Neurophysiol. 1976). The passage of steady depolarizing IC current facilitated repeated spike initiation with extracellularly delivered pulses. The passage of steady hyperpolarizing IC current prevented repeated spike initiation with the extracellularly delivered pulses.

Reversible decreases in spike height were observed with the passage of depolarizing currents, intracellularly, but not with delivery of extracellular currents, even though they were as much as 50-100 times greater. No indications that extracellularly applied currents of these magnitudes excited by depolarizing the inside of the neuron towards critical firing threshold were obtained from recordings with intracellular electrodes close enough to the regions of spike initiation to pass weak intracellular currents sufficient to excite the cell or alter its response to the extracellularly applied currents.

Repeatable PSP activity was not detected when repeatable spike initiation by extracellular current was prevented by superimposed, steady hyperpolarizing current, delivered intracellularly. This indicates that the EC current did not excite through pre-synaptic terminals via PSP's produced by chemical neurotransmission.

Apparently, weak EC nA currents can facilitate unit excitation by means other than internal depolarization or PSP production. Earlier studies using EC nA stimulation (Woody et al. op cit.; Brons et al. Fed. Proc. 1977) indicate that currents of either polarity can frequently excite at equal strengths, although positive polarities are preferred, and that variations in amounts of current required to excite as a function of behavioral state are a consequence of altered neurotransmission. TISSUE CULTURE

1668 REGULATION OF ARYLSULFATASE A AND B IN CULTURED MOUSE NEUROBLASTOMA. V. J. Aloyo, S. J. Tarnowski* and S. V. Molinary. Dept. Biochem., UTCHS, Memphis, TN 38163.

The differentiation of mouse neuroblastoma C1300 is accompanied by a variety of biochemical and electrical changes as well as neurite formation. We show below that in clone N18 the specific activities of arylsulfatases A (ARA) and B (ARB) are differentially regulated by culture conditions.

The cells were grown in Falcon Tissue culture flasks in Dubbecco's Modified Eagle's Medium supplemented with 10% Fetal Calf Serum (FCS) at 37°C in an atmosphere of 10% CO_2 & 90% air. To initiate the experiments, the log phase cells were dislodged from the flasks and planted in media containing a final concentration of 1% or 10% FCS. Forty eight hours later the media were exchanged with fresh media containing either 0, 1 or 10% FCS. At specific times after planting, the cells were harvested by incubation at 37°C for 10 min. in versene. Harvested cells were diluted to approximately 2 x 10^6 cells/ml with distilled water. Sonication with intermittent cooling periods was used to rupture lysosomal membranes. Assays for ARA, ARB and protein were conducted on aliquots of the sonicate.

During log phase growth, the specific activity of ARA in the undifferentiated cells remained unchanged; the more differentiated cells (grown in 1% FCS) showed a small increase in specific activity. When the growth rate was decreased by reaching stationary phase or reducing the concentration of FCS (1% or 0%), increased differentiatiation of the cells occurred and the specific activity of ARA increased approximately two-fold.

In contrast, during log phase the specific activity of ARB increased 2 fold for the cells grown in either 1 or 10% FCS. The differentiated cells (grown in 1% FCS) showed a higher specific activity. Increased differentiation (and reduced growth rate) did not result in any further increase in the specific activity of ARB.

These results indicate that the arylsulfatases are independently altered with respect to cell differentiation or growth.

1669 ACETYLCHOLINE SYNTHESIS AND STORAGE BY SPINAL CORD NEURONS GROWN IN DISSOCIATED CELL CULTURE WITH MUSCLE. Darwin Berg. Dept. Biol., UCSD, La Jolla, CA 92093.

Many dissociated spinal cord neurons from 4 day old chick embryos form cholinergic synapses on muscle when grown in cell culture. The studies reported here examined the synthesis and storage of acetylcholine (ACh) by spinal cord cells in order to follow the development of cholinergic neurons in culture and to determine what factors influence the availability of neurotransmitter at cholinergic synapses.

Dissociated spinal cord cells from 4 day old embryos were grown on pre-plated muscle cultures. ACh synthesis was measured by incubating cultures in a balanced salt solution (BSS) containing (^{3}H)choline; cell extracts were prepared and assayed for (^{3}H)ACh by high voltage paper electrophoresis and scintillation counting. ACh production was linear with time for periods up to 1 hour and was proportional to the number of spinal cord cells initially added(1-12x10^5/35 mm dish). High choline concentrations (100 µM) were needed to achieve maximum rates of synthesis. Values of 30 and 400 pmoles/hr/mg protein were obtained at 0.5 and 100 µM choline for 8 day old spinal cord-muscle cultures seeded with 4x10^5 spinal cord cells. At all choline concentrations (0.5-100 µM) 10-20% of the total radioactivity accumulated in a 1 hour period was present as (^{3}H)ACh. Pre-incubation of cultures for 1 hour in BSS lacking choline or containing 75 mM K+ (to depolarize the cells) had no appreciable effect on the amount of ACh synthesized or total radioactivity accumulated by the cells.

Studies on the stability of intracellular ACh distinguished two pools. Spinal cord-muscle cultures were incubated in 1 µM (^{3}H)choline for 1 hour to label internal ACh stores. The cultures were rinsed, transferred to BSS containing 10 mM unlabeled choline, and analyzed at appropriate times. About 40% of the (^{3}H)ACh present was lost during the first 3 minutes of the chase period. The remainder was depleted with a half-time of *ca.* 0.5 hr. Thus at least a sub-population of chick embryonic spinal cord neurons can use exogenous choline to synthesize ACh and can store a large fraction of the ACh in a relatively stable pool.

Development of the cholinergic neuron population as monitored by capacity for ACh synthesis proceeded in a continuous manner. Rates of synthesis measured either at 1 µM or 50 µM choline increased linearly with culture age over a 2-1/2 week period. Spinal cord cells grown for 1 week on collagen-coated dishes in the absence of muscle synthesized ACh at rates comparable to those observed for cells grown with muscle. By this criterion post-synaptic muscle cells were not necessary for the initial stages of development of the cholinergic neurons. 1670 CARBACHOL DOWN REGULATES ACETYLCHOLINE RECEPTORS IN MOUSE MUSCLE CELL CULTURES. Thomas H. Brown, Mark Noble* and John H. Peacock. Dept. Neurol., Stanford Univ. Sch. Med., Stanford CA 94305.

Acetylcholine (ACh), in its role as a depolarizing agent mediating neurotransmission, is important for down regulation of ACh receptor levels in skeletal muscle in situ. However, there have been no successful attempts to down regulate the number of ACh receptors by continuous application of ACh to denervated, isolated muscle (1). Indirect evidence from in vivo work (2), where synaptic cleft ACh is increased after AChesterase block, supports the argument that ACh down regulates its receptor, but is subject to alternative interpretations. In the present experiments we demonstrate directly that carbachol, a stable ACh analogue, produces a substantial down regulation of receptor levels in noninnervated muscle cell cultures after a 2-5 day incubation period. Cultures were prepared from the G8 mouse myoblast line which has high receptor levels and shows little or no desensitization to prolonged ACh application. Effective carbachol concentrations (10^{-3}-10^{-4}M) were somewhat lower than estimates (3) of peak endogenous ACh concentration at the neuromuscular junction (3x10^{-4}M).

Data from three methods used to measure ACh receptor levels are in agreement. (i) Specific binding of ^{125}I-α-bungarotoxin is decreased by 30-50% (Table). This reduction is not due to increased receptor degradation rates or desensitization. (ii) Maximum sensitivity to iontophoretically applied ACh (Table) is decreased by about 70%. ACh sensitivity was evaluated in blind experiments 1-6 hours following a control medium change to eliminate any possible desensitization. (iii) Autoradiography shows decreased labeling of both focal receptor patches and diffusely distributed receptor. The results demonstrate directly that a nicotinic agonist can down regulate ACh receptor levels and offer another approach to understanding such regulatory mechanisms.

CONDITION	BINDING fmol toxin/mg protein ± SE(n)	RESTING MEMBRANE POTENTIAL mv ± SE(n)	MAXIMUM ACh SENSITIVITY mv/nC ± SE(n)
Carbachol (10^{-4}M)	4.9 ± 0.21(8)[a]	47.3 ± 1.1(34)[c]	834 ± 198(34)[c]
	8.3 ± 0.56(8)[b]		
Control	8.1 ± 0.35(8)[a]	47.0 ± 1.2(24)[c]	3042 ± 386(24)[c]

1671 LOCAL CONTROL OF NEURITE GROWTH AND SURVIVAL BY NERVE GROWTH FACTOR. Robert B. Campenot (SPON: Paul H. Patterson). Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115

A tissue culture system has been devised in which dissociated rat sympathetic neurons grown on a collagen surface in liquid medium send their neurites across a barrier into a separate compartment. Although the barrier seal is permeable to the growing neurites, it is sufficiently impermeable to medium to hold a 5 mm hydrostatic head for at least 4 days without appreciable equalization. This culture system makes it possible to study the effects of chemical gradients on neurite growth and the effects of local application of substances to either the neurite endings or the somas.

Sympathetic neurons plated into medium containing nerve growth factor (NGF, 1 µg/ml) regularly sent neurites across the barrier into compartments which also contained NGF, but neurites never entered compartments to which no NGF had been added. This result shows that the local NGF concentration to which the growth cone is exposed can control the direction of neurite growth.

Experiments in which NGF was withdrawn from chambers after the neurites had entered suggested that local NGF is also essential for neurite survival. The neurites degenerated after local NGF withdrawal even though other portions of the neurons, including the somas, had continuous access to NGF. In contrast, the somas were not dependent on local NGF. Many somas survived withdrawal of local NGF, provided they were associated with neurite bundles that had crossed into compartments containing NGF. All the neurons in the same cultures which clearly had not sent neurites across the barrier degenerated. In summary, it seems that regions of a sympathetic neuron retrograde from a local NGF source are maintained, whereas regions orthograde from the source degenerate.

The results of these experiments are consistent with the notion that NGF released by sympathetic target tissues plays an important role in establishing and maintaining appropriate neuron-target connections during development.

1672 **IN VITRO DEVELOPMENT OF ENTERIC GANGLIA.** **H. Cheng* and M. Bjerknes* (SPON: R. E. Stull). School of Basic Medical Sciences, University of Illinois, Urbana, ILL 61801.**

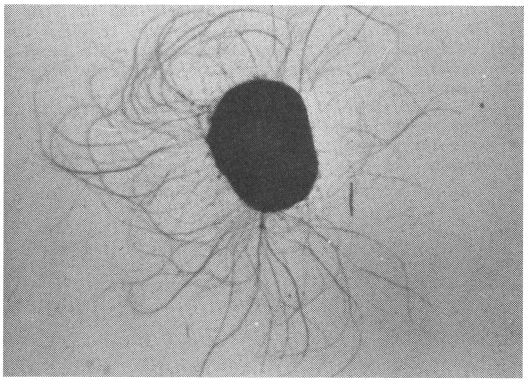
The intestine from 15-day old White Leghorn chicken embryos was removed and placed in iced-cold sterile Tyrode's solution. The mesentery was then removed and the intestine minced with fine scissor. The explants were plated in 60 mm Falcon tissue culture dishes which had been pretreated with 2% gelatine and incubated at 37°C in an atmosphere of 5% CO_2 and 100% humidity. The medium (modified Waymouth MB 752/1 with 10% fetal calf serum, 50 U/ml of penicillin and 50 ug/ml of streptomycin) was changed every week. Outgrowth (fibroblastic or epithelial) from intestinal explants was observed as early as 24 hours after initiation of culture. In a week's time ganglia consisting of various numbers of large neurones can be observed to develop in or near the explant. Ramification of nerve processes (some well over 1 mm in length) from these neurones was soon observed followed by appearance of large nerve bundles. Nerve processes have been observed to terminate on cells or end free in the medium. Nerve bundles were often found connecting two ganglia. With fluorescence microscopy after drying over phosphorus pentoxide and exposure to formaldehyde vapour, both the ganglia and nerve bundles exhibit yellowish green fluorescence indicating their adrenergic nature. Such cultures have been maintained for over 45 days and in no cases was nerve growth factor added. These results demonstrated development of enteric ganglia in vitro from chicken intestine. (Supported by a grant from The National Foundation-March of Dimes.)

1673 A FIXED-ARRAY, GOLD MULTI-MICROELECTRODE SYSTEM FOR LONG-TERM SIMULTANEOUS RECORDING OF SINGLE UNIT ACTIVITY IN VITRO. Guenter W. Gross*, Ellen Rieske*, Andreas Meyer* & Alfred Polityckí* (SPON: Paul Cancalon). Exp. Neuropath. Sect., Max Planck Inst. for Psychiatry 8 Munich 40, and Forschungslaboratorien München der Siemens AG, 8 Munich 80, FRG.

We have developed a new high density, fixed-array multi-electrode system for long-term monitoring of extracellular neuronal activity in vitro. The electrode system is manufactured with conventional microelectronics and new laser microbeam methods. It consists of a 4x4 cm glass plate that serves as the floor of a culture chamber and carries 36 gold conductors (10 μm wide and 2 μm thick). The conductors start at contact strips at either side and terminate in a centered matrix of 6 rows (200 μm spacing) and 6 columns (100 μm spacing). The conductors are insulated by the application of a silicone resin to the electrode plate spinning at 2500 rpm. This yields a 1 to 2 μm thick insulation layer that is then increased to 100 μm over the conductor bands outside the 0.5 x 1 mm recording area. In this manner the shunt impedance between the culture medium and the gold conductors is maintained above 300 megohms at 1 kHz and signal attenuation is minimized. The electrode tips are de-insulated by utilizing a UV laser microbeam system (BTG Biotechnik, Munich). Highly reproducible insulation breakthrough is accomplished with a single 8 nanosecond laser pulse. This is carried out in saline so that the impedance can be monitored during tip production. Impedances of 5 to 30 megohms can be produced by varying the area of the exposed metal surface from 100 to 10 μm^2. Preliminary testing of the electrode system with excised ganglia of the snail Helix pomatia has demonstrated that single unit activity can be easily obtained from a variety of sizes of neurons. Spikes of 250 μV can be recorded from submerged ganglia that are resting against the recording matrix. Insulation layers are stable for several weeks if large and sudden temperature variations are avoided. Insulating materials that allow convenient sterilization and promote cell adhesion are presently being tested.

1674 CLOCKWISE GROWTH OF NEURITES FROM RETINAL EXPLANTS. Anne M. Heacock and Bernard W. Agranoff. Neuroscience Laboratory, University of Michigan, Ann Arbor, Michigan 48109.

Goldfish retinal explants exhibit a vigorous neuritic outgrowth when cultured on a collagen-derived substratum, provided the optic nerve had been crushed one to two weeks prior to explantation. On the fibrous collagen surface, the neurites are randomly oriented and show no obvious directionality. We report here that polycation-coated glass or plastic surfaces also support neuritic outgrowth from goldfish retinal explants, but that on such surfaces, the neurites show a marked tendency to curve in a clockwise direction. Curving neurite outgrowth is observed both on surfaces coated with synthetic polycations such as poly-L-lysine, and on those coated with naturally occurring polycations such as protamine. The clockwise directionality is not imparted by the chirality of the poly-L-lysine or protamine substrata or by external guidance factors such as electromagnetic, gravitational or Coriolis force fields. A relationship of the clockwise pattern to an anatomical frame of reference within the explant or derived from the donor was also ruled out. We conclude that the observed clockwise directionality is somehow a consequence of an inherent helicity of the neurites which is expressed as the growing tip advances on a suitable adhesive planar surface. The phenomenon may have some relevance to the mechanisms by which retinal fibers find their way to selected sites in the brain in a highly ordered fashion. (Supported by PHS MH12506.)



1675 REGENERATION OF RETINAL GANGLION CELL AXONS IN VITRO. Pamela R. Johns, Anne M. Heacock, and Bernard W. Agranoff. Neuroscience Laboratory, University of Michigan, Ann Arbor, Michigan 48109.

We previously reported that neurites grow out from explants of goldfish retina, and we suggested that these neuritic processes are the regenerating axons of the retinal ganglion cells. This inference was based on indirect evidence: 1) only ganglion cells have long axons which extend outside the retina in vivo, and 2) the neuritic outgrowth is more vigorous and rapid when the optic nerve is crushed 10-14 days prior to explantation.

In the experiments reported here we took advantage of the laminar arrangement of the retinal neurons to trace the neurites to their cells of origin using light and scanning electron microscopy. Full thickness retinal explants were prepared either as 500 μm squares or as 100 x 400 μm strips. The strips were oriented cut side up so that the retinal layers were seen in "cross section," whereas the larger, square explants were placed with either vitreal or photoreceptor surface up and viewed as "flat mounts." Holmes silver staining was used to visualize the retinal neurons and their processes. Many of the neurites outside the explant were contiguous with the parallel array of axons in the optic fiber layer within the explant. In instances in which individual neurites could be traced back to their cells of origin, the perikarya invariably exhibited the characteristic morphology of retinal ganglion cells and were found in the appropriate retinal layer. Neurites were also traced to ganglion cells in explants examined by scanning electron microscopy. In addition, light microscopic examination of the retinal explants revealed that most or all of the retinal cells other than the ganglion cells had degenerated after three weeks in culture.

From these observations we conclude that the neurites are indeed ganglion cell axons. Explant culture of adult goldfish retina therefore provides a model system for the study of optic nerve regeneration. (Supported by PHS NS05518 to P.R.J. and MH 12506 to B.W.A.)

1676 CHEMICAL CHARACTERIZATION OF GLIA MATURATION FACTOR. Taiji Kato*, Shuang S. Troy*, David E. Turriff and Ramon Lim. Brain Research Institute, University of Chicago, Chicago, IL 60637

Glia maturation factor (GMF), a protein that promotes the morphological and chemical maturation of glioblasts in culture, was identified in our laboratory in the adult brain and some other organs (Science, 185:63-66, 1974; Science, 195:195-196, 1977). The physicochemical and biological properties of GMF distinguish it from other related factors such as nerve growth factor (NGF), fibroblast growth factor (FGF) and epidermal growth factor (EGF).

Recently we have worked out a new isolation technqiue for the purification of GMF from lyophilized crude pig brain extracts by means of successive chromatography through sephadex G-200, DEAE sephadex and sephadex G-150 columns. With this method the native protein (MW.350,000) is dissociated into a smaller component (MW. 40,000) which remains the biological activity.

Partial characterization of GMF indicates that: (i) it is sensitive to pronase and resistant to trypsin, but there is no enhancement of activity by trypsin treatment as would have been expected in an enzyme-proenzyme system; (ii) it is sensitive to heating at 100°C but stable in 4M urea; (iii) its isoelectric point is slightly acidic; (iv) using potentiometric and spectrophotometric assay, GMF has neither esterase activity on N-Benzoylarginine-ethylester , N-Benzoyltyrosine-esthylester and Tosylarginine methylester substrate, nor amidase activity on N-Benzoylarginine-p-nitroamilide substrate; (v) reducing reagents such as Dithiothreitol, alkylating reagents such as iodeacetamide, and reagents for chemical modification of active serine (Diisopropyl-fluorophosphate) do not destroy or reduce the biological activity of GMF. Attempts at obtaining specific antibody against GMF is currently underway. (This work was supported by U.S. Public Health Service Grants No. NS-09228, CA-19266 and NS-07376)

1677 MEMBRANE PROPERTIES OF A HUMAN NEUROBLASTOMA; EFFECTS OF DIFFERENTIATION. T. Kuramoto, J.R. Perez-Polo and B. Haber, (Spon. S. Wolf) The Marine Biomedical Institute, Dept. of Human Biol. Chem. and Genetics, and Dept. of Neurology, University of Texas Medical Branch, Galveston, Texas 77550

The SK-N-SH cell line is a human neuroblastoma (J. Biedler) which when grown under standard culture conditions remains relatively undifferentiated, and has only short processes. We have previously shown that the undifferentiated SK-N-SH cells are relatively inexcitable; they show only partial active responses to injections of current and appear to lack the depolarizing component of the action potential generating mechanism. The relative inexcitability of these cells as determined by intracellular recording techniques has been confirmed by measurement of $^{22}Na^{+}$ fluxes in the presence of 0.1mM veratridine. In the present study we have utilized a subclone of the SK-N-SN, the SK-N-SHIN (referred to as SHIN) which exhibit a remarkable degree of morphological differentiation when grown with 1mM dibutyryl CAMP. Fully differentiated SHIN cells have resting membrane potentials in the range of 50-80mV, which are much higher than the resting potentials seen in undifferentiated SK-N-SH cells. The input resistance and time constants of the differentiated SHIN cells is also increased. Most importantly, action potentials could be recorded from these cells after one week in culture. The amplitude of the spike potentials was variable, and the timing of spike initiation depended on the extent of development of the local potential induced by outward current injections from the cell body. These findings indicate that the spike generating mechanism is present on the processes and is distal to the cell body. In fact spikes were often recorded in cells with processes longer than 100μ. The presence of an Na^{+} dependent depolarizing component of the action potential generating mechanism was verified by the use of TTX. The TTX blockade of the action potential implies the presence of Na^{+} channels in the cell membrane. In other experiments, this was further confirmed where the passive influx of $^{22}Na^{+}$ was stimulated by veratridine: Such a stimulation is a property of fully excitable cells. In summary, we suggest that extensive morphological differentiation of this human neuroblastoma is a necessary prerequisite of the acquisition or expression of Na^{+} channels and the development of electrical excitability.

1678 MORPHOLOGICAL PROPERTIES OF THE DENDRITES AND AXONS OF DISSOCIATED RAT SYMPATHETIC NEURONS. Story C. Landis, Department of Neurobiology, Harvard Medical School, Boston, MA 02115

Neurons dissociated from the superior cervical ganglia of newborn rats and grown in mass cultures extend processes which eventually form a complicated network. Within this network, as in other culture systems, it is difficult to distinguish axons from dendrites with the phase microscope or in random thin sections. This raises the question of whether neurons which differentiate in culture develop distinct axons and dendrites with properties similar to those in vivo. Single neurons were grown in microcultures, approximately 300 μm in diameter, with small numbers of heart cells, then serially thin-sectioned perpendicular to the substrate so that processes were cut in cross section and reconstructed. In this simpler system, it is possible to clearly distinguish axons and dendrites.

Most neurons possess one to six relatively thick processes identifiable as dendrites which stain heavily with silver. These processes are up to 50 μm long and taper from 5 μm in diameter near the soma to approximately 2 μm near the tip. They may branch and end in a blunt tip or in finger-like extensions. Each process contains a central core of neurofilaments surrounded by microtubules scattered in a relatively dense cytoplasm. Close to the soma, the processes contain rough endoplasmic reticulum and free polysomes, but more distally only smooth endoplasmic reticulum and mitochondria are present. These processes are post- but not presynaptic and in general resemble the dendrites of sympathetic neurons in vivo except for their lack of small catecholamine-containing vesicles.

Distal regions of the axons are easily distinguished from dendrites. They are smaller, 0.5-1 μm in diameter, except at varicosities or synapses. The axoplasm is electron-lucent and contains predominantly microtubules with some neurofiliaments. Smooth endoplasmic reticulum and mitochondria are present but less prominent than in dendrites. The axon arises from the soma, but it extends for some distance before it acquires the appearance of the distal axon. This proximal portion contains more neurofilaments, not arranged in a central core, and denser axoplasm than the distal axon. A typical initial segment is lacking. Axonal processes are presynaptic to both dendrites and the soma, but not to other axonal processes.

Thus dissociated sympathetic neurons in culture develop processes which are morphologically very similar to dendrites and axons of sympathetic neurons in vivo.

1679 **THE EFFECTS OF BUPIVACAINE (MARCAINE) ON CULTURED SKELETAL MUSCLE CELLS.** **G. J. Markelonis*, T. H. Oh and E. C. B Hall-Craggs*. Dept. Anatomy, Univ. Maryland Sch. Med., Baltimore, MD 21201.**

Intramuscular injection of the local anesthetic Marcaine produces degeneration of skeletal muscle fibers followed by rapid regeneration (Hall-Craggs, Exp. Neurol. 43: 349, 1974). We have now investigated the effect of this drug on chick embryo skeletal muscle fibers. Serial observations were made of selected fields of cultures under the inverted microscope. When exposed to Marcaine (1×10^{-3}M) spontaneous contraction of fibers ceased immediately. Within 10-20 min fiber diameter had decreased, cross-striations disappeared, and longitudinal striations become more apparent. Over the same period blebs appeared on the surface of fibers, increased in size and finally become detached from the fiber. This finding was more pronounced in young myotubes. At 30-40 min nuclei rounded up and seemed to dissociate from the surrounding cytoplasm leaving a clear area. These changes were more frequently observed in peripherally located nuclei which on occasions were seen to be partially separated from the fiber. After 60-120 min all fibers showed gross structural disorganization and subsequently detached from the substrate. At a similar concentration the drug produced cytoplasmic vecuolation and the appearence of small blebs in mononucleate precursor cells and in fibroblasts. Cultures exposed to a lower concentration of Marcaine (5×10^{-4}M) showed loss of cross-striations in mature fibers and the appearence of blebs in young myotubes. However, withdrawal of the drug after 24 hrs was followed by regeneration. In conclusion, Marcaine causes degenerative changes in muscle fibers, young myotubes and mononucleated cells in vitro. The myotoxic effects of the drug are exhibited as changes in the morphology of the contractile apparatus and nuclei, and a reductien of fiber diameter associated with the extrusion of cytosol. Supported by Grants from NIH (NS13296) and NSF (BNS76-15370).

1680 NGF ALTERS SPECIFIC PROTEIN SYNTHESIS IN RAT PC12 CELLS. Jeffrey C. McGuire* and Lloyd A. Greene*. (SPON: Nicholas T. Zervas). Dept. of Neuropathology, Harvard Medical School and Dept. of Neuroscience, Children's Hospital Medical Center, Boston, MA. 02115.

PC12 cells are a clonal line derived from a rat adrenal medullary pheochromocytoma. PC12 cells respond to ngm levels of 2.5 S Nerve Growth Factor (NGF) by stopping cell division and acquiring neuronal properties, e.g., electrical excitability, long processes and small clear vesicles. We have investigated the protein composition of PC12 cells by SDS polyacrylamide gradient gel electrophoresis. Of the 60 bands consistently resolved on SDS gels, 5 are found in significantly increased amounts in NGF-treated cells (MWs ca. 290,000; 232,000; 75,000; 65,000; 21,000) and 1 is found in decreased amounts after NGF treatment (MW 24,000). Such changes in composition occur within 2 days after addition of NGF and take place before cessation of cell division and the beginning of process outgrowth. Similar results are seen on stained gels and on autoradiographs of gels labeled by growth of cells in medium containing labeled amino acids. The effect of NGF on synthesis of these proteins is reversible within 2 days after removal of NGF from pretreated cells. The RNA synthesis inhibitor camptothecin, when added with NGF, blocks both morphological and protein changes caused by NGF without affecting the relative levels of other proteins. The protein changes caused by NGF do not appear to be related to cessation of cell division since they are not caused by treatment with 1 μM cytosine arabinoside. The changes do not require morphological differentiation since they are not blocked by 0.1 μM colchicine, which prevents process outgrowth in NGF. We conclude that NGF stimulates the synthesis of specific proteins at the transcriptional level. This effect precedes, and may be required for, NGF-induced process outgrowth by PC12 cells. Supported by grants from NIH, Sloan Foundation, National Foundation-March of Dimes.

1681 DIFFERENTIAL EFFECTS OF DIMETHYL SULFOXIDE AND ELEVATED TEMPERATURE ON MYOBLAST FUSION. A. Miranda, G. Nette*, S. Khan*, K. Brockbank* and M. Schonberg*. Depts. of Pathology and Neurology, College of Physicians and Surgeons, Columbia University, New York, N.Y. 10032.

Dimethyl sulfoxide (DMSO) induces differentiation in culture neuroblastoma and erythroleukemic cells. Application of this agent (2%) to L8 cells, a rat-derived transformed myogenic line (Richler and Yaffe, 1970) for 48h or longer causes a modulation of their growth pattern from a randomly oriented, multilayered cell sheet to a regular whorled monolayer of flattened elongated fibroblast-like cells, which, even upon removal of DMSO fail to fuse and form myotubes. The treated cells which adhere more firmly to the substrate exhibit elevated endogenous cyclic AMP levels. The cells remain viable, but the population doubling time, mitotic index and pulse-label thymidine index decline. During DMSO treatment and subsequent removal there is no significant rise in creatine phosphokinase (CPK) levels.

Cultivating L8 myoblasts for 72 h at 41°C induces massive fusion of these cells with coincident rise of CPK (3-fold or higher). In identical cultures grown at 37°C myoblast fusion is less extensive, and occurs later (120h). When the cells are cultivated at cloning density for 72h, 80% or more of the cell colonies exhibit moderate to extensive fusion at 41°C, whereas only 15% of the colonies grown at 37°C show some degree of fusion. Myoblast cultures treated with DMSO as indicated above fail to fuse on exposure to elevated temperature. In this system DMSO does not promote myogenic differentiation but elevated temperature accelerates it.

1682 SURVIVAL OF CHICK CILIARY GANGLION NEURONS IN DISSOCIATED CELL CULTURE WITH MUSCLE AND THE FORMATION OF NERVE-MUSCLE SYNAPSES. Rae Nishi and Darwin Berg. Dept. Biol., UCSD, La Jolla, CA 92093.

Chick ciliary ganglion (CG) neurons are attractive for studying neuronal survival and synapse formation. Between days 8 and 14 *in ovo*, cell death reduces the number of neurons/CG from 6500 to 3200(1). The remaining neurons innervate iris striated muscle and choroid layer smooth muscle. *In vitro* studies have shown that intact ganglia can innervate skeletal muscle(2), and some dissociated neurons can survive for several days when grown with heart-conditioned medium(3). We have found that dissociated CG neurons survive in large numbers for weeks when grown in culture with skeletal muscle and that many of the neurons form functional nerve-muscle synapses.

Ganglia from 8 day old embryos were dissociated by enzymic and mechanical means to yield 1.2×10^4 neuronal + non-neuronal cells/ganglion. When added to muscle cultures *ca.* 50% of the total cells (90% of the possible neurons) attached to the substratum, extended processes, and took on a characteristic neuronal morphology within 24 hrs. The number of such cells (5600±200 per original ganglion, mean±SEM) remained constant in culture over a 5 week period. Intracellular stimulation of the cells elicited conventional action potentials. In contrast, only 20% of the cells plated with conditioned medium on polyornithine- or collagen-coated dishes in the absence of muscle were able to extend processes in the first 24 hours, and less then 5% remained at 6 days.

Many muscle fibers in CG-muscle cultures repeatedly twitched spontaneously. The presence of functional nerve-muscle synapses was demonstrated by stimulating neurons with intracellular or extracellular microelectrodes while using an intracellular electrode to record evoked postsynaptic potentials (PSPs) in muscle. Synaptic transmission was detected as early as 20 hours after adding CG neurons to muscle cultures. At 1 week about 70% of the neurons tested with intracellular stimulation evoked PSPs in nearby muscle fibers contacted by the neurons (18/25 neurons, 6 cultures). Evoked PSPs were blocked by 0.4 μg/ml α-bungarotoxin and reversibly blocked by 50 μg/ml d-tubocurarine.

Thus CG neurons can express highly differentiated functions in culture with skeletal muscle. More neurons survive in culture than predicted from *in vivo* cell counts, and no decline in neuronal survival is observed with culture age. These observations raise the possibility that the muscle cells have rescued neurons in culture that would have undergone cell death *in vivo*. (Supp. by USPHS Grant #12601-01, Musc. Dyst. Assoc., & Amer. Heart Assoc.)

1683 MOUSE MYOGENIC CELL LINES G7 AND G8. John H. Peacock, Daphne Rush* and Mark Noble*. Dept. Neurol., Stanford Univ. Sch. Med., Stanford CA 94305.

Fetal mouse myoblasts from primary muscle cell cultures have a capability for extended proliferation in culture when conditions are such to discourage myoblast fusion and subsequent differentiation into myotubes. For culture, muscle was dissected from hindlimbs of Swiss Webster mouse fetuses of 17 and 18 days gestational age. Factors contributing to continued cell division include subculturing at low cell densities and use of plastic not collagen-coated growth surfaces. 6 floating cell passages are possible and occasionally more than 10 trypsin dissociated passages can be obtained. One culture was colony cloned after several passages and clones G7 and G8 obtained. These clones differ from each other with respect to chromosome number, growth characteristics, morphology, acetylcholine receptor levels, capability for neuromuscular synapse formation by dissociated spinal cord neurons, and tumorigenesis in host mice.

Clone G7 has a modal number of 40 chromosomes and a generation time of about 19 hours. Myoblasts fuse poorly, despite increased calcium concentrations up to 10mM in growth medium. Both the large mononucleated cells and the thin myotubes containing few nuclei have acetylcholine (ACh) sensitivity and can contract with electrically elicited action potentials. Occasional spontaneous contractions occur. In comparison to G7, G8 has a modal chromosome number of about 67 and a generation time of about 25 hours. Differentiated G8 cultures form large multinucleated myotubes which contract spontaneously.

G8 cultures have 8-12 fold greater specific binding of ^{125}I-α-bungarotoxin (fmol/mg prot) to ACh receptors than G7. Both autoradiography and ACh iontophoretic mapping of G8 myotubes reveal nonuniform receptor localization on many cells which have focal ares ($<2\mu M^2$) of high receptor density and ACh sensitivites up to 8000 mv/nC and background sensitivities of about 500 mv/nC or lower. Other cells show uniformly high sensitivites of about 1000 mv/nC. Of interest, ACh responses in G8 exhibit little or no desensitization to ACh.

Postsynaptic potentials (blocked by 10^{-7}M d-tubocurare) occur in about 30% of G8 myotubes cocultured with spinal cord neurons and less than 1% of similarly cultured G7 myotubes. Thus G8 can be innervated as readily as primary mouse myotubes (about 20%).

G8 cells formed no tumors (0/7 mice) after subcutaneous innoculation into host mice but G7 cells were tumorigenic (6/7 mice). Histology of G7 tumors show the two cell types found in culture.

The different properties of these cell lines offer several comparative features for investigation of myogenesis and nerve-muscle interaction. (Supported by NIH grant NS12151 and NSF grant GB43526 to J.H.P.)

1684 GLIAL PROPERTIES OF A HUMAN CLONAL CELL LINE. B. Rothman*, R.L. Suddith*, L. Eng, D. Obert*, E. Tiffany*, K. Werrbach-Perez*, J.R. Perez-Polo and B. Haber (Spons. J.S. Kittridge), The Marine Biomedical Institute, and Dept. of Human Biological Chem. and Genetics, and Dept. of Neurology. The University of Texas Medical Branch, Galveston, Texas 77550, and Dept. of Pathology, V.A. Hospital, Palo Alto, California 94305.

The BT-510 is one of a number of clonal cell lines derived from a primary culture of a human brain tumor, metastatic from the lung. In culture, the BT-510 cells display an astrocytic-like morphology, similar to the rat C_6 astrocytoma. Chromosomal analysis of the BT-510 confirms that it is a human aneuploid cell line with a mean chromosomal number of 39. Aneuploidy was established by standard Giemsa banding techniques. In order to establish the glial nature of this cell line, we measured the levels of the glial fibrillary acidic protein (GFA). The BT-510 cells grown to stationary phase contain approximately 16% of the GFA content present in the C_6 cells. We have previously shown that choline transport in a variety of glial cell lines is stimulated by lowering the Na^+ concentration in the incubation medium (Neurochem. Res. 1, 201, 1976). Choline transport in the BT-510 cells was similarly stimulated by the withdrawal of Na^+ from the media. These human cells were found to have 9.7 nM/mg. Prot/min of GPDH activity. Prolonged exposure of stationary BT-510 cells to cortisone did not significantly enhance the specific activity of GPDH in the cells; in contrast to the established cortisone induction of GPDH in C_6 cells, and confirmed in these experiments. We have further compared the effects of cortisone on the expression of Monoamine Oxidase (MAO) in the BT-510 cells and in the C_6 astrocytoma (ATTC-CL107). Concentrations of cortisone ($5x10^{-7}M$) which induce GPDH in C_6 cells also markedly increase MAO activity in these experiments; the increase is as great as three times control values. In contrast, the MAO activity in BT-510 cells is only slightly elevated by higher concentrations of the hormone ($5x10^{-5}M$). The BT-510 cells are similar to other glial lines tested in their susceptibility to the cytotoxic effects of 6-hydroxydopamine. In summary, this cell line appears to be a reasonable model in which to study some properties of human glia.

1685 KINETICS OF SYNTHESIS AND RELEASE OF ACETYLCHOLINESTERASE MOLECULAR FORMS IN CHICK MUSCLE CULTURE. Richard L. Rotundo* and Douglas M. Fambrough. Carnegie Institution of Washington, Dept. of Embryology, Baltimore, Maryland 21210.

Four molecular weight forms of acetylcholinesterase (AChE) can be distinguished in normal chicken muscle by their sedimentation constants (Vigny, et al., FEBS Letters 69: 277, 1976). Of these, three can be found in chick muscle grown in culture: during the first 5 days only the 6.5S and 11S forms are observed; however, after this time small amounts of a lower molecular weight form become apparent. We find part of the muscle AChE associated with the outer portion of the cell membrane. In addition to the three forms of AChE present in the myotubes, a considerable amount of enzyme is released by the cells in the culture medium (Wilson, et al., Develop. Biol. 33: 285, 1973). We find that its sedimentation constant is intermediate between those of the two major cellular forms, and that during velocity sedimentation the enzyme moves as a broad band, suggesting molecular heterogeneity. This released form of the enzyme is precipitable by Concanavalin A, indicating it to be a glycoprotein.

Using a sensitive radiometric assay for acetylcholinesterase and culture medium pretreated with diisopropylfluorophosphate (DFP) to inhibit serum and embryo extract esterases we have studied the kinetics of synthesis and release of AChE by chick embryo muscle cells in culture. Following the addition of fresh DFP treated medium there is a rapid accumulation of AChE in the medium. This accumulation is temperature dependent, is inhibited by puromycin (10 µg/ml) and cycloheximide (100 µg/ml), and is blocked by 10^{-3} M dinitrophenol or 10^{-5} M carbonyl cyanide-m-chloro phenyl hydrazone. Experiments involving inhibition of protein synthesis indicate an intracellular pool of AChE molecules equivalent to the amount released during a three hour period. The glycoprotein nature of the AChE molecule, its association with the outer membrane of the cells, the size of the intracellular pool, and the effects of various metabolic inhibitors on the release of the enzyme in culture are consistent with models of release involving either secretion or sloughing off of the membrane. The temporal and biochemical similarities between the release of AChE on the one hand, and the incorporation of the acetylcholine receptor molecule into the muscle cell membrane on the other, suggest that the two processes are metabolically related.

1686 ANTI-OLIGODENDROCYTE SERUM DEMYELINATES CULTURED CNS TISSUE. T. Saida*, O. Abramsky*, D.H. Silberberg, D. Pleasure, R.P.Lisak and M. Manning*. Dept. Neurol., U. of Pa., Phila., Pa. 19104.

The cytotoxic effect of anti-oligodendrocyte serum (AOS) was studied using cultured cerebellum. Oligodendrocytes were isolated from calf white matter using the method described by Poduslo and Norton. Purified oligodendrocytes were essentially devoid of attached myelin when studied with the electron microscope. Biochemical studies support the purity of the isolated cell preparation (Pleasure et al, Trans. Am. Soc. Neurochem., 1977). Using indirect immunofluorescence technique, AOS stained oligodendrocyte surface components in brain sections as well as in suspension. The antisera also reacted weakly with myelin but not with other brain cells (Abramsky et al, Neurology 4, 342, 1977).

7 New Zealand rabbits were injected with oligodendrocytes with complete Freund's adjuvant (FA) and reinoculated monthly with complete or incomplete FA. Myelinated mouse cerebellum cultures were exposed to nutrient medium containing 30% AOS with 10% guinea pig serum as a source of complement. AOS from 4 rabbits, after the second and third inoculations, produced demyelinative changes several hours after application to cultures. Oligodendroglia showed degeneration of cytoplasmic organellae and pyknotic changes, and splitting and destruction of myelin were seen, with electron microscopy. Axons remained intact. New formation of myelin was inhibited when mouse cerebellum cultures were continuously exposed to 5% AOS with 5% guinea pig serum, from the time of explantation. Both demyelination and myelination inhibition were heat-labile (complement dependent). The activities were removed by adsorption with oligodendrocytes but were only partially decreased by adsorption with myelin and not affected by adsorption with liver or kidney. Myelinated mouse dorsal root ganglian cultures showed no change after 5 days application of 50% AOS. Antigalactocerebroside and antiganglioside antibody levels were not elevated in the active sera, as determined by an agglutination test using liposomes containing the appropriate lipid hapten.

These findings suggest that antibodies directed to oligodendrocyte surface components, which appear to be distinct from antigalactocerebroside antibody, can destroy oligodendroglia and produce demyelination. Similar antibodies might be involved in the immunopathogenesis of demyelinating disorders.

1687 DEXAMETHASONE-INDUCED MORPHOLOGICAL DIFFERENTIATION OF A MURINE C-1300 NEUROBLASTOMA CLONE. D. Sandquist*, T.H. Williams, S.K. Sahu*, S. Kataoka*. Dept. of Anatomy, University of Iowa, Iowa City, Iowa, 52242.

Previous work has shown that glucocorticoids have profound effects on developing neural crest tissue. This includes an increase in the number of SIF cells in superior cervical ganglion tissue *in vivo* and *in vitro* and in extra-adrenal chromaffin tissue, and an increase in phenylethanolamine-N-methyl transferase activity of the adrenal medulla and sympathetic ganglia (for review, see Chapter 15, SIF Cells, Fogarty Internat. Center Proc., No. 30). Dexamethasone, a potent synthetic glucocorticoid, was used to investigate differentiation responses in neuroblastoma, a malignant tumor of neural crest origin, grown in tissue culture.

NBP_2, a clone derived (by K. Prasad) from murine C-1300 neuroblastoma, was used. 50,000 cells were plated per 60 mm dish and treated the following day with dexamethasone 10 or 50 µg/ml (10 µg/ml = 0.025 mM). Controls were either untreated or treated with the solvent (ethyl alcohol). Drug and medium (F-12 with 10% GG-free newborn calf serum and antibiotics) were changed daily. 400 cells in separate areas were counted daily and scored as differentiated if extending a process twice the soma diameter. Six cultures were scored per treatment. Dexamethasone 50 µg/ml produced morphological differentiation in almost 65% of the population after four days of treatment. Dexamethasone 10 µg/ml produced differentiation in over 40%. Both treatments induced significantly more differentiation than untreated and solvent-treated controls, which did not differ significantly from each other. Dexamethasone also inhibited population growth. By 2 days post-treatment there was complete inhibition with dexamethasone 50 µg/ml. When the drug was withdrawn after 4 days of treatment, recovery of growth was slow, requiring 4 days to double cell numbers. By phase contrast microscopy, dexamethasone-treated cells appeared to have larger somata and more numerous perinuclear granules.

In conclusion, dexamethasone has a dose-dependent effect on morphological differentiation and growth inhibition of this neuroblastoma clone. This is in addition to the drug's effect on catecholamine fluorescence, previously reported (Anat. Rec. 187:704, 1977). Additional experimental results relating to the mechanism of action of dexamethasone will be discussed.

1688 CELLULAR IMMUNE RESPONSES TO MYELIN BASIC PROTEIN IN MULTIPLE SCLEROSIS AND STROKE. William Sheremata, Susan Colby-Germinario* and Edwin H. Eylar*, Department of Neurology, McGill University Montreal, Quebec, Canada.

In vitro evidence of cellular immune responses to myelin basic protein (BP) has been reported to correlate with clinical activity of multiple sclerosis. This suggests an *in vivo* role for such sensitization in pathogenesis. In the present study lymphoblastic transformation (LBT) and the Thor-Rocklin MIF assay were used simultaneously to detect cellular immune responses to BP. Eleven acute multiple sclerosis patients were matched with 11 stroke patients for age, sex and time after onset of neurological deficit and the results compared with 24 control subjects. Seven of 10 MIF results in MS patients were significantly different ($p < 0.01$) as compared with normals (Mean index = 76 + 21.7). One of five patients suffering first stroke gave a positive assay (MI = 127 + 35) and all patients with repeat strokes (MI = 69 + 8). Three of eleven multiple sclerosis patients (MI = 1.83 + 1.4), but no primary stroke patients (MI = 1.00 + 0.45), and only one of 4 repeat stroke patients (MI = 1.51 + 1.6) showed a significant LBT response. Of the patients with other illnesses one patient each with Guillain-Barre, asthma, andsepticemia gave positive MIF responses, but only one with septicemia gave an LBT response.

An initial episode of brain damage did not result in the earlier appearance of the cellular immune response to myelin basic protein, but repeated injury may do so. Further studies will be required to illucidate the time of appearance and magnitude of this response in young stroke patients and further evaluate the significance of this response in multiple sclerosis and in stroke.

1689 γ-GLUTAMYL TRANSPEPTIDASE ACTIVITY IN CULTURED NEURONS, GLIA, ENDOTHELIA AND ISOLATED BRAIN CAPILLARIES. D.H. Shine*, R.L. Suddith*, H. Eisenberg and B. Haber, The Marine Biomedical Institute, Depts. of Human Biological Chemistry and Genetics, Neurology and Division of Neurosurgery, University of Texas Medical Branch, Galveston, Texas 77550.

γ-glutamyl transpeptidase (γ-GTP) (2.3.2.1) is an enzyme that catalyzes the transfer of the γ-glutamyl moiety of glutathione to amino acid or peptide acceptors. This enzyme may function in part as an amino acid transport system in tissues such as liver, kidney, pancreas and choroid plexus, where its presence has been demonstrated. We have measured the activity of γ-GTP in a preparation of mouse brain microcapillaries, using a colorimeteric assay and an artificial substrate, γ-L-glutamyl-p-nitroanilide. The capillary preparations have significant levels of both γ-GTP and Na^+/K^+ ATPase activities. At present, it is not clear whether the γ-GTP activity of brain capillaries is localized in the endothelial cells, or reflects a contribution of astrocytic end feet present in such bulk isolated capillary fractions. We have therefore measured the γ-GTP activity in several clonal lines of neuronal and glial origin. The SH-IN, a subclone of the SK-N-SH human neuroblastoma and the rat neuronal line (B-50) have low, but measurable levels of γ-GTP. In contrast, subclones of the rat C_6 astrocytoma ($C_6$1A, $C_6$2B), the rat glial line (B-104) and a human line (BT510) of probable glial origin developed in this laboratory all have γ-GTP activities with specific activites minimally tenfold higher than those seen in the neuronal lines tested todate. In preliminary experiments on the subcellular localization of γ-GTP in the C_6 cells, maximal specific activities of this enzyme are found in a fraction defined as microsomal. All the cell lines tested exhibit maximal activity in the stationary phase of the growth cycle, and both neurons and glia have roughly a similar Km (10mM). Human endothelial cells in primary culture, obtained via collagenase digestion of postpartum umbilical veins do not have any γ-GTP activity, as measured by the enzymatic assay. The high specific activity of γ-GTP in several lines of cultured glia coupled with the absence of such enzymatic activity in endothelial cells of peripheral origin suggests that the γ-GTP activity of brain microcapillary preparations reflects contamination by astrocytic end feet. Alternately, the presence of γ-GTP in endothelial cells of CNS origin may reflect the inductive effects of glial and/or neuronal interactions with capillary endothelium in the CNS.

Supported by Welch Grant H-504, and PHS Grants NS 11255 and NS 11354. The B-lines, C_6 astrocytoma subclones, and SK-N-SH cells were kindly supplied by Dr. D. Schubert, J. de Vellis and J. Biedler respectively.

1690 ELECTROPHYSIOLOGICAL RESPONSES OF SINGLE SMOOTH MUSCLE CELLS TO ACETYLCHOLINE, NORADRENALINE, AND HISTAMINE. C. Nelson Sinback* and William Shain. AFRRI, Bethesda, Maryland 20014.

Smooth muscle cells of a continuous line derived from human oviduct retain the same electrical properties as smooth muscle cells in vivo including action potentials and electrotonic current spread among cells (Sinback and Shain, Neuroscience 1976). Using dissociated cultures we describe the distribution of acetylcholine, noradrenaline, and histamine receptors on individual smooth muscle cells--something which cannot be studied in vivo due to current spread among cells.

We located receptors on 138 cells using (1) single iontophoretic electrodes containing histamine, acetylcholine, or noradrenaline, or (2) using two iontophoretic electrodes: one containing histamine and the other containing acetylcholine or noradrenaline while recording intracellularly with 1 or 2 microelectrodes. Single smooth muscle cells isolated from one another have receptors for acetylcholine, noradrenaline, and histamine. However, each cell did not have all three receptors. Virtually all cells tested (89%) contained histamine receptors, about half the cells tested (54%) contained acetylcholine receptors, and about half the cells tested (46%) contained noradrenaline receptors.

Acetylcholine and histamine each elicited one of three electrical responses from single cells. For instance, in 68 cells, histamine elicited hyperpolarizing responses in 37 cells (54%), depolarizing responses in 13 cells (19%), and biphasic hyperpolarizing-depolarizing responses in 9 cells (13%). All three responses were due to increased ion flow, desensitized, and were blocked by antagonists. Histamine receptors did not increase the flow of the same ions in every cell since hyperpolarizing responses and depolarizing responses had different reversal potentials.

The cell dimensions (20μ x >100μ) allowed mapping of receptor distribution on the membrane by iontophoresing a constant charge of histamine or acetylcholine at different positions. Receptors were concentrated on cell membranes, causing localized regions of high sensitivity to histamine and acetylcholine. Responses elicited in regions of high receptor density were >10 times the amplitude of responses in surrounding areas of low receptor density. Also, single cells segregated receptors causing hyperpolarizing responses and receptors causing depolarizing responses. This segregation of hyperpolarizing and depolarizing receptors was responsible for biphasic responses.

In conclusion, these results establish that the contributions of single smooth muscle cells to neural and hormonal responses of smooth muscle tissue, which cannot be studied in vivo, can be studied using dissociated cultures of single smooth muscle cells.

1691 NEURAL ACTIVITY IN AGGREGATING CULTURES OF FETAL RAT CNS. Carl E. Stafstrom, Daniel Johnston, David Brus, and J. R. Sheppard. Dight Institute of Human Genetics and Dept. Neurol., U. Minn., Minneapolis, MN 55455.

Extracellular recordings from fetal rat brain reaggregate cultures indicate that this system may prove valuable in the study of CNS development. The reaggregates are prepared by forcing brain tissue through a series of nylon sieves, which generates a suspension of single cells. When the cells are transferred to a flask containing tissue culture medium on a gyratory shaker (78 rpm), they reassociate into uniform 1 mm spheres and reorganize themselves within these spheres.

Using standard extracellular recording techniques, predominantly negative-going spontaneous neural activity is observed as a microelectrode (6-10 MΩ) contacts the reaggregate surface. Activity of maximum amplitude is observed just below the surface, and activity often reverses sign with deeper electrode penetration. The activity sometimes exhibits rhythmic behavior (1-3 Hz). A developmental sequence appears to be followed; amplitudes average 0.3 mV the first day in vitro, which increases to 1 mV on the fourth and subsequent days. This method of amplitude averaging allows quantitative investigation of the ionic and pharmacological mechanisms underlying the electrical activity, by comparing discharges of reaggregates from a control medium with discharges from reaggregates incubated in various experimental solutions. Preliminary results indicate that tetrodotoxin or a lowered Na^+ concentration increases the average amplitude of the activity, whereas Mg^{++} or Mn^{++} (a known Ca^{++} antagonist) appear to decrease the activity. Each of these agents exhibits a characteristic dose-response curve. Activity amplitude is also affected by several hormones and other pharmacological agents.

Supported by grants from the National Foundation-March of Dimes and NS-09784-04A1.

1692 CHANGE IN THE DISTRIBUTION OF ACETYLCHOLINE RECEPTORS AFTER INNERVATION OF MUSCLE FIBRES IN TISSUE CULTURE. Willem F. Stevens*, Dick W. Slaaf*, Jacob Hooisma*, Tom Magchielse* and E. Meeter*(SPON: B. Kulig). Med. Biol. Lab. TNO, Rijswijk, The Netherlands.

The distribution of the acetylcholine (ACh) sensitivity along muscle cells is considered to be indicative for the maturation of the neuromuscular junction in vivo. In innervated and reinnervated muscle fibres the ACh sensitivity of the motor endplate region is much higher than that of the non-endplate region. Denervated and foetal muscle fibres are highly sensitive to ACh over their entire membrane.

In tissue culture an anomalous situation has been reported. The membrane of muscle cells, grown for about 10 days in culture , contains spots of hypersensitivity to ACh, so-called "hot-spots". These hot-spots are formed in the absence of innervating neural tissue but disappear in the mature muscle fibres. In our hands cultured non-innervated muscle fibres develop no hot-spots, which is a great advantage for the study of the effect of innervation on receptor density.

Chick leg muscle cells were grown in bicarbonate buffered MEM medium with 15% horse serum and 5% embryo extract, pH 7.3, 320 mosm. Sensitivity to ACh was measured by iontophoretic application of ACh, the density of the receptors by autoradiography using ^{125}I-α bungarotoxin (gift Z. Vogel, Rehovot, Israel).

With the electrophoretic method 81.000 μm^2 of membrane of non-innervated myotubes was tested with very small steps along the membrane. In an individual fibre the ACh sensitivity never varied more than a factor of 3.6, whereas the average variation was 1.5 x. Abrupt spatial differences in sensitivity were never found. These results were confirmed by autoradiography.

In myotubes cultured together with either chick ciliary ganglia or mouse spinal cord explants ACh sensitivity was measured in muscle cells which showed endplate potentials. The overall ACh sensitivity was found similar to that found in non-innervated myotubes. In the vicinity of possible endings of neurites, however, areas were found where the sensitivity was abruptly higher than that of the background. In such areas the mean ratio in ACh sensitivity over background was 10.2 (range 4.1-36.4)in myotubes innervated by the ciliary ganglion and 5.8 (range 4.3-8.1) if the cells were innervated by spinal cord explants. Autoradiography showed that many fibres in a small circular zone around the explant contained (several) clusters of ACh receptors, whereas myotubes further away from the explant had hardly any cluster on its surface.

These observations are consistent with earlier observations about the distribution of innervated myotubes around an explanted ciliary ganglion (Hooisma et al., Brain Res.85, 79, 1975) and with the region in which a spinal cord explant exerts its trophic influence (Hooisma et al., in preparation).

1693 FINE STRUCTURE OF MECHANICALLY DISSOCIATED RAT CNS AGGREGATING CELL CULTURES. B. D. Trapp*, P. Honegger*, H. deF. Webster and E. Richelson (SPON: M. R. Murray). NINCDS, NIH, Bethesda, MD 20014 and Dept. Pharmacology, Mayo Foundation, Rochester, MN 55455.

To supplement earlier biochemical studies (Honegger and Richelson, 1976) the morphology of mechanically dissociated fetal (15-16 d gestation) rat brain was investigated at 4, 19, 26 and 40 days in vitro. The aggregates were spherical in shape and ranged in diameter from 337μ ± 78μ (mean ± SD) at 4 days in vitro to 430μ ± 53μ at 40 days in vitro. At 4 days most cells were undifferentiated; some macrophages and ependymal cells were also present. At 4 and 19 days, mitotic figures were apparent; the neuropil was loosely packed and contained growth cones. Synaptic contacts and initiation of myelin formation were found in 19 day cell aggregates. At 26 days in vitro most cells could be identified as neurons, astrocytes or oligodendrocytes. The neuropil was tightly packed and synaptic complexes and compact myelin sheaths were present. At 40 days in vitro degenerative changes were observed in central regions of the aggregates. An increase in filaments within astrocytic processes and a dramatic decrease in the number of synapses was found at 40 days. In summary, cells within aggregating cultures differentiate prior to 26 days in vitro. Synapses and myelin sheaths are found, as suggested by biochemical data on similar cultures. Our results provide additional evidence that these aggregating cell cultures are useful for correlative biochemical, pharmacological and morphological studies of CNS development.

1694 EARLY CHEMICAL EVENTS INDUCED BY GLIA MATURATION FACTOR. David E. Turriff, Shuang S. Troy*, John Prunskis*, Taiji Kato* and Ramon Lim. Brain Research Institute, University of Chicago, Chicago, IL 60637.

The protein, Glia Maturation Factor (GMF), induces the morphological and biochemical differentiation of cultured glioblasts to mature astrocytes. Previously, we have reported that enhancement of DNA synthesis occurs at twelve hours after exposure to GMF (Lim et al., Science, 195, 195, 1977). This increase remains even with our most highly purified sample. However, inhibition of DNA synthesis with cytosine arabinoside does not inhibit the response of glioblasts to GMF. Enucleated glioblasts do not differentiate after GMF stimulation, however, indicating that a complex relationship exists between the nucleus and the differentiation capacity of the cells. We have detected increases in guanosine cyclic monophosphoric acid (cGMP) as early as one hour after stimulation with GMF. Attempts to correlate the cGMP increase with increased DNA synthesis and mitosis have failed since the cyclic nucleotide analogues, 8-bromo cyclic GMP and dibutyryl cyclic GMP, do not enhance glioblast cell division or DNA synthesis. Furthermore, bromo- or dibutyryl cyclic GMP neither cause glioblast differentiation by themselves nor enhance GMF-stimulated maturation. Consequently, although cGMP increases are the earliest detectable response to GMF, no role has yet been found for this cyclic nucleotide in the maturation process. (USPHS Grants No. 09228, CA-19266, NS-07376 and NS-05017).

1695 DISSOCIATED CELL CULTURE OF CHICK CILIARY GANGLION: SURVIVAL AND DEVELOPMENT WITH AND WITHOUT TARGET TISSUES. Jeremy B. Tuttle.* (SPON: Guillermo Pilar). Physiology Section, Biological Sciences Group, Univ. of Connecticut, Storrs, CT 06268.

The avian ciliary ganglion and ciliary nerve-iris are preparations used extensively in studies of neural development. This usefulness might be extended if methods for long-term culture of these tissues were available. We report here that ciliary ganglion cells can be maintained in dissociated cell culture for extended periods (7-8 wks), and that the survival of some cells is not entirely dependent upon the presence of the natural target tissue (iris muscle).

Ganglion cells removed at different embryonic stages, dissociated by several techniques, and cultured in different media formulations, display wide variations in survival. In the least successful cases, cell death was immediately apparent, and only non-neural cells remained at 24-48 hrs in culture. Other regimes and formulations allowed survival of some neurons for 4-10 da. However, the most successful combination supported ganglion cell survival and development for about two months. Optimum age for isolation was found to be 7 da. in ovo (St. 31-32), survival was best when gentle trypsinization (0.08% trypsin) with mechanical disruption was used, and the medium was a modified Eagle's MEM, with 10% (v/v) heat-inactivated horse serum and 4-5% CEE_{50}. Supplemental NGF was not included in the medium. The substrate used was not critical for survival, as poly-D-lysine and poly-L-ornithine (PORN)-coated tissue culture dishes and collagen-coated surfaces all supported some cell survival. Collagen surfaces promoted non-neural cell growth, while PORN-coated ones did not. "Microcultures", or low-density "island" cultures on small spots of substrate were also prepared and axonal "connections" could form between adjacent "islands".

The developmental status of ganglion cells in culture was examined using several criteria. Ganglion cells could generate essentially normal action potentials soon after explantation, and retained this excitability for several weeks. If co-cultured with chick iris or leg myoblasts, the ganglion cells could rapidly form junctions with the muscle tissues. Cultures of ganglion cells also synthesize ^{3}H-acetylcholine from ^{3}H-choline, which suggests that the synthetic pathway for this neurotransmitter is present in culture. These results, and those of ultrastructural studies, indicate that prolonged culture of dissociated parasympathetic neurons is possible, even in the absence of exogenous NGF, and that long-term interactions between parasympathetic neurons, their target tissues, and other cell types may now be examined in cell culture. Supported by NIH-NS 10338 and NS 5382-01 and the Univ. of Connecticut Research Foundation.

TROPHIC FUNCTIONS

1696 LOCALIZATION OF NERVE GROWTH FACTOR IN THE VERTEBRATE BRAIN. Larry I. Benowitz and Victor E. Shashoua, McLean Hospital, Mailman Res. Ctr., Dept. Biol. Chem., Harvard Medical School, Belmont, MA 02178.

Nerve growth factor (NGF), a trophic protein required for the development and maintenance of certain ganglionic neurons, is synthesized in vitro by C6 glioma (Murphy et al., J. Cell. Biol., in press), and by glia derived from dorsal root and sympathetic ganglia (Varon, Exp. Neurol. 48, 75, 1975). A central occurrence of the protein has traditionally been doubted, although homogenized neuraxes of fish, as well as those of embryonic mouse and chick, have been shown to exert NGF-like activity in culture (Winick & Greenberg, Pediatrics 35, 225, 1965). To determine whether NGF is actually localized in specific elements of the vertebrate CNS, brain sections from goldfish, mouse and chick were reacted first with monospecific rabbit antisera against NGF (courtesy M. Young and R.A. Murphy), then with a marker antibody, goat anti-rabbit IgG conjugated with fluorescein.

An extensive plexus of fibers immunologically reactive with anti-NGF serum was found to be present throughout all levels of the goldfish brain. The fibers were plentiful in the ependymal zone from the spinal cord up through the forebrain, and in certain other sites (e.g., fiber and outermost layers of the vagal lobe) that are rich in glial processes. This labeling pattern partially corresponds with that of the glial fibrillary acidic protein (GFA-- derived from fibrous astrocytes: Dahl and Bignami, Brain Res. 61, 279, 1973), and is also similar to the distributional pattern of fibers containing β, a 32,000 MW soluble protein whose turnover rate is altered by conditioning in the goldfish (Shashoua, PNAS 74, 1743, 1977; Benowitz & Shashoua, Brain Res., in press). However, unlike the β protein, NGF is not found in cell bodies. In the mouse and chick, a much less extensive fiber plexus was stained with the anti-NGF serum, confined primarily to external and periventricular surfaces of the brainstem. These results indicate that while a protein immunologically similar to NGF may be associated with processes of brain cells, presumably non-neuronal, in all 3 vertebrate classes, it is particularly rich in the primitive ependymal zone of the fish. (Supported by The Medical Foundation, Inc. and The Scottish Rite Schizophrenia Research Program.)

1697 PHYSIOLOGICAL EVIDENCE FOR TROPHIC EFFECTS: IXth NERVE SECTION CAUSES RAPID FAILURE OF TASTE RESPONSES. Daniel Berland*, Joyce Chu*, Lee B. Jones*, Jon Kaliszewski*, William Lawler*, and Bruce Oakley. Div. Biol. Sci., Univ. Mich., Ann Arbor, MI 48109.

Neural innervation is a necessary factor for the maintenance and regeneration of mammalian taste buds. The mechanisms of such neurotrophic dependencies have remained obscure, although chemical agents have long been suspected. We have developed a physiological assay system for the neurotrophic effects of taste axons using the IXth nerve of the Mongolian gerbil. From the intact IXth nerve summated multi-unit discharges to chemical stimulation can be recorded. These responses are stable for at least 14 hours. The relative responsiveness to different chemicals is similar, but not identical, to that of the rat IXth nerve. NH_4Cl is the most effective of the 15 chemicals tested. If the gerbil's IXth nerve is transected, the taste responses will rapidly decline to 0-25% of the initial summated response. The responses do not always decline in parallel for compounds representing the four basic tastes (0.5M sucrose, 0.03M HCl, 0.3M NaCl, and 0.01M quinine hydrochloride). This loss of evoked activity does not result from degeneration of the axons with subsequent failure to propagate impulses because: (a) compound action potentials can still be elicited by electrical stimulation of a cut IXth nerve that has become quiescent to chemical stimulation of the tongue, and (b) there is no difference in the rate of response decline monitored simultaneously from two sites on the nerve, one near and one far from the cut end. Efferent fibers are unnecessary for maintaining the physiological responses. When the IXth nerve is *cut proximal to the petrosal ganglion normal taste* responses can be recorded from the intact distal portion of the nerve 5, 7, 11, 13, and 30 days later. The time of taste response failure (1-4 hours) is a linear function of the length of the distal IXth nerve stump attached to the tongue. This suggests that the taste axons may maintain taste buds by transported trophic chemicals. Accordingly we tested procedures, such as local nerve cooling, designed to block axoplasmic transport in the uncut nerve. A nearly complete loss of taste responses was observed 1-4 hours after treatment.

We conclude 1) that chemical interactions, rather than impulse activity, are responsible for the trophic effects upon taste buds and 2) that the short-term physiological function of taste buds is maintained by the continued anterograde or retrograde transport of chemical agents along sensory axons.

1698 NEUROTROPHIC REGULATION OF PROTEIN SYNTHESIS IN REGENERATING NEWT FORELIMBS: AN IN VITRO ASSAY OF PUTATIVE NEUROTROPHIC FACTORS. A.H.F. Choo*, D.M. Logan* and M.P. Rathbone. Dept. of Biol., York University, Toronto, and MRC Group in Developmental Neurobiology, Dept. of Neurosciences, McMaster Univer. Med. Centre, Hamilton, Ontario, Canada L8S 4J9.

Regeneration of amputated amphibian limbs requires the presence of nerves which regulate the rates of DNA, RNA, and protein synthesis in the regenerates. The infusion of nerve or brain homogenates into denervated limb regenerates in vivo mimics this neurotrophic effect and has been used as a bioassay for factors with putative neurotrophic activity (Singer, M. et al., J. Exp. Zool. (1976) 196:131-150). Because this is a technically difficult assay and variability in the rates of limb regeneration produces variable results, we have developed an alternative simple, reproducible in vitro assay for testing neurotrophic activity. Newt forelimbs are amputated just proximal to the elbow. The resulting blastemas are amputated after 18-20 days. Second blastemas form after 6-7 days and are explanted into amphibian culture medium containing radioactive amino acids. The second blastemas are synchronized in developmental stage and have similar rates of macromolecular synthesis. After denervation in vivo or culture in vitro the rate of protein synthesis in blastemas increases transiently, but subsequently falls and remains below the values observed for protein synthesis in blastemas of innervated limbs. Addition of nerve extracts to culture medium of denervated synchronized blastemas prevents these changes and maintains normal protein synthesis. Blastema proteins are separated using two dimensional isoelectric point focusing-polyacrylamide gel electrophoresis. There are differences in the incorporation of radioactive amino acids into various proteins of innervated and denervated blastemas. The incorporation of radioactivity into proteins of blastemas cultured with nerve extracts is similar to that of blastemas denervated in vivo. Thus the effects of nerve extracts in vitro are similar to those of nerves in vivo. Using this assay with synchronized blastemas cultured for 10 hours, we have demonstrated that the neurotrophic activity in chick brain extract is heat labile and destroyed by proteases. It has a molecular weight of <20,000 daltons. Although the activity is restricted to nerve tissue it is not species specific and is found in neural tissue of both newts and chickens.

1699 A TROPHIC FACTOR FROM A PRESYNAPTIC NEURON INCREASES ACETYCHOLINE RECEPTOR AGGREGATION ON MYOTUBES. C.N. Christian*, M. Daniels, H. Sugiyama*, Z. Vogel* and P.G. Nelson, NIH, Bethesda, Md. 20014 and Weizmann Institute, Rehovot, Israel.

During synaptogenesis between NG108-15 hybrid cells and embryonic mouse muscle cells cultured in vitro, hybrid cells probably seek out or produce areas of high acetylcholine (ACh) sensitivity on myotubes (Christian, et al., Science 196:995).

We studied the distribution of ACh receptors on mouse myotubes by indirect immunoperoxidase staining of bound α-bungarotoxin (Daniels and Vogel, Nature 254:339). One third of the cultured mouse myotubes exhibited local aggregates of ACh receptors, with an average diameter of 10 μm. Hybrid cells were added to muscle cultures and cocultured for one week in Dulbecco's Modified Eagle Medium plus 5% Horse Serum and 1 mM dibutyryl cyclic AMP (dbCAMP), a medium in which these two cell types form functional cholinergic synapses. Mouse myotubes cocultured with hybrid cells showed a 3 fold increase in the number of ACh receptor aggregates per myotube (A/M) when compared to myotubes in cultures without hybrid cells. In 4 separate experiments comprising 7 cocultures, the increase in A/M ranged from 1.8 to 4.4 fold. The increase in A/M did not require dbCAMP.

Medium from hybrid cell myotube cocultures, diluted by 50% with fresh medium, produced a 2.2 fold increase in A/M when added to muscle cultures. Medium without serum from hybrid cell cultures produced a 3.4 fold increase in A/M in muscle cultures. The effect was not produced by media from human diploid fibroblasts or HeLa cells, nor by medium plus 1 mM ACh.

These striking changes in A/M do not result from a modulation of a number of ACh receptors. Hybrid cell medium did not change the number of myotube receptors by more than 10%, as shown by measurements of ^{125}I-α-bungarotoxin binding to control and hybrid cell medium treated muscle cultures. Hybrid cell medium produced a 3.1 fold A/M increase within 21 hours in the presence of 100 ug/ml of cycloheximide.

These observations suggest that NG108-15 hybrid cells produce a factor which aggregates ACh receptors present on mouse myotubes. The factor may cause the alignment of cholinergic presynaptic release sites with postsynaptic aggregations of acetylcholine receptors, and may play a more general role in neuron muscle recognition.

1700 NEURAL CONTROL OF CHLORIDE CONDUCTANCE IN RAT EDL MUSCLE. T.E. DeCoursey*, S.H. Bryant and S.G. Younkin (SPON: R.J. Lipicky). Dept. Pharmacol. and Cell Biophys., Univ. of Cincinnati Coll. of Med., Cincinnati, OH 45267.

It was previously reported that exposure of nerve to colchicine resulted in a reduction of resting membrane chloride conductance (G_{Cl}) in rat fast (EDL) muscle (Camerino and Bryant: J. Neurobiol. 7:221, 1976), as has been observed following denervation of mammalian skeletal muscle. Neuromuscular transmission was not directly measured in that study, and Westgaard's finding that direct stimulation of denervated rat soleus can return total membrane conductance (G_m) to normal levels (J. Physiol. 251:683, 1975) raises the possibility that the reported reduction of G_{Cl} after colchicine treatment was the result of a possibly significant loss of muscle activity.

We exposed the sciatic nerve to cotton soaked in 30 or 60 mM colchicine in 0.9% saline, for 45 minutes. Five to seven days later, indirect twitch and tetanic tensions were measured *in vivo* in EDL muscles from treated and contralateral control sides. Muscle cable parameters were then measured using the two-electrode square pulse technique, in normal and (methylsulphate-substituted) chloride-free physiological solutions. Resting membrane resistance (R_m) in chloride-free solution was assumed equal to the reciprocal of potassium conductance (G_K). G_m was assumed equal to $1/R_m$ in normal solution, and equal to G_K+G_{Cl}.

Indirect twitch and tetanic tensions were about 40% lower in experimental than contralateral EDL muscles in 4 rats ($p<0.01$). This reduction presumably reflects a substantial loss of impulse transmission to at least some fibers. In this group of animals, mean (±SE) G_{Cl} was 18% lower in treated than control fibers (2081±223 and 2552±309 μmho/cm^2). In a second group of 4 rats, twitch and tetanic tensions were not significantly different from control. In these animals G_{Cl} was 29% lower ($p<0.01$) in fibers from the treated side (2184±49 and 3095±160 μmho/cm^2). G_K was not significantly different from control in either group; combined mean control and treated were 165±18 and 198±48 μmho/cm^2.

If the reduction of G_{Cl} after acute exposure of nerve to colchicine were due to a loss of neuromuscular activity, G_{Cl} would presumably be reduced to a greater extent in the group of rats exhibiting significant loss of impulse transmission than in the group with normal response to indirect stimulation. Since this did not occur, we conclude that G_{Cl} was reduced in this study by an action of colchicine on nerve which is not related to a change in muscle activity.

1701 NEUROTROPHIC PROTEIN(S): ROLE OF AXONAL TRANSPORT IN THEIR INTERCELLULAR MOVEMENT. Hugo L. Fernandez, Myron Duell*, Thomas G. White* and Barry Festoff, Neurobiology Research Lab, V.A. Hospital, Kansas City, MO 64128 and University of Kansas Medical Center.

An extract of rat sciatic nerve, termed soluble nerve protein (SNP) was previously shown to: a) cause weakness and neuromuscular fatigue in SNP-immunized sheep; and, b) produce antibodies against three polypeptide components of SNP (1). It was further demonstrated that SNP enhanced growth and differentiation of chick embryo muscle cells in culture (2). The suggestion of these studies was that some component(s) of SNP served a "trophic" function and that the syndrome elicited in the sheep may have been an "autoimmune" response to some similar endogenous factor present in the sheep. Since axoplasmic transport (AT) has been shown to be an important mediator in the "trophic" regulation of skeletal muscle (3), the present work was undertaken in an effort to determine whether SNP is conveyed by A.T.

SDS-PAGE electrophoresis, immunoelectrophoresis, and double immunodiffusion of SNP, prepared from 1 cm sections of rat sciatic nerve and spinal cord, showed that: the major component of SNP is an acidic 65,000 daltons protein; this component in both sciatic nerve and spinal cord cross-reacts selectively with sheep anti-SNP antibody; and, it is distinct from tubulin in terms of MW and immunological specificity.

Quantitative radial immunodiffusion of SNP indicated that 10-20 days after ligating the sciatic nerves this major SNP protein component accumulates both proximal and distal to the ligatures. Accordingly, this SNP component would appear to be conveyed by retrograde, as well as, orthograde A.T. It must be noted, however, that 6 hr after intraspinal injection of 25 Ci ^{3}H-leucine into the L5 ventral roots, labeled SNP was not detected around the sciatic nerve ligatures. In turn, significant amounts of labeled SNP were found close to the injection site. It follows that if the major component of SNP is transported, it must do so at a slow rate of A.T. Alternatively, what we have termed SNP might reflect Schwann cell cytoplasm. Current experiments are designed to further define the origin of this SNP protein.

1702 BIOCHEMICAL STUDY OF THE FISH VISUAL SYSTEM DURING NEURONAL REGENERATION. Dana Giulian* and David Cowburn* (SPON: B. S. McEwen). The Rockefeller Univ., and Cornell Univ. Med. Coll. New York, N.Y. 10021.

In order to investigate biochemical events involved in the regeneration of transected retinal ganglion axons of the goldfish, a separation of cell types and identification of major proteins of the visual system was carried out. Microdissection has yielded a unique preparation of isolated ganglion cells that was free of glial elements as shown by light microscopy and transmission and scanning electron microscopy. Patterns of polypeptides studied by polyacrylamide gel electrophoresis in sodium dodecyl sulfate indicated that the ganglion cells and optic nerve fibers have a similar composition that contrast with other cellular layers of the retina or of the optic tectum. Actin and tubulin were major proteins of the ganglion dissection while myelin proteins were a significant component of the optic fibers. Studies of protein synthesis and axonal transport in normal tissue and, then in the regenerating system, was carried out by intraocular or intratectal injection of, or in vitro incubation with, labelled precursors.

The ganglion dissection was the only retinal layer to show increased ^{3}H-L-leucine incorporation during regrowth with a peak of synthesis around 30 days after transection. In addition to altered production and transport of major protein components, electrophoretic gel patterns showed the appearance of several minor polypeptides, one (about 150,000 daltons) in the regenerating ganglia by day 10 and another (~400,000 daltons) in the optic fibers by day 30. Events specific to the tissues and to the time course during regeneration have been identified by studying these profiles of synthesis. This provides ground work for the study of putative regulatory factors controlling specificity during regrowth.

1703 DOES NEUROTROPHIC MATERIAL CONTROL SYNAPSE FORMATION IN THE ADULT RAT BRAIN? Dan Goldowitz* and Carl W. Cotman. Dept. Psychobiol., Univ. Calif., Irvine, CA 92717.

Diamond and co-workers have obtained evidence from studies on the salamander hind-limb that collateral nerve growth occurs in normal nerves when a neighboring nerve is either sectioned or blocked from transporting material. These results suggest that a transported "negative neurotrophic substance" may regulate nerve growth in peripheral nerves. It was our purpose in these studies to determine if connections in the mammalian brain follow similar influences.

The molecular layer of the dentate gyrus was analyzed for possible changes in its synaptic density following applications of colchicine to the fimbria. From previous ultrastructural work it is known that in the weeks following a lesion of either the entorhinal or commissural afferents to the dentate gyrus there is a reappearance of synapses which restores the synaptic density of the neuropil to near-normal levels. We wanted to determine if, by the inhibition of axonal transport in the commissural fibers, we could induce synapse formation without the need of a lesion.

Colchicine applied to the fimbria inhibited axonal transport of proteins to the treated hippocampus and also interferred with the transport of AChE from the septum. Electron microscopic analysis of the fimbria and molecular layer of the dentate gyrus did not reveal the presence of degenerating fibers or boutons at 4, 11, or 60 days after treatment. Moreover electrophysiological analysis showed that colchicine application did not noticeably change the response of the commissural system, whose fibers course through the colchicine treated area. Over time, transport of radio-labeled proteins was restored to normal. At 60 days after colchicine treatment the density of synapses in the dentate molecular layer was surveyed by electron microscopy. There was a 20% increase in the number of synapses/unit area in the commissural region. These results suggest that colchicine treatment can induce a hyperinnervation of the dentate. Our finding supports the notion that a "neurotrophic substance" may regulate synapse formation in the mammalian CNS. (Supported by NIMH grant MH 19691 and NIMH Pre-doctoral fellowship MH 05308).

1704 NEURONAL STIMULATION OF [^{3}H]THYMIDINE INCORPORATION BY NON-NEURONAL CELLS. G.R. Hanson* and L.M. Partlow. Dept. Pharmacol., Univ. Utah Col. Med., Salt Lake City, UT 84132.

Stimulation of [^{3}H]thymidine incorporation in non-neuronal (glial) cultures by intact neurons was demonstrated by McCarthy and Partlow (Brain Res. (1976) 114:415) using highly purified and recombined primary cultures of neuronal and non-neuronal cells isolated from sympathetic ganglia of 11-day chick embryos (Brain Res. (1976) 114:391). The results presented herein further characterize this neuronal-glial interaction. First, the dose-effect relationship between the number of neurons added and degree of stimulation of glial [^{3}H]thymidine incorporation was found to be dose-dependent and biphasic. The dose-effect curve first plateaued at a neuron-to-glial cell ratio of 1:5 (~4-fold stimulation) but then increased further and reached a second plateau at a ratio of 1.2:1 (~ 50-fold stimulation). Second, the time course of neuronal stimulation of [^{3}H]thymidine incorporation by non-neuronal cells was examined. Neurons initially plated with the glia stimulated non-neuronal cell proliferation throughout the 72 hour period studied. In addition, neurons added to pure non-neuronal cultures after 48 hours in vitro stimulated [^{3}H]thymidine incorporation. Third, embryonic neurons stimulated [^{3}H]thymidine incorporation by slowly proliferating mature glia. Thus, addition of embryonic sympathetic neurons to cultures of sympathetic non-neuronal cells from 14-day posthatch chickens caused a 2.5-fold increase in [^{3}H]thymidine incorporation. Fourth, CNS and peripheral neurons stimulated both CNS and peripheral non-neuronal cells. Both optic lobe and sympathetic neurons from 7-and 12-day chick embryos, respectively, increased [^{3}H]thymidine incorporation in embryonic glial cultures from 12-day dorsal root ganglia, 12-day sympathetic ganglia, and 7-day cerebral cortex. In summary, neuronal stimulation of [^{3}H]thymidine incorporation by non-neuronal cells occurs in both central and peripheral portions of the nervous system, and in mature as well as embryonic glia. The stimulatory effect is dependent on the neuron-to-glial cell ratio and can increase non-neuronal proliferation by as much as 50-fold. (Supported by USPHS grants DE-05054 and NS-12812 and by a grant from the Epilepsy Foundation of America.)

1705 CENTRAL CONTROL OF NEURONAL NUMBER IN THE LATERAL MOTOR COLUMN OF CHICK EMBRYOS: AN EXPERIMENTAL EVALUATION. Randolph B. Malloy and C. H. Narayanan. Dept. Anat., L.S.U. Med. Ctr., New Orleans, La. 70119.

Peripheral control of cell number within a neuronal population has been shown in several investigations. There has been little attention directed to the possibility of afferent input in terms of its relationship to the control of cell numbers at cord levels. Three series of experiments were, therefore, done to determine if sensory input was in any way important in the regulation of cell numbers in the L.M.C. of the chick embryo at leg levels. In the first series of experiments, the neural crest was removed from lumbosacral cord levels by microcautery. In the subsequent experiments, a gap was placed just rostral to the lumbosacral cord and finally a combination gap and neural crest removal was accomplished. The embryos in control and the three experimental groups were sacrificed at 6 days, 12 days, and 18 days of incubation and the tissue was processed via routine histological procedures and stained using Orange G and Hematoxylin. Cell counts were accomplished on the lateral motor column (L.M.C.) of the lumbosacral cord in the four animals of each group. Analysis of L.M.C. cell counts at 6 days indicated no significant differences among experimental and control groups. At 12 days, however, the neural crest and neural crest plus gap groups had significantly reduced cell numbers when compared to gap and control groups. Results in the 18 day groups corresponded to the 12 day findings. These results indicate that central influences from afferent spinal cord sources do have an affect on the maintenance of L.M.C. cells of the chick embryo.

1706 TWO WAYS THAT AN ELECTRICAL CONNECTION IS RE-ESTABLISHED IN THE LEECH. Kenneth J. Muller and Salvatore Carbonetto* (SPON: D. Olton). Dept. of Embryology, Carnegie Institution of Washington, Baltimore, MD. 21210.

Precise regeneration of an electrical synapse between particular interneurons in the medicinal leech was traced physiologically and morphologically with intracellular recording and injection of horseradish peroxidase (HRP). HRP is particularly useful because it is visible both in light and electron microscopes and it does not fill neurons that are electrically coupled to the injected cell. The normal synapse between S-cell interneurons lies in the connective midway between segmental ganglia, except near the head and tail of the animal, and when the connective is crushed near one ganglion, the axon of only one S-cell is severed. In the ensuing days the injured cell regenerates, but its uninjured "target" cell in the next ganglion does not grow. The severed distal segment of the regenerating neuron continues for weeks to conduct impulses and remains connected to the uninjured target S-cell. After the sprouts of the regenerating neuron cross the crush, one or a few branches find the surviving distal segment and grow along it toward the region of normal synapse. In some cases there is particularly rapid restoration of electrical coupling and subsequent transmission between S-cells (within 2 or 3 weeks). In these instances the regenerating neuron has synapsed upon its severed distal segment, forming a basket of processes around the severed axon, but growth continues toward the point of normal synapse. Alternatively, the regenerating neuron's processes do not synapse until, after 3 or 4 weeks, they reach their normal target, where electrical junctions form and further growth ceases. Normal electrical transmission between the fine, regenerated fiber and the larger, target axon occurs in stages, including one-way transmission of impulses across the non-rectifying junction from the large fiber to the small but not vice versa. Within 2 or 3 months the regenerated neuron has grown to full caliber, the distal segment has degenerated and function is normal. These experiments indicate that the regenerating neuron is guided to its proper synaptic target by recognizing and following its severed distal segment. In some instances the distal segment itself becomes an intermediate, and in that sense imperfect, synaptic target.

1708 DIFFERENCES IN THE CATECHOLAMINE-SENSITIVE ADENYLATE CYCLASE AND β-RECEPTOR BINDING BETWEEN FAST-TWITCH AND SLOW-TWITCH SKELETAL MUSCLES OF RAT. K.L. Oliver*, N.B. Reddy* and W.K. Engel.
National Institutes of Health, Bethesda, Md. 20014

One of the several differences that exist between mammalian fast-twitch (FT) and slow-twitch (ST) skeletal muscles is their differential response to β-adrenergic catecholamines (Catechols) (Bowman and Nott, Pharm. Rev. 21, 27, 1969). Since most of the effects of β-adrenergic Catechols on target tissues are believed to be mediated by activating adenylate cyclase (AC) through their interaction with β-receptors, we investigated the properties of AC and β-receptor binding in a sarcolemmal (SL) membrane preparation of FT (extensor digitorum longus) and ST (soleus) muscles of rat.

Basal and NaF-stimulated activities of SL-bound AC were about the same in both muscles. Activation of the AC by Catechols differed markedly in the two muscles. Isoproterenol (Isop), 10 μM, caused about 3-fold stimulation of ST SL AC while the FT SL AC was stimulated by only 60-80% over their respective basal activities. Similar pattern was obtained with epinephrine (Epi) and norepinephrine (NEpi). Phenylephrine (10 μM), an α-adrenergic agonist, showed no effect on SL AC of either ST or FT muscle. The order of potency of Catechols in activating AC was, however, similar in both ST and FT muscles and found to be Isop > Epi > NEpi. The EC_{50} values for Isop, Epi and NEpi were 0.1, 0.8 and 20 μM respectively in both ST and FT muscles. In both the muscles, the (-)isomers of Isop and Epi were at least two orders of magnitude more potent, on molar basis, than their corresponding (+)isomers. The augmentation of AC caused by Isop (10 μM) in SL of both muscles was completely abolished by β-blocking agents, propranolol and alprenolol. The (-)isomers of these β-blockers were more potent inhibitors than were their corresponding (+)isomers. The IC_{50}s for (-)isomers of propranolol (20 nM) and alprenolol (30 nM) were similar for the FT and ST muscles.

The β-receptor density in SL of ST and FT muscles was determined by following the binding of ^{3}H-dihydroalprenolol (DHA), a potent β-blocker. The specific ^{3}H-DHA binding (per mg SL protein) was 40-60% greater in FT than in ST muscle, which is in contrast to the activation of AC by Catechols in these two muscles.

The results suggest that: a) the level of Catechols-stimulated AC is not indicative of the β-receptor density, and b) the AC and β-receptor are independent entities and their extent of coupling is differentially regulated in FT and ST muscles, perhaps by yet-unidentified "trophic influence(s)" of nerves innervating each muscle. (N.B.R. supported by an MDAA Research Fellowship).

1709 NEUROTROPHIC FACTOR (NTF) EFFECT ON CHICK MUSCLE CELL GROWTH, DIFFERENTIATION, AND MAINTENANCE *IN VITRO*. Heinz Popiela*(SPON: J. E. Heavner). Dept. Biochem. University of Washington, Seattle, Wa. 98195.

An aqueous extract from adult chicken sciatic-ischiatic-peroneal nerves (NTF) was tested for growth promoting activity on dissociated embryonic chicken muscle cells and for maintenance activity on differentiated myotubes *in vitro*. Growth promoting activity of NTF was compared with embryo extract (EE) and other tissue extracts. The results indicate NTF to substitute for EE and to superiorly promote muscle cell growth. NTF maintains differentiated myotubes in a viable state and prevents or greatly reduces the characteristic degeneration of them as observed in its absence. After ischiatic-peroneal nerve ligation for 3 days, extractable NTF activity is reduced three fold from nerves distal to the ligation. NTF supports muscle cell growth only when concomitantly present with horse serum; NTF by itself does not sustain growth. When extracts from various embryonic tissues are compared to whole embryo extract no significant differences in activity are found. Abundant growth promoting activity extracted from embryonic brains is present at an extremely low concentration in brains of young adult or adult chickens. The results are interpreted as supporting the hypothesis that all embryonic cells produce a NTF-like substance(s) whereas in the adult certain nerve cells only retain the capacity to produce it while other cells in the adult have drastically reduced NTF-like substance(s) production (Singer, Quart. Rev. Biol. 27:169, 1952)

1710 NEURONAL AND GLIAL INTERACTIONS IN TISSUE CULTURE. Barry H. Smith, Maureen A. Ward*, Theodore Liszczak* and Paul K. Kornblith*.
Neurosurgical Service, Massachusetts General Hospital, Boston, MA 02110.

Neuronal and glial cell lines and conditioned media derived therefrom have been used to study molecular interactions regulating cell mitosis, growth, metabolic and maturational control. Normal human brain cell explants, as well as neuroblastoma and astrocytoma (Grades I-IV) cell lines have been utilized. All cells have been grown under constant culture conditions at 35°C with Ham's F-10 (Gibco) medium and with or without 10% fetal calf serum (Gibco). In an effort to confirm previous reports of glial-induced differentiation of neuroblastoma cell lines, medium "conditioned" for 72 hours in the presence of various human astrocytoma lines was added to neuroblastoma cultures. No consistent effect of such media was observed under our culture conditions for periods of 24 hours to 1 week. However, preliminary results suggest that neuroblastoma cells themselves may differentially inhibit the growth of certain astrocytoma cell lines, suggesting support for the idea of neuronal control of glial cell mitosis. Cell-cell contact appears to be necessary for the effect, but the involvement of a diffusable factor has not been ruled out. Finally, cyclic nucleotides and various other agents, including transmitters and hormones, are being examined for their effect on neuronal and glial mitosis and growth control. Dibutyl c-AMP alters human astrocytoma cell behavior in culture in a temporally limited fashion, dependent on the cell line. The quantitative and molecular mechanisms of such effects are under study.

1711 FAILURE OF PRODUCTS FROM DEGENERATING NERVE FIBERS TO INFLUENCE THE ELECTROPHYSIOLOGICAL PROPERTIES OF NORMAL FAST AND SLOW MUSCLE FIBERS. T. N. Tiedt*[1], E. X. Albuquerque[1] and L. Guth[2].
Dept. Pharmacol. and Exp. Ther.[1] and Dept. Anat.[2], Univ. Maryland Sch. of Med., Baltimore, MD 21201.

As a result of numerous physiological and biochemical studies using a variety of experimental approaches the conclusion has been reached that peripheral nerve fibers release a trophic substance which maintains certain properties of the muscle membrane. An alternative explanation has been suggested that products of the degenerating nerve release substances which are responsible for inducing the denervation changes in muscle membranes. As evidence in support of the latter interpretation, Cangiano & Lutzemberger (Science, 196, 542, 1977) recently reported that the innervated muscle fibers of partially denervated muscles exhibited at the neuromuscular junction a resistance to the action of tetrodotoxin (TTX) similar to that of the denervated muscle fibers. To examine further this finding, partial denervation of the extensor digitorum longus muscle was accomplished by cutting spinal nerve L4 and of the soleus muscle by cutting L5. (1) In 16 rats examined 48-216 hours postoperatively, innervated surface fibers (i.e., fibers from which miniature endplate potentials (MEPPs) could be recorded), had membrane potentials similar to those of the control, unoperated side (-77±0.6 mV, extensor; -76±0.4 mV, soleus). Denervated fibers (from which MEPPs could not be recorded) had membrane potentials of -57±0.5 mV (extensor) and -58±0.4 mV (soleus). (2) Extrajunctional acetylcholine sensitivity (range 100 to 400 millivolts/nanocoulomb) was found along the entire surface only in those fibers which were depolarized and which did not exhibit MEPPs. (3) Extrajunctional TTX-resistant action potentials were recorded along the surface of the denervated (depolarized and without MEPPs) fibers, while the innervated fibers of the same muscles in general showed no resistance to this drug either extrajunctionally or at the neuromuscular junction. Rarely (<1%) partially TTX-resistant action potentials were found at the neuromuscular junction of innervated fibers of control as well as partially denervated muscles. This phenomenon, which has also been reported by Thesleff et al. (Acta Physiol. Scand., 91, 196, 1974), thus cannot be considered as a sign of denervation. These results do not support the hypothesis that products of nerve degeneration influence properties of innervated muscle fibers but do support the hypothesis of neurotrophic regulation of muscle. 1712 EFFECT OF CHRONIC β-BUNGAROTOXIN TREATMENT ON THE DISTRIBUTION OF ACETYLCHOLINE RECEPTORS IN THE RAT DIAPHRAGM.
Gene S. Tobias* and Leona M. Masukawa. Naval Medical Research Institute and Armed Forces Radiobiology Research Institute, NNMC, Bethesda, MD 20014.

Within a few days after axotomy the denervated muscle undergoes changes in electrical properties including the appearance of extrajunctional sensitivity to acetylcholine (ACh). This spread of ACh sensitivity following denervation can be mimicked by chronic application of botulinum toxin or β-bungarotoxin (β-BuTX), toxins which act presynaptically to inhibit ACh release. The ability of these toxins to mimic denervation suggests that continuous ACh release is necessary and sufficient to maintain the electrical properties of the normally innervated muscle. However, β-BuTX also has phospholipase A (PLA) activity, and presynaptic endings treated with β-BuTX undergo morphological changes reminiscent of denervated nerve endings. Therefore, the ability of β-BuTX to mimic denervation may be related to its degenerative action and not to its pharmacological effects. We have endeavored to separate the morphological and pharmacological actions of β-BuTX with regard to its ability to mimic denervation effects in muscle. Rat phrenic nerve-diaphragm muscle preparations were chronically treated for 1 to 14 days by intrathoracic application of enzymatically active or inactive β-BuTX. Active β-BuTX had PLA activity, while inactive β-BuTX had been heat treated at high pH so that PLA activity was eliminated. After treatment in vivo, diaphragms were removed and assayed for distribution of ACh sensitivity by iontophoretic application of ACh and by ^{125}I-α-bungarotoxin binding. We found that chronic treatment with equivalent amounts of either active or inactive β-BuTX yields a significant enhancement of ^{125}I-α-bungarotoxin binding over the whole muscle surface compared to untreated diaphragms. The increase in binding was not as great as that in denervated muscle at the same time period, however. The binding results were corroborated by electrophysiological findings as well. Untreated muscles responded only to ACh iontophoresed onto endplate regions; muscles treated with either active or inactive β-BuTX had junctional and extrajunctional sensitivity to ACh. Our results support the hypothesis that ACh provides a "trophic" influence which maintains electrical properties characteristic of normally innervated muscles.

1713 EFFECT OF ELECTRICAL STIMULATION ON LEVELS OF ACETYLCHOLINESTERASE ACTIVITY IN DENERVATED DYSTROPHIC CHICKENS. Paul M. Weidoff Jr.* and Barry W. Wilson. (SPON: R.C. Carlsen). Dept. Avian Sciences, Univ. of California, Davis, CA 95616.

Electrical stimulation of denervated muscles of normal chickens partially prevented the increase in acetylcholinesterase (AChE) activity that normally occurs with denervation and reduced its activity once it had risen (Linkhart and Wilson, Exp. Neurol. 48:557, 1975). It was suggested that electrically evoked excitation or contraction were partially responsible for this effect. A defect in the regulation of AChE exists in muscles of chickens with hereditary muscular dystrophy in which high AChE activity is present in the sarcoplasm around the motor end plate and spectrophotometrically measured activity in muscle homogenates is 2-3 fold higher than in the normal. This study examined whether or not denervated dystrophic muscle could respond to electrical stimulation in a manner similar to denervated normal muscle.

Posterior latissimus dorsi muscles of normal and dystrophic chickens were denervated and implanted with stainless steel wires for continuous electrical stimulation in situ. Trains of square wave pulses at a frequency of .2/S were continued for 21 H/day for 7 days. Voltages were adjusted to give supramaximal twitches and ranged from 0.5 to 6 V. At the conclusion of the stimulation program, stimulated and contralateral control muscles were removed and compared histologically and biochemically. In normal muscle, stimulation prevented 58% and in dystrophic muscle 54% of the increase in AChE activity that normally accompanies denervation. In addition, in dystrophic muscle 52% of the increase in non-specific cholinesterase activity that normally accompanies denervation was prevented, while no effect was noted in normal muscle. Lactate dehydrogenase activity was unaffected by stimulation in both normal and dystrophic muscles after denervation. Polyacrylamide gel electrophoresis of muscle homogenates from stimulated animals revealed the same molecular forms of AChE that appear with denervation alone. Histochemical staining for AChE in muscle cross sections showed intense extrajunctional activity after stimulation of dystrophic denervated but not normal denervated muscles. The results suggest that factors in addition to muscular contraction and bioelectric activity are involved in modulation of AChE activity in denervated dystrophic muscle. (supported by NIH grants GM01934, NS10957, and the MDA).

1714 PREVENTION OF THE DENERVATION INDUCED DROP IN RMP IN ORGAN CULTURED RAT EDL. S. G. Younkin, L. H. Younkin*, R. S. Brett*, and B. Davey*. Dept. Pharmacology, Univ. of Cincinnati College of Medicine, Cincinnati, Ohio 45267.

In agreement with earlier studies we have found that denervation of rat EDL muscle causes the muscle resting membrane potential (RMP) to drop from 78.5±0.5 to 61.7±1.1 mV in 2 days. When rat EDL muscles were removed (and therefore denervated) and cultured for 2 days in 10 ml of oxygenated (95% O_2-5% CO_2) Trowell's T8 medium to which EDL muscle extract had been added much of the decrease in RMP was prevented (RMP=71.4±0.4 mV). Extracts were prepared by homogenizing tissue in 4 ml of T8 medium at 4° C using a Potter-Elvehjem homogenizer. After addition of 4 ml of T8 medium the extract was centrifuged in the cold (4° C) at 2700XG for 10 minutes. Additional T8 medium was then added to the supernatant medium so that each ml of the final supplemented medium contained the extract of 10 mg of tissue. Extracts of sciatic nerve (68.5±0.9 mV), whole brain (71.3±1.1 mV), whole diaphragm (71.2±0.5 mV), nerve free diaphragm (71.0±0.5 mV) and 15% rat serum (71.8±0.8 mV) were also effective in preventing the decrease in RMP. Muscles did not usually survive well in medium supplemented with liver extract so RMP could not be measured. Spleen extracts could not be demonstrated to prevent the drop in RMP associated with denervation (RMP=64.0±0.9 mV). The effect of muscle extract was dose dependent. As the amount of muscle extracted into each ml of T8 was decreased from 10 mg/ml to 0.1 mg/ml the mean RMP after culturing for 2 days fell from 71.1±0.4 to 63.8±1.0 mV. Much of the activity in muscle extracts seems to be in macromolecules having a molecular weight between 100,000 and 300,000. When whole diaphragm extract is passed through a filter (Amicon, XM300) which retains molecules of greater than approximately 300,000 M.W. the filtrate retains activity (RMP=71.1±0.6). When this filtrate is passed through a filter which retains molecules of greater than approximately 100,000 M.W. (Amicon, XM100A) activity is lost in the filtrate (RMP=64.4±1.4) but can be recovered by resuspending the filter cake in T8 and using this medium to culture (RMP=73.4±1.0). We are currently examining the effect of extracts on the decrease in acetylcholinesterase and the increase in ACh sensitivity which are caused by denervation.

VESTIBULAR SYSTEM

1715 A COMPARISON OF HORIZONTAL AND VERTICAL VESTIBULOOCULAR REFLEXES OF THE RABBIT. N. H. Barmack. Neurological Sciences Institute, Good Samaritan Hosp. & Med. Cntr., Portland, OR 97209.

Recent anatomical and physiological studies have suggested that different areas of the brain control vertical and horizontal eye movements. The present report examines whether these anatomical differences are evident functionally in the horizontal and vertical eye movements evoked by vestibular stimulation in unanesthetized rabbits. Rabbits were placed in a servo-controlled, bi-axial, rate table with their heads at the intersection of the vertical and longitudinal axes. The table was sinusoidally oscillated (.001 - .8 Hz, ± 10 deg) about the vertical axis, evoking the horizontal vestibuloocular reflex (HVOR), and about the longitudinal axis, which because of the lateral placement of the eyes of rabbits, evokes a vertical vestibuloocular reflex (VVOR). Eye movements were measured in total darkness with an infra-red light projection technique. Measurements of gain and phase of eye movements with respect to head movements were made. The gain of the HVOR was low, .2 - .3, and there was a large phase lead, 95 - 130 deg, at a stimulus frequency of .01 Hz. The gain increased to a maximum, .6 - .9, and the phase lead decreased to 10 - 15 deg at .1 Hz. At higher stimulus frequencies (.5 Hz) the gain decreased to .4 - .6, and the phase lead decreased further to 0 - 5 deg. The VVOR was dramatically different. The gain was high, .8 - .95, and the phase lead was 0 deg at a stimulus frequency of .01 Hz. As the frequency was increased from .01 Hz to .05 Hz the gain decreased to .7 - .8 and the phase lead increased to 5 - 10 deg. With further increases in frequency, the gain again increased and phase lead increased until at .1 Hz - .8 Hz the gain and phase of the VVOR were identical to the gain and phase of the HVOR. The high gain of the VVOR at low stimulus frequencies suggests that the VVOR is evoked by the conjoint action of inputs from the semicircular canals and otoliths, and that the functional contribution of the otolithic input occurs primarily at low stimulus frequencies (below .05 Hz). The dynamics of the eye movements evoked in the HVOR and VVOR are also different. At stimulus frequencies above .05 Hz, compensatory horizontal eye movements are repeatedly interrupted by saccades before reaching an extreme position of gaze. The occurrence of these re-setting saccades is dependent on both eye position and eye velocity. Vertical eye movements travel to more extreme positions and attain higher velocities before they are interrupted by re-setting saccades. These data suggest that the VVOR is based on two classes of afferent information, and that eye movements evoked by the HVOR and VVOR are controlled by different central neural mechanisms. (Supported by N.I.H. grant EY-00848 and The Oregon Lions Sight Foundation).

1716 FUNCTIONAL ORGANIZATION OF THE MEDIAL VESTIBULAR NUCLEUS (MVN) IN THE SQUIRREL MONKEY. L.P. Bernstein*, J.M. Goldberg, and C. Fernandez* (SPON: P.R. Huttenlocher). University of Chicago, Chicago, Illinois, 60637.

Single units were studied in the MVN of barbiturate-anesthetized squirrel monkeys. The topographic distribution of ampullary inputs was determined by the location of units responding to stimulation in the plane of a single canal pair. One canal pair was studied in each animal. Electrode punctures were reconstructed and assigned to one of five equal rostro-caudal zones (1 the most rostral). Units were designated in terms of the canal ipsilateral to the side of recording. Horizontal canal units (HC) were most strongly represented in zones 1 and 2 while superior canal (SC) and posterior canal (PC) units were most frequently encountered in zones 3 and 4. No segregation of inputs in the coronal plane was observed. Roughly half of the units had Type I and half Type II responses (typing after Duensing and Schaefer).

In a separate series of animals the response of units to individual stimulation of all three canal pairs was studied. Of the units responding to rotation approximately 75% were related to 1 canal plane. The remainder had convergent inputs from 2 (or rarely all 3) canal planes. Plugging the canals ipsilateral or contralateral to the side of recording did not appreciably change the percentage of convergent units. Most units had a bilateral and reciprocal response to polarization of the round window. More than 2/3 of responsive units could be monosynaptically activated from the ipsilateral side. None of the units studied responded only to tilt. Units sensitive to somatic stimulation were rarely encountered.

The MVN differs from the superior vestibular nucleus (Abend, Brain Res., in press) in having a stronger HC input, a larger number of Type II units, and a greater incidence of neurons influenced by stimulation of more than 1 canal plane. Supported by NIH and NASA.

1717 POWER SPECTRAL ANALYSIS OF POSTURAL FORCE TRAJECTORIES IN PATIENTS WITH PERIPHERAL, EIGHTH NERVE AND POSTERIOR FOSSA LESIONS. F. Owen Black, Conrad Wall, III and Dennis P. O'Leary, Dept. of Otolaryngol., Div. of Vestibular Disorders, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA. 15213

A computerized posturography technique was developed in order to quantitatively study characteristics of the human vestibulospinal control system in normal and vestibular deficient humans (1). The characteristics of postural control as reflected in fluctuations in the amplitude of center-of-force polar vectors were used as a basis for comparison. Specific characteristics were estimated from the power spectral densities, such as energy estimates obtained by integrating power spectra. The characteristics of postural control in these three groups of patients were found to vary systematically as functions of frequency of movement required to control upright posture and/or the energy content of the oscillations required to control center-of-force postural trajectories.

1718 EFFECTS OF VESTIBULAR STIMULATION ON CEREBELLAR DENTATE NUCLEUS NEURONS IN RAT. Robert H. I. Blanks* and Victoria Chan-Palay (SPON: S. L. Palay). Harvard Med. Sch., Boston, MA 02115.

Intra- and extracellular potentials were recorded from dentate neurons in nembutalized rats following electrical stimulation of the ipsilateral and contralateral VIIIth nerve. Dentate neurons were identified antidromically following stimulation of their projection sites to the brachium conjunctivum (latency 0.5-0.7 msec), interstitial nucleus of Cajal and ventrolateral nucleus of the thalamus (latency 0.65-0.9 msec). Recording sites in the dentate were confirmed by marking them histologically with the dye Pontamine Sky Blue 6BX. Many dentate neurons displayed a short-latency spike activation following ipsilateral (1.2-4 msec) and/or contralateral (1.5-6 msec) vestibular nerve stimulation, whereas other neurons remained unaffected by stimulus strengths of up to 4-6 x N_1 threshold (threshold for monosynaptic activation of second order vestibular neurons). The early activation observed in most neurons was most often evoked from stimulation of the ipsilateral labyrinth, but in a number of these neurons activity was evoked following stimulation of the contralateral vestibular nerve. On the basis of their latency and resistance to barbiturate anesthesia, it is suggested that these potentials were conveyed by a pathway involving one or possibly two interposed synapses between each labyrinth and dentate neurons. Occasionally, this early activation of dentate neurons was followed by suppression of spontaneous activity lasting approximately 40 msec which, when recorded intracellularly, was shown to result from vestibular-evoked IPSPs. Presumably these IPSPs were mediated by Purkinje cells simultaneously activated by the vestibular nerve stimulation. Histological verification of recording sites revealed that vestibular evoked activity was most often obtained from the caudal, ventral aspects of the nucleus.

The present study provides electrophysiological evidence for a direct, excitatory vestibulo-dentate projection. Such a pathway has been demonstrated anatomically, by Carpenter et al.(1972) in monkey, and Chan-Palay (1977) in rat and monkey. The significance of these connections needs to be further elucidated. However, since the dentate plays an important role in the control of distal limb musculature, vestibulo-dentate connections may be related to hand-eye coordination and head movements.

1719 ACTIVITY OF UNITS IN AND AROUND THE VESTIBULAR NUCLEI OF ALERT MONKEYS DURING VERTICAL SMOOTH EYE MOVEMENTS AND VESTIBULAR STIMULATION. M.C. Chubb,* A.F. Fuchs, and G.W. Johanson,* (SPON: H.D. Patton). Regional Primate Center and Dept. Physiology and Biophysics, Univ. of Washington, Seattle, WA.

Previous studies have tested the relation of unit activity in the vestibular nucleus to horizontal vestibular stimuli and smooth pursuit. Little attention has been given, however, to unit firing patterns during vestibular stimulation and smooth eye movements in the vertical plane.

Single unit activity was recorded in and around the vestibular nuclei of alert monkeys that were trained to track a button while undergoing sinusoidal angular acceleration. Unit activity was studied during three conditions: 1) while the monkey was oscillated and the target moved 180°out of phase with his head. 2) while the monkey suppressed his vestibulo-ocular reflex, and 3) while he made smooth pursuit eye movements in the absence of imposed chair movement. Units ranged from those modulated with vestibular stimulation and not modulated during smooth pursuit to those strongly related to smooth eye movements with no apparent vestibular sensitivity. Activity of many other units was strongly related to both vestibular stimuli and eye movements.

When unit modulation was tested in planes 45° from the sagittal plane, to preferentially excite one coplanar pair of vertical canals, units usually showed an increase in modulation in one of these 45° planes and a reduced modulation in the other.

In cases where the horizontal sensitivity also was tested, many units were strongly modulated with both vertical and horizontal eye movements and angular acceleration. These observations suggest that there is convergence of horizontal and vertical canal input.

In general, the unit firing patterns in relation to vertical eye movements and adequate vestibular stimulation resemble those reported for the horizontal plane.

1720 THE ROLE OF THE FLOCCULUS IN THE VESTIBULO-OCULAR REFLEX OF THE CHINCHILLA. P. D. Daniels*, M. Hassul*, J. Winfield* and J. Kimm. Univ. of Washington, Seattle, WA 98112.

The dynamics of the vestibulo-ocular reflex (VOR) in the chinchilla produce compensatory eye movements equal in magnitude to and 180° out of phase with head movements only at frequencies of rotation greater than 0.2 Hz if no visual fixation point is present. At lower frequencies, in the absence of visual input (i.e., in the dark) eye movement amplitude is lower than head movement amplitude and the phase of eye position leads the phase of normalized head position (head position minus 180°) by up to 60°. With a visual fixation point present, eye movements are in phase with normalized head movements at all frequencies tested (0.03 to 1.0 Hz).

After bilateral flocculectomy, two changes in the VOR response are observed:

1) The phase lead of the VOR response in the dark for a given frequency below 0.2 Hz is greater in the flocculectomized animal than in the normal animal. This effect can be quantified by approximating the VOR as a first order system, a "leaky integrator", with a time constant of 3 sec. for the normal animal and a time constant of 2 sec. for the lesioned animal.

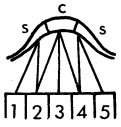
2) In contrast to normal animals, the presence of a visual fixation point does not modify the VOR response in lesioned animals. That is, the phase of the VOR of lesioned animals rotated with a visual target present is the same as the phase of the VOR of lesioned animals rotated in the dark.

A model of the role of the flocculus in the VOR of the chinchilla has been developed which accounts for these experimental observations. Since the output of the flocculus is known to impinge on brain stem structures involved in the VOR and it has been recently demonstrated that in addition to head velocity information the flocculus also receives eye movement and retinal information, we have incorporated the flocculus in our model as an important neural structure influencing visual-vestibular dynamics. The model shows that the flocculus can use eye velocity information to improve the time constant and can use retinal input to modify the low frequency phase response of the VOR.

The relation to this model of recent single unit data obtained in the chinchilla will be discussed in a separate presentation (Winfield, et al., this issue).

1721 PROJECTIONS INTO THE CRISTA'S RIDGE REGION OF THE HORIZONTAL AMPULLARY NERVE FIBERS IN THE GUITARFISH. Robert F. Dunn, Dept. of Otolaryngol. Div. of Vestibular Disorders, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA. 15213

The dynamic response characteristics of the nerve fibers comprising the horizontal ampullary nerve (HAN) of the ray, Rhinobatos productus have previously been shown to vary according to their position within the HAN (1,2). An analysis of serial cross-sections (1 μm, toluidine blue stained) was undertaken to determine the nerve fiber projection patterns by tracing individual nerve fibers from the HAN trunk (HANT) to the basilar lamina of the horizontal crista. The ridge region of the horizontal crista was defined as that area located between the ventral and dorsal plena semilunata. In cross-sections, the ridge of the horizontal crista may be divided into three portions, the anterior and posterior slopes (S) and the crest (C). The demarkation between the slope and the ridge approximates the mean angle of a line drawn tangent to the apical receptor surface of the slope compared to that at the crest. Whereas a projection pattern based upon division of the HANT into three equal parts was completed, the results presented in this communication are based upon a division of the HANT into five equal cross-sectional portions. The procedure entailed a color coding of the individual nerve fiber on each of the successive cross-sections with only those nerve fibers being included which extended from the HANT to penetrate the basilar lamina. Seventy-two nerve fibers satisfied this criterion, a sample which represents 5% of the mean number of fibers in the HAN (2).



The following projection patterns were considered consistent with the functional response data (2): HANT area 1 to slope; HANT 2 to slope and crest; HANT 3 to crest; HANT 4 to crest and slope, and; HANT 5 to slope, with the added constraint that the projections must be to the ipsilateral slope. Of the 72 nerve fibers followed, 86.1% (n=62) had these projection patterns; while 12.5% (n=9) projected from HANT 3 to the slopes; and 1.4% (n=1) crossed the midline by projecting from HANT 2 to the contralateral slope.

1722 SINGLE UNITS RECORDED FROM THE VESTIBULAR NUCLEUS OF CATS WITH FREELY MOVING HEADS. James H. Fuller. Biol. Sci. Group, Univ. Connecticut, Storrs, CT 06268.

Single units were recorded from the vestibular nuclei of cats trained to make head movements between two targets displayed on an 80°-wide screen. Surgically implanted bolts fixed the cat's head to a shaft which allowed rotation about a vertical axis centered above the first-second cervical joint. The shaft could be rigidly fixed to the platform on which the animal was seated and the whole animal rotated about the same axis by a servo-controlled motor.

Units located in and near the medial vestibular nuclei showed a modulation of their firing rate when the animal was passively rotated with sinusoidal wave forms in darkness (head shaft fixed to platform); the peak firing rate was roughly in phase with peak velocity, suggesting a semicircular canal origin of the modulation. When a cat moved its head voluntarily or when the neck was deviated passively by externally fixing the animal's head and rotating the platform about the stationary head, there were slight, spurious changes in firing rate.

However, when impediments to voluntary head movement (inertia, elastic and static friction) were added, the units consistently fired when the animal moved its head in a direction opposite to that which elicited peak firing rates when the whole animal was passively rotated, i.e., opposite the presumed semicircular canal input. The modulation of firing during active movements was proportional to the position of the head if elastic resistance was added, or to the amount of torque produced (measured in the vertical and horizontal planes by strain gauges) if static friction was added. If the head was stabilized in space and the platform allowed to rotate freely, attempted head movements--now independent of semicircular canal stimulation--resulted in increased firing according to the amount of horizontal head torque produced, as on previous occasions in which the head moved against resistance.

It is proposed that these units, resembling those seen in monkey (Fuller and Miles, 1974, Soc. Neurosci.), receive an input representing the summed errors from an earlier stage; and their output reflects an error signal, representing any mismatch of intended and resulting head movements. The semicircular canal signal represents a final summed feedback signal for velocity control of head movement.

1723 EFFERENT VESTIBULAR SYSTEM IN THE SQUIRREL MONKEY. Jay M. Goldberg and César Fernández.* Depts. Pharm. Physiol. Sci. and Surgery (Otolaryngology), University of Chicago, Chicago, Ill. 60637

A retrograde transport technique was used to label efferent neurons in the neonatal squirrel monkey. Observations confirm those made in the cat (Gacek and Lyon; Warr). There are 300-400 ipsilateral efferent neurons and a comparable number of contralateral neurons. The distribution of labelled cells is similar on the two sides. The main efferent group consists of a relatively discrete column of cells located dorsal to the exiting facial nerve and interposed between the abducens and superior vestibular nuclei.

The efferent pathways were electrically stimulated, while afferent activity was monitored in Scarpa's ganglion. The uncrossed and crossed components could be activated either simultaneously or separately. In all cases, efferent stimulation resulted in excitation, reflected by an increase in background activity. Tetanic stimulation was required. Maximum effects were obtained at high shock rates (200-333/sec), but responses were also seen at more physiological rates (50/sec). Response dynamics were slow. Irregularly discharging afferents were characterized by responses 5-10 times larger than those of regularly discharging fibers. Three observations argue the specificity of the response. 1) The effects were abolished by intracranial vestibular-nerve section, but not by facial-nerve section or bilateral cervical sympathectomy. 2) The same electrode placement could result in excitation of vestibular afferents and inhibition of cochlear afferents, the latter effect presumably arising from stimulation of auditory efferents. 3) An intense afferent inhibition, which silenced afferent discharge, could also abolish the efferent response. Since afferent inhibition originates within the sensory epithelium, this suggests a similar locus for the efferent responses. There is a potential artifact not ruled out by our observations. The excitatory response, rather than being synaptically mediated, could possibly be the result of abnormal impulse traffic within the sensory epithelium which could influence afferent activity, say, by increasing extracellular K^+ levels. It is unclear, however, how such a mechanism could explain the differential responsiveness of regular and irregular afferents. On the other hand, were the responses synaptically mediated, the differences in the two classes of afferents could be accounted for by differences in the efferent innervation of Type-I and Type-II hair-cell systems.

1724 VISUAL FIXATION DURING HEAD SHAKE: ITS MODIFICATION BY LONG-TERM ADAPTATION TO VISION REVERSAL. A. Gonshor* and G. Melvill Jones (SPON: A.T. Tan). Aviation Medical Research Unit, McGill University, Montreal, Canada H3G 1Y6.

These experiments examine the effect of long-term plastic adaptation to vision reversal on the ability a) to visually track an oscillating target with head still and b) fixate a stationary target whilst oscillating the head about a vertical axis. All experiments were performed on a human subject at a time when he was fully adapted to prolonged (14-28 days) and maintained vision reversal and was consistently producing a reversed vestibulo-ocular reflex (VOR) in response to sinusoidal rotation at 0.17 Hz in the dark. dc EOG and a head-mounted electromagnetic search coil measured eye and head movement respectively. Head oscillation was voluntarily generated with a sinusoidally oscillating sound to "pace" the frequency of oscillation. The mean gain of ocular response (eye angle/head angle) was assessed from the peak to peak amplitudes of 10 consecutive cycles of eye and head rotation. Gains were assessed respective-ly as positive or negative according to whether the mean phase of eye movement was less than 70°, or greater than 110° shifted from that of target movement relative to the head. All tests were made in normal light on the fully adapted subject but with the reversing prisms temporarily removed.

No modification was ever seen in the frequency dependent limi-tation to the visual tracking of a moving target with head still. However, marked changes were found with the head oscillating relative to a stationary target. Instead of the normal moderate increase of ocular gain from about +0.9 to +1.0 over the frequency range 0.5 to 5.0 Hz, the following mean gains were found in the adapted subject: (-)0.5 at 0.5 Hz, (-)0.1 at 1.0 Hz, +0.2 at 2.0 Hz, +0.4 at 3.0 Hz and +0.5 at 5.0 Hz. These findings are surprising since one might have expected that at low frequencies visual tracking would have successfully predominated over the reversed (ie adapted) VOR, whilst at high frequencies the reversed VOR would have predominated since visual tracking then becomes ineffective. In reality we found the exact opposite of these anticipated results! The findings are however compatible with a lower frequency response in the adapted (multineuronal?) than the original (disynaptic?) VOR central pathways. It is concluded that the visual tracking capability per se is not modified by long-term adaptation to vision reversal, but that there is "more than meets the eye" in the resulting VOR modification.

1725 VESTIBULAR COMPENSATION: INFLUENCE OF SPINAL CORD ON SPONTANEOUS ACTIVITY OF VESTIBULAR NUCLEI. David W. Jensen. Dept. Neurosciences, Sch. Med., UCSD, La Jolla, CA

One of the most striking examples of plasticity of the nervous system is demonstrated by the disappearance of the overwhelming postural asymmetries that follow a unilateral labyrinthectomy in higher vertebrates ("vestibular compensation"). Spinal lesions or limb blockades are known to disrupt the compensatory symmetry ("decompensation"). A study was performed on the neural correlates of decompensation. Spinal preparations of guinea pigs which had compensated to a unilateral labyrinthectomy were monitored for the return of spinal reflex activity and then given a postbrachial spinal transection or lumbar plexus blockade with 2% Xyolocaine. No decompensation asymmetry was measurable in passive resistance to stretch or in forelimb extensor and neck EMG activity, which remained at low levels. Compensatory changes confined to the spinal cord are therefore unlikely to account for body postural decompensation asymmetry. Integrated multiunit activity in the vestibular nuclei (VN) of intact and compensated animals was tested for effects of cold blocks performed at spinal T-7. The animals were locally anesthetized and paralysed; temperature and heart activity, monitored continuously, remained steady throughout. For a given locus, the net multiunit VN activity either did not change, decreased, or increased in response to the T-7 cold block. Each type of effect was reversible, repeatable and consistent for a given preparation. Complex responses were also obtained, including single units in a population that behaved differently from the rest of that population. Fluctuating levels of spontaneity were commonly seen also. In the 31 loci studied that proved to be in the Descending VN (DVN) (14 loci in 5 intact, and 17 loci in 5 compensated animals), the mean effect in intact DVN was a 0.3% increase, while compensated DVN showed a mean 27.7% decrease ($p<0.016$). Three mechanisms are proposed to account for this result: i) Collateral sprouting of inputs to the DVN, ii) Changes in synaptic efficacy of DVN cells receiving inputs directly of indirectly from the spinal cord, and iii) Changes in levels of activity in DVN-input pathways directly or indirectly from the spinal cord.

This research was supported by grants to Professor T.H. Bullock from the NASA, NSF and NIH.

1726 WHAT ACTIVATES VESTIBULO-OCULAR ADAPTATION TO VISION REVERSAL? G. Melvill Jones and G. Mandl. Aviation Med. Res. Unit, McGill University, Montreal, Canada H3G 1Y6.

Previous experiments have shown that optical reversal of vision during head movement in normal light leads to marked adaptive changes in the (opposed) vestibulo-ocular reflex (VOR). There appear to be two possible sources of physiological drive for this adaptation: (1) conflict between the reversed visual and normally acting (ie opposed) vestibular inputs to the oculomotor system and (2) retinal image slip due to incomplete resolution of this conflict.

To investigate the adaptive significance of these factors, 4 human subjects wearing dove-prism reversing goggles were continuously exposed to strobe light at 4 Hz flash frequency whilst moving as best they could about the laboratory for 5 consecutive hours. Flash duration of the strobe was sufficiently short to prevent significant retinal image slip. One subject had participated in the previous experiments conducted in normal light. The degree of adaptation was tested A) by measuring VOR gain (eye angle/head angle; with mental arithmatic) during sinusoidal head rotation (1/6 Hz; 60° amp.) in the dark; and B) by a sensitive subjective test for image slip without vision reversal ("blur" test) whilst shaking the head at 3 Hz in normal light. Both tests were performed before, and at the end of, the 5 hour experiment in strobe light.

The results of test A) showed a significantly lower gain attenuation (20%) than had previously been found after 5 hours of vision reversal in normal light (50%). The "blur" test, always positive after 10-15 min vision reversal in normal light, was uniformly negative after 5 hours visual reversal in strobe light. Furthermore, "motion" sickness although always manifest after 10-15 min vision reversal in normal light, was never present during the strobe experiments. These latter two findings raise the possibility that the 20% VOR attenuation seen in strobe light was artifactual, perhaps due to lack of arousal associated with subject "fatigue". Thus VOR adaptation is much reduced (possibly absent) when image slip is prevented by strobe light. In a companion communication (Mandl, G. & Melvill Jones, G.) it is shown that reversed pursuit eye movements are nevertheless still present in the strobe light condition. It is therefore concluded that image slip, rather than the presence of conflicting oculomotor drives, probably provides the main source of long-term VOR adaptation to vision reversal.

1727 EFFECTS OF ATTENTION REQUIRING TASKS ON VESTIBULAR NYSTAGMUS Paul Kileny*, Brian F. McCabe* and Jai H. Ryu. Depts. Speech Path/Audiol. & Otolaryngology, U. of Iowa, Iowa City, IA 52242.

The purpose of this investigation was to determine the influence of two types of attention requiring tasks on vestibular nystagmus elicited by caloric stimulation: mental arithmetic and a short conversation consisting of brief questions and answers. The nystagmus parameters measured were slow phase velocity and beat frequency. The subjects were divided into four groups according to stimulus paradigm and task.

Group A: Fifteen subjects undergoing monaural or binaural 5 cc ice water calorics were instructed to perform a mental arithmetic task. When slow phase velocity reached its peak, mental arithmetic was discontinued and a short conversation was initiated. An increase in slow phase velocity occurred with the initiation of the conversation. Beat frequency remained unchanged.

Group B: Six subjects underwent monaural 2 cc ice water calorics repeated up to 50 times at 30 sec intervals. No attention requiring task was assigned during the trials with the exception of a short conversation initiated with the last stimulus. Stimulus repetition resulted in a decline in slow phase velocity, reversed with the initiation of the conversation. There was no change in beat frequency.

Group C: Six subjects were subjected to monaural 2 cc ice water irrigations repeated up to 50 times at 30 sec intervals. The task was mental arithmetics. There was a significant slow phase velocity decline in three subjects. Beat frequency did not change significantly in all subjects.

Group D: The stimulus paradigm utilized for the six subjects. included in this group was identical to the one utilized in groups B and C. The attention requiring task consisted solely of conversation. No significant response decline occurred in this group with stimulus repetition.

There was a tendency in all subjects for a right or left conjugate lateral eye deviation to occur at the beginning of conversation periods. This eye deviation appeared as a baseline shift.

1. Our results reaffirm the strong dependence of vestibular nystagmus on the general arousal reaction.

2. Conversation appears to be more effective and predictable in maintaining or re-eliciting the general arousal reaction necessary for the prevention of vestibular suppression.

3. It is generally recognized that a spontaneous conjugate lateral eye deviation is one of the accompaniments of the general arousal reaction. To the degree this occurred in our subjects, it is further evidence that conversation is an elicitor of the general arousal reaction.

1728 PROGRESSIVE PATHOPHYSIOLOGICAL CHANGES IN THE INNER EAR OF THE SQUIRREL MONKEY DURING THE FIRST YEAR FOLLOWING RAPID DECOMPRESSION. Jack P. Landolt, Ken E. Money*, E.D.L. Topliff*, A. Nicholas* Def & Civil Inst. Env. Med., P.O. Box 2000, Downsview, Ont. Canada, M3M 3B9, and W.H. Johnson* Dept. Otolaryng. Univ. Toronto, Toronto, Canada.

Squirrel monkeys were tested for vestibular function and then decompressed from 274 meters of sea water (msw). A discrete inner ear "hit" was identified by the sudden onset of spontaneous nystagmus and gross motor instability during the decompression phase of the dive between 61 msw and the surface. Following such a successful dive, the monkeys were tested more formally for vestibular function and then sacrificed for histological examination at intervals from one hour to one year after the dive.

Up to about 7 days after a successful dive, the monkeys show some form of motor instability. Furthermore, electronystagmographic tests indicate the presence of strong spontaneous and positional nystagmuses, and reduced sensitivity to post-rotatory stimulation. Histological sections of the temporal bones of these monkeys show a dense precipitated material (probably blood proteins), strongly agglutinated to the cupula. This is likely responsible for the positional effects encountered. Though hemorrhagic incidents appear in the cochlea (mainly as a result of tissue damage in the scalae) in animals sacrificed within 48 hours after a dive, this is not the case in the vestibular apparatus. When hemorrhage does occur in the vestibular apparatus (> 48 hours after a dive), it always appears in the perilymphatic spaces, and usually close to the region where nerve fibers enter the neuroepithelia. Formations of new connective tissue and bone in tissue-damaged regions are quite evident in monkeys sacrificed 2 months or more following decompression. In these long-term survival monkeys, there is no evidence of position nystagmus; and, furthermore, there is an apparent recovery of the post-rotatory nystagmus even though there is still evidence of pathology in the end organs.

1729 CONDUCTION VELOCITY AND OTHER PHYSIOLOGICAL PROPERTIES IN CAT'S HORIZONTAL CANAL PRIMARY AFFERENTS. Charles H, Markham, Toshiaki Yagi* and Norman E. Simpson*. Dept. Neurol., Sch. Med., UCLA, Los Angeles, CA 90024.

The conduction velocity and other physiological characteristics of the first order horizontal canal afferents were studied in cats anesthetized with pentobarbital. From their spontaneous discharge patterns, neurons were classified into three groups: regular, intermediate and irregular. The irregular units tended to have a low resting rate, high sensitivity to constant angular acceleration, frequently exhibited stimulus adaptation during prolonged acceleration, and showed a short latency from the time of electric stimulation of the labyrinth to recording the action potential near Scarpa's ganglion. The regular units tended to have a high resting discharge rate, low sensitivity, were mostly non-adapting, and showed longer latency to electric stimulation. The intermediate units had a mixed character of regular and irregular units.

Wersäll (1956) and Dunn & O'Leary (1976) have shown thickest afferent nerve fibers terminate in the sensory epithelium on the summit of the crista, thin fibers on the slope, and intermediate size fibers in both areas. Since the conduction time is due predominantly to conduction in the first order axon, and since there is a direct linear relation between conduction velocity and fiber diameter in the medullated nerve fibers, we conclude that the regular firing neurons with thin fibers innervate receptors on the slope of the crista, the irregular neurons with thick fibers go to the summit of the crista, and the intermediate units with medium caliber fibers innervate both the slope and simmit of the crista ampullaris.

1730 DISPLACEMENT OF THE SEMICIRCULAR CANAL CUPULA DURING SINUSOIDAL ROTATION. Jay W. McLaren and Dean E. Hillman, Dept. of Physiol. & Biophys., Univ. of Iowa, Iowa City, IA and Dept. of Physiol. & Biophys., NYU Med. Sch., N.Y., N.Y. 10016.

The cupula has typically been described as a gelatinous structure which is displaced by endolymph as if it were hinged at its receptor cell base. During compression of the canal wall, cupulae that have been injected with a dye track move as diaphragms with greatest displacement near the central axis of the ampulla. (McLaren, J.W. and Hillman, D.E.; Neurosci. Abst. 2: 1060). In this study, displacement of the horizontal semicircular canal cupula of the bullfrog was observed over a physiological range of sinusoidal rotation. A glass micropipette was inserted through the cupula from apex to crista and withdrawn with simultaneous pressure injection of oil droplets darkened with Sudan black. The distances between the opaque droplets in the cupula and reference markers fixed to the ampulla were then measured using frame by frame analysis of high speed motion pictures that were made during sinusoidal rotation of the frog. The results show that the cupula moves through a distance of 8-14 µm for angular velocities of about 200°/sec. (± 40°; 0.75Hz). The region of greatest displacement was approximately 200 µm from the crista, just above its thin, non-planar portion. Displacement was less from this point to the crista and to the apex. When graded angular velocities less than 200°/sec. were applied, measured cupular displacement was proportionally lower. It is concluded that during physiological angular motion, the cupula functions as a diaphragm with maximal displacement close to the crista rather than the apex. (Supported by USPHS, grant NS-13742 from NINCDS).

1731 VESTIBULO-OCULAR RESPONSES IN THE RHESUS MONKEY FOLLOWING PROLONGED OPTICAL REVERSAL OF VISION. F.A.Miles, D.J.Braitman* and B.B.Eighmy*. Lab. Neurophysiology, NIMH, Bethesda, MD 20014.

Two rhesus monkeys were fitted with dove prism spectacles to provide left-right reversal of vision (cf., Gonshor & Melvill Jones, J. Physiol. 256, 381, 1976) and placed in a primate chair allowing free head movement. Horizontal vestibulo-ocular reflex (HVOR) gains (=eye velocity/head velocity) were assessed by measuring eye movements during passively imposed sinusoidal oscillations of the whole body about a vertical axis in total darkness. The HVOR gain of the first animal declined to about 1/3 normal over a 9-day period, at which level it remained for the rest of the experiment (8 weeks). Only minor phase changes (lag) were observed. The second animal received additional daily sessions of forced oscillation about the vertical axis; its HVOR gain fell almost to zero over a 2-week period, at which level it remained for several weeks before increasing but now in the "reversed" direction. The vertical VOR remained unchanged. With 0.4 hz sinusoids (±20°), the HVOR gain reached a maximum of 0.47 with eye velocity almost exactly in phase with chair velocity. However, further tests revealed that these "reversed" responses have unusual dynamic characteristics, often giving way to normally directed responses under some conditions, and are of very limited functional significance: 1. With lower frequency sinusoids eye velocity became markedly phase advanced on head velocity, and with alternating velocity steps (triangle waveform oscillations) the "reversed" responses showed roughly exponential decays with time constants of 0.6-1.0 sec. This contrasts with time constants in excess of 20 sec in both normal monkeys and those that have undergone "pure" VOR gain changes as a result of wearing telescopic spectacles. 2. Caloric nystagmus induced by cold water irrigation frequently commenced in the "reversed" direction but rapidly reverted to the normal after only a second or two, eventually achieving peak slow wave velocities about 1/3 normal. These brief "reversed" responses were at best very weak and easily overlooked, but since they were never observed in the normal animal they are unlikely to be due to some spurious thermal transient in the irrigation fluid. 3. Self-generated head turns in total darkness (measured by coupling the head to a rotary potentiometer) were usually accompanied by "reversed" compensatory eye movements. However, even with the largest head movements (up to 100°) these "reversed" eye movements were invariably small (rarely more than 6°) and always transient, terminating within 0.3-0.6 sec even if the head movement was still in progress. Indeed, when a head movement did continue beyond this time, a second period of ocular "compensation" was often evident in which the eyes now moved, albeit weakly, in the normal direction (i.e., opposite to the head), so that the overall ocular response was biphasic.

1732 COMPARISON OF DYNAMIC RESPONSE CHARACTERISTICS OF AMPULLAR ENDOLYMPHATIC POTENTIALS AND FIRST-ORDER AFFERENTS IN THE ISOLATED GUITARFISH SEMICIRCULAR CANAL. Dennis P. O'Leary and F. Owen Black, Dept. of Otolaryngol., Div. of Vestibular Disorders, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA. 15213.

Dynamic response characteristics of ampullar endolymphatic potentials (AEPs) were studied by recording them simultaneously with first-order afferent spike trains during stimulation with rotational acceleration. One or two afferent units were maintained for multi-hour recordings using forceps electrodes. Beveled micropipettes filled with concentrated salt solutions or endolymph from the contralateral utricle were inserted through the ampullar wall along a vector that bypassed the cupula. Steady state AEPs were in the range +(4 to 10) mV, relative to indifferent electrodes in the perilymph. White-noise rotational acceleration stimuli were applied over a .04 to 4 Hz bandwidth, and cross-correlated with both the AEPs and afferent responses to obtain linear system characteristics. Afferent sensitivities and system characteristics remained stable before, during and after insertions of AEP pipettes, implying minimal receptor damage. AEP response dynamics were fitted by overdamped, second-order system equations of significantly lower bandwidths than those described for afferent responses from this receptor (O'Leary, et al, J. Neurophysiol., 39: 645, 1976). These results are important for modeling transduction and afferent encoding mechanisms in the semicircular canal.

Supported by a grant from NIH (NS 12494-01) and Eye and Ear Hospital of Pittsburgh.

1733 EFFECTS OF LINEAR ACCELERATION ON SINGLE UNITS IN RAT VESTIBULAR NUCLEI. A. A. Perachio, D. S. Miller*, D. Rice* and W. Bouris, Yerkes Primate Center, Emory Univ., Atlanta, GA 30322.

Characteristics of the dynamic responses of neurons in the vestibular nuclei of urethane/ketamine anesthetized rats have been examined during sinusoidal vertical acceleration of the head over a frequency range of 0.2-0.5 Hz. The vestibular stimulus, which was presumed to act mainly on macular receptors of the saccule (Fernandez, C. et al., J. Neurophysiol., 35, 1972; Spoendlin, H. H., NASA SP 77, 1965), consisted of a series of single cycle, up-and-down, translational movement, at a selected frequency over a fixed distance (17-19 inches). The axis of motion was orthogonal to the horizontal plane of the stereotaxic frame. The head of the animal was fixed in a stereotaxic instrument with the nose pitched downward at an angle of 20°. Single units were found to respond over the full range of acceleration (+0.07 to +0.5 g). Neurons were classified as Z negative sensitive if their activity increased when acceleration was directed upward and were labelled Z positive if firing increased during downward acceleration.

To date, 12 Z positive and 9 Z negative cells have been analyzed. There did not appear to be a characteristic resting level of activity distinguishing either type of cell. No recorded units exhibited regular activity. Coefficient of variation (C.V.) indicated that Z axis cells had low resting rates and fired irregularly, e.g., a typical Z negative unit had a mean resting frequency of 5.7 ± 1.5 impulses/sec, C.V. = .532; and a typical Z positive unit had a mean resting frequency of 11.5 + 3.1 impulses/sec, C.V. = ,235.

Although most recordings were made from the region of the superior and lateral vestibular nuclei, Z axis sensitive units have also been found in the medial vestibular nuclei and ventrally in the region of the medullary reticular formation. Of the spontaneously active cells recorded in the vestibular nuclear complex, Z axis cells represented less than 10% of the sample.

1734 RESPONSES OF MEDIAL VESTIBULAR NUCLEUS NEURONS DURING VESTIBULAR NYSTAGMUS. Robert H. Schor, Shozo Nakao*, Hiroshi Shimazu*. Inst. Brain Research, Univ. Tokyo Med. Sch., Tokyo, Japan.

One of the excitatory inputs to lateral rectus motoneurons comes from the contralateral medial vestibular nucleus (MVN). Axon recordings within the abducens nucleus suggested that the spike activities of MVN neurons are modulated during vestibular nystagmus. Extracellular spike discharges of single MVN neurons were recorded in encéphale isolé cats, under local anesthesia (EEG monitoring showed alternating fast waves and spindle bursts). Units were chosen which showed a clear response to rotation in the horizontal canal plane. Many units having a type I response to rotation (increased firing with ipsilateral rotation) exhibit a rhythmic modulation of their firing rate in association with nystagmus elicited by rotation or electrical stimulation of the labyrinth. The most prominent aspect of this rhythm is an abrupt cessation of firing during the quick inhibitory phase of the contralateral lateral rectus motoneurons. Those MVN neurons which could be activated antidromically from the contralateral abducens nucleus almost invariably exhibited such rhythms.

Recordings were also obtained from type II units (increased firing with contralateral rotation) which were activated at short latencies (3-4 msec) from the contralateral labyrinth. Many of these units also have a nystagmic rhythm, showing an increase in activity at the quick inhibitory phase of the contralateral abducens nucleus. Simultaneous recordings from both type I and type II vestibular neurons show that the increased activity of type II neurons corresponds to the pause of type I neurons during the quick inhibitory phase.

Such type II neurons may be inhibitory interneurons of the crossed commissural inhibitory pathway between the vestibular nuclei. In order to observe the possible synaptic effects of such type II neurons, the membrane potential of type I neurons was averaged using extracellular type II spikes as a trigger signal. With this technique, it was possible to reveal an IPSP with monosynaptic latency, suggesting that the type II neuron directly inhibited the type I cell. Thus a periodic inhibition mediated by type II neurons contributes to the rhythmic nystagmic modulation of type I neurons projecting to the contralateral abducens nucleus.

1735 NATURAL VESTIBULAR STIMULATION: EFFECT ON NEURAL ACTIVITY IN THE MESENCEPHALON OF THE FROG. Barry Skarf. Aviation Medical Res. Unit, Dept. of Physiol., McGill Univ., Montreal, Canada H3G 1Y6.

The adult frog has well developed optokinetic and vestibulomotor reflexes which apparently operate to stabilize the visual image on its retina. It seems likely, therefore, that this animal would need to integrate information concerning head and whole body movement with the visual signals that are received in its primary visual center, the mesencephalic optic tectum.

To investigate whether vestibularly-evoked signals project to the mesencephalon of the frog (Rana pipiens), single and multiunit potentials were recorded extracellularly from the tectum and subtectum of curarized animals (appropriate topical anesthesia having been used). Vestibular influence was inferred when neural activity could be systematically modified by sinusoidal rotation of the animal about a vertical axis in the dark. Frequency of oscillation varied from 0.1-0.5 Hz and peak to peak angular displacement between 20 and 90°. A variety of influences were noted. Vestibular stimulation occasionally resulted in suppression of the "spontaneous" neural activity which was often present in the absence of visual or vestibular stimulation. More frequently, however, there was an increase in impulse frequency during periods of stimulation. Most vestibularly-evoked responses displayed a periodic component of neural activity which was either superimposed on the overall excitatory or suppressive effect or which, in itself, was the predominant characteristic of the response. Both unimodal (ie, one peak of activi-ty per cycle) and bimodal periodic responses were observed.

Units responding to this type of natural vestibular stimulation were found infrequently and only in the deep layers of the tectum and subtectum. In each case, simple manually controlled visual stimuli were also effective in evoking responses at the same recording site. In order to demonstrate an interaction between the two sensory modalities, visual cues complementary to the vestibular stimulus were added by rotating the animal while it was surrounded by a stationary illuminated optokinetic pattern. This type of combined optokinetic and vestibular stimulation enhances the behavioural response to rotation in the unparalyzed animal. Generally, the effect of combined stimulation on the neural unit response was to strengthen its periodic characteristics when compared to the response elicited by exclusive vestibular stimulation.

These observations establish that there is a close association of visually- and vestibularly-evoked signals in the frog mesencephalon and suggest that these two sensory inputs may interact in a functionally significant manner there.

1736 THE NEURAL SIGNAL OF ANGULAR HEAD POSITION IN CAT PRIMARY AFFERENT VESTIBULAR NERVE AXONS PRESUMED TO INNERVATE THE SACCULUS. David L. Tomko and Robert J. Peterka. Dept. Pharmacology, Sch. of Med., Univ. of Pittsburgh, and Biomedical Engineering Prog., Carnegie-Mellon Univ., Pittsburgh, Pa. 15261.

The response of single eighth nerve neurons to head positions through 360° of rotation was determined in barbiturate anesthetized cats. A polarization vector orientation was calculated for each neuron (Fernandez, Goldberg & Abend, 1972; Loe, Tomko, & Werner, 1973). In the present study, all canal afferents encountered in a penetration were typed to insure that the recording procedures sampled from both the superior and inferior divisions of the nerve, hence from the afferents innervating both the utriculus and sacculus.

It was found that in the cat, as has been reported for the squirrel monkey, there are two populations of polarization vectors; The first, which we reported earlier (Loe, Tomko, & Werner, 1973), lie in a plane tilted by approximately 30° with respect to the Horsley-Clarke horizontal plane, and these units most commonly occur in penetrations where horizontal and anterior canal units are encountered. The orientation of this plane corresponds in general to that of the utriculus and the horizontal semicircular canal. The second population lies in a plane which is tilted by about 30° from the midsagittal plane, and these units most commonly occur in penetrations where posterior canal units were encountered. This second population of afferents is presumed to be made up of neurons which innervate receptor cells of the sacculus. (Supported by NIH grant NS12308).

1737 RESPONSES OF VESTIBULAR 2ND ORDER NEURONS IN THE CHINCHILLA DURING SINUSOIDAL OSCILLATION IN THE PRESENCE AND ABSENCE OF A VISUAL INPUT. J. A. Winfield*, P. D. Daniels*, J. Kimm (SPON: J. Miller). Univ. of Washington, Seattle, WA 98112.

Compensatory eye movements in the chinchilla exhibit phase leads and lower amplitudes of modulation relative to normalized head position in the dark at frequencies of rotation below 0.2 Hz (Daniels et al., this issue). Based on these observations an investigation of the dynamic properties of vestibular nuclei neurons was undertaken with similar stimulus conditions. Chinchillas were implanted with horizontal EOG electrodes and a recording chamber was fixed to the skull over the brainstem vestibular area. The response characteristics of simple cells were recorded at frequencies from 0.06 Hz to 1.0 Hz in the presence and absence of visual input.

Two basic categories of unit responses were observed, 53% were classified as Type I and 47% as Type II cells. These units could be further subdivided as follows:

1) VESTIBULAR + EYE MOVEMENT RELATED CELLS: 66% of the unit population responded with peak firing rates in phase with maximum head velocity. In addition, these cells burst prior to saccades in the direction opposite to the direction of vestibular activation; i.e. a Type I cell in the right brainstem bursts to a left saccade.

2) VESTIBULAR ONLY CELLS: The remaining 33% of the cells had their peak firing occurring at about maximum head velocity, but showed no relationship to any type of eye movements.

Only those units where activity were correlated with eye movement showed light-dark differences in their response patterns. The types of changes most notable were:

1) DC THRESHOLD SHIFTS: During periods of oscillation in the dark, there was a decrease in the amplitude of modulation, due to a concomitant equal decrease in spontaneous firing rate. That is, the same sinusoid could fit both the light and dark responses with a DC shift accounting for the lower firing rates observed in the dark.

2) GAIN CHANGES: Additionally, other units increased their firing rates during oscillation in the light.

Some of these units exhibited both effects, however, no units showed any significant change in phase for either lights on or off.

A model was formulated to account for the observed phase and gain shifts occurring during low frequency oscillation in the dark based on these non-linear unit responses.

1738 THE VESTIBULO-OCULAR RESPONSE TO SMALL AMPLITUDE AND HIGH FREQUENCY ROTATIONS IN THE RABBIT. Barbara J. Winterson*, Han Collewijn*, and Robert M. Steinman. (SPON: Frank Baker) Dept. Physiol., Erasmus Univ. Rotterdam, the Netherlands and Dept. Psychol., Univ. of Md., College Park, Md. 20742

Dutch-belted rabbits were rotated sinusoidally on a torsion swing with eyes covered (darkness) and with eyes open (light) while their eye movements were monitored (noise level = 18" arc) by an implanted search coil in a magnetic field. Torsion swing amplitudes ranged from 30' arc down to zero, and frequency ranged from 0.22 Hz to 11.5 Hz.

The vestibulo-ocular response in the dark (VOR) was always observed, that is, the VOR was evident until it could not be distinguished from small (< 5') spontaneous drifts of the eye. Compensation provided by VOR was not perfect. Mean gain (amplitude of VOR/amplitude of swing rotation) ranged from 0.19 at the lowest frequency and was never better than 0.45 at higher frequencies. The VOR to small amplitudes, although far from perfect showed signs of linearity in that gain was not influenced systematically by amplitude.

In the light slow compensatory eye movements were more effective for frequencies up to 3.7 Hz. Gain ranged from 0.42 to 0.52 and phase leads were diminished under this condition. Compensation was not improved at the highest frequencies (9.0 Hz and 11.5 Hz).

We conclude that the vestibulo-ocular response in the rabbit to small rotations is not fundamentally different from the vestibulo-ocular response to large rotations (Baarsma & Collewijn, 1975). However, the VOR to small, as well as large, amplitude rotations is insufficient to stabilize the retinal image, even when it is allowed to work with visual input.

Similar results have been found in the human where compensation provided by VOR, even with visual input, is not sufficient to stabilize the retinal image perfectly (Winterson, Steinman, Skavenski, Hansen & Robinson, 1975). These results raise visual and perceptual questions because visual acuity and perceptual stability cannot arise directly from the perfection of oculomotor compensation.

1739 A CONFLICT MODEL FOR VISUAL AND VESTIBULAR INFLUENCES ON PERCEPTION OF ROTATION ABOUT THE VERTICAL. Greg L. Zacharias* and Laurence R. Young, Dept. Aero & Astro, M.I.T., Cambridge, MA 02139.

Subjects in a moving-base flight trainer were given control over their own rotation about the vertical, and were asked to keep themselves stationary in space. A pseudo-random wide-band vestibular stimulus was applied to the trainer drive. A visual motion cue was simultaneously given the subject via a moving stripe pattern projected on the trainer's side windows, in the subject's visual periphery. Three types of visual cues were used: constant speed, space stationary, and pseudo-random. Subject response was analyzed in the time and frequency domains to infer motion sensation dependence on combined cue presentation. The results confirm low-frequency visual cue dominance (circularvection) and high-frequency vestibular dominance, and support a non-linear visual-vestibular "conflict model" (see below). This parsimonious descriptive model is shown to be consistent with unit recordings in the monkey vestibular nucleus, under similar stimulus conditions.

PARALLEL CHANNEL CONFLICT MODEL

1740 COMPARISON OF ANTERIOR AND POSTERIOR VIIITH NERVE INPUT TO THE GOLDFISH MAUTHNER CELL. Steven J. Zottoli. Res. Inst. on Alcoholism, Buffalo, N.Y. 14203 and Dept. of Physiology, SUNYAB.

A comparison was made of excitatory post synaptic potentials (EPSPs) evoked by stimulation of the anterior and posterior branches of the VIIIth nerve in the goldfish Mauthner cell (M-cell). Intracellular recordings were made with KCl and K_2SO_4 electrodes positioned in the M-cell soma and the lateral dendrite up to 400 μm lateral to the axon cap. As has been previously found, stimulation of the posterior VIIIth branch evoked two main peaks. The first is a short latency (< 0.2 msec) electrotonic EPSP which increased in amplitude (up to 40 mV) laterally; this finding is consistent with the postulate that this potential originates from myelinated club endings located on the distal lateral dendrite (Furshpan, Science. 144:878, 1964). This electrotonic PSP, which is sufficiently powerful to excite the M-cell, is followed by a longer latency monosynaptic chemically mediated EPSP. In contrast, predominantly chemical PSPs were evoked on stimulation of the anterior VIIIth branch. In some cases this response was preceded by an electrotonic component no more than 10-15% the amplitude of the chemical component. The chemically mediated component was capable of bringing the M-cell membrane potential to the firing level, at high stimulus strengths.

Goldfish display a rapid M-cell initiated startle response to sound. Their inner ears consist of three semicircular canals and at least three otolithic organs, the sacculus, lagena and utriculus. The posterior branch of the VIIIth nerve arises in part from the first two, which are primarily auditory receptor organs, while the anterior branch contains afferents from the utriculus, which is more involved in the maintenance of equilibrium. This behavioral and morphological evidence is consistent with the observed differences between anterior and posterior VIIIth nerve inputs to the M-cell. Although input activity in both might be expected to modulate M-cell excitability, synchronous activity in the latter is more likely to produce the rapid excitation of the M-cell underlying the startle response. (Supported in part by NIH Postdoctoral Fellowship No. F32 NS 5282 and Grant No. NS-12132).

VISION

1741 A SUBDIVISION OF EFFERENTS FROM STRATUM GRISEUM SUPERIFICIALE IN THE TREE SHREW SUPERIOR COLLICULUS. J.E. Albano, T.T. Norton and W.C. Hall, Dept. Anatomy, Psychology and Physiology, Duke Univ., Durham, North Carolina 27710

The superficial layer of the superior colliculus, stratum griseum superficiale, can be subdivided into at least two sublamina in the tree shrew, Tupaia glis. An upper sublamina contains a population of small neurons which have small receptive fields and respond briskly both to the onset and offset of stationary and to moving stimuli. A lower sublamina contains a mixture of large and small cells which exhibit several types of receptive field organization. In general, these cells have larger receptive fields than those in the more superficial sublamina and respond only to moving stimuli (Albano, Humphrey & Norton, Anat. Rec. 181: 299, 1975; Albano, Ph.D. Thesis: Duke Univ, Univ. Microfilm,1977).

The present experiments were designed to determine whether these sublaminae can also be distinguished on the basis of their efferent connections. To answer this question, 0.1 to 0.2 µl of 40% horseradish peroxidase dissolved in saline was injected into three known diencephalic targets of the superficial layers of the superior colliculus in the tree shrew, the dorsal and the ventral lateral geniculate nuclei and the pulvinar (Harting, Hall, Diamond & Martin, JCN, 148: 368, 1973).

Following injections in either the dorsal or the ventral lateral geniculate nucleus, horseradish peroxidase reaction product was found predominantly in the small cells in the upper sublamina. In contrast, following injections in the pulvinar, the reaction product was restricted primarily to the large cells in the lower sublaminae.

Taken together, these results suggest that two visual relays to cortex, the pulvinar and the dorsal lateral geniculate, can be distinguished on the basis of the kinds of information they receive from the superior colliculus. The dorsal and ventral lateral geniculate nuclei, on the other hand, may be receiving similar kinds of information from a relatively homogeneous population of colliculus cells.

1742 THE RETINOTOPIC ORGANIZATION OF THE SECOND VISUAL AREA IN THE CAT. K. Albus[x] and R. Beckmann[x] (SPON: B.B.Lee). Max Planck Instit.f.Biophys.Chemistry, Dept.Neurobiol. 34 Göttingen, Fed.Rep.Germany

The representation of the horizontal meridian (HM)and the upper visual field (VF) in the second visual area (V2) of the cat have been controversial topics. We have been studying the extent and the location of V2 in anesthetized (Nembutal) and paralyzed (Flaxedil) cats using single and multiple unit recordings.Results:On the lateral gyrus (LG) the border between V2 and the third visual area (V3) represents the periphery of the lower VF. At anterior Horsley Clarke levels the border runs along the top of the LG,turning down - at posterior Horsley Clarke levels - the lateral flank of the LG.The representation of the area centralis in V2 extends from the transition zone between LG and postlateral gyrus (PLG) some mms posteriorly on the lateral flank of the PLG. From this cortical area the representation of the HM spreads out in a latero-posterior direction covering the bottom of the postlateral sulcus (PLS) and the medial bank of the posterior suprasylvian gyrus (PSSG). Characteristically the receptive field (RF) centres at the HM cover up to 50 degrees eccentricity in the VF, whereas in the adjacent lower and upper VF representation they cover only up to 20 degrees. At the lateral end of the HM representation a reversal in RF positions indicating the existence of V3 was seen in only one out of 3 cats. The upper VF is found to be represented in the latero-ventral extension of the posterior PLS(PPLS). In the posterior bank of the PPLS that sector of the VF is represented which adjoins the vertical meridian. In the anterior bank of the PPLS that sector of the VF adjoining the HM is represented. The remaining part of the VF occupies the bottom of the PPLS. Exploring the upper part of the anterior bank of the PPLS and the posterior part of the PSSG a reversal in RF positions indicating V3 was not found. However proceeding further down the PPLS and the posterior PLG in a latero-ventral direction the RF positions were found to move back from the upper VF periphery to the area centralis. It is likely that this cortical region laterally adjoining V2 is V3 and that therefore the border between V2 and V3 on the posterior PLG represents the periphery of the upper VF. We conclude that in the cat's visual cortex there is a second mirrored relationship across the periphery of the VF, forming the boundary between V2 and V3.

1743 BINOCULAR RIVALRY: AN EXPERIMENTAL PARADIGM FOR THE STUDY OF THE PHYSIOLOGY OF PERCEPTION. J. M. Allman, J. Myerson and F. M. Miezin*. Division of Biology, California Institute of Technology, Pasadena, CA 91125.

In sensory neurophysiological experiments, the organism typically is treated as a passive object. We envision an alternative approach in which one asks the question: where in the nervous system do the responses of neurons covary with changes in the perception of the stimulus and not just with changes in the physical stimulus. In binocular rivalry, when one eye views bars moving in one direction and the other eye views bars moving in the opposite direction, the perceived scene alternates abruptly every few seconds from what one eye sees to what the other eye sees, and the bars appear periodically to reverse their direction of movement. We have trained a monkey, Macaca fascicularis, to report changes in the direction of movement of bar gratings by tapping one of two keys. We did this in order to test the feasibility of recording from single neurons in visual cortex while monkeys experience binocular rivalry and report their ongoing changes in perception. During the initial training, each eye viewed a separate oscilloscope with gratings moving in the same direction for both eyes. Following training, rivalry-inducing stimuli (gratings moving in opposite directions for each eye) were presented on approximately 40% of the trials. Rivalry presentations were terminated with catch trials by reversing the direction of one of the gratings so that both eyes viewed movement in the same direction. Stimuli ranged from 2 to 8 degrees/sec in velocity and from 0.5 to 1.5 cycles/degree in spatial frequency. Rate of perceived alternation in direction of movement increased as a function of velocity and spatial frequency for the monkey and for human subjects tested with the same procedure. Gamma functions with nearly equivalent parameter values describe the distributions of rivalry phase durations in both monkey and man. These functional similarities between binocular rivalry in monkey and man are evidence of the accuracy of the monkey's reports of his perceptions. The rivalry-inducing stimuli which we have used permit the testing of hypotheses concerning underlying neural mechanisms. The waxing and waning of activity in cortical neurons showing directional selectivity or differential responsiveness to monocular stimulation, if correlated with reported perceptual changes, would be evidence for selective facilitative and/or suppressive processes.

1744 BINOCULAR INTERACTIONS IN STEADY STATE VISUAL EVOKED RESPONSES. P. Apkarian,* K. Nakayama,* C. W. Tyler* (SPON: C.K. Peck). Smith-Kettlewell Institute of Visual Sciences, University of the Pacific, San Francisco, CA 94115.

The steady state visual evoked response (VER) was measured with sinusoidal gratings which were temporally modulated in counterphase. VER amplitude measures were obtained with a synchronous narrow-band filter of 2% bandwidth (-6db) at a center frequency equal to the reversal frequency between 10 and 50 rps.

Binocular interactions were investigated as a function of spatial frequency, contrast, and retinal location. The response amplitude showed narrow peaks as a function of both spatial and temporal frequency. All peaks recorded showed some degree of binocular summation in comparison to the mean monocular response. Some peaks showed marked binocular facilitation of as much as 4x the mean monocular response. Binocular facilitation tended to be stronger at higher contrasts. Binocular summation occurred for horizontal gratings for which stereopsis is not possible, but facilitation greater than 2x the monocular response was not obtained.

The spatial frequency of the response peaks depended markedly on the retinal location of the stimulus. Thus the degree of binocular interaction varied with different retinal locations. In some cases a single peak could be isolated as deriving exclusively from a retinal location as small as one square degree. The largest VER was usually obtained outside the fovea at all spatial frequencies.

These results indicate a high degree of specificity in the evoked potential as a function of many basic stimulus parameters.

1745 ANATOMICAL OBSERVATIONS ON THE VENTRAL LATERAL GENICULATE NUCLEUS (LGNv) OF MONKEY. Richard S. Babb, Pedro Pasik and Tauba Pasik. Dept. Neurol., Mount Sinai Sch. Med., CUNY, New York, N.Y. 10029.

The LGNv of the monkey (M. mulatta) consists of two distinct laminae. The ventral lamina appears orally within the incoming fibers of the optic tract concurrently with the anterior pole of the LGNd. It is rich in neurons and very poor in myelinated fibers. The dorsal lamina, which is initially separated from the ventral lamina by optic tract fibers, becomes contiguous at more caudal levels, but remains distinct due to its richness in myelinated fibers. Specimens prepared by the Golgi-Kopsch method show at least 3 neuronal types: an elongated cell, 15x10 µm, with dendrites oriented in a bipolar fashion within the coronal plane of the section and bearing twig-like protrusions with enlarged endings; a round neuron, 15 µm in diameter, with long delicate dendrites having smooth outlines and terminal arborizations with bulbous appendages; a larger cell, over 20 µm in diameter, with thick long dendrites exhibiting spine-like protrusions and oriented ventralward, sometimes reaching the LGNd capsule. The distribution of these types is unclear although the smooth dendrite category was observed only in the ventral lamina. The dendrites of the other types may extend into both laminae.

Thin sections from individual laminae were prepared for electron microscopy. They were obtained from oriented blocks where clear identification of the laminae could be made in 1 µm sections of the entire face. Three neuronal types are identified: a fusiform cell, 20x10 µm, with scant cytoplasm, poor in organelles, and with very few axosomatic synapses; a roundish cell, about 18 µm, with a richer perikaryon, light large mitochondria, small stacks of rough endoplasmic reticulum, and up to 6 axosomatic synapses in a given section; a larger neuron, over 20 µm in diameter, with very rich cytoplasm, numerous organelles, small dark mitochondria, many large stacks of rough endoplasmic reticulum, and up to 14 axosomatic synapses in a section. Dendritic profiles exhibit protrusions and spines particularly abundant in the dorsal lamina. Profiles containing synaptic vesicles are at least of 4 types. The most frequently seen has dark mitochondria and mostly round vesicles. A smaller, cup-shaped terminal has dark mitochondria and small spheroidal vesicles. A large ending contains large pale mitochondria and larger spheroidal vesicles. A profile with pleomorphic vesicles shows medium dense mitochondria and occasional cisterns. The latter element exhibits both presynaptic and postsynaptic sites and participates in complex arrangements involving triadic and serial synapses with the other 3 axon terminals and purely dendritic profiles. These complex synapses are more common in the ventral lamina which resembles the dorsal lateral geniculate nucleus. Aided by N.I.M.H. Grant # HM-02261.

1746 THE CHOLINERGIC SYSTEM IN THE DEVELOPING CHICK RETINA. Charles R. Bader*, Janet L. Moore* and Robert W. Baughman. Dept. Neurobiology, Harvard Medical School, Boston, MA 02115.

In the chicken retina there is a Na dependent, hemicholinium-3 (HC-3) sensitive high affinity (HA) uptake of choline localized to a small number of retinal cells and required for acetylcholine (ACh) synthesis (Baughman and Bader, 1977). In the present work the activity of choline acetyltransferase (CAT) and Na dependent, HC-3 sensitive ACh synthesis were studied during development of the chicken retina. CAT activity per mg protein in retinal homogenates increased 30-fold between embryonic days 7 and 11 and then remained constant through hatching at day 21. The synthesis and storage of ^{3}H ACh, determined following an in vitro incubation in the presence of ^{3}H Ch, however, increased in two stages. The first stage coincided with the increase in CAT activity (days 7-11), and through day 13 ACh synthesis was not blocked when HC-3 was present or when sucrose replaced NaCl in the incubation medium. The second stage occurred between days 14 and 19, but now, as in the adult, ACh synthesis appeared to be linked to HA choline uptake since it was blocked by HC-3 or the absence of Na. The second increase in synthesis is concurrent with synaptogenesis (Hughes and LaVelle, 1974) and the appearance of visual function (Witkovsky, 1963). Thus, in addition to the increase in CAT activity, which is completed relatively early, there is a second process appearing with final maturation, possibly related to HA choline uptake, that is important for synthesis and storage of ACh in the developing chick retina.

1747 QUANTITATIVE RESPONSE PROPERTIES OF NEURONS IN THE DORSOMEDIAL AREA (DM), A THIRD TIER VISUAL AREA IN THE OWL MONKEY. J. F. Baker*, F. M. Miezin*, J. Myerson, W. T. Newsome*, S. E. Petersen*, and J. M. Allman (SPON: V. Lewis). Div. of Biology, California Institute of Technology, Pasadena CA 91125.

The visual cortex immediately anterior to the second visual area in the owl monkey, Aotus trivirgatus, contains five separate representations of the contralateral visual hemifield. We have studied single neuron response properties in one of these third tier areas, the dorsomedial area (DM), in chronically prepared sedated animals. In experimental sessions an animal initially received a tranquilizer, trifluprom azine, followed by hourly doses of ketamine. The eyes were anesthetized locally with dibucaine before fixing them to immobile rings. Computer controlled visual stimuli were presented while recording from single DM neurons with glass insulated platinum-iridium electrodes. Stimuli were moving bars of various orientations, velocities, lengths, and widths presented in pseudorandom order. Responses were calculated as the difference between the mean impulse rate during the stimulus presentation and the mean spontaneous impulse rate. Most DM cells were orientation selective; they responded best to a stimulus of a particular orientation moving in either direction orthogonal to that orientation and gave a less than half maximal response to the orthogonal orientation. A few DM cells were directionally selective; they had a preferred direction of movement and gave a less than half maximal response to the opposing direction. The remaining cells were pandirectional, with all orientations and directions evoking a response at least half the maximum. These categories were not sharply distinct. Instead, our measures showed a continuous distribution from the extremes of orientation selectivity and direction selectivity to pandirectionality. DM cells responded maximally to stimulus velocities of 25 deg./sec or greater and responses were nearly proportional to the logarithm of velocity up to the optimal speed. Responses showed approximately linear summation with increasing stimulus length, usually up to the full extent of the cell's mapped receptive field. Further increases in stimulus length had no effect. Increasing stimulus width beyond an optimal small value (about 1 deg.) either had no effect or resulted in decreased firing. Virtually all DM cells were binocularly activated with the majority of cells driven about equally by the two eyes. Some cells' responses were strikingly affected by variations in horizontal retinal image disparity, and several patterns of disparity tuning were observed. This research was supported by NIH grants NS-12131 and NS-00178 and by Sloan, Spencer, and Weizmann fellowships.

1748 EFFERENT INNERVATION AND CIRCADIAN RHYTHMS IN THE LIMULUS VISUAL SYSTEM. Robert B. Barlow, Jr., and Steven C. Chamberlain.* Institute Sensory Research, Syracuse U., Syracuse, NY 13210

An endogenous clock mechanism significantly influences the response characteristics of the Limulus visual system. The properties of the circadian clock have been studied with physiological, anatomical, and behavioral techniques. The physiological studies show that when Limulus is kept in continuous darkness the electroretinographic and optic nerve responses from the lateral eye are larger at night than during the day. The spontaneous discharge recorded in the dark from single optic nerve fibers also exhibits a circadian rhythm: the rate of the spontaneous discharge is low at night and high during the day. The circadian rhythms in the neural activity of the lateral eyes are mediated by efferent fibers that fire synchronous bursts of impulses at night and few or no impulses during the day. Illumination of the median eyes can modulate the discharge of the efferent fibers and thereby influence the neural activity of the lateral eyes. A comparison of the daytime and nighttime intensity-response functions for a single ommatidium indicates that the efferent input increases both the quantum catch and the gain of the photoreceptors.

Anatomical studies are beginning to reveal the underlying neural organization which mediates efferent control of visual sensitivity and interactions between visual organs. Results of cobalt sulfide-silver studies have shown the detailed morphology of the primary visual inputs to the brain. The extensive innervation patterns of single optic nerve fibers from the median and lateral eyes have areas of overlap. The second optic ganglion receives primary inputs from the ventral, median, and lateral eyes as well as from mechanoreceptors on the carapace. Relationships between these inputs and nearby neurosecretory centers are being studied with HRP and Alcian blue-yellow procedures.

Behavioral studies reveal circadian rhythms in the locomotor activity of Limulus. The animals' nocturnal periods of maximal locomotor activity correspond reasonably well to the period of elevated retinal sensitivity. The circadian changes in the response characteristics of the Limulus visual system may adapt the animal for functioning in dim light, a result supported by preliminary behavioral studies in the field (ocean).

1749 THE FOVEAL LOCAL ERG WITH TRANSIENT AND STEADY STATE FLICKERING STIMULI. W.S. Baron and R.M. Boynton. SRI, Menlo Park, CA 94025 and UCSD, Dept. Psych., La Jolla, CA 92093.

The foveal local ERG (LERG) of the monkey has been shown, over a limited range, to behave in a linear fashion under steady state flicker conditions. Using a criterion response amplitude within this range, its temporal modulation transfer function has been obtained. From these data we have calculated theoretical impulse responses and integrated them over a 400 msec period. Comparisons between these derived responses and experimentally obtained responses to 10% incremental and decremental impulse and rectangular pulse stimuli, shows that the linear Fourier transform does not hold. A b-wave appears to be present in the experimental incremental responses which is not as apparent in the theoretically derived responses, and is absent in the decremental impulse response.

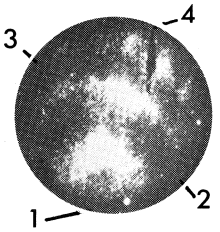
1750 UPTAKE SYSTEMS FOR γ-AMINOBUTYRIC ACID IN THE CHICKEN RETINA. Robert W. Baughman, Thomas L. Schwarz* and Charles R. Bader.* Dept. Neurobiology, Harvard Medical School, Boston, MA 02115

The transport of γ-aminobutyric acid (GABA) and its analogs into cells in the chicken retina was examined. When pieces of retina were incubated in vitro in medium containing ^{3}H GABA at concentrations ranging from 0.05-100 μM and subsequently analyzed autoradiographically, differences in the distribution of GABA uptake were observed. At the lowest concentrations uptake into horizontal and ganglion cells was significant, but amacrine cells were only weakly labelled. In the range 1-25 μM all three cell types were labelled, consistent with previous studies carried out in this range (Marshall and Voaden, 1974). At 100 μM uptake into ganglion cells was negligible compared to the levels observed in horizontal and amacrine cells. In the mammalian CNS 2,4-diaminobutyric acid (DABA) and β-alanine (β-Ala) have been reported to block uptake of GABA into neurons and glia respectively (Kelly and Dick, 1975). In the present study these GABA analogs were used to further characterize the uptake mechanisms in the various cell types. After incubation with ^{3}H DABA (8.3 μM) label was observed in horizontal and amacrine cells, but not in ganglion cells. On the other hand, ^{3}H β-Ala (2.8 μM) was taken up only by ganglion cells and not by horizontal or amacrine cells. As with GABA, neither DABA or β-Ala was taken up by photoreceptors, bipolar cells or Mueller glial cells. A 400-fold excess of DABA effectively blocked ^{3}H GABA uptake into amacrine cells, but even a 5000-fold excess did not effect uptake into horizontal or ganglion cells; a 400-fold excess of β-Ala blocked ^{3}H GABA uptake into ganglion cells, but a 5000-fold excess did not effect uptake into horizontal or amacrine cells. The selective inhibition of GABA uptake observed is consistent with the pattern of DABA and β-Ala uptake, except for the failure of DABA to block GABA accumulation by horizontal cells. Such a complete lack of inhibition was unexpected in view of the high rate with which horizontal cells accumulated ^{3}H DABA. The different behavior for uptake under the conditions described suggests that in the chicken retina horizontal, amacrine and ganglion cells may each possess biochemically distinct transport systems for GABA.

This research was supported by NIH Grant EY00606.

1751 FURTHER OBSERVATIONS ON THE PROJECTIONS OF THE LAYERS OF THE SUPERIOR COLLICULUS IN THE RHESUS MONKEY WITH AUTORADIOGRAPHIC TRACING METHODS. Louis A. Benevento and Michael Rezak. College of Medicine, University of Illinois Medical Center, Chicago, IL.

Two previous degeneration studies(Benevento & Fallon, JCN 160: 339,1975;Partlow et al.,JCN171:285,1977)have produced conflicting results regarding the projections of the superior colliculus(SC) to the dorsal lateral geniculate nucleus(DLG), intralaminar nuclei(IL), posterior nuclear group(PNG), lateral and ventral posterior nuclei, pretectum(PT) and accessory optic nuclei. These conflicts could have been due to the number of SC layers lesioned, the survival time used, or to destruction of axons of passage from the PT. We have attempted to clarify these discrepancies and also add to the previous findings by further examining our autoradiographic material on the projections of the layers of the SC and PT(e.g.,Benevento & Rezak,Brain Res.108:1,1976;Benevento et al. Brain Res.in press:1977). Our autoradiographic studies confirm that the superficial cell layer of the SC projects to the DLG. In addition, heavily labelled fibers were found between all layers of the DLG, and a moderate density of grains was seen among the cells of the magnocellular and parvocellular layers(Fig). The amount of label found in the DLG was too dense to be considered solely due to labelled axons destined for the ventral lateral geniculate(VLG) which contained only a moderate amount of grains medially. Labelled axons destined for the VLG take a direct route through the brachium while those destined for the DLG pass through the inferior pulvinar(PI) where a complex distribution of grains is also found as described before(Brain Res., 1976). The results also show that the retinorecipient superficial cell layer does not project to the IL, but that the deep layers do project to the IL, including part of the centromedian. Thus, it is the deep SC layers, like the PT, which project to visuomotor and arousal systems. Labelled axons were again found in the lateral and ventral posterior nuclei but these now appear to be axons of passage destined for other targets(JCN,1975;Brain Res., 1977). Injections in the superficial cell layer also produced a moderate amount of grains in the deep SC layers, the sublentiform and olivary nuclei, within and about the inferior colliculus and in the dorsal and lateral terminal nuclei(NAOT and "Z" in JCN,1975). In many cases dense label was found in the suprageniculate and limitans nuclei, confirming a SC projection to the PNG.(Supported by NSF Grant BNS 75-07349).



Darkfield of grains between & in DLG layers

1752 PATTERN EVOKED POTENTIALS IN A BLIND HUMAN LACKING VISUAL ASSOCIATION CORTICES. I. Bodis-Wollner, A. Atkin, E. Raab* and M. Wolkstein*, Mount Sinai School of Medicine of CUNY, New York 10029

Visual evoked potentials to diffuse light-flashes, to coarse checkerboards, and to gratings of low spatial frequency were recordable and of normal size in a blind boy. His vision had been normal until age 2 years, when as a consequence of a febrile illness he was left deaf, blind, and slow in developing. While hearing and motor coordination had ultimately returned to normal, at 6 years of age there was still no sign of vision. Ophthalmological examination revealed normal retinae and intact oculomotor and pupillary responses. Computerized axial tomography revealed bilateral destruction of cortical areas 18 and 19, while a strip of occipital cortex on the left corresponding to area 17 was preserved.

A rare opportunity was provided by the following features of this case. At least 2 years of normal visual pathway development occurred prior to blindness. The CT scan and pattern EP are new techniques which were available for correlating anatomy and electrophysiological functions in this living human. In addition we were able to correlate these studies with behavioral observations. The absence of vision, the destruction of areas 18-19, with the apparent preservation of area 17 and the temporal cortex, and the presence of normal flash and low spatial frequency pattern EPs suggests the following consideration. Blindness may result from the destruction of the visual association cortices either because they are per se essential for vision or because they are required as a relay to the inferotemporal cortex. Either hypothesis is noteworthy in view of subhuman primate studies. In subhuman primates, when cortical areas 18 and 19 are destroyed but area 17 is spared, visual acuity and the ability to sort objects are preserved (Denny Brown, D. and Chambers, A.: Arch. Neurol. 33:219, 1976). However, the animals may lose the capacity to learn new discriminations between visual patterns, apparently because destruction of areas 18-19 interrupts the pathway from the primary visual projection cortex to the inferotemporal cortex (Mishkin, M.: in Brain and Behavior, ed. A.H. Karczmar and J.C. Eccles, Springer-Verlag, Berlin-Heidelberg, 1972; pp. 187-208).

In any case it is apparent from this human study that EPs can be elicited by patterns of low spatial frequency when area 17 remains in spite of destruction of the visual association cortex. Furthermore behavioral and electrophysiological indices of pattern detection may no longer be correlated after the visual association cortex has been destroyed.

1753 VISUAL CORTICAL EYE MOVEMENT POTENTIALS AND THEIR ASSOCIATION WITH ALERTING RESPONSES. R.M. Bowker*, J.C. Hendricks*, and A.R. Morrison, School of Veterinary Medicine, University of Pennsylvania, Philadelphia, Pennsylvania.

We recently demonstrated that during wakefulness the alerting response, which ranges from "sizing up" of stimulus significance to startle, is the main determinant of amplitude of the visual cortical eye movement potential (EMP), not the level of illumination. We now show that EMP are present during alerting, but not during non-alerting behaviors, even in well-lighted conditions. Three cats were chronically implanted for recording EEG,EOG, and neck EMG activity. Transcortical electrodes were placed in the visual cortex. Recordings were correlated with the behaviors observed during food presentation to a fasted cat. Food presentation produced an orientation consisting of a head and neck movement toward the food source and 2-5 scanning eye movements. Each eye movement was accompanied by large EMP. The cat then rapidly approached and consumed the food. Eye movements were present during this goal-directed phase, but EMP were consistently absent. EMP reappeared only during spontaneous searching following food consumption. Daily feeding by repeated presentations resulted in gradual attenuation of EMP amplitudes during orientation. By the fourth day, even though the cat remained highly motivated as evidenced by its persistent ravenous appetite, EMP were no longer discernible above the baseline recording unless a non-specific, uncontrollable stimulus appeared. However, large EMP were always present between trials. With the introduction of novel objects amplitudes returned to equal those recorded during initial training and PGO waves during PS. Other non-alerting behaviors associated with eye movements but not EMP included responses to petting, grooming and food and water consumption. However, when transient scanning interrupted these activities, EMP reappeared. These results demonstrate that under well-lighted conditions EMP appear during alerting behaviors in association with eye movements, but that during non-alerting, goal-directed, and simple learned tasks, visual cortical EMP no longer accompany eye movements. Furthermore, the absence of EMP with these behaviors indicates that contrary to previous suggestions, EMP do not represent simple corollary discharges. Our findings support the idea that they represent an enhancement of the transfer of information in the visual system which would be particularly important during alerting behaviors. These findings are in keeping with our initial hypothesis that the spontaneous PGO wave during PS represents a sign of the activation of an alerting network.

1754 A VISUAL QUICKIE: A BISYNAPTIC RETINAL PATHWAY TO THE VESTIBULO-CEREBELLUM AND OCULOMOTOR NUCLEAR COMPLEX. N. Brecha, H.J. Karten, Stephen Hunt*, Department of Psychiatry, S.U.N.Y., Stony Brook, N.Y. 11794.

The accessory optic nuclei, which include the nucleus of the basal optic root (nBOR), are readily identifiable in sighted vertebrates. The nBOR in pigeons receives a specific projection from the displaced retinal ganglion cells (Karten, Fite, and Brecha, PNAS, 1977) and projects upon the vestibulo-cerebellum (Brauth and Karten, Exp. Br. Res., 1977), and possibly the oculomotor nuclear complex (Herrick, 1948). These findings suggest that this system plays a role in oculomotor reflexes.

The displaced ganglion cells are located at the margin of the inner nuclear layer and inner plexiform layer of the retina Following injection of horseradish peroxidase (HRP) into nBOR retrogradely labelled displaced ganglion cells were identified and serial sections of these cells examined in the electron microscope. These studies have revealed axodendritic and axosomatic terminals upon the displaced ganglion cells. Some of the somatic endings arise from myelinated axons. No synaptic ribbons were found in the presynaptic profiles. These findings indicate the afferents to displaced ganglion cells probably arise from amacrine cells and centrifugal axons.

Unilateral injections of 20μCi ^{3}H-leucine within nBOR have demonstrated projections upon both the oculomotor nuclear complex and vestibulo-cerebellum. These projections have been confirmed by the injection of HRP into the terminal projection fields of nBOR and subsequent identification of HRP labelled cells within nBOR. The nBOR projects upon the contralateral dorsolateral and ipsilateral ventromedial and ventrolateral nuclei of the oculomotor nuclear complex. Axons of nBOR also join the ipsilateral brachium conjunctivum cerebellopetale, partially decussate in the dorsal cerebellar commissure and terminate bilaterally as mossy fibers within the granule cell layer of folia IXc, IXd and paraflocculus (uvula). Intraocular injection of 850μCi ^{3}H-proline and a survival period of 12 days results in the appearance of longitudinally aligned bands of label within folia IXc, d of the cerebellum. This presumably reflects the terminal distribution of nBOR efferents following transneuronal movement of label from retinal terminals to cell bodies within nBOR.

These findings indicate that displaced ganglion cells constitute a unique population of retinal neurons that give rise to a bisynaptic pathway to the vestibulo-cerebellum and oculomotor nuclear complex.

1755 INTRACELLULAR RECORDING IN OUTER SEGMENTS OF RED AND GREEN RODS OF THE TOAD RETINA. Kenneth T. Brown and Dale G. Flaming*. Dept. Physiol., Sch. Med., Univ. Calif., San Francisco, CA 94143.

Amphibian green rods have been inaccessible to intracellular recording because of their sparse representation and very thin inner segments. We have now developed microelectrode techniques which permit systematic intracellular recording in the outer segments of toad rods, which are 5.0-7.5 µm in diameter. An electrode puller has been developed which reliably forms tips only 0.02-0.07 µm in diameter. These tips are also exceptionally short, hence have resistances of only 25-165 MΩ when filled with 5M K-acetate, and are stiff enough to be beveled by techniques reported previously. We have also devised a stepping hydraulic microdrive that advances by high speed steps featuring high acceleration, velocities up to 2 µm/msec, and negligible after-vibrations. Detection of a cell's membrane potential may be used to stop this microdrive on the same 1 µm step that carries the electrode into the cell, thus preventing cell damage by over-penetration. Using an isolated and inverted retina, contact of the electrode with the tip of a rod outer segment is visualized by infrared light and a high-resolution TV camera. At shallow depths containing only rod outer segments, several are often penetrated along a single low-angle electrode track. Large light responses have been obtained (up to 30 mV) and held for 1-2 hrs with no sign of deterioration. In agreement with previous work, the red rod thus far appears univariant, its responses being influenced only by summative interaction with other red rods. At short wavelengths near the λmax of its photopigment, the green rod gives a hyperpolarizing response similar to that of red rods. But the green rod is not univariant. It exhibits a hyperpolarizing input from another class of receptor tentatively identified as the red rod. Furthermore, at long wavelengths it shows a delayed and slow depolarization, probably due to inputs from single cones. These receptor interactions differ from those reported to date in other vertebrate photoreceptors, and are thus of special interest, especially since they occur in a short wavelength receptor that appears to participate in color vision. (Supported by NIH grant No. EY 00468).

1756 LARGE VISUAL RECEPTIVE FIELDS IN A POLYSENSORY AREA IN THE SUPERIOR TEMPORAL SULCUS OF THE MACAQUE. Charles J. Bruce*, Robert Desimone*, and Charles G. Gross. Dept. Psychol., Princeton Univ., Princeton, NJ 08540

Multi-unit and single unit activity was recorded from the dorsal bank of the superior temporal sulcus in immobilized macaques under N_2O. 70 multi-unit penetrations revealed an area responsive to visual, auditory and somesthetic stimuli which corresponds approximately to Jones and Burton's cytoarchitectonic Area T3 (JCN 168, 197). Of 79 isolated single neurons, 96% were responsive to visual stimuli, 55% to somesthetic and 29% to auditory; 44% were bimodal and 18% trimodal. The visual responses were binocular and the visual receptive fields huge: 75% extended into the monocular crescent of both eyes and 78% extended more than 45° into both upper and lower fields. Responsiveness to stimuli in the far periphery was usually similar to that at the fovea. Virtually all the somesthetic receptive fields were also large and bilateral.

Almost all units responded more to moving than flashed stimuli; size, orientation and direction of movement were usually unimportant but many cells were differentially sensitive to visual stimuli entering or leaving the field, approaching or withdrawing, and expanding or contracting. Some units had other specific visual trigger features.

This area receives an input from inferior temporal cortex and is reciprocally connected with area 7 (Jones and Powell, Brain 93, 793; Mesulam et al., Br. Res., in press); its units share some properties with both these areas.

1757 AN AUTORADIOGRAPHIC STUDY OF PRIMARY RETINAL PROJECTIONS IN GROUND SQUIRRELS. Laura L. Bruce* and Earl Kicliter, School of Basic Medical Sciences and Neural and Behavioral Biology Program, University of Illinois at Urbana-Champaign, IL 61801.

Retinal projections of 13-lined ground squirrels (Citellus tridecemlineatus) were determined with autoradiographic methods after unilateral intraocular injections of 50 µCi-1 mCi ^{3}H-proline and post-injection survivals of 24 hours to 10 days. The following targets were identified: Suprachiasmatic nucleus: SCN labeling is denser contralaterally. Accessory optic system: Contralateral medial, lateral and dorsal terminal nuclei receive retinal projections. Ventral lateral geniculate: LGv is bounded dorsally by the intergeniculate leaflet which receives a bilateral projection. Label in the remainder of LGv is denser contralaterally and is distributed in both internal and external sublayers of the external layer. Dorsal lateral geniculate: Three laminae are revealed in coronal sections. Laminae 1 and 3 receive a contralateral projection, while lamina 2 receives an ipsilateral projection. Pretectum: Of the three pretectal nuclei which receive retinal projections, only the olivary pretectal nucleus (OP) receives projections from both eyes. Both ipsilateral and contralateral projections to OP are divided into two segments. The posterior pretectal nucleus (PPN) lies posteromedial to OP and receives a diffuse contralateral projection. The retinal projection to the contralateral nucleus of the optic tract (NOT) begins dorsally and slightly posterior to OP; silver granules are arranged in dense clusters. Posteriorly, OP, PPN and NOT merge at the medial edge of the brachium of SC. Superior colliculus: In the contralateral SC, stratum zonale and stratum opticum (SO) are densely labeled; stratum griseum superficiale (SG) contains less label. The ipsilateral SC contains small puffs of grains distributed primarily in the lateral, anterior region of the SC, at the boundary of SG and SO. Medial geniculate nucleus: Diffuse but distinct labeling is observed in animals which receive high doses of ^{3}H-proline. Pulvinar: Silver grain distribution indicates bundles of axons of passage and a possible small projection. The present results correlate closely with previous investigations except for projections to SCN, MGN and pulvinar. Of these, that to MGN is intriguing since Kalil and Schneider (Brain Res. 100:690, 1975) observed a retinal projection to MGN after ablation of the SC and brachium of the inferior colliculus in neonate hamsters. The projection observed by Kalil and Schneider may thus represent only increased axonal termination in MGN rather than an entirely new projection. (Supported by USPHS Grant EY-01736 to E. K. and NSF SER 76-18255.)

1758 A COMPARISON OF SUPRAGRANULAR TO INFRAGRANULAR CONNECTIONS IN THE VISUAL CORTEX OF NORMAL AND VISUALLY DEPRIVED RATS. Albert B. Butler and John A. Jane. Dept of Neurosurgery, University of Virginia, Charlottesville, VA 22901

We have examined the connections between supragranular and infragranular layers of visual cortex in normal animals and animals who underwent neonatal bilateral eyelid suture. Thermal lesions were made through the intact skull in layers I, II, and the upper part of layer III in visual cortex of both normal and visually deprived adult rats. Transcardial perfusion fixation with aldehydes was performed on post-lesion days 2 or 3 for electron microscopy. 1 X 1 mm blocks of tissue extending through the depth of the cortex were taken from the lesioned area and embedded using routine electron microscopic techniques. The infragranular cortex of both groups was then examined using light and electron microscopes. The identification of specific laminae was determined by examining adjacent thick (1 µm) and thin sections. The thin section was first studied for areas of degeneration and the location of these areas determined by comparing these zones to the same areas on thick sections. In the normal animal, degenerating axon terminals are seen almost entirely within layer V and are found mainly on dendritic spines and less often on dendritic shafts. In the deprived animals, however, an apparent redistribution of degenerating axon terminals is seen with a relative decrease in the number of terminals ending on dendritic spines, with a relatively greater number ending on dendritic shafts and neuronal perikarya.

1759 EFFECTS OF VISUAL DEPRIVATION ON THE DEVELOPMENT OF VISUAL PATHWAYS IN THE GALAGO. V. A. Casagrande, D. Raczkowski*, and I. T. Diamond. Dept. Anat., Vanderbilt Univ., Nashville, TN 37232, Dept. Psych., Duke Univ. Durham, N. C. 27706.

We examined geniculate cell sizes and distribution of retinofugal and geniculocortical axons in two galagos raised for 1 year with a monocular lid closure. Measurements of cell size in the lateral geniculate nucleus showed that deprived cells in both the binocular and monocular segments were significantly smaller than cells innervated by the open eye. However, mean asymmetries between sizes of deprived and non-deprived cells were on the average considerably greater in the binocular segment (30%) than in the monocular segment (12.5%). These findings support results obtained in monocularly deprived cats and monkeys indicating that both binocular imbalance and deprivation per se affect cell growth (Von Noorden et al. Brain Res. 111: 277, 1976; Hickey et al. JCN 172: 265, 1977).

Comparisons of cell measures in individual layers indicated that changes in both absolute and relative cell size within the magnocellular layers were within the range of cell size changes seen in the parvocellular layers.

Changes in retinal and geniculo-cortical properties were investigated following injections of ^{3}H proline into either the open or sutured eye in the deprived galagos and into one eye in each of the normal galagos. No evidence was found for changes in the distribution of retinal axons to geniculate nucleus or to the superior colliculus. In both normal and deprived galagos label in the superior colliculus appeared continuous contralateral to the eye injection and patchy ipsilateral to the eye injection. No obvious differences in the width of these ipsilateral patches nor discontinuities of the contralateral distribution could be seen between animals.

In contrast with the retino-tectal projections, transsynaptically transported label to striate cortex showed several changes following deprivation. Injections into the sutured eye resulted in distinct patches with the binocular portion of layer IV of both the ipsilateral and contralateral striate cortex. These patches were much more pronounced than those seen in the normal galago. Injections into the non-deprived eye revealed continuous label within layer IV of striate cortex in both hemispheres. These results are consistent with earlier reports in cat and monkey showing rearrangement of geniculo-cortical axons following monocular deprivation.

1760 RELATIONSHIP BETWEEN INTEROCULAR ALIGNMENT AND BINOCULARITY OF STRIATE CORTICAL NEURONS IN SIAMESE CATS. Y.M. Chino* and M.S. Shansky*. Division of Visual Science, Illinois College of Optometry, Chicago, IL 60616. W.J. Pizzi. Dept. of Psychology, Northeastern Illinois University, Chicago, IL 60625. (SPON: T.S. Brown)

Responses of cortical cells in the striate cortex of Siamese cats were recorded extracellularly, under nitrous oxide/oxygen anaesthesia and with tungsten-in-glass-microelectrodes. Binocular activation of each unit was assessed by determining its ocular dominance group (Hubel and Wiesel, 1962). In addition, responses were recorded from cortical cells in normal cats for the purposes of comparison. Although the dominance distributions for the Siamese strongly favors contralateral innervation, there are a higher percentage of binocularly-activated cells than has previously been reported, and many of these had receptive fields within 8° of the area centralis. Furthermore, the data suggests an inverse relationship between the percentage of binocularly excited cells and the extent of convergent misalignment exhibited by individual Siamese cats.

1761 PULVINAR LESIONS IN MONKEYS PRODUCE ABNORMAL SCANNING OF COMPLEX VISUAL ARRAYS. Carol A. Christensen* and Leslie G. Ungerleider. Psychology Department, Vassar College, Poughkeepsie, N.Y. 12601 and Laboratory of Neuropsychology, NIMH, Bethesda, MD. 20014.

Visual orientation and habituation to a complex stimulus array were studied in rhesus monkeys with bilateral pulvinar lesions (N=4) and in normal control monkeys (N=4). The stimulus array consisted of 16 geometric figures; it was presented for 5-sec trials, 40 trials per day, on two consecutive days. On the first and last 10 trials of each day's session, all of the figures appeared as white stimuli on a black background; on trials 11-30, one of the figures within the array was colored red. Using a corneal reflection technique, visual orientation and habituation to this novel stimulus were recorded by video taping the monkey's eye movements as he scanned the stimulus array. Subsequent to behavioral testing, the video tape records were analyzed to determine the monkey's point of fixation at 200-msec intervals for each trial.

The results revealed that pulvinar lesions did not alter either visual orientation or habituation to a novel stimulus. Both normal monkeys and monkeys with pulvinar lesions shifted their gaze towards the figure to which color was added; habituation to the novel stimulus occurred at varying rates for individual animals, but did not differ between normal and operated monkeys. However, pulvinar lesions did affect visual behavior in two significant ways. First, unlike normal monkeys, monkeys with pulvinar lesions displayed a paucity of saccades off the stimulus array; that is, they appeared "visually captured" by the stimuli. Second, the visual fixations of monkeys with pulvinar lesions were abnormally prolonged, on the average 300 msec longer than those of normal monkeys. Prolonged fixations were observed both when the operated monkeys fixated the white geometric figures and when they fixated the novel stimulus. In contrast to these abnormalities in visual scanning, damage to the pulvinar did not produce any detectable oculomotor impairment; results of neurological tests indicated that optokinetic nystagmus, convergence, vertical and horizontal saccades, and visual pursuit were all normal in monkeys with pulvinar lesions.

We have previously reported that monkeys with pulvinar lesions demonstrate visual capture and prolonged fixations during visual discrimination learning (ARVO Meeting, 1977). The present results extend these findings: scanning abnormalities produced by pulvinar damage occur not only during discrimination training but also during spontaneous viewing of a complex stimulus array.

1762 NASO-TEMPORAL DIVISION OF RETINOTHALAMIC PATHWAY IN NORMAL AND SIAMESE CATS. Michael Lee Cooper* and John Pettigrew* (SPON: Masakazu Konishi). Div. of Biology, Calif. Inst. of Technology, Pasadena CA 91125.

The naso-temporal division of the retinothalamic pathway was studied in normal and Siamese cats. One lateral geniculate nucleus (LGN) of each cat was filled with horseradish peroxidase (HRP); two days later both retinae were removed and reacted with benzidine in order to visualize HRP retrogradely transported to the ganglion cell bodies. Ganglion cell density maps of the temporal retinae were then constructed from retinal whole-mounts.

The normal cats showed clear vertical decussation lines passing through the area centralis (AC). The ipsilateral decussation was sharp and passed through the center of the AC; the contralateral decussation was somewhat less sharp, with scattered cells extending a few degrees into the temporal retina (as previously reported by Stone).

In the Siamese cats there was no sharp vertical decussation line between areas projecting ipsilaterally or contralaterally; rather, there was overlap in the temporal retina between cell populations projecting to each hemisphere. Thus, there was no region of exclusive contralateral misprojection extending 20° temporally from the vertical meridian. Contour maps of the percentages of cells projecting ipsilaterally showed a smooth gradient-like decrease in the percentage of cells misprojecting contralaterally as one proceeded temporally. In other words, there was no special region of unilateral projection; all parts of the temporal retina projected bilaterally. In addition, the ganglion cell isodensity lines were elongated along the horizontal visual streak in both ipsilateral and contralateral retinae.

Cell-size measurements were made at equivalent points in the ipsilateral and contralateral retinae. In a field approximately 20° along the horizontal meridian in the temporal retina, about 2% of the large cells projected ipsilaterally, while about 96% of these large cells projected contralaterally. At this location, about 30% of the total retinothalamic population sent axons ipsilaterally, indicating that the large (presumably Y-type) cells are more affected by the Siamese defect than the ganglion cell population as a whole.

A differential effect of the Siamese defect as a function of cell class was supported by anterograde transport of tritiated proline from the eye. This revealed labeling of the ipsilateral C1-lamina over a wider range of eccentricities than the ipsilateral A1-lamina, suggesting that W-type cells maintain their normal projections in regions in which cells destined for the A1-lamina tend to misproject.

1763 TECTAL PROJECTION OF DISPLACED RETINAL GANGLION CELLS IN THE CHICK EMBRYO. James E. Crandall*, Marieta B. Heaton and Idania M. Alvarez* (SPON: Christiana M. Leonard). Dept. Neuroscience, Coll. Med., Univ. Fla., Gainesville, FL. 32610.

Displaced ganglion cells (DGC's) were first described in the avian retina by Dogiel in 1888. These cells resemble typical retinal ganglion cells in most respects, but rather than residing within the ganglion cell layer, they occupy a seemingly aberrant position, just above the boundary of the inner plexiform and inner nuclear layer. These cells may have a special functional significance since they appear to be the only retinal ganglion cells receiving a direct centrifugal projection (Maturana and Frenk, Science,150:359, 1965), but it is not known whether their field of innervation differs from those of the normal ganglion cells. We studied the projections of the DGC in the chick embryo retina by making discrete (.1-.4 µl) tectal injections of horseradish peroxidase (HRP) and incubating the tissue in diaminobenzidene followed by paraffin embedding and sectioning. These studies revealed the following: Approximately 7,900 DGC's are labeled in the retina of 18 day chick embryos following tectal injections. These labeled cells are between 10-15 µ in diameter, about twice the size of orthotopic ganglion cells. Since unlabeled DGC's could not be distinguished from giant amacrine cells, it was not possible to determine what proportion of the total DGC population projects to the tectum. Discrete tectal injections as early as 10.5 days of incubation revealed labeled DGC's. Labeled DGC's have been previously seen following HRP tectal injections in rats (Bunt, et. al., Brain Res. 73:215, 1974). However, experiments in chick hatchlings (LaVail and LaVail, JCN 157:215, 1974) and adult pigeons (Karten, ARVO, 1977) have suggested that the major projection is extratectal in the avian. The DGC tectal projection in chick embryos may represent collaterals of fibers terminating in extratectal sites or may originate from a separate DGC population.

1764 TOPOGRAPHIC PROJECTIONS OF RETINA AND OPTIC TECTUM UPON THE AVIAN VENTRAL LATERAL GENICULATE NUCLEUS. W.J. Crossland. Dept. Anat., Sch. Med., Wayne State Univ., Detroit, MI 48201.

The avian ventral lateral geniculate nucleus (GLv) located in the ventral diencephalon consists of two laminae oriented parallel to the optic tract. The outer lamina, proximal to the tract, contains loosely scattered cell bodies in a matrix of neuropil. The inner lamina, distal to the tract consists of a layer of densely aggregated cell bodies. Golgi studies have revealed that these cells project toward the optic tract within the outer lamina. By making small injections of 3H-proline into the retina and using the autoradiographic tracing method, we have found, 1) that the retinal input is confined to the outer lamina (neuropil) with a peak of terminal density near the junction of the inner and outer laminae, 2) that the Glv is retinotopically organized: anterior retina projects upon rostromedial Glv, posterior retina upon caudolateral GLv, superior retina upon caudomedial GLv and inferior retina upon rostrolateral GLv.

Stereotaxic injections of tritiated amino acids made into the optic tectum revealed a topographic projection of the tectum upon the GLv. Analysis of the retinogeniculate and retinotectal projection indicates that the tectogeniculate map is in register with the retinogeniculate map. In contrast with the retinal projection, the distribution of tectal terminals is relatively sparse near the inner cell lamina. Thus there is some segregation of input to different strata of the outer lamina. (Supported by NIH Grant EY-01796.)

1765 QUANTITATIVE STUDIES OF IN VIVO FROG RETINAL GANGLION CELL RESPONSES TO CHROMATIC AND SPATIAL STIMULI. Peter F. Cummings*, Gerald F. Hungerford* and Richard L. Binggeli. Dept. Anat., Sch. Med., USC, Los Angeles, CA 90033.

Frog retinal ganglion cells (GC) were studied using an in vivo eyecup preparation. Adult, pithed Rana pipiens obtained from Northern Mexico were used. Extracellular recordings were made from either GC bodies or axons using sodium-acetate filled glass micropipiettes at a depth of 20 to 150μ from the retinal surface. The preparation was studied with a constant background illumination of about 1 X 10^9 photons/mm^2/sec. All stimulus presentations were centered in the apparently active receptive field of the GC, and were repeated 10 times. The stimulus duration was 500 ms. on and 1500 ms. off. 21 different stimuli were presented to each cell. Only cells which were held for 30 min. and presented with all 21 stimuli were included in the data.

The intensity of all stimuli was adjusted with neutral density filters to approximately 1.5 X 10^{12} photons/mm^2/sec. A monochrometer was used to set the light wavelength of each of the spatial stimuli at 432 nm, 502 nm, and 572 nm. Seven spatial stimuli were used which included light spots (2.5°, 5°, & 22°), light annuli (2.5°x5°, 2.5°x22°, & 5°x22°), and dark annuli (2.5°x5°).

Ganglion cell responses, recorded on magnetic tape, were processed and compiled into post-stimulus-time-histograms from the 10 replications. These were used to generate statistics quantitatively descriptive of the response. These statistics were presented as distributions for all cells in all 21 stimulus conditions. Preliminary analysis of this data shows wide variation in response from cell to cell (0-13 spikes per on period). Cells showing spontaneous activity, adaption, and chromatic & stimulus size differentiation were observed. In general, the mean number of spikes during the on period of the stimulus presentations was low (1-3) and the variation between means was small. The mean value of the on response to the 5° spot tended to be larger than the response to the 2.5° or 22° light spot.

1766 SPATIO-TEMPORAL RECEPTIVE FIELD STRUCTURE OF RETINAL NEURONS IN THE CATFISH. Wes Davis* and Syozo Yasui* (SPON: K. I. Naka). Dept. of Physiology & Biophysics, University of Texas Medical Branch, Galveston, Texas 77550.

Various types of receptive fields, spatio-temporal response patterns of vertebrate retinal neurons, have been described but no systematic effort has been made to correlate underlying morphology to the functional receptive fields. We have recorded from and dye-injected and recovered in flat mount more than 200 catfish (Ictalurus punctatus) retinal neurons. We have defined their spatial organization by stimulating the retina with a moving white-noise spatial grating and cross-correlated the resulting responses recorded intracellularly against the input. The first order correlation is the best linear approximation of the field organization revealed by a bar of light moving across the field at a constant speed. The use of a white-noise spatial grating has many advantages over the much simpler method of moving a single bar of light.

Morphological and functional correlation was made by superposing the images of neurons on the cross-correlograms.

We have found 1) the cell bodies and axons of the external horizontal cells formed a monophasic receptive field although the latter's field was much wider, 2) all bipolar cells (as defined morphologically) had an antagonistic center-surround field and both the on- and off-center variants had almost identical spatial dynamics, 3) the sustained amacrine cells showed a complex field organization, and 4) some ganglion cells formed antagonistic center-surround fields whereas others formed a monophasic field. The size of the field of the proximal neurons was often equal to or smaller than the size of their dendritic field.

We will discuss how morphological subclasses of each neuron type form different functional fields.

1767 COMBINATION OF MONOCULAR AND DIRECTIONAL DEPRIVATION IN THE KITTEN VISUAL CORTEX. Nigel W. Daw, Nancy Berman and Michael Ariel.* Department of Physiology and Biophysics, Washington University Medical School, St. Louis, MO 63110.

Six kittens were reared with both monocular (in this case reverse suture) and directional deprivation to see if the effects of different types of visual deprivation are independent of each other. The kittens were placed in a drum rotating in one direction with one eye open from 2 1/2 to 5 weeks, followed by a drum rotating in the other direction with the other eye open from 5 to 12 weeks. Recordings were then made in the visual cortex. The percentage of cells driven by one eye or the other and the overall percentage of unidirectional cells was found to be a function of the reverse suture. Among unidirectional cells, the proportion of cells preferring one direction versus the other was a function of the directional deprivation. The results of reverse suture plus directional deprivation were the sum of the results of these two deprivations taken alone. However reverse suture affected the directional properties of the cells, just as directional deprivation has been shown to affect the ocular dominance histogram.

1768 EXTRACELLULAR POTASSIUM ACTIVITY IN THE MUDPUPPY RETINA; ITS RELATIONSHIP TO THE B-WAVE OF THE ERG. Evan Dick* and Robert F. Miller. Division of Neurobiology, Dept. Physiol., SUNYAB, Buffalo, N.Y. 14214.

In the perfused retina-eyecup preparation of the mudpuppy, double-barreled microelectrodes were used to simultaneously record changes in extracellular potassium (K^+_o) activity and the ERG evoked by diffuse light stimuli.

In the distal retina, near the R-membrane, the K^+_o reponse consists of an immediate, gradual decrease to light onset and a gradual return to the dark baseline at offset. This response is unaffected by a brief application of 2mM Co^{++}, consistent with its generation by photoreceptors. Near the level of the maximum inverted b-wave (70% retinal depth) the K^+_o response to light onset consists of a transient increase followed by a slow decrease and return to baseline at light offset. The K^+_o increase at light onset is abolished by Co^{++} indicating that it results from post receptor neuronal activity. In the proximal retina the K^+_o response consists of a slow increase to both light onset and offset.

We studied the effects of a number of pharmacological agents (6% ethanol, 2mM GABA, 2mM glycine, 0.8mM alpha-aminopimelic acid, and combinations of these) in order to assess whether the K^+_o increase to light onset observed in the distal vs. proximal retina results from activity of a single class of cells. Our data clearly show that different populations of neurons are associated with proximal and distal K^+_o activity.

Application of agents which increase b-wave amplitude (ethanol, ethanol plus GABA) also causes an increase in the distal K^+_o increase seen at light onset. These same agents either have no effect on or, in some cases, diminish the light evoked K^+_o response in the proximal retina. Similarly, other agents (GABA, alpha-aminopimelic acid) which cause a marked reduction in the proximal K^+_o response have little or no effect on either the b-wave or the distal K^+_o increase.

Our findings suggest that light evoked increases in K^+_o activity in the proximal and distal retina can be pharmacologically separated and must be generated by more than one population of cells. We further suggest that the K^+_o increase seen in the distal retina in response to light may be associated through Muller cell depolarization with the site of b-wave initiation. Intracellular recordings from neurons suggests that depolarizing bipolars may be intimately linked to b-wave generation.

1769 RECEPTIVE FIELD CHARACTERISTICS OF VISUAL CELLS IN THE SUPERIOR COLLICULUS OF THE GOLDEN HAMSTER. James Dixon* and Barry E. Stein (Spon: R.J. Krieg). Dept. Physiology, Medical College of Virginia, Richmond, VA 23298.

Neurons activated by moving and/or stationary visual stimuli were studied in all strata of the hamster superior colliculus (SC). Animals were anesthetized with urethane and, in selected experiments, paralyzed with gallamine triethiodide and artificially respired. Neuronal recordings (n=264) were conducted using tungsten microelectrodes. Visual receptive fields (RFs) were mapped on a translucent hemisphere positioned 28 cm in front of the animal. Moving and stationary light stimuli were presented on this hemisphere and quantitative evaluation of RF properties was facilitated by the use of a galvanometer-driven mirror system with which precise changes in stimulus parameters were accomplished.

The upper laminae of the SC were exclusively visual, whereas somatic, acoustic, nociceptive and multimodal cells were encountered in the intermediate and deeper layers. The frequency of visual cells decreased with depth in the SC and their RFs increased in size. However, upper and lower layer cells had many characteristics in common.

For most cells, RFs could not be subdivided on the basis of responses to stationary pulsed light. However, systematic changes in the size of a light bar which was moved through the RF revealed a nonhomogeneous internal organization. Optimal responses were initiated in 94% of the cells when the stimulus was 35% or less of the RF extent. Increasing stimulus size byyond the optimum resulted in progressive and significant decrements in impulse frequency. Further, but less dramatic, decrements were initiated in 61% of the cells when stimuli extended beyond the RF borders. Direction of movement was a critical variable in 56% of the cells. A bar of light was moved through the RF in 8 directions (4 axes) and directional selectivity was defined as a 2:1 ratio between the discharge rates elicited by opposing movements in the same axis. The one direction most frequently preferred was temporal-nasal. Directional selectivity decreased as velocity was shifted from the optimum (most frequently 5-10°/sec or 40-50°/sec).

The laminar organization of sensory representation in the hamster and cat SC are similar. Furthermore, visual SC cells of both species are similar in their preferences for moving stimuli. However, while the optimum velocities are the same for the two species, their directional preferences are 180° out of phase. At present we know of no ecological requirements which would favor this difference in neuronal specialization.

1770 DIVERGENT PROCESSING OF VISUAL INFORMATION IN AREAS 17 AND 18 OF THE RHESUS MONKEY. Bruce Dow, Division of Neurobiology, Department of Physiology, SUNY/BUFFALO, Amherst, N.Y. 14226, and NATIONAL EYE INSTITUTE, Bethesda, Md. 20014.

Moving bars of light have been used to test the responses of foveal cortical cells in areas 17 and 18 of anesthetized rhesus monkeys. Tuning curves obtained with such stimuli have been converted into points on a scatter plot, with "directionality" as the ordinate and "angular selectivity" as the abscissa. This display permits comparison of cells with regard to location in two-dimensional specificity space. Distinct clusters of direction cells and orientation cells are evident in the scatter plot. Each cluster contains cells from both area 17 and area 18. Direction cells are sensitive to velocity as well as direction of movement. Orientation cells require elongated as well as properly oriented stimuli. Among 268 cells (179 in area 17, 89 in area 18) 40% are orientation cells and 15% are direction cells. The proportions are the same in areas 17 and 18.

About 26% of the cells in each area are color cells. The great majority of color cells fall outside of the orientation and direction clusters. In area 17, only 6% of the cells are both orientation- and color-specific, and even fewer (1%) are both direction- and color-specific. In area 18, 1% are orientation- and color-specific, and 1% are direction- and color-specific.

The laminar distribution of 198 cells (119 in area 17, 79 in area 18) has been determined. Direction cells tend to be most common in layer 4A (just above the granule cells) in each area, whereas color cells are rarely found in layer 4A. Orientation cells are about equally common in all layers of both areas.

The data suggest the existence of neuronal mechanisms in areas 17 and 18 for refining and separating different kinds of visual specificity (line orientation, movement direction, color).

1771 ELECTRON MICROSCOPIC EVIDENCE OF A DORSOTEMPORAL TO VENTRONASAL GRADIENT IN FIBER SIZE WITHIN PIGEON OPTIC NERVE. Thomas A. Duff and Grayson Scott*. Depts. of Neurosurg. and Anatomy, Univ. of Wisc., Madison, WI 53706.

Using a uniform sampling method, electron microscopic examination of pigeon optic nerve revealed a dorsotemporal to ventronasal gradient in mean fiber size. The ventronasal portion of the nerve contained large myelinated axons possessing a mean cross sectional area, including myelin sheath, of 0.89 μ^2, S.D.=0.98. In the dorsotemporal portion small myelinated axons (mean area=0.43 μ^2, S.D.=0.35) were predominant. Also unique to this region were scattered clusters of fine, unmyelinated fibers. Axons located in the area between these two regions possessed a mean area of 0.72 μ^2, S.D.=0.78. This temporal to nasal gradient was found to be a constant feature throughout the length of the nerve.

The total number of fibers within the nerve, excluding those comprising the unmyelinated clusters, was calculated to be approximately 2.5 x 10^6. The overall distribution in fiber size was found to be unimodal, with the peak at 0.24 - 0.40 μ^2, and overall mean fiber area = 0.69 μ^2.

Although other investigators have reported a homogeneous spectrum in fiber size throughout pigeon optic nerve, the findings of the present study may be more compatable with anatomical and physiological features of pigeon retinotectal organization. These features include visual field acuity gradients, ganglion cell population pattern, difference in length of tectal afferents arising from ventronasal vs. dorsotemporal retina, and density fields of tectal afferent terminations.

1772 OCULAR ALIGNMENT AND VISUAL FIELD ABNORMALITIES FOLLOWING NEONATAL SECTION OF THE POSTERIOR CORPUS CALLOSUM IN THE CAT. Andrea J. Elberger* (SPON: J. M. Sprague). SUNY at Stony Brook, Stony Brook, New York, 11794.

In young cats, the posterior portion of the corpus callosum was sectioned 13-41 days after birth. The animals' eyes were photographed at weekly intervals for 6 months using the pupil-reflex method. From the corneal reflection evident in the photographs the degree of alignment for the optical axes of each cat was estimated (Sherman, 1972). The 17 experimental cats all showed a clear, permanent divergent strabismus, as compared to 6 normal cats.

After 7 months the limits of the visual field were determined for both groups of cats using a perimetry technique similar to that of Sprague and Meikle (1965). With both eyes open experimental and normal cats could see to 90° on either side of the vertical midline. With one eye open normal cats responded from 90° ipsilateral to 45° past the vertical midline into the contralateral visual field, while with either eye the experimental cats saw no more than 2-3° past the vertical midline. That loss of visual responsiveness is within the contralateral region of the normally binocular zone.

Three normal adults, 9, 13 and 20 months old, were photographed for at least 5 consecutive weeks using the pupil-reflex method. These results were identical to those of normal cats 5-7 months old. Then, the adults received section of the posterior corpus callosum. Photographs of the pupil reflex were taken again for at least 5 consecutive weeks after surgery. These results were identical to those of pre-surgery. In addition, adults were tested on visual field perimetry 3-4 months after surgery. These results were identical to those of normal young cats.

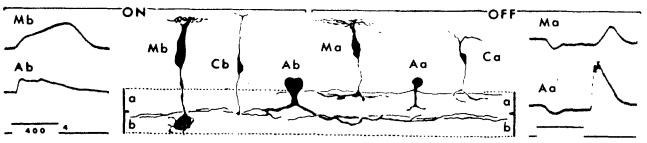
The present results indicate that the normal process of ocular alignment in young cats may be disrupted by early posterior callosal section. It is not known whether the observed abnormalities result from arrested development, or disruption of intrinsically determined ocular alignment. In either case, there is a limited time period for callosal surgery to produce abnormal interocular alignment and abnormal visual field perimetry.

Preliminary results using both photographs of the pupil-reflex method and projection of optic discs indicate that in paralyzed experimental cats there is no evidence of an abnormality in eye position. This suggests that the divergence characteristic of the waking state reflects some dynamic imbalance of ocular alignment. (Supported by NIMH Grant #25643).

1773 NEURONAL ARCHITECTURE OF ON AND OFF PATHWAYS IN CARP RETINA. E. Famiglietti, A. Kaneko* and M. Tachibana*. Departments of Physiology, Wash. Univ. Sch. Med., St. Louis, MO and Keio Univ. Sch. Med., Tokyo, Japan.

It has been demonstrated that the inner plexiform layer (IPL) of cat retina can be divided into two sublaminae (a & b), containing the terminals of flat and invaginating cone bipolars, respectively [1]. In that study, the majority of retinal ganglion cells could be subdivided into types a and b, according to the sublamina in which their dendritic trees were confined. Subsequently, intracellular staining was used to confirm the hypothesis that sublamina a contains the synapses for OFF responses and sublamina b for ON responses.[2]. We find that carp retina is similarly organized.

Procion yellow-stained carp bipolars (25) could be divided into large (M) and small (C) varieties (fig.). These in turn could be subdivided into types a and b, according to the destination of terminals in the IPL. All type a cells were hyperpolarizing (OFF) and all type b cells were depolarizing (ON). All bipolars showed a maximal response to red in the receptive field center. Many had color-opponent, green-dominant surrounds.



Procion-stained amacrine and ganglion cells (25) were also restricted in their branching to sublamina a or b, when their dominant (sustained) response was OFF or ON, respectively (fig.). ON-OFF cells branched diffusely in a & b. Cells with branches in stratum (S)3 showed complex chromatic responses with prominent short wavelength effects. The terminals of color-coded Ma and Mb bipolars in S1&2 and S4&5, respectively, lie in appropriate position to determine sustained amacrine responses of similar polarity, as well as center-opponent responses of red-green, double opponent ganglion cells. These data indicate that bisublaminar organization of the IPL, separating ON and OFF mechanisms, is a general principle of retinal organization in vertebrates.

1774 VISUAL AND EXTRA-VISUAL RESPONSES OF SINGLE NEURONS IN THE PULVINAR AND LATERALIS POSTERIOR NUCLEI OF THE CAT. Steven E. Fish* and Leo M. Chalupa* (SPON: J. S. Robinson). Dept. of Psychology, University of California, Davis, CA 95616.

Extra-cellular single cell recordings were carried out from the pulvinar and lateralis posterior nuclei of cats maintained on a mixture of nitrous oxide and oxygen. Neurons were tested for responses to visual, auditory, and somatosensory stimulations and for responsive cells, receptive field characteristics were investigated.

Approximately 55% of all cells isolated in the pulvinar-LP complex did not respond reliably to sensory stimulations, although some of these could be diffusely activated by one or more modalities. About 30% of the cells tested yielded secure responses to visual stimulation. Typically these had large receptive fields (about 20 degrees in diameter), and generally did not show directional selectivity or orientation specificity. A small proportion of the visual cells exhibited complex response properties, including speed preferences, directional selectivity and/or orientation specificity. The remaining 15% of the cells tested responded to auditory and/or somatosensory stimulation. Multimodal cells were grouped in the ventral portion of the pulvinar-LP complex. This region receives a direct projection from the deeper layers of the superior colliculus. Some of the multimodal cells showed a clear correspondence of visual and extra-visual receptive fields.

1775 THE ACCESSORY OPTIC SYSTEM AND OPTOKINETIC NYSTAGMUS. Katherine Fite, Tony Reiner*, and Stephen Hunt*. Dept. Psychol. U. Mass. Amherst, 01003 and Dept. Anat., SUNY at Stony Brook, 11794.

In nearly all vertebrates, the accessory optic nuclei of the midbrain receive a direct retinal projection. In pigeons, this projection originates from large, displaced ganglion cells located primarily in the peripheral retina whose axons terminate upon the nucleus of the basal optic root (nBOR)--a component of the accessory optic nuclei (Karten, Fite & Brecha, PNAS, 1977). NBOR, in turn, projects monosynaptically to the vestibulocerebellum (uvula, folia IX) and to the oculomotor nuclear complex (Brauth & Karten, Exp. Brain Res., 1977). It has been suggested that some aspects of oculomotor function may be mediated via these pathways, and Lazar (1973) has shown that lesions of the accessory optic nuclei in frogs completely eliminates optokinetic nystagmus (OKN).

The present study demonstrates that stereotaxically placed electrolytic lesions which damage portions of the nBOR of pigeons (Columba livia) and turtle (Chrysemys picta picta) are correlated with either a decrease or a loss of optomotor response when compared with pre-lesion response functions obtained on individual subjects. Using a conventional optokinetic stimulator, the average frequency of head movements/minute were measured as a function of pattern velocity over a range of 5-80 degrees/sec. for each subject and were obtained under both binocular and monocular viewing conditions for clockwise and counterclockwise directions of pattern movement. Following several weeks of post-lesion behavioral testing, both eyes of each subject were injected with 100 μC of (^{3}H) proline. One to four days later, subjects were anesthetized, perfused and the brains subsequently processed for autoradiography. This procedure enabled both a detailed reconstruction of lesion topography and the accurate assessment of remaining (intact) post-lesion optic projections to the accessory optic nuclei, as well as to the other midbrain retinal targets (pretectal complex, optic tectum).

In both pigeon and turtle, the extent of post-lesion change in OKN was correlated with the size and extent of damage to nBOR and to the degree of bilateral involvement. In several instances, lesions which destroyed a large portion of nBOR completely eliminated any measureable optomotor responses from the contralateral eye when tested monocularly with both directions of pattern movement. Thus, nBOR appears to mediate at least some portion of optomotor response in these two nonmammalian species.

1776 RESPONSES OF SINGLE UNITS IN VISUALLY ACTIVATED THALAMIC - PRETECTAL NUCLEI OF THE TELEOST, MICROPTERUS SALMOIDES. Michael J. Friedlander* (SPON: C.L. Prosser). Dept. of Physiology and Biophysics, University of Illinois, Urbana, IL 61801.

Responses of more than 200 diencephalic - pretectal units were investigated. All animals were optically corrected before recording. Recording sites were established by reconstruction of electrode tracks.

Penetrations at increasing depths within 300 microns of the midline revealed: 1) A dorsomedial thalamic region. Units with small (<5°) and large (>20°) receptive fields were found. Latency distribution histograms of responses to optic nerve shock were unimodal with a peak at 7 msec., suggestive of direct retinal input. 2) An intermediate ventromedial thalamic zone. It contained multimodal cells responding to tactile or lateral line input as well as visual stimuli. Most of these cells had longer latencies to optic nerve shock (>10 msec.). 3) A deep ventral thalamic - hypothalamic region. The cells in this region had wide fields (>20°). Latency to optic nerve shock was >10 msec.

In addition to visual input, cells of areas 2 and 3 (above) received descending input from ipsilateral telencephalon, primarily from dorsolateral areas. Latencies to telencephalic shock were 4 to 18 msec., suggesting both monosynaptic and polysynaptic pathways. In some cells, rebound effects lasting up to several hundred msec. were seen after telencephalic stimulation. When visual stimuli were paired with telencephalic shocks at different intervals, an early inhibition followed by facilitation resulted.

Lateral to the medial thalamic area in the central pretectal region, are cells with small to medium fields (3°-11°). These cells showed a high degree of directional selectivity and preference for moving targets. A bimodal latency distribution to optic nerve shock was seen with peaks at 8 and 12 msec. Some of these cells were activated by tectal stimulation.

More laterally, units in nucleus rotundus had a wide range of receptive field sizes (8°-35°). Most of these cells were driven by ipsilateral tectal shock. A small number of these cells also gave an antidromic spike upon tectal stimulation, demonstrating reciprocal connections. Latencies to optic nerve shock were always >13 msec. This area did not show activation from telencephalic stimulation.

1777 THE EFFECT OF RELATIVE MOTION ON DIRECTIONALLY SPECIFIC PIGEON TECTAL UNITS. B. J. Frost and S. C. P. Wong, Dept. Psych., Queen's Univ., Kingston, Ont., Canada, K7L 3N6.

A large body of psychophysical literature indicates that the context in which a stimulus occurs can exert a dramatic influence on its appearance. This has been demonstrated for dimensions such as brightness, hue, line orientation and motion. Experiments on motion perception have suggested that rather than absolute retinal image motion, movement of one pattern relative to another (whether stationary or moving) is the prime determinant of perceived motion. Although stimuli in the real world seldom occur in isolation most single unit studies usually manipulate parameters of a single stimulus. We have varied the motion characteristics of surrounding background stimulus patterns and have found that they differentially modify the response to moving test stimuli presented to directionally specific pigeon tectal units. The motion characteristics of 130 cells from all laminae were studied using standard recording techniques and a dual channel optical system which permitted the independent manipulation of the motion characteristics of the two stimuli. Test stimuli were presented through one channel while moving background patterns of random dots, grating and noise patterns were presented through the other. Eighty-five percent of directionally specific neurons were completely inhibited by background patterns moved in the same direction (in-phase) as the stimulus. With the background moving in the opposite direction (anti-phase) there was no inhibition and in many cases their response was facilitated. Movement of the background pattern alone elicited no response from these units. However, movement of the test stimulus across a stationary background produced PSTH's similar to those produced by the test stimulus alone. For the majority of these cells different background patterns produced the same results although a few required specific patterns before they exhibited the effect. It might be argued that the results of these experiments could be produced by cells that are both direction and size specific. However, facilitation by backgrounds moving in anti-phase argues against such an interpretation, and suggests that relative motion rather than size is the important variable. Furthermore, in some cases velocity tuning curves appear to be sharpened by backgrounds moving in anti-phase compared with tuning curves obtained with a solitary test stimulus.

1778 RECEPTIVE FIELD PROPERTIES OF RETINAL GANGLION CELLS IN TURTLE. J.E. Fulbrook* and A.M. Granda. Inst. for Neuroscience, Univ. of Delaware, Newark, DE 19711.

Single unit receptive fields were investigated in ganglion cell axons to moving or flashing colored light spots. Four cell types were distinguished: on, off, on-off and sustained. All of the cells were sensitive to moving stimuli at about 9^{o} sec^{-1}; many were directionally selective. Receptive fields were most sensitive to red light. In some cases the fields also showed sensitivity to green and blue light matched for equal quanta with red. Under dark-adapted conditions, receptive fields to red light were 3^{o} - 6^{o} in diameter. Receptive fields for equated green and blue lights were larger, 4^{o} - 10^{o} in diameter for the same cell. With light-adaptation, red receptive fields were little affected, but most green and blue fields disappeared. Plotted fields were often surrounded by an inhibitory annulus. In directionally-selective fields, however, the surround was asymmetric with a strong inhibitory region just prior to the receptive field in the preferred direction. A few cells were exceptionally sensitive to high-velocity scans, firing optimally to spots moving in excess of 180^{o} sec^{-1}.

1779 ANALYSIS OF SIMPLE AND COMPLEX DIRECTIONALLY SELECTIVE RECEPTIVE FIELDS IN AREA 17 OF THE CAT WITH PAIRS OF SEQUENCED LIGHT FLASHES. Leo Ganz and Ralph Felder. Dept. of Psychol., Stanford U., Stanford, CA 94305.

The interaction between ON-region activation and OFF-region activation has been studied in some 110 neurons recorded from 55 cats. Directionally selective neurons with simple receptive fields typically show ON- OFF-interactions reminiscent of the center-surround antagonism found in retinal ganglion cells and lateral geniculate nucleus neurons. For example, we have found that turning off a stimulus in an ON-region has the effect of inhibiting a subsequent OFF-response in an adjoining OFF-region in neurons with simple receptive fields and sustained temporal properties. This inhibition occurs even in stimulus sequences which are in that neuron's preferred direction of motion. We have found this inhibition to be strongest for stimulus asynchronies of 100 msec.

Directionally selective complex neurons typically show ON-Off-interactions which are sequence selective and facilitatory. For example, an ON-ON sequence in an ON-region and in the preferred direction exerts a very powerful facilitatory effect on the turning off of a stimulus in an adjoining OFF-region. This facilitatory effect is not present if the ON-ON sequence is presented in a non-preferred direction of motion. This mutual facilitation represents a further, decidedly non-linear response of complex cells. Our data suggests that this facilitatory interaction between ON-directionally selective regions and OFF-directionally selective regions can provide a mechanism for width selectivity as well as for selectivity to black-on-grey vs. white-on-grey moving objects.

We have also analyzed some of the temporal properties of these directionally selective facilitatory interactions between ON- and OFF-regions of complex cells. Strong effects (5-10 fold facilitations) can still be obtained with 700 msec between induction and test.

1780 BINOCULAR SPACE-TIME INTERACTIONS IN CAT VISUAL CORTEX. Jill C. Gardner * and Max Cynader . Dept. Psych., Dalhousie U., Halifax, N.S. B3H 4J1, Canada.

Units in ocular dominance groups 2,3,5 and 6 of Hubel and Wiesel respond with different strength to stimulation of each eye. We have found that a difference in response strength frequently corresponds with a difference in response latency, and that the latency through the stronger eye is consistently shorter. In a sample of 101 units, cells driven equally by the two eyes had nearly identical latencies through each eye (mean interocular difference: 2.2 msec), while units in OD groups 3&5 and 2&6 showed mean interocular latency differences of 7.1 and 13.1 msec respectively. Since simultaneous stimulation of the two eyes would result in asynchronous input to the cortical cell, units with interocular latency differences should respond best to stimuli which fell on the two receptive fields at slightly different times. To determine the sensitivity of units to the timing of input from the two eyes, we presented flashed stimuli to each eye with variable interocular delays. By varying space (position of stimuli on the two receptive fields) and time (interocular delay) simultaneously, it was seen that both factors influence the binocular responses of single cells.

All but a few units showed spatial interactions and, as described by other investigators, these responses showed summation, facilitation and/or inhibition. Sensitivity to interocular delay characterized many of the units encountered and those with interocular latency differences generally responded best with delays that represented simultaneity of input to the cortical cell. In some cells, inputs from the two eyes resulted in strong facilitation or inhibition only when they occurred within $\pm$ 10 msec of interocular synchrony. In other cells the range of temporal selectivity was broader, with units showing interactions over ranges of $\pm$ 30-50 msec. Units that were highly sensitive to the timing of input from the two eyes could discriminate 2 msec of interocular delay.

The interocular latency difference in cells driven unequally by the two eyes is similiar to that which can be produced psychophysically in humans by placing a dimming filter over one eye. In this case, one observes the Pulfrich phenomenon. It is proposed that a local Pulfrich-like phenomenon occurs in cat cortical cells activated binocularly with unequal latency. The units' sensitivity to interocular delay could provide the substrate for a time-based depth perception mechanism.

1781 A COMPUTER TECHNIQUE FOR MAPPING AND QUANTIFYING THE RETINAL PROJECTION ONTO THE SUPERIOR COLLICULUS. J.D. Gerard*, J.G. Pollack, and T.L. Hickey. School of Optometry/The Medical Center, University of Alabama in Birmingham, Birmingham, AL 35294

Autoradiographs of monkey superior colliculus show that axons arising from retinal ganglion cells end in discrete patches in the superficial layers. In an attempt to reconstruct, three-dimensionally, the pattern of retino-collicular input in the monkey, we have developed a computer technique which allows the position of each of the two-dimensional patches to be localized relative to its position in a given cross-section of the colliculus. When such information is obtained for serial sections it is possible to reconstruct, and quantify, the overall pattern of retino-collicular input.

Camera lucida drawings are made from either frontal or parasagital serial sections of paraffin embedded monkey superior colliculus. On each drawing the areas of retino-collicular input, as determined by the distribution of silver grains, are outlined as well as the overall outline of the colliculus and adjacent brainstem structures. Similar drawings are made for each of the 14μ thick serial sections throughout the rostral-caudal or medial-lateral extent of the colliculus. Once all camera lucida drawings are completed, the drawings are re-traced using a Graph-Pen system. This system makes it possible to digitize the position of each patch of retinal input relative to the surface of the colliculus. It is then possible to straighten the surface of the colliculus, keeping all underlying patches of retinal input in their relative positions but allowing them to be represented along a flat surface. By re-tracing each of the serial sections with the Graph-Pen, storing the digitized version of each section on computer discs and plotting out the flattened drawings sequentially, it is possible to look at the three-dimensional pattern of retinal input. Besides quantifying the overall extent of retinal input, this technique also allows us to look at the pattern of retinal input at different depths in the colliculus. Although we have only used this technique for looking at the three-dimensional pattern of retinal input to the colliculus, the technique is equally applicable to other structures. By using trans-synaptic autoradiography, it should be possible to map the three-dimensional pattern of cortical ocular dominance columns. Since this procedure could be carried out in both normal and visually deprived animals, it should also be possible to quantify any differences in geniculo-cortical input.

1782 PROJECTIONS TO THE DIENCEPHALON AND MIDBRAIN FROM THE STRIATE CORTEX OF THE RABBIT: AN AUTORADIOGRAPHIC STUDY. R.A. Giolli, L.C. Towns, A.N. Karamanlidis*, T.T. Takahashi* and D.D. Williams* Dept. Anat., Sch. Med., UCI, Irvine, CA 92717 and Dept. Anat., Sch. Osteopath., Kirksville, MO 63501.

The projections of the rabbit's striate cortex (visual cortical area 1) to diencephalic and midbrain nuclei has previously been studied in detail by Giolli and Guthrie (J. Comp. Neurol., 142: 351-376, 1971) using the method of fiber degeneration. Because of the advantages that the autoradiographic method (ARG) has been reported to show over the fiber degeneration method, these projections of the rabbit's striate cortex have been reinvestigated using the ARG method.

An injection of ^{3}H leucine was made within sectors of the striate cortex in each of eighteen adult albino rabbits, and the brains were processed according to the method described by Cowan et al. (Brain Res., 37: 21-51, 1972). The results have confirmed the findings utilizing the fiber degeneration method by showing that the thalamic reticular nucleus, the ventral and dorsal lateral geniculate nuclei, the pulvinar (as defined by Rose, J. Comp. Neurol., 77: 469-523, 1942), the anterior and posterior pretectal nuclei and the superior colliculus receive inputs from the striate cortex. However, in disagreement with the observations using the method of fiber degeneration, the present study using the ARG method has revealed the following regarding the projections of representative sectors of the striate cortex: (i) both the ventrolateral nucleus and posterior thalamic nucleus (as defined by Rose (1942) are consistently seen to receive a cortical input and (ii) the nucleus of the optic tract, reported to be innervated by axons from the striate cortex in fiber degeneration studies (Giolli and Guthrie, 1971), is consistently found to lack a cortical input. (Supported by NIH grant 5RO1-EY00607).

1783 FUNCTIONAL PROPERTIES OF POSTERIOR PARIETAL CORTEX OF THE MONKEY. II. BEHAVIORAL ENHANCEMENT OF VISUAL RESPONSES. Michael E. Goldberg, David Lee Robinson, and Gregory B. Stanton. Armed Forces Radiobiology Research Institute, Bethesda, Maryland 20014

Neurons in areas 5 and 7 of the rhesus monkey have been described to discharge in association with eye and hand movements. We have shown that such neurons have visual and/or somatosensory responses that can be demonstrated in the absence of any active response on the part of the monkey toward the stimulus used to excite the neuron. When the animal used the stimulus as the target for an eye or hand movement, the discharge of some neurons in posterior parietal cortex can be enhanced.

Three rhesus monkeys were trained to fixate a spot of light, and then to make one of three responses: continue to fixate the spot and ignore any other visual stimuli which might appear on the screen; reach out and touch a panel should it be illuminated; make a saccadic eye movement to a small peripheral target. In this paradigm the same visual stimulus could take on three different meanings to the monkey: a target for a hand movement, a target for an eye movement, or an irrelevant, negligible stimulus. Extracellular single-unit recordings were done while the animals were performing their tasks. All behavioral control and on-line data analysis was done using a PDP 11-10 computer.

The visual responses of nearly half of the visually responsive neurons in areas 5 and 7 were brisker and more regular when the animal was going to make a saccadic eye movement to fixate or reach out to touch the target. This enhancement response was not entirely dependent upon the presence of the movement, because if in a series of trials the monkey made an occasional erroneous response, the enhancement was still present. The response, however, was absolutely dependent upon the presence of the stimulus. If the monkey made the proper movement under conditions when the proper stimulus was absent, the neuron did not discharge in relation to the movement.

The enhancement is spatially specific. When the animal sees two stimuli, one in the receptive field of the neuron and the other outside of the receptive field, the neuron has an enhanced discharge only when the animal makes a saccadic eye movement to fixate the stimulus in the receptive field. There is no enhancement when the animal makes saccades to a stimulus outside of the receptive field.

These data indicate that posterior parietal cortex acts as an association area for sensory and behavioral data, which processes may provide a physiological basis for the psychological process of attention. These data do not support the hypothesis that posterior parietal neurons command movement except to delineate an environment in which movement may be appropriate.

1784 INTERACTIONS AMONG RODS IN THE ISOLATED RETINA OF BUFO MARINUS. Edwin R. Griff* and Lawrence H. Pinto* (SPON: Jay Mittenthal). Dept. Biol. Sci., Purdue Univ., W. Lafayette, In 47907.

We searched for interactions among rods in the isolated retina of Bufo marinus by comparing the responses evoked by stimuli of different geometry. For each stimulus geometry, the luminous flux passing axially through the rod was measured. Circular stimuli of diameters 30 μm (small stimulus) and 500 μm (large stimulus) were adjusted such that equal flux passed through an impaled rod. Responses were recorded from rod outer segments. The peak response evoked by the large stimulus was always larger than the peak response evoked by the small stimulus. In addition, the sensitivity of a rod was measured to both small and large stimuli. After adjusting for the measured difference in illuminances of the large and small stimuli, the sensitivity of a rod to the large stimulus was 1.06 ± 0.27 (S.E.M.) log units greater than the sensitivity to the small stimulus. The larger response and greater sensitivity of the rods to the large stimulus must be mediated by the additional cells stimulated by the large stimulus. Thus, interactions among rods exist in the isolated retina.

Comparison of the time course of responses evoked by large and small stimuli of high illuminance allowed partial analysis of the mechanism mediating the interactions among rods. When stimuli were equated for equal flux through the rod, the response to the large stimulus reached a maximum faster than the response to the small stimulus. For the first 200 msec, the response to the large stimulus was more hyperpolarized than the response to the small stimulus. At about 200 msec, the response amplitudes were equal and, for the next 200 msec, the response to the large stimulus was less hyperpolarized than the response to the small stimulus. Interactions mediated solely by passive electrotonic spread cannot account for these response characteristics.

The contribution to the response made by rods at increasing distances from an impaled rod was analyzed by examining the responses of the impaled rod when a slit-shaped stimulus was presented at each of several displacements across the retina. A plot was made of the peak response amplitude vs. the displacement of the stimulus from the impaled rod. Data points fitted an exponential; for 10 cells, the mean space constant was 34.5 ± 6.9 (S.E.M.) μm.

Thus, in the isolated retina, a preparation used to study the mechanism of transduction, the response recorded from a single rod is not solely the result of quanta which stimulate that rod.

1785 ATTEMPTS TO REVERSE THE EFFECTS OF MONOCULAR DEPRIVATION IN THE ADULT CAT'S CORTEX W.A. Harris* and M.P. Stryker. Dept. Neurobiology, Harvard Medical School, Boston, Massachusetts 02115.

Monocular deprivation early in life causes the deprived eye to lose permanently its influence on most cells in the visual cortex (Wiesel and Hubel, J. Neurophysiol. 26:1003, 1963). Recent reports have suggested that this effect can be reversed either by enucleating the "normal" eye (Kratz et al., J. Neurophysiol. 39: 501, 1976) or by pharmacological means (Duffy et al., Nature 260: 256, 1976). The results are consistent with a model in which the spontaneous activity of the normal eye somehow inhibits responses from the deprived eye.

Retinal ganglion cell activity of the normal eye was silenced reversibly by raising intra-ocular pressure while single unit recordings were made in the lateral geniculate nucleus and the corresponding part of the visual cortex. The result was a reduction in spontaneous activity in the geniculate layers supplied by the blocked eye. Meanwhile, nearly all cortical cells studied remained uninfluenced by the deprived eye; most did, however, show reduced spontaneous activity against which it occasionally became possible to discern responses that had previously been masked by the background activity in both the unit studied and in smaller simultaneously recorded units. Enucleation of the normal eye produced similar changes to pressure blockade, although in the cortex changes in background activity of individual cells could not be assessed. Like those of Kratz et al. our cortical recordings with enucleation showed about one-third of the active cells to be influenced by the deprived eye. But the reduction in spontaneous activity seen with the pressure blockade leads us to interpret these results differently.

To examine further whether silencing the ganglion cells of the normal eye increases cortical responses to stimulation of the deprived eye (as suggested by Kratz et al.), an experiment was designed using Sokoloff's histochemical method for determining cerebral glucose uptake. A restricted lesion was placed in the retina of the normal eye by laser photocoagulation. This greatly reduced firing in the corresponding parts of the geniculate and cortex. We injected ^{14}C-2-deoxyglucose while visually stimulating the deprived eye. Autoradiograms showed somewhat reduced labelling density over the cortical region corresponding to the retinal lesion, probably reflecting a reduced activity in this region.

These experiments suggest that the ocular dominance distribution in monocularly deprived cats results not from tonic suppression by the normal eye, but rather from changes in the balance of excitation from the two eyes.

Support: EY00605 & EY00082. We thank Dr. D. Dueker.

1786 RESPONSES OF FISH RETINAL GANGLION CELLS TO MOVING CONTOURS. Thomas F. Hay* and Bruce H. Pomeranz. Dept. of Zoology, University of Toronto, Toronto, Ontario, Canada, M5S 1A1.

Fishes are used as subjects in many investigations of vision but there are relatively few reports on the tuning characteristics of single retinal ganglion cells. Metal-filled electrodes were used to record from ganglion cell terminations in the optic tectum of three species of fishes, goldfish, yellow perch and pumpkinseed sunfish. The electrode was placed so that receptive fields were located laterally and below the eye axis. At locations separated by at least 40 microns depth the activity of the largest single unit was isolated by a window discriminator and its response properties tested.

Of the 141 cells, 139 responded to dark, moving contours although 20 of these responded best to large objects or to darkening the field (dimming detectors). 86% evidenced clear velocity tuning, 64% showed object size preferences and 30% were directionally selective. Perch and sunfish had a smaller proportion of directionally selective cells than did goldfish, but more of their cells responded best to temporal-ward movement. Movement gated responses to stationary objects were rare; most cells responding to stationary objects were classified as dimming detectors. Depth within a penetration was not related to cell response properties in any clear or general manner. (Supported by NIH 1-F-32-N505400.)

1787 VARIABILITY IN PATTERNS OF LAMINATION IN THE HUMAN LATERAL GENICULATE NUCLEUS. T.L. Hickey. School of Optometry/The Medical Center, University of Alabama in Birmingham, Birmingham, AL 35294.

The patterns of cellular lamination have been studied in the dorsal lateral geniculate nuclei (LGN) of 53 human brains ranging in age from newborn to 40 years. Two fundamental patterns of lamination can be seen in frontal sections through the human LGN. The first pattern is characterized by 2 magnocellular layers and 4 parvocellular layers throughout much of the binocular segment of the nucleus. The second pattern, which is seen in approximately 25% of the LGN's studied, is characterized by a further splitting of one of the parvocellular laminae, resulting in 6 parvocellular layers (or leaflets) over a part of the binocular segment of the nucleus. Both patterns of lamination can be seen in neonates and adults, indicating that the differences are not a result of postnatal development.

Although the pattern of lamination varies within a single LGN as one moves from the rostral to caudal pole of the nucleus, the changes in the laminar patterns are usually quite predictable. In a few brains, however, this regular pattern of lamination is interrupted in the rostral third of the nucleus. In these brains the ipsilaterally innervated magnocellular layer 2 and parvocellular layer 3 can be seen ventral to the contralaterally innervated laminae 1 and 4. As one moves more caudally, the normal pattern of lamination appears with the exception that a few clusters of large layer 1 cells remain isolated between the parvocellular layers 3 and 4. Such isolated groups of large cells usually occur near the medial border of the nucleus and, by tracing through serial sections, can always be seen to merge with layer 1. This abnormal pattern of lamination has been seen in both frontally and parasagitally cut sections.

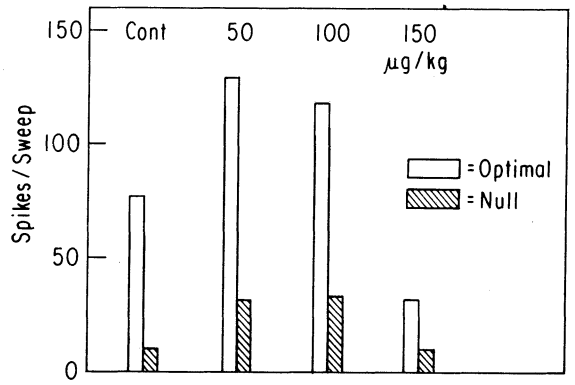
1788 EFFECTS OF LSD ON NEURONS IN VISUAL CORTEX. M. Hilmy*, B. Connors*, P. Fox and G. Somjen. Dept. Physiol. Pharmacol., Duke University Medical Center, Durham, NC 27710.

The impulse discharge of neurons was recorded in the visual receiving area of cats anesthetized with N_2O before and after the administration of lysergic acid diethylamide (LSD) (25 to 150 µg/kg wt cumulative, i.v. in two or three divided doses over several hours). Impulse histograms were time-locked to stimulus movement. Stimuli were luminous slits of various orientation swept back and forth over the receptive field. Of seven direction-selective cells (in 7 cats), the responses of four were depressed, of two enhanced at low but depressed at high dose (see figure) and of one unchanged. In cases of enhancement the response to non-optimal stimuli were more affected, reducing optimal/null response ratios, and unstimulated "background" was also increased. Overall effect of the drug may be a diminished signal-to-noise ratio, possibly the basis of distortions in visual sensory function. This may be a direct effect on the visual pathway, or a modification of input from non-visual subcortical sources. Our observations agree with those reported by Rose and Horn (Exptl. Brain Res. 27:71, 1977). (Supported by DA 01458)



Average responses of a single cell during a total of 5 hours.

1789 EFFECTS OF EARLY EXPERIENCE ON SPONTANEOUS ACTIVITY, RESPONSE VARIABILITY AND VISUAL RESPONSIVENESS OF NEURONS IN THE STRIATE CORTEX OF THE CAT. H.V.B. Hirsch & A.G. Leventhal. Center for Neurobiology, SUNYA, Albany, New York 12222.

The spontaneous activity, response variability and peak response to visual stimulation of neurons in the striate cortex of normal cats and of cats deprived of visual experience by dark-rearing (7-12 months from birth) were studied quantitatively.

Cortical cells in deprived animals displayed lower mean spontaneous discharge rates, greater response variability and lower peak responses than did neurons in normal cats. Significant numbers of neurons that were not responsive to visual stimulation were observed in deprived but not in normal cats. Thus, the visual responsiveness of cortical neurons is effected severely by visual deprivation.

In dark-reared cats virtually all orientation sensitive cortical cells have small response fields and respond only to stimuli moving slowly(low cutoff velocity); neurons with larger response fields and/or higher cutoff velocities do not display orientation sensitivity in these cats (Leventhal, A.G. & Hirsch, H.V.B., Proc. Nat.Acad.Sci. 74, 1272-1276, 1977). Two lines of evidence suggest that for some cells the loss of orientation selectivity is not simply the result of a drop in visual responsiveness. In dark-reared cats: (1) non-selective cells respond more strongly to visual stimulation than do orientation selective cells and, (2) non-selective cells respond strongly to stimuli of any orientation. Finally, while there are orientation selective neurons in the visual cortex of normal cats that respond to all stimulus orientations, their response to non-optimal stimuli is considerably weaker than: (1) their response to optimally oriented stimuli and, (2) the response of many non-selective cells in dark-reared cats to any stimulus orientation.

These results suggest that many non-selective neurons in dark-reared cats lack inhibitory inputs which, in normal animals, give rise to orientation sensitivity. A decrease in the efficacy of excitatory connections alone cannot explain why neurons with large response fields and/or high cutoff velocities in deprived cats respond well to all stimulus orientations while similar cells in normal animals do not. It is suggested that inhibitory connections in the mammalian visual system are especially dependent upon visual experience for the development or maintenance of normal function. 1790 VISUAL RESPONSES OF NEURONS IN THE NUCLEUS OF THE OPTIC TRACT OF VISUALLY DEPRIVED CATS. K.-P. Hoffmann, K. Behrend and A. Schoppmann. Dept. Neurobiol. University Ulm (MNH), D-7900 Ulm, West Germany.

A specific class of neurons in the nucleus of the optic tract (NOT) in the pretectum of cats can be identified by the following criteria: (1) large pattern rich in contour are more effective visual stimuli than single spots or lines. (2) All cells are excited by movements from the periphery to the center of the visual field and inhibited by movements in the opposite direction. (3) Effective stimulus velocities in the preferred direction were within the range of $\leq 0,1 - < 50^{o}/s$. (4) Latencies to electrical stimulation of the optic chiasma lay between 4 - 6 ms. (5) All units sharing the above listed properties could be antidromically activated from the inferior olive. 60 % of the neurons recorded in the NOT of normal cats were binocularly driven. The remainder were activated from the contralateral eye only.

In adult cats of which one eye was kept closed from birth the properties of NOT neurons listed above remained largely unaltered except the neurons did not follow up to such high velocities and the inhibition by movements in a direction opposite to the preferred one was less pronounced in neurons driven from the deprived eye. There was however a complete loss of binocular influence onto the NOT, neurons in i.e. the NOT contralateral to the deprived eye were exclusively driven from the deprived eye and in the NOT ipsilateral to the deprived eye by the non-deprived eye.

Also after a lesion of the visual cortex direction selectivity and velocity tuning of neurons recorded in the NOT ipsilateral to the lesion remained largely normal. Again there was a complete loss of the influence from the ipsilateral eye.

In a normal cat an optokinetic nystagmus (OKN) can be elicited in the two horizontal directions even if one eye is stimulated alone. In the NOT on either side of the brain all cells prefer only movements from temporal to nasal in the contralateral hemifield. Each eye can however activate neurons in the two NOT preferring opposite directions of movement because of the binocularity of NOT neurons. If binocularity is lost due to deprivation or decortication each eye only activates the contralateral NOT. As a consequence OKN is only elicited by patterns moving in temporonasal direction if the deprived eye is stimulated alone.

1791 FOURIER ANALYSIS APPLIED TO SPATIAL PROPERTIES OF NEURONS IN THE CAT'S VISUAL CORTEX.
R.A. Holub, Robert Michael Jones* and Mary Morton Gibson. Depts. Neurophysiol. & Ophthalmol., Univ. of Wisconsin, Madison 53706.

We employed a Maxwellian view optical system to study the spatial properties of cells in the visual cortex of lightly anesthetized, paralyzed cats. Suprathreshold spatial frequency tuning curves measured with drifting sinusoidal gratings resembled spatially selective channels used to explain the results of various human psychophysical experiments. With rare exceptions, the responses of cells increased linearly with contrast up to saturating levels. The discharge pattern preserved the sinusoidal waveform of the input regardless of spatial frequency or drift-rate in many cells. For cells showing these two linear properties, Fourier analysis was used to compute the spatial frequency tuning curve expected from the responses to drifting edges and slits. The computed curves were compared to data recorded with sinusoidal gratings drifted at the same rate and of less-than-saturating contrasts.

For cells whose discharge pattern preserved the input waveform (these tended strongly to have 'simple' properties), the optimal spatial frequency was accurately predicted from either edge or slit responses. The curve computed from the PST histogram to the edge usually showed good agreement with the measured data at spatial frequencies below the optimum but was usually above the data at higher frequencies. Curves computed from slit responses had much more low frequency content than was measured. This discrepancy was eliminated and the computed curve brought into agreement with measured points if likely inhibitory zones of the receptive field were represented by negative discharge rates. The nature of these inhibitory zones was estimated by differentiating the PST's to edges, since the response to a narrow slit is the derivative of the response to an edge in a linear system. As might be expected from current thought about receptive field organization, similar attempts to simulate inhibitory regions in PST's to edges produced much less dramatic effects on the computed spatial frequency tuning curves.

We have found that Fourier analysis can be applied to the prediction of the effective sine-frequency-spectrum using responses to edges or narrow slits of light for cells whose output faithfully reflects a sine input. Thus, one can compute approximate responses to a wide variety of stimulus patterns from knowledge of the spatial frequency tuning curve.

1792 MICROELECTRODE ANALYSIS OF THE ORIENTATION COLUMN SYSTEM IN THE STRIATE CORTEX OF THE TREE SHREW (Tupaia glis). A.L. Humphrey, T.T. Norton and J.E. Albano, Depts. of Psychology and Physiology, Duke University, Durham, NC 27706.

An anatomical picture of the orientation column system in the tree shrew striate cortex has been obtained with deoxyglucose autoradiography (see abstract by Skeen et al., these meetings). In the present study we compare that picture to one obtained from microelectrode penetrations through striate cortex in paralyzed, N_2O anesthetized tree shrews.

We found that about half of the cells encountered within layer IV responded well to all stimulus orientations. This is consistent with the continuous horizontal strip of deoxyglucose uptake found throughout layer IV in animals stimulated with vertically oriented stripes. In contrast, most neurons above and below layer IV were selective to stimulus orientation. About half of these responded to stimuli deviating up to $\pm 20^{o}$ from the optimal orientation. On vertical penetrations we found that cells of similar optimal orientation were arranged radially in the cortex; from penetrations parallel to the cortical surface, we found orderly, progressive changes in optimal stimulus orientation. The slopes of the orientation change across cortex, together with the orientation tuning properties of the neurons, indicate that the width of the radial zones of increased deoxyglucose uptake correspond to the distribution of neurons expected to discharge to vertical stripes.

The slope of the orientation change with electrode movement parallel to the cortical surface varied considerably with the direction of that movement, suggesting an asymmetry in the representation of the orientation system. When we compared penetrations moving in various directions across cortex to the topographic maps obtained with the deoxyglucose method, we found that penetrations with high slopes ($250\text{-}600^{o}$/mm) ran generally perpendicular to the mapped iso-orientation lines, while those with low slopes (10^{o}/mm) ran generally parallel to the lines.

We conclude that the electrophysiological and the deoxyglucose techniques provide compatible and complementary pictures of the system for optimal stimulus orientation in Tupaia. The deoxyglucose method yields a better picture of the system's global organization, while the electrophysiological method yields a better picture of its microstructure.

1793 A METHOD FOR SECURING ENHANCED ANTEROGRADE TRANSPORT OF HORSERADISH PEROXIDASE (HRP), USING THE RAT RETINOHYPOTHALAMIC PATHWAY. Stephen K. Itaya*, Terence H. Williams, and Edgar L. Engel. (SPON: J. Y. Jew). Dept. Anat., Univ. Iowa, Iowa City, IA 52242, and Dept. Anat., UTCHS, Memphis, TN 38163.

The first objective for the experiments reported below was to develop a reliable method for securing anterograde transport of HRP, and consistent results have hitherto eluded investigators. The second purpose was to use this method as a tracer to study the retino-suprachiasmatic pathway in detail. On the basis of the observation (Ryser and Hancock, Science 150:501, 1965) that poly-L-ornithine increases micropinocytosis in cultured cells, it was hypothesized that this agent would enhance uptake and subsequent anterograde transport of HRP by retinal ganglion cells.

Optimal results were obtained by 50 µl intraocular injections of 15 mg HRP (type VI, Sigma Chem. Co.) in 0.1 M phosphate buffer with one to ten µg/ml poly-L-ornithine (Sigma Chem. Co.), injected over a period of 30 min., provision being made for release of intraocular pressure. After 48 hrs., animals were perfused with 2% glutaraldehyde, 2% paraformaldehyde and 2% sucrose in 0.1 M phosphate buffer. Brains and optic nerves were immersed overnight in fixative, followed by a 24 hr. wash in buffer with 5% sucrose. Optic nerve and hypothalamus were isolated and 50 µm serial sections were cut with a Vibratome (Oxford Laboratories). Sections were incubated in 0.05% diaminobenzidine with 3% of 0.3% hydrogen peroxide in phosphate buffer for 30 min. on ice. Following 30 min. postfixation in 1% osmium tetroxide, the suprachiasmatic nucleus (SChN) was isolated from each section of hypothalamus and prepared for electron microscopy. Controls included (1) incubation without hydrogen peroxide and (2) injection of vehicle only.

Good results have been obtained in six of seven animals injected in the prescribed manner. With the light microscope, reaction product was evident in numerous optic nerve axons and was scattered bilaterally in the SChN, with most on the contralateral side. The electron dense, membrane bound reaction product was found in pre- and postsynaptic neural processes, at both symmetric and asymmetric terminals of the SChN. Controls were devoid of intraaxonal HRP.

Retinal ganglion cell synapses can be identified in the SChN by the modified technique for anterograde HRP transport which may have widespread application for tracing CNS pathways.

1794 RESPONSES OF CELLS IN THE INFERIOR TEMPORAL CORTEX OF MONKEYS DURING VISUAL DISCRIMINATION REVERSAL. Charlene Drew Jarvis and Mortimer Mishkin, Laboratory of Neuropsychology, NIMH, Bethesda, Md. 20014

Cells in the inferior temporal cortex of awake monkeys can be driven selectively by stationary visual patterns and colors that the monkeys are required to discriminate (Jarvis and Mishkin, Neurosci. Abstr. 1: 61, 1975). In the present study we asked whether the responses of these cells could be modified by changing the motivational significance of the stimuli. To explore this possibility, two rhesus monkeys were trained on a task in which a white ring (the positive stimulus) was paired with each of 24 negative stimuli in separate blocks of trials. The two stimuli were presented successively in random order on the left of two response keys. A correct response to the positive stimulus (left-key press) resulted in juice reward, while a correct response to the negative stimulus (right-key press) led only to advance of the random stimulus generator. If either stimulus was found to be effective in driving a cell, the reward values of the two stimuli, and the response requirements associated with them, were reversed. If the reversal resulted in a change in the firing characteristics of the cell, one or more additional reversals of that pair were given before other stimulus combinations were presented. Ninety-eight cells were studied using this paradigm. Eighty of these cells showed no apparent changes in their firing characteristics during reward reversal. Of the 18 cells that did show changes, only a few seemed to be sensitive to shifts in stimulus-reward association per se. The others were excluded from this category either because they showed changes in spontaneous discharges rather than in stimulus-locked activity, or because their changes in stimulus-locked activity appeared to reflect differences in the duration of fixation of the same stimulus in the two reward conditions. The data suggest that inferior temporal neurons are more concerned with the physical properties of stimuli than with their motivational significance. By implication, the visual impairment after inferior temporal lesions is more likely to reflect a disorder in stimulus processing than in stimulus-reward association.

1795 VISUAL RESPONSES DURING SACCADIC EYE MOVEMENT: VISUAL MASKING IN STRIATE CORTEX. Stuart J. Judge and Robert H. Wurtz, Laboratory of Neurobiology, National Institute of Mental Health, Bethesda, Maryland 20014.

Each saccadic movement of the eyes smears across our retinae the image of the scene before us, a fact of which we are normally unaware. If the scene is illuminated only during eye movement, however, the smearing is clearly perceived. Thus masking by stimuli present on the retinae before and after each saccade must account for our lack of perception of the saccadically smeared image (Wurtz and Campbell, 1977). We have looked for a physiological correlate of this masking effect in the striate cortex of the awake monkey, Macaca mulatta, trained to perform a visual fixation task. We recorded from striate cortex representing the lower visual field between 5 and 15 degrees from the fovea. Approximately one third of the neurons isolated responded to stimuli moving at saccadic velocities. These neurons responded similarly whether the retinal stimulation was produced by rapid movement of a stimulus across the stationary receptive field or by a saccadic movement of the eye which swept the receptive field across a stationary stimulus. The responses of such neurons to a stimulus swept across their receptive field by a twenty degree saccade (a sweep stimulus) could be attenuated or extinguished by stimulation of the receptive field before and/or after the saccade. (The stimuli were 10 cd/m^2 spots of light on a background of 1 cd/m^2.) Stimuli present before the saccade completely abolished the response of about 90% of neurons to the sweep stimulus, whereas stimuli falling on the receptive field after the saccade abolished the response in only about 30% of the neurons. When the monkey made no eye movement and a stimulus was swept across the receptive field before the onset or after the offset of a stationary receptive field stimulus, there was a similar attenuation of the response to the sweep stimulus, which was more sustained when the stationary stimulus preceded the sweep stimulus. Precise alignment of the stationary stimulus on the center of the receptive field of the neurons was not necessary to produce such response attenuation effects: elimination of the response to the sweep stimulus was observed using stationary stimuli which fell on the surround of the receptive field. This physiological effect may underlie the perceptual masking of the smeared retinal image produced by saccadic eye movement.

1796 EFFECTS OF MONOCULAR DEPRIVATION ON THE GROWTH OF LATERAL GENICULATE CELLS IN THE CAT. R.E. Kalil, Dept. of Anatomy, Univ. Wisc., Madison, WI. 53706

Although there is abundant evidence concerning the influence of monocular deprivation on geniculate cell size in the cat, little is known concerning the development of these effects. To study this question, the lids of one eye in 21 kittens were sutured shut between 7 and 10 days after birth. Following survival periods that ranged from 2 to 32 weeks (3,4,8, 12 and 16 weeks intervening), the cats were perfused with 10% formalin. For comparison, 2 kittens were deprived for 16 weeks by suturing shut the nictitating membrane of one eye. The brains were embedded in celloidin, sectioned in the frontal plane at 20µ, and stained with cresyl violet. Near the rostrocaudal midpoint of each lateral geniculate, the areas of 100 cells from lamina A1, and from the binocular and monocular segments of lamina A were measured at 1000x. The brains of 3 cats were examined at each survival period. Not until four weeks after lid suture is it possible to detect a significant difference in size between deprived and normal geniculate cells. At this time, deprived cells are approximately 16% smaller than normal. After longer periods of deprivation, cell size differences first increase, reaching a maximum at 12 and 16 weeks (26% for binocular A cells) and then decline slightly at 32 weeks (20% for binocular A cells). Closing the nictitating membrane for 16 weeks leads to cell size changes equivalent to those produced by lid suture. Comparing the percent shrinkage of deprived binocular and monocular A cells at each survival period indicates that at 8,12,and 16 weeks binocular A cells are affected by monocular lid suture more severely than monocular A cells. The differential effect is slight, however, averaging only about 6%, and it is not found in the long term deprived animals that survived for 32 weeks. Cell growth curves show that the consequences of monocular lid suture are threefold. Firstly, cell growth in deprived laminae is halted during the 8 weeks immediately following lid closure. Secondly, between 8 and 16 weeks,deprived cells undergo a progressive atrophy and are smaller at 4 months after lid suture than at 2 months. Finally, between 16 and 32 weeks there occurs a partial recovery of size which is most pronounced in deprived binocular A cells. In summary, eyelid suture abruptly arrests geniculate cell growth and this immediate effect is followed, approximately 2 months later, by a period of atrophy from which limited long term recovery is possible. Monocular deprivation appears to affect binocular segment cells slightly more severely than monocular cells, but only for intermediate length periods. When deprivation is prolonged, differential binocular segment-monocular segment effects are abolished.

1797 LAMINAR SEPARATION OF ON AND OFF COMPONENTS OF THE PROXIMAL NEGATIVE RESPONSE AND K^+-FLUX IN FROG RETINA
Chester J. Karwoski* and Luis M. Proenza, Vision Res. Lab., Dept. of Psychol., Univ. of Ga., Athens, 30602

Field potentials and changes in extracellular potassium concentration ($[K^+]_o$) were recorded from the retina of the frog (Rana pipiens) in response to a wide variety of photic stimuli. As previously reported by Oakley & Green (J. Neurophysiol., 39:1117, 1976), light stimulation induces a decrease in $[K^+]_o$ in the distal retina and an increase proximally. We further characterize the proximal K^+-increase by showing that it is maximal with small spots, is very sensitive to stimulus position, and exhibits ON as well as OFF components. Thus, the stimulus dependent behavior of the K^+-increase in frog is quite similar to that previously reported by us in mudpuppy (J. Neurophysiol., 40:244, 1977).

In frog, a species with a thick, well-developed inner plexiform layer (IPL), the maximum K^+-increase and proximal negative response (PNR) at light onset occur at about 33% retinal depth (within the IPL), whereas maximum K^+ and PNR responses at light offset are registered some 25 μm more distal, at 42% (which in frog is the boundary of the IPL and inner nuclear layer--INL). These results support the proposal of Holden (J. Physiol, 221:173, 1972) in the pigeon, and of Kolb, Famiglietti, & Nelson (Science, 194:193, 1976; & personal communication) in cat, that ON and OFF systems are represented in separate sublaminae of the IPL, with the OFF system being more distal.

In mudpuppy, a species with a thin, poorly developed IPL, maximum K^+-increase and PNR at both light onset and offset occur at about 20% retinal depth (which in mudpuppy is the boundary of the IPL & INL). If a differential depth distribution of the ON and OFF components of the PNR and K^+-increase exists in mudpuppy, it must be on the order of less than 10 μm.

1798 A QUANTITATIVE STUDY OF ASCENDING AND DESCENDING INPUTS TO THE RABBIT LATERAL GENICULATE NUCLEUS AND SUPERIOR COLLICULUS.
Amy S. Kelly* and Patricia C. Fox (SPON: K. L. Chow). Dept. Neurol., Stanford U. Med. Ctr., Stanford, CA 94305.

We have used the method of retrograde transport of horseradish peroxidase to study the distributions of cortical and retinal cells which provide inputs to the rabbit lateral geniculate nucleus (LGN) and superior colliculus (SC). Peroxidase (.5 μl, 10% solution in 0.5 M NaCl) was pressure injected through a recording micropipette into retinotopically identified sites in the LGN or SC in different animals. Whole mounts of retinas were processed, and the distributions of labelled ganglion cell body sizes were compared. A diverse group of ganglion cells were found to project to SC, including both large and small cells. A more homogeneous group of small to medium sized cells were labelled with LGN injections. These results can be correlated with functional differences known to exist in the postsynaptic cell populations [Chow et al., Brain Res. 33, 337 (1971)], and with recent results from axonal transport work (Wagner, Kelly and Kelly, Neurosci. Absts., 1977) which show that different proteins are transported in optic nerve fibers going to LGN and SC in the rabbit. In striate cortex (VI), large pyramidal cells in the superficial one-half of layer V were labelled with SC injections. About 50% of the cells in the labelled region contained label. Smaller pyramidal cells in the superficial one-half of layer VI were labelled with LGN injections, and approximately 75% of the cells were labelled. The corticofugal projections in rabbit are thus more restricted within sublayers than in some other species. These data can also be related to receptive field properties of cells in layers V and VI.

1799 SUPRATHRESHOLD VISUAL TEMPORAL INTEGRATION IN HUMANS: A COMPARISON OF REACTION TIME AND TWO-PULSE DISCRIMINATION RESPONSES.
M. L. Kietzman*, R. Rutschmann-Jaffe , E. Shapiro* and I. Berenhaus*. Queens College of CUNY, Flushing, N.Y. 11367 and Barnard College, N. Y., N. Y. 10027.

The characteristics of temporal integration or summation (Bloch's law or stimulus intensity-time reciprocity) were measured and compared for two distinct responses--simple reaction time (RT) and two-pulse discrimination--in human observers. Temporal integration was measured for both responses by using a non-typical stimulus array consisting of two sequentially presented pulses of light of fixed luminance separated by a variable (in msec) interpulse interval of darkness, i.e., a two-pulse stimulus array. The independent variable was the duration of the two-pulse array measured from the onset of the first pulse to the offset of the second pulse. The light pulses transilluminated a white-appearing, foveally-fixated target that subtended a visual angle of 21'. The RTs were simple finger lifts to the double-pulse stimuli, measured from the onset of the first pulse of light. The two-pulse discrimination task consisted of a temporal forced-choice procedure in which the observers were required to discriminate various double-pulse stimuli of the same luminous energy from a brief (4-msec) equal-energy, fully-integrated, single pulse of light.

Results showed that all observers displayed several of the expected characteristics of temporal integration for both responses: complete integration (stimulus intensity-time reciprocity); partial integration; and a region of no integration, i.e., a region for the longer duration stimuli where changes in the stimulus did not affect the response. A partial integration index showed for the same stimuli more partial integration for discrimination than for RT. Stated differently, utilization time (the longest stimulus duration displaying partial integration) was briefer for RT than for two-pulse discrimination.

A review of other psychophysical and neurophysiological studies measuring both response latencies and response frequencies, or their equivalents, suggests that response latencies are most meaningfully related to the latency of the underlying neural response while response frequencies are related to the amplitude of the underlying neural response.

1800 AMACRINE CELL CONTRIBUTION IN THE CENTER RESPONSE OF CAT RETINAL GANGLION CELLS.
Albert W. Kirby. Ophthal. Dept., Kresge Eye Institute, Wayne State University, Detroit, Michigan 48201

Gamma-aminobutyric acid (GABA) can be localized to amacrine cells in the cat retina, suggesting that a subpopulation of amacrine cells utilize GABA as a transmitter. It has been previously reported that bicuculline, a GABA antagonist, has a substantial effect on center-surround organization in Y-type cat retinal ganglion cells. Surround dominated responses are greatly reduced or abolished while center dominated responses are somewhat less reduced. The net effect of the GABA antagonism is to shift center-surround balance in favor of the center. It was reported in 1975 at this meeting that the physical dimensions of the center, as estimated by area-threshold curves, are also reduced following bicuculline administration. Since the area-threshold curves on which this was based were determined by auditory thresholds of ganglion cell firing, and if correct as previously reported implicate amacrine cells in the organization of receptive field centers as well as surrounds, an objective determination of the same information was required.

Using a PDP-11 computer programmed to determine ganglion cell threshold from extracellularly recorded single units in the optic tract of anesthetized cats, the area-threshold experiments were repeated giving an objective determination of ganglion cell center size. Since the choice of a threshold criterion is arbitrary, threshold here was selected as the stimulus strength necessary to produce an average of three extra spikes in the response. Because the three extra spikes were measured in a 100 msec window, a threshold response would therefore be one of 30 spikes/sec, well within the linear stimulus-response range. The results, i.e., that the diameter of the receptive field center is reduced following GABA antagonism, confirmed those previously reported and support the conclusion that at least a portion of the center signal from Y-type receptive fields in cats reaches the ganglion cell through amacrines.

(This work was supported by a Wayne State University faculty research award to the author and by grant EY 00206 to C. Enroth-Cugell.)

1801 ANALYSIS OF MAINTAINED SPIKE DISCHARGES IN THE CAT VISUAL PATHWAY DURING DARKNESS AND STEADY LIGHT, Wlodzimierz M. Kozak, Dan Schweitzer-Tong*, Arthur C. Sanderson*, and Jakub Segen*. Biomed. Eng. Prog., Carnegie-Mellon University, Pittsburgh, Pennsylvania 15213. (SPON.: J. R. Boston).

Spike trains in single Optic Tract (OT) Fibers and Lateral Geniculate (LGN) neurons were recorded extracellularly during darkness and six levels of steady diffuse illumination (5×10^{0} - 5×10^{-5} ftL) in Urethan-anesthetized cats. To insure that the data were reliable, each luminance level was repeated at least twice. Single units were categorized according to their respective field sizes and discharge properties. Monotonic relationship between mean rate and luminance level was seldom encountered, and instead, in the 10^{-4} - 10^{-3} ftL range, a maximum or minimum was often observed. For similar mean rates at high and low luminances significantly different temporal spike distributions were frequently found. For a given luminance, characteristic types of distributions were regularly and repeatably elicited. Simultaneous recordings from the input (unitary Excitatory Synaptic Potentials) and output (soma spikes) of single LGN neurons revealed several types of spike train transformation at these synapses.

Supported by NSF Grant ENG-75-15736 to A.C. Sanderson and W.M. Kozak, and NIH Research Fellowship 1-F32-EY05062-01 to D. Schweitzer-Tong.

1802 EFFECTS OF DARK REARING ON PHYSIOLOGY AND ANATOMY OF THE CAT'S LATERAL GENICULATE NUCLEUS. K.E. Kratz, R. Kalil, and S.M. Sherman, Dept. Physiol., Univ. VA Med. Sch., Charlottesville, VA and Dept. Anat., Univ. Wisc. Med. Sch., Madison, WI.

Electrophysiological recordings were made from 156 single LGN neurons in 4 cats dark reared from birth to 4 months of age. Two of the cats were studied immediately upon removal from the dark with no visual experience, while the two remaining animals were given 13 or 28 months of normal light rearing before recording. Cells in laminae A and A_1 were sampled and were classified as X or Y on the basis of conduction velocity, receptive field linearity, etc. Using the same criteria with identical techniques in normal cats, we found that 50-60% of LGN neurons were Y-cells. Of the 156 LGN cells studied in the dark reared cats, 120 (77%) were normal X-cells, 30 (19%) were abnormal or unresponsive, but only 6 (4%) were normal Y-cells. This represents a significant reduction in the normal proportion of Y-cells ($p<0.001$ on a χ^2-test). No significant inter-animal differences were noted (e.g., the range of Y-cells for the 4 cats was 0-7%), and the dark reared-light reared cats exhibited roughly the same percent of Y-cells (6%) as did the cats with no visual experience (2% Y-cells; $p>0.2$ on a χ^2-test). As previously reported (Sherman et al., *J. Neurophysiol., 35:* 532, 1972), we conclude that visual deprivation affects Y-cells more than it does X-cells. However, dark rearing has a much more profound effect than does binocular lid suture (4% Y-cells vs. 29% Y-cells; $p<0.001$ on a χ^2-test), presumably because lid suture permits considerable, unpatterned light to strike the retina. Finally, histological measurements were made of cell area and packing density in 5 normal controls, 6 cats dark reared to 16 weeks and sacrificed, and 3 cats dark reared to 16 weeks and then light reared under normal conditions for 4 to 18 months. No histological differences among groups were found. It thus seems unlikely that the reduction in Y-cell percentages caused by dark rearing are due to simple changes in electrode sampling characteristics brought about by abnormal cell sizes or packing densities. We therefore conclude that dark rearing causes a marked reduction in the percent of Y-cells in the LGN. This effect is not reversed by subsequent periods of prolonged light rearing nor is it mirrored anatomically by any apparent changes in cell size.

1803 SPATIO-TEMPORAL PROPERTIES OF S-POTENTIALS IN CATFISH RETINA. Howard I. Krausz. Dept. of Physiology & Biophysics, University of Texas Medical Branch, Galveston, Texas 77550.

Previous studies of horizontal cell potentials (S-potentials) have focused exclusively on either temporal properties or spatial properties. Temporal dynamics have been measured in various retinas using intensity modulated light spots. Spatial properties of S-potentials have been measured by recording the steady-state voltage at various distances from the center of a spot or slit of light with constant intensity.

The present work is an attempt to integrate both temporal and spatial properties into a simple yet comprehensive model able to account for two new findings:

1. As the diameter of a white-noise modulated light spot is increased, the high frequency gain also increases.
2. As the stimulating spot is moved away from the recording electrode, the overall gain first increases noticeably and then declines.

By treating the horizontal cell layer as a flat conducting disk (S-space) with feedback onto nearby receptors it is possible to obtain a closed-form solution for the spatio-temporal transfer function of the receptor→horizontal cell system. The model accounts for the findings above and makes other testable predictions.

1804 THE PATHWAY FROM THE CAT'S SUPERIOR COLLICULUS TO THE PARABIGEMINAL NUCLEUS: A STUDY OF ITS CELLS OF ORIGIN.
T. Langer*, H. Sherk, and A. Graybiel. Dept. of Psychology, Massachusetts Institute of Technology, Cambridge, Mass. 02139.

The cat's parabigeminal nucleus has been shown to receive a dense projection from the superficial layers of the superior colliculus, and in turn to project densely to the upper part of the superficial collicular layers on both sides. We have examined the population of neurons in the cat's superior colliculus that project to the parabigeminal nucleus. Our aims were to determine the laminar distribution of these neurons and to characterize their morphology.

In order to identify these cells, we have used the retrograde horseradish peroxidase (HRP) cell-labelling technique. HRP was injected electrophoretically into the parabigeminal nucleus of 4 cats (bilaterally in 1) after the nucleus was located by recording visual cell responses. Brains fixed by mixed aldehyde perfusion were prepared by modified Graham-Karnovsky (DAB and BDH) protocols.

Cells in all layers of the superior colliculus were labelled after HRP injections in the parabigeminal nucleus, but the majority (about 70%) were in the superficial gray layer. Labelled neurons were most numerous in the lower two-thirds of this layer, a zone receiving inputs from the ipsilateral retina and visual cortical areas. Fewer labelled neurons appeared above this, in the tier receiving dense inputs from the contralateral retina and the parabigeminal nuclei. About 30% of the labelled collicular cells lay deep to the superficial gray layer, for the most part in the stratum opticum and intermediate gray layers but also in the deep layers and central gray substance (ca 5%.) Throughout the colliculus, small to intermediate sized cells were labelled. A variety of neuronal types were labelled, but in the superficial layers many HRP-positive neurons had vertically aligned dendrites, while in the deeper layers stellate cells predominated.

The finding of labelled neurons in the deep as well as in superficial layers is notable because the projection from the parabigeminal nucleus to the superior colliculus terminates mainly, if not exclusively, in the superficial layers. These deep neurons were labelled after even the smallest injections, which were confined to the lateral half of the parabigeminal nucleus. It is possible that tectal fibers passing lateral to the nucleus were responsible for labelling of deep-layer collicular neurons; however, this cell-labelling could indicate instead the existence of an indirect pathway from the deep to superficial layers of the superior colliculus.

1805 BILATERAL RETINO-WULST PROJECTIONS IN FALCON REVEALED BY TRANSNEURONAL TRANSPORT OF ^{3}H PROLINE. Stephen Lehmkuhle*, V. A. Casagrande, and Robert Fox. Departments of Anatomy and Psychology, Vanderbilt University, Nashville, Tennessee 37240.

Stereoscopic depth perception has been demonstrated by behavioral methods in the American Kestrel, a small falcon with bifoveate retinae (Fox et al., Neur. Sci. Abs. 2: 1075, 1976). We now report anatomical investigations of the Kestrel visual system using autoradiographic techniques. To examine retinal projections to first order mesencephalic and diencephalic structures we injected 0.5 Mc of ^{3}H proline into the vitreous of one eye and allowed the birds to survive for 24 hours. To measure transsynaptically transported labelled protein to the telencephalon, we injected intraocularly a total of 4.5 Mc ^{3}H proline and allowed the bird to survive for 14 days.

Following a short survival time, label was present only in regions contralateral to the injected eye; specific structures containing dense label were the OPT complex, the superficial layers of the tectum, the pretectal nuclei, the accessory optic nuclei, and the ventral lateral geniculate nucleus. Following a long survival time transsynaptic transport occurred depositing labelled protein in both the ipsilateral and contralateral areas of the Wulst. The contralateral label formed a dense, extended, continuous band within the posterior Wulst. The ipsilateral label was lighter and appeared to be divided into a medial and lateral segment. The medial segment was anterior to the lateral segment and slightly more ventral than the contralateral label. Transsynaptically transported label was also observed in the ipsilateral OPT complex, bilaterally in nucleus rotundus, ipsilaterally in the isthmic nuclei and in the mesencephalic reticular formation and pons. Above background label was also observed in all zones lying adjacent to heavily labelled retinal targets. Above background label was not observed within the ectostriatum.

These results, which demonstrate binocular innervation of the Wulst, are quite congruent with behavioral evidence for stereopsis. Moreover, the general organization of the falcon visual system is highly similar to that found in pigeon and owl by degeneration methods (e.g. Karten et al., JCN 150: 253, 1973). The overlapping and displaced portions of the contralateral and ipsilateral label correspond to the incomplete segregation of ocular input implied by electrophysiological recording from the Wulst of pigeon (Cuenod, The Neuroscience 3rd Study Program: Chap. 2, 1974). Finally, the results lend support to the general hypothesis that birds with binocular visual fields and perhaps all binocular vertebrates are equipped with pathways which permit extensive exchange of information from both eyes. (Supported by EY01778 and EY00931).

1806 POSTNATAL DEVELOPMENT OF OCULAR DOMINANCE COLUMNS IN LAYER IV OF THE CAT'S VISUAL CORTEX S. LeVay, M.P. Stryker, and C.J. Shatz. Dept. Neurobiology, Harvard Medical School, Boston, MA 02115

The segregation of geniculocortical fibers representing the two eyes was studied by transneuronal transport of radioactive proline injected into one eye, and by physiological recordings. As late as 15 days postnatally radioactive label formed a continuous band in layer IV on both sides of the brain, suggesting that afferents serving the two eyes are intermingled. At 22 days of age, periodic variations in grain density first appeared, but only on the side ipsilateral to the injected eye. This variation was more distinct at 33 days and achieved the adult appearance at 39 days. On the contralateral side such variation was not apparent until 39 days.

Interpretation of these findings was complicated by the possibility that significant amounts of radioactivity might spill over into the inappropriate laminae of the lateral geniculate nucleus and label the wrong set of cortical afferents. This was studied in autoradiograms of 1 μm Epon sections by measuring the ratio of labelling density over neuronal nuclei in laminae A and A1. We found that this spillover was always greater on the contralateral side, and greatest in the youngest animals. When spillover was taken into account quantitatively in the interpretation of grain counts made from the cortical autoradiograms, three findings emerged: 1) At 8 and 15 days, the continuous appearance of radioactive label on the ipsilateral side is not due to spillover but reflects a real uniformity in the distribution of ipsilateral-eye afferents. 2) The continuous pattern of label seen prior to 39 days on the contralateral side is uninterpretable owing to spillover. Other considerations, however, make it seem likely that the process of segregation proceeds synchronously for the two sets of afferents. 3) In the adult each eye's afferents occupy the centers of the appropriate ocular dominance columns almost exclusively, but they overlap at the borders.

The late onset of segregation (as compared with the monkey, Rakic, Nature 261:467, 1976; Hubel, Wiesel, and LeVay, Phil. Trans. Roy. Soc. B. 278:377, 1977) allowed us to examine whether transient functional connections are originally made uniformly along layer IV, in an unsegregated pattern. Tangential penetrations through layer IV in young kittens showed most of the cells to be nearly equally driven through the two eyes, in contrast to the adult (Stryker and Shatz, Neurosci. Abstr. 2:1645, 1976). This finding suggests that functional connections may be broken and reformed during development. It is striking that the onset of segregation coincides roughly with the beginning of the critical period (Hubel and Wiesel, J. Physiol. 206:419, 1970). 1807 LAMINAR DIFFERENCES IN RECEPTIVE FIELD PROPERTIES OF CELLS IN CAT VISUAL CORTEX. A.G. Leventhal and H.V.B. Hirsch. Center for Neurobiology, SUNYA, Albany, New York 12222.

Receptive field properties of neurons in the visual cortex of normal adult cats were analyzed quantitatively. Neurons were classified into one of two groups: (1) S-cells, which have discrete excitatory and inhibitory regions in their receptive fields and/or display "on" and/or "off" responses to flashing stimuli; (2) C-cells, which do not possess discrete excitatory and inhibitory regions in their receptive fields and give an "on-off" response or no response to flashing stimuli.

S-cells in a given lamina have smaller response fields, lower cutoff velocities, lower preferred velocities, and lower peak responses than do C-cells in the same lamina. In addition, S-cells, regardless of their laminar location, display lower relative degrees of binocularity and are more selective for stimulus orientation than are C-cells. Many of the receptive field properties of cortical cells vary with laminar location. Within the class of S-cells, receptive field size, cutoff velocity and preferred velocity increase with depth (layers V-VI) in the cortex. However, S-cells in all layers of the cortex display similar orientation sensitivities, mean spontaneous discharge rates, peak responses and degrees of binocularity. Laminar differences also exist within the class of C-cells. C-cells in layers V-VI display high mean spontaneous discharge rates, weak orientation preferences and high relative degrees of binocularity when compared to C-cells in layers II-III. The receptive field sizes, cutoff velocities and preferred velocities of C-cells increase with depth (layers V-VI) in the cortex.

The present results are compatible with the suggestion that most S-cells in the striate cortex receive LGNd X cell afferents and that most C-cells receive afferents from Y cells in the LGNd. The small relative receptive field sizes and low relative cutoff velocities of C-cells in layers II-III, as well as the large relative receptive field sizes and the high relative cutoff velocities of some S-cells in layers V-VI, are not reconciled easily with this hypothesis. The receptive field properties of cells in layers V-VI of the striate cortex suggest that LGNd Y cells project more heavily to the lower cortical layers than to the upper ones, thus preserving the distribution of Y cells found in the LGNd. 1808 EFFECTS OF VISUAL DEPRIVATION ON THE CAT'S GENICULO-CORTICAL PATHWAYS. C.S. Lin and S.M. Sherman, Dept. Physiol., Univ. VA Med. Sch., Charlottesville, VA.

Horseradish peroxidase (HRP) was injected focally into cortical area 17 or 18 of normal and monocularly deprived (MD) cats to assess the size and distribution of LGN cells projecting to these areas. After bilateral area 17 injections in one normal cat, 68-76% of the LGN cells (mostly smaller and medium size) were labelled; after bilateral area 18 injections in another normal cat, 24% of the cells (mostly large) were labelled. In 2 MD cats area 17 was injected with HRP in both hemispheres; all LGN layers had 63-74% of the cells labelled. Therefore, although labelled cells in the deprived laminae were somewhat smaller than those in non-deprived laminae, roughly equal numbers of labelled neurons were found in all laminae. In 3 other MD cats, HRP injections were limited to area 18, one in the hemisphere contralateral to the deprived eye, and two, ipsilateral to this eye; but results from both sides were indistinguishable and are considered together. Nondeprived laminae had 22-27% labelled neurons, but labelling in deprived laminae was very light and at most included 11-13% of the neurons which represents a significant reduction. However, the labelled cells in deprived laminae were only 13-14% smaller than those in nondeprived laminae. Two other MD cats were raised with a small retinal lesion in the open eye to produce an artificial monocular segment (AMS) for the deprived eye. This AMS and surrounding region of area 18 was injected in these cats. Labelling in the LGN was essentially limited in the deprived laminae to the AMS region and was found in the nondeprived laminae only outside the zone of transneuronal degeneration associated with the lesion. We conclude that in MD cats the deprived LGN connections to area 17 seem less disrupted than those to area 18 in terms of the percentage of labelled cells. Since X-cells project only to area 17 whereas Y-cells project both to areas 17 and 18 (Stone and Dreher, J. Neurophysiol., 36: 532, 1973), this suggests that the Y-cell projections are more affected by the deprivation than are those of X-cells (Sherman et al., J. Neurophysiol., 35: 532, 1972). Finally, since labelling was intense in the deprived AMS of LGN after injections of HRP into area 18, this supports the contention that development of these Y-pathways is dependent upon competitive interactions between pathways from each eye (Sherman et al., Brain Res., 100: 441, 1975).

1809 CAT RETINAL GANGLION CELL SENSITIVITY AND RETINAL OXYGEN TENSION DURING HYPOXIA. R.A.Linsenmeier*, C. Enroth-Cugell, and T.K. Goldstick*. Biomedical Engineering Center, Northwestern University, Evanston, IL. 60201.

Previous work has shown that the massed optic nerve discharge is reduced during hypoxia, but the work reported here is the first attempt to study single ganglion cells during mild hypoxia.

Recordings were made from X and Y cells in the optic tract of anesthetized, paralyzed adult cats. The stimulus was a sinusoidal grating of relatively high spatial frequency, drifting across the receptive field so that the temporal modulation remained constant at 2 Hz. A computer collected PST histograms of the cell's discharge (which was sinusoidally modulated at the drift frequency), measured the peak-to-peak response amplitude, and adjusted the contrast of the grating to maintain a criterion response. At the spatial frequency chosen, the criterion response of 20 spikes/sec could be elicited by about 10% contrast before hypoxia. Repeated determinations showed that the contrast sensitivity (the reciprocal of the required contrast) was stable. Hypoxia was then induced by changing the breathing gas, and sensitivity was tracked during and after hypoxia. Simultaneously the oxygen tension in the vitreous humor 100 to 200 microns from the retina (Pr) was measured with a Clark type oxygen electrode. Intermittent measurements of arterial oxygen tension (Pa) were also made.

The time course of changes in sensitivity and Pr was similar, but not identical. When sensitivity changes occurred they usually began about 3 min. after the onset of hypoxia. Pr began to change in about 30 sec. and reached a hypoxic steady state in 2 to 3 min. When, following hypoxia, the animal was returned to air breathing, sensitivity and Pr recovered rapidly, but Pr overshot the initial value by as much as 100% before stabilizing.

Sensitivity did not always change. In fact the results indicate that ganglion cells are quite resistant to hypoxia. No change in sensitivity was observed provided that Pa was above about 35 mm Hg. Below this value of Pa sensitivity was reduced by varying amounts, but frequently the change was so great that the criterion response could not be elicited even with a stimulus contrast of 80%. The maintainance of normal sensitivity appears to depend on the efficiency of retinal oxygen autoregulation. The relation at steady state between Pa and Pr can be well described by a function consisting of two parts: 1) As Pa drops from 100 to 35 mm, Pr is well regulated, dropping from about 20 to about 14 mm Hg. 2) As Pa decreases further, Pr drops precipitously, reaching zero at a Pa of about 20. Thus the large sensitivity changes occur when the retinal circulation is unable to maintain retinal oxygen tension.

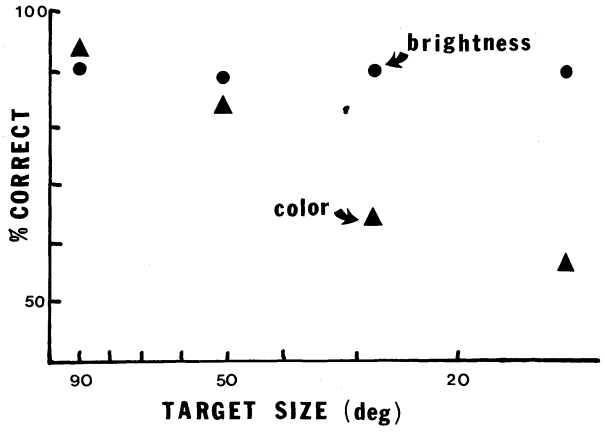
1810 EFFECT OF TARGET SIZE ON COLOR DISCRIMINATION IN THE CAT. Michael S. Loop and Laura Bruce. Neural and Behav. Biol. Program and Dept. of Physiol. & Biophysics, Univ. of Ill., Urbana, Ill. 61801

The "problem" of cat color vision exists because both negative and positive findings have been reported and positive findings have generally suggested that the discrimination of color is, at best, very difficult for the cat. Recent improvements in cat behavioral testing (Berkley,1970) and a simplified color vision test (Vis. Res.16:951,1976) encouraged us to return to this interesting question. Over a period of several weeks four cats were trained to discriminate blue vs grey or blue vs green. The cats' performance remained above chance but below criterion through manipulations of intensity, contrast, and pupil dilation. Increase in target size, however, improved the performance of three cats bringing two to the 90% correct level. Subsequent systematic variation in target size indicated that, for the cat, brightness but not color, is a feature of objects subtending a visual angle of 20 degrees or less. Supported by MH 28268-01.



1811 FUNCTIONAL DIFFERENTIATION OF THE LAMINAE OF THE LATERAL GENICULATE NUCLEUS OF THE RHESUS MONKEY. Joseph G. Malpeli and Peter H. Schiller*. Dept. Psych., M.I.T., Cambridge, MA 02139.

In that portion of the rhesus lateral geniculate nucleus (LGN) representing the central visual fields, there are 2 parvocellular and 1 magnocellular laminae receiving projections from each eye, for a total of 6 laminae. We have examined functional differences among these laminae in several male monkeys (Macaca mulatta) and have found a more pronounced laminar specialization than has been previously reported. Magnocellular neurons respond transiently to flashed stimuli, receive rapidly conducting retinal input, and have rapidly conducting axons. Cells of the parvocellular laminae have a relatively sustained response, receive slowly conducting retinal input, and have slowly conducting axons. The upper 2 parvocellular laminae (6 and 5) are generally heavily dominated by ON-center cells, while the lower 2 parvocellular laminae (4 and 3) are dominated by OFF-center cells. An exception to this rule are cells which respond vigorously to blue light (Wratten #47B). Virtually all give ON responses and are located in laminae 4 and 3. Thus, to a first approximation, color-opponent cells in laminae 6 and 5 are red or green OFF-center, while those in laminae 4 and 3 are red or green OFF-center, or blue ON-center. In the magnocellular laminae (2 and 1) ON- and OFF-center cells are present in roughly equal proportions and do not have color-opponent properties. The overall segregation of ON- and OFF-center cells in the parvocellular layers is complete enough to allow selective reduction or elimination of the dark-edge response of many neurons in striate cortex by microinjection of a local anesthetic into lamina 4 or 3.

1812 VISUAL TRACKING WITH SHORT-TERM REVERSED VISION DURING HEAD MOVEMENT: FUNCTION OF RETINAL IMAGE SLIP? G. Mandl and G. Melvill Jones, Aviat. Med. Res. Unit, McGill Univ.,, Montreal, Canada H3G 1Y6.

Head turning to, say, the left, evokes a vestibulo-ocular reflex (VOR) designed to drive both eyes, in a compensatory fashion, to the right. This reflex is normally capable of maintaining a stable retinal image of the visual world moving momentarily to the right relative to the head.

With optically reversed vision (left-right), however, head turning to the left will create an apparent motion of the visual world to the left. This results in conflicting vestibular and optokinetic drives to the oculomotor system, leading in turn to retinal image slip. It has been previously demonstrated that long-term visual reversal in normal light eventually leads to adaptive modification (gain and phase) of the VOR, with the apparent goal of minimizing retinal image slip.

We now report that, under stroboscopic illumination, subjects exposed to optically reversed vision for the first time, can almost immediately produce reversed smooth tracking eye movements in response to head rotation, in opposition to the prevailing vestibulo-ocular drive, and despite the absence of significant retinal image slip with this intermittent form of illumination.

Subjects wearing reversing prism goggles were seated, with heads fixed to a turntable, rotating either sinusoidally (velocity amplitudes 5,15 and 30°/sec, 0.17 Hz), or with a square wave velocity of amplitude 10°/sec, 0.1 Hz. Eye movements were recorded by dc EOG. After an initial control period in the dark, stroboscopic illumination (2 Hz) was suddenly switched on. Almost immediately, episodes of smooth tracking eye movements in the "reversed" (i.e. VOR opposing) direction could be recorded. In some cases, the first two light flashes were sufficient to induce reversed smooth pursuit eye movements during several 500 millisecond dark intervals between consecutive flashes.

1813 NEURAL MECHANISMS OF ORIENTATION DISCRIMINATION IN PRIMATE VISION. R. J. W. Mansfield, Steven F. Ronner* and Gordon E. Legge.* Dept. Psych., Harvard University, Cambridge, MA 02138.

The striate cortex in man and other primates plays an important role in fine pattern discrimination. Differential responses to oriented stimuli are a distinguishing feature of striate neurons in both man and Rhesus monkey. We have investigated the neural basis of orientation acuity by comparing the receptive field properties of striate neurons in the Rhesus monkey with the results of human psychophysical experiments.

Receptive field properties were quantitatively assessed in 256 cortical units recorded in either foveal (0 - 2°) or parafoveal (4 - 7°) *projection regions of Area 17 in unanesthetized Rhesus* monkey. The majority of units recorded in the upper layers of the striate cortex (Layers II - IVb) possessed complex receptive fields with well-defined orientation selectivity. Orientation tuning curves were produced by varying in random order the angle of a stationary flashed bar or moving bar or slit. Parallel psychophysical experiments using human observers were conducted with similar pattern stimuli.

The following comparisons could be drawn: (1) the form of the human threshold curves for both foveal and parafoveal oriented targets was isomorphic to the corresponding population distribution functions for optimal orientations confirming a previous result (Mansfield, 1974, Science, 186, 1133); (2) for binocularly activated neurons, both the similarity of the orientation tuning curves and the low value for average orientation disparity, 5°, are consistent with the marked binocular interactions observed in the detection of oriented stimuli; (3) for the neural orientation tuning curve, half-bandwidth at half-amplitude was distributed in a unimodal log-Gaussian manner with median value close to that obtained for human orientation channels, 22°; (4) both neural and psychophysical orientation bandwidth were independent of optimal or adapting orientation; (5) both neural orientation tuning curves and the threshold curves defining human orientation channels were well-fit by theoretical functions calculated from a simple mathematical model based on sustained responses from non-oriented subunits.

These results support the hypothesis that the population response profile for neurons in Area 17 determines behavioral discriminability for oriented targets. (Supported by NSF grant BNS 75-08437 and NIH fellowship EY 05075.)

1814 MORPHOLOGY OF RETINO-GENICULATE AXONS AND THEIR TERMINALS IN THE DORSAL LATERAL GENICULATE NUCLEUS (LGN) OF THE CAT. C.A. Mason* and J.A. Robson* (SPON: R.W. Guillery). Dept. Anatomy, Univ. Wisconsin, Madison, WI 53706

When retino-geniculate axons are diffusely filled with horseradish peroxidase (HRP), Golgi-like detail can be seen. Injections (0.2μl) of 50% HRP (Sigma, type VI) were made into the optic tract. After 24 hr survival and routine aldehyde fixation, brains were cut at 100μm on a Vibratome. Sections were soaked in 0.5% $CoCl_2$ in 0.1M Tris buffer (Adams, 1977, Neuroscience 2:141), and then incubated in DAB. Cobalt treatment changes the reaction product to blue-black. This procedure produces continuous filling of axons and their terminals, and it is our experience that it occurs only if the axons are cut. Axonal filling extends only about 1 cm from the injection site, and, as with the Golgi methods, not every axon is stained. Axons of varying diameters enter the LGN, and some are seen to be collaterals of axons in the optic tract. In laminae A and A1 axons are of large diameter and form terminal arrays aligned perpendicular to the laminae. These axons divide into several branches, and their terminal configurations are formed by swellings of several shapes and sizes, as shown below. Large swellings (7-10μm) are elongated and commonly crenulated; they occur singly (b1) or in the center of a cluster (b2). Medium-sized swellings (3-7μm) tend to be smoother and more spherical. They can be grouped around a large swelling in a cluster (b2), can occur at the end of fine axons (a1), or can form chains connected by fine axons (a2). Small swellings (1-2μm) can also occur at the end of (b3,c1), or as part of chains of (c2), fine axons. The C layers contain axons that are finer and run parallel to the laminae. These axons branch less frequently and give rise to swellings similar to the small swellings in A and A1. Axons in the medial interlaminar nucleus show no obvious alignment and resemble axons in the A layers both in terms of fiber diameter and shape of swellings. This labeling method reveals a far richer display of retino-geniculate terminations than do the Golgi techniques. Because myelinated segments are filled, axons and their branches can be traced over great distances, demonstrating that single axons form a variety of morphologically distinct terminal patterns.

1815 TILT CONSTANCY MECHANISMS IN KITTEN VISUAL CORTEX. Jacqueline Metzler† and D. Nico Spinelli. Departments of Computer and Information Science and Psychology, University of Massachusetts, Amherst, MA 01003.

The visual world remains perceptually quite stable whenever we tilt our head. There is physiological evidence (Horn, et al., 1969, 1972; Spinelli, 1970; Denney and Adorjani, 1972) that in the cat this phenomenon of orientation or tilt constancy might result from changes in the orientation selectivity of a small percentage (about 6%) of the neurons in the visual cortex during head and body tilt. In an effort to test the effects of experience on the development of tilt constancy, eight kittens were reared under conditions of selective visual experience beginning at about 3-1/2 weeks of age. Each animal's total visual experience consisted of viewing two vertical bars with one eye and two horizontal bars with the other eye. In one eye the two bars were gravity-stabilized so that their orientation remained constant whenever the kitten rotated its head, while in the other eye the two bars were fixed so that they always maintained a constant orientation on the retina even when the kitten's head was tilted. Electrophysiological recordings of single units in visual cortex (area 17) were taken when the animals were between 12 and 20 weeks old. The receptive field of a cell was mapped when the animal was in the standard position, when tilted 23° clockwise or counterclockwise, and again in the standard position.

The receptive fields of 94 units were thoroughly analyzed and classified as either diffuse (55%) or elongated (45%). Units with elongated receptive fields responded to input from only one eye. Furthermore, when mapped in the standard position, the receptive field orientations were coincident with the bar pattern to which the eye had been exposed. When the kitten was rotated about its longitudinal axis, the orientation of those receptive fields that could be mapped only through the eye that had viewed the pattern having a fixed retinal orientation during development rotated by the same amount in the same direction; i.e., these receptive fields were not tilt constant. In contrast, the receptive field orientation of cells activated only by the eye that had been exposed to the gravity-stabilized pattern during development remained unchanged following body tilt; i.e., these receptive fields appeared to demonstrate tilt constancy. The results corroborate the findings that the receptive field properties of some cells in visual cortex can be modified, one of the modifying influences being head or body orientation. 1816 COLOR VISION MECHANISMS IN MONKEY STRIATE CORTEX. Charles R. Michael. Dept. of Physiology, Yale School of Medicine, New Haven, Conn. 06510.

Extracellular recordings were made with tungsten microelectrodes from 863 color-sensitive cells in the striate cortex of 26 rhesus monkeys. In area 17 there were four classes of color-coded neurons: concentric, simple, complex and hypercomplex. All four types responded only to monochromatic stimuli.

Cells with concentric receptive fields (137, 16%) had one red-green opponent-color system in the circular field center and the opposite organization in the annular surround. Simple color cells (131, 15%) had receptive fields consisting of a central rectangular strip containing one red-green opponent-color system and two antagonistic flanks with the reverse opponent-color arrangement. Complex color cells (382, 44%) responded only to moving bars or edges of monochromatic light. Hypercomplex color cells (213, 25%) similarly were excited only by moving monochromatic line stimuli but in this case they had to be limited in length at both ends.

Evidence from multiple-unit recordings has led to the following proposed synaptic connections: lateral geniculate afferents (two types) to concentric cells to simple units to complex neurons to hypercomplex cells.

Color units were arranged in vertical columns which extended through all six cortical layers. Within a column all cells were color-sensitive but varied in their individual chromatic properties, receptive-field organization, axis orientation and eye preference. The boundaries of the color columns were independent of those for the axis orientation and ocular dominance columns. Color columns were generally 100-200 μm wide but sometimes extended over greater distances. In a column color cells often had common or related chromatic properties, indicating evidence for a serial processing of wavelength information.

Complex and hypercomplex color cells were found in layers II, III, V and VI. Concentric and simple cells were confined almost entirely to layer IV. Most of the cells in IVC were concentric units.

All concentric cells and almost all simple units were monocular. The majority of complex and hypercomplex cells were binocularly activated.

1817 CORTICOGENICULATE AXONS FROM AREA 17 AVOID GENICULATE SEGMENTS THAT RECEIVE AN ABNORMAL RETINAL INNERVATION IN SIAMESE CATS. V. M. Montero* and R. W. Guillery (SPON: C. N. Woolsey). Depts. of Neurophysiology and Anatomy, University of Wisconsin, Madison WI 53706.

Lamina A1 of the lateral geniculate nucleus of Siamese cats has a lateral segment that receives a normal uncrossed input from peripheral (20°-40°) parts of the temporal retina and a medial segment that receives an abnormal crossed input from more central (0°-20°) parts of the temporal retina. Injections of ^{3}H proline were made bilaterally in 4 adult "Midwestern" Siamese cats in area 17 on the medial wall of the lateral gyrus, 3 mm or 6 mm below the dorsal surface. At 3 mm, microelectrode recordings showed receptive fields about 5° into the contralateral visual field of the contralateral eye and no responses from the ipsilateral eye. At 6 mm, receptive fields were from the ipsilateral and contralateral eyes, 20° or more into the contralateral visual field. These two injection sites thus showed corticogeniculate projections to the abnormal and normal geniculate segments respectively. In 5 hemispheres, injections were made at 3 mm and these showed a characteristic dense distribution of label to layers A and C, but an almost complete absence of label in the interposed abnormal segment of layer A1. In contrast to this, 3 hemispheres with injections at 6 mm showed dense label in all geniculate layers, including the normally inervated segment of layer A1.

One of these Siamese cats had one eye sutured at 9 days of age, two had one eye removed (on the 8th and 19th postnatal day) and one was normal. Of the five hemispheres that showed avoidance of the abnormal segment of A1, one was from the normal cat, two from the lid sutured cat and two from the 19 day enucleate. The relative density of label in the geniculate layers was not affected by the deprivation or enucleation. In two normally pigmented cats, one with a unilateral (8 day) enucleation, the other with a (8 day) lid suture, bilateral cortical injections at 3 mm showed even, symmetrical label in all geniculate layers. These results suggest that the avoidance of the abnormal segment of layer A1 in Siamese cats is not dependent on visual experience. Corticogeniculate axons are present at birth in cats (Anker and Cragg, J.Comp.Neurol.154:29,'74), develop in anophthalmic mice (Kaiserman-Abramoff et al.,Neurosc.Abstract 1:102,'75) and appear to be unaltered by early enucleation or deprivation in our cats. The avoidance of the abnormal segment of layer A1 in Siamese cats must depend either upon the left:right reversal of connections or upon an intrinsic abnormal innervation pattern that distinguishes the abnormal from the normal retinogeniculate pathway.

1818 RESPONSE PROPERTIES OF CELLS IN THE NUCLEUS LATERALIS POSTERIOR OF THE CAT ASSOCIATED WITH VISUAL ORIENTATION. Brad C. Motter* and Donald B. Lindsley. Depts. of Psychology and Physiology, University of California, Los Angeles.

Extracellullar single unit recordings were obtained in the posterior extent of the nucleus lateralis posterior in cats trained to orient toward and fixate a small (0.75°) spot of light projected at various positions on a dimly illuminated (15 mcd/m^2) tangent screen located 60 cm. in front of the animal. During recording sessions the animal's head was fixed relative to the tangent screen and eye position was monitored with Ag-AgCl DC electrodes. Stimulus presentations were limited to those areas of the visual field in which each animal would maintain a visual fixation. A significant proportion of spontaneously active cells was found to tonically increase or decrease firing rate during fixation on the stimulus. Most cells in this category exhibited a gradient of responsiveness associated with the absolute position of the fixated spot within the visual field. No clear relationship between saccadic amplitude or direction and this gradient could be established. Firing rates of these cells were observed to return to background levels with eye movements away from the stimulus or at the offset of the two-second stimulus. Occassionally changes in the firing rates occurred with spontaneous fixations, i.e., when the stimulus spot was not present. A second group of cells showed an excitatory response to the onset of the stimulus spot, but were either non-responsive or phasically activated during the ensuing fixation. These cells had clear, but large receptive fields (based on initial eye position) usually including 2 or more receptive field quadrants. In nearly one half of the recorded cells there were no detectable changes in firing rate either to the presentation of the stationary spot or during fixation on that stimulus, however, changes in firing rates of some of these cells were observed during presentations of moving stimuli. Supported by USPHS grant NS-8552 and Grant Foundation supplementation.

1819 THE EFFECT OF ABLATION OF THE EXTRASTRIATE VISUAL SYSTEM ON VISUAL REVERSAL LEARNING IN THE RABBIT. E. Hazel Murphy and Eric Rappaport*.Dept. of Anat. The Med.Coll. of Pa.Phila.19129

The relative development of the extrastriate visual system (measured by the ratio of the pulvinar nucleus/ lateral geniculate nucleus) has been related to phylogenetic status. Greater development of the extrastriate visual system in mammals such as the tree shrew and bushbaby has been correlated with differentiation of visual areas of the temporal lobe and with the ability to form a learning set during successive reversals of a visual discrimination. Ablation of extrastriate visual cortical areas results in loss of this ability. In contrast, lesser development of the extrastriate visual system in mammals such as the rat and hedgehog has been correlated with lesser differentiation of visual areas of the temporal lobe and no learning set acquisition on daily reversal of a visual discrimination task. Because of this poor reversal learning performance, the effects of ablation of extrastriate visual cortex on reversal learning in these mammals have not been investigated. (Killackey et al. J.C. P.P. 1972, 81, 45., Masterton et al. Brain, Behav. and Evol. 1974, 10, 322.)

In rabbits, the pulvinar/ lateral geniculate ratio is similar to that of the rat and hedghog. However, we have previously shown that the occipital and temporal cortical areas of the rabbit contain several differentiated visual areas (Montero & Murphy,Anat. Rec. 1976). In the present study, we tested rabbits on tasks of brightness discrimination and reversals of this discrimination. The results showed that when normal rabbits were tested to criterion on each reversal (instead of being given daily reversals) then clear evidence for a learning set for visual reversals was obtained; the number of errors to criterion decreased significantly with each successive reversal. However, in rabbits, with ablation of extrastriate visual cortical areas in the occipital and temporal lobes, there was no evidence for a learning set; the number of errors to criterion on successive reversals remained constant. Normal and operated rabbits did not differ in their rate of learning the initial brightness discrimination. The results suggest that the extrastriate visual system of the rabbit has the same function in visual learning and learning set formation as it does in those mammals in which the system is, structurally, more highly developed.

1820 EARLY STRABISMUS PROTECT NEURONS IN KITTEN AREA 17 FROM THE EFFECTS OF MONOCULAR DEPRIVATION. Michael J. Mustari* and Max Cynader (Spon. I.A. Meinertzhagen). Department of Psychology; Dalhousie University; Halifax NS B3H 4J1.

It is now well established that rearing kittens with one eyelid sutured during early development results in the majority of single cells in Area 17 being driven only by stimuli presented to the non deprived eye. Hubel and Wiesel (1965) have reported that in kittens reared with artificial strabismus, the majority of cells were monocular but could be driven by either eye and that the separation between ocular dominance columns was more distinct in these cats then in normal cats. These data raise an interesting question, that is whether rearing kittens with artificial strabismus, thus separating ocular dominance columns, might produce a cortex that is less susceptable to the devestating effects of monocular deprivation. This study considers this question.

Two groups of kittens were used in this study. The first group (5 animals) were reared normally until day 45 (±3), monocularly sutured and recorded 8 days later. 200 units were studied in both hemispheres. The deprived eye lost functional connections with the visual cortex.

The second group of kittens were reared normally until day 15, and then were made strabismic by sectioning the right medial rectus muscle. They were kept in a normal visual environment until day 45 (±3) and then either the strabismic eye (11 animals) or normal eye (2 animals) was sutured closed for 8 days before recording from single cells (511 units) in Area 17. In the cortex contralateral to the monocularly deprived eye most neurons were monocular but driven by either eye. Regular shifts in ocular dominance occurred as a function of depth of the oblique electrode penetration. The ocular dominance distribution obtained from the cortex ipsitateral to the monocularly deprived eye in group two cats was very different and strongly resembled the ocular dominance distribution of the control cats. The results indicate that the cortex contralateral to the deprived eye in previously strabismic cats was resistent to the effects of monocular deprivation.

The data obtained in this study strongly argue that the physiological effects of monocular deprivation are medicated by competition between axons in right and left eye ocular dominance columns at the cortical level. The ipsilateral-contralateral differences found in the strabismic cats can best be accounted for by considering the anisotropy in size and distribution of ocular dominance columns found in normal cats. Correlative anatomical studies on these animals are in progress.

1821 CONVERGENCE AS A FUNCTION OF ECCENTRICITY IN THE RETINO-GENICULO-STRIATE SYSTEM OF THE OWL MONKEY. J. Myerson, P.B. Manis*, F.M. Miezin*, and J.M. Allman. Div. of Biology, Calif. Inst. of Tech., Pasadena, CA 91125.

In primates, the central portion of the visual field receives a greatly expanded representation in striate cortex. Investigators disagree, however, as to whether this is solely because of increased ganglion cell density near the center of the retina, i.e., "peripheral scaling," or whether the cortex provides additional "magnification." We compared the relative proportions of ganglion cells and striate cortical neurons for visual field zones of different eccentricities in the owl monkey. Calculations were based upon ganglion cell counts along horizontal and vertical meridians by Webb and Kaas (1976) and measurements of a three-dimensional brain model constructed on the basis of serial sections and electrophysiological mapping by Allman and Kaas (1971). The relative number of cells per degree^2 decreased more rapidly with increasing eccentricity in striate cortex than in the retinal ganglion cell layer. Functionally this suggests that in primates striate cortex is even more specialized than the retina for processing information concerning the center of the visual field. Anatomically, this means that the ratio of retinal ganglion cells to neurons in striate cortex increases with eccentricity. More specifically, the relationship between number of cells/degree^2 for corresponding portions of striate cortex (M_C) and the retinal ganglion cell layer (M_R) is describable by a power function: $M_C(\phi_1,\phi_2) = aM_R(\phi_1,\phi_2)^{**}2.35$. It follows that the ratio of ganglion cells (N_R) to striate neurons (N_C) is a power function of the area (A) per ganglion cell:

$$\frac{N_R(\phi_1,\phi_2)}{N_C(\phi_1,\phi_2)} = k\left|\frac{A(\phi_1,\phi_2)}{N_R(\phi_1,\phi_2)}\right|^{1.35}$$

Recent findings demonstrate that although some primate retinal ganglion cells send collaterals to the superior colliculus, all ganglion cells send axons to the lateral geniculate nucleus (LGN) (Bunt et al., 1975) and nearly all cells in the LGN project to striate cortex (Norden, 1974). Thus the preceding equation describes anatomical convergence in the retino-geniculo-striate system, i.e., the mapping of the retinal ganglion cell layer onto striate cortex. Our findings explain the results of recent autoradiographic studies (Kaas, Lin and Casagrande, 1976; Tigges, 1977). Following intraocular injection of tritiated proline, transneuronal labeling in foveal (dorsal) striate cortex is much less dense than in peripheral (calcarine) striate cortex because the ratio of ganglion cells/cortical neurons increases with eccentricity. 1822 BLINDNESS IN MONKEYS AFTER LESIONS OF NON-VISUAL CORTEX. Richard K. Nakamura and Mortimer Mishkin, NIMH, Bethesda, Md. 20014

Visual discrimination habits in monkeys are now known to depend not only on striate cortex, but also on secondary visual and associated limbic areas. In the present study we asked whether the visual and limbic systems acting together are sufficient for retention of such habits or whether any of the cortex outside these two systems also plays a significant role. To examine this question we restricted vision to a single hemisphere and then removed all the cortex in this hemisphere outside the visual and limbic systems. Since, in past studies, complete removal of sensorimotor cortex in the seeing hemisphere did not prevent visually guided motor behavior, we assumed that our planned lesions in this hemisphere would also spare such behavior sufficiently to permit an assessment of the role of non-visual, non-limbic cortex in retention of visual habits.

Four monkeys (2 rhesus and 2 cynomolgus) were trained on a visual pattern discrimination. The forebrain commissures and the right optic tract were then severed in each. Following retraining, three animals were given total left hemisphere cortical ablations sparing only: striate, prestriate, inferior temporal cortex; and medial temporal, ventral frontal, cingulate cortex. The fourth animal (a cynomolgus) received the same lesion except that the cortex anterior to the arcuate sulcus was spared.

Within two days of the cortical ablation all animals were able to right and feed themselves. Unexpectedly, however (though see Gazzaniga, Exp.Neurol, 16:289, 1966), it became clear at this point that all were behaviorally blind. Food could be found only by use of auditory, olfactory or tactile cues; fearful objects evoked no reaction; and unfamiliar environments were explored using only tactile cues. Two weeks after surgery these monkeys could not determine which of two foodwells contained exposed rewards without tactile searching. Twenty-five days after surgery one rhesus monkey was able to locate the exposed reward visually at just above chance; this ability was fully recovered after twenty days of further training, at which point the animal showed good first-day retention of the pattern discrimination habit though still exhibiting many of the earlier signs of blindness. This was the only monkey that could be tested. The other rhesus monkey showed no signs of recovery for 42 days and was sacrificed for histology; the lesions in this animal were as intended, and the primary visual pathways in the left hemisphere were found to be intact. The two cynomolgus monkeys have been kept alive for over 200 days and remain behaviorally blind.

We are currently testing whether this phenomenon is due to diaschisis of the visual system or to a visual-motor disconnection.

1823 RELATION OF THE DELAYED GANGLION CELL RESPONSE AND THE E-WAVE TO ROD ACTIVITY IN THE FROG, RANA PIPIENS. Eric Newman* (SPON: L. S. Frishkopf). Dept. Biol., Research Lab of Electronic, M.I.T., Cambridge, Mass. 02139

The onset of both the delayed ganglion cell response and the e-wave have long latencies following light flashes presented to dark adapted eyes. An eye-cup preparation was employed to study the properties of these delayed responses and the mechanism generating the long delays. In this study, the e-wave appeared as a sharp, negative notch superimposed on a slow positive voltage recorded with an intra-retinal electrode referenced to the vitreous. It has latencies of from 2 sec to over 1 min, depending on flash intensity and adaptation state. Ganglion cell (types 3 and 4) activity was recorded while monitoring the e-wave response. A light flash produced a prolonged burst of activity following a silent period of as long as 1 min. Over a 5 decade range of flash intensities, producing delays of from 2 to 65 sec., ganglion cell activity occurred simultaneously with the e-wave. The latency to the start of the e-wave and the delayed ganglion cell response was roughly proportional to log flash intensity.

The extracellular mass receptor response was recorded in aspartate-treated eye-cups to determine the relation between receptor activity and the delayed retinal responses. Light flashes produced rod responses having prolonged plateaus, with onsets of decay from saturation delayed for up to 60 sec. The delay to the beginning of rod response decay for a given flash intensity corresponded closely to the delays seen to the onset of the e-wave and ganglion cell response. Retinal sensitivity, determined by a criterion local b-wave, was examined as a second measure of rod response. Retinal threshold remained elevated following flashes until the appearance of a sharp rod-cone break where the threshold fell steeply, indicating recovery of the rods from saturation. The onset of the e-wave occured concurrently with the beginning of the steep fall of retinal threshold. It is concluded that the delayed ganglion cell response and the e-wave both represent rod-driven events whose latencies are determined by the delay to the beginning of the rod response decay. 1824 A QUANTITATIVE EM INVESTIGATION OF CHANGES IN THE SYNAPTIC ORGANIZATION OF THE OPTIC TECTUM FOLLOWING ENUCLEATION IN XENOPUS. J.J. Norden, A.-J.C. Ostberg*, and J.A. Freeman. Vanderbilt Univ., Nashville, TN and NIMR and University College, London, England.

The morphological changes which occur in synapses following denervation are of considerable interest inasmuch as they may reveal important aspects of underlying mechanisms of synaptogenesis. Of particular interest is whether denervation can induce sprouting of other fibers which project to the region and if so, whether these fibers innervate vacated postsynaptic sites or induce new specializations.

In the present study, the time course and changes in synaptic organization which occur following denervation were examined quantitatively in the optic tectum of Stage 66 Xenopus using EM at times ranging from 12 hrs to 6 mos following unilateral enucleation. For each animal, the total number of synapses were counted in 10 grid squares at symmetric loci in the superficial tectal layers. Synapses were classified into 4 types ranging from normal to late degenerating. The number of vacant sites or postsynaptic specializations unopposed by a presynaptic element with clustered vesicles and the amount of glial and axonal debris were also counted.

Preliminary results indicate that by 24 hrs following enucleation over 20% of the synapses in the denervated tectum are undergoing degeneration. There is little difference between the denervated and control sides in the number of vacant sites or amount of debris. By 4 days, nearly 40% of the total number of synapses are degenerating and there is a dramatic increase in the amount of debris. The most significant finding at 4 days, however, is a large decrease in the total number of synapses without a significant increase in the number of vacant sites on the denervated side. The presence of pre- and postsynaptic elements still in contact within glial cells at this time suggests that both elements are removed by gliosis, leaving few vacant postsynaptic specializations. These findings suggest that following enucleation in Stage 66 Xenopus, fibers from the diencephalon and contralateral tectum which also synapse in the superficial tectal layers do not sprout to occupy postsynaptic sites vacated by optic nerve fibers. Any newly formed synapses would require the de novo synthesis of postsynaptic specializations.

1825 HOW DO VISUAL CELLS SYNTHESIZE RESPONSES TO MOVING LIGHT STIMULI? J. Outerbridge*, G. Mandl and M. Gorayeb*. (SPON: R. Capek) Aviat. Med. Res. Unit and BioMed. Engrg. Unit, McGill Univ., Montreal, Canada H3G 1Y6.

In an attempt to answer this question, the present experiments examined the responses of 3 cells to (1) spatial sequences of identical stimuli delivered successively to several non-adjacent locations within the central activating region; and (2) temporal sequences of two stimuli, delivered at varying inter-stimulus intervals to individual locations within the activating region. METHODS. Extracellular microelectrode records were obtained from visual cells in the intermediate and deeper layers of the superior colliculi of acute, unanaesthetized cats whose brainstems had been transected at the pretrigeminal level. To stimulate spatial sequences of non-adjacent receptive field regions, an opaque mask containing up to 5 narrow slits (2x40mm), spaced some 2° apart, was placed over the receptive field. A single light-dark border, moving across the slits at uniform velocities of 4-256°/sec, produced step-like unidirectional changes of light intensity (dimming) at successive, fixed locations. Temporal sequences of dimming stimuli, confined to individual locations, were produced by using a receptive field mask with a single slit. A two-step sequence of light intensity (double borders, white-grey, grey-black) was moved across the stationary slit, at a fixed velocity of 320°/sec, but with varying spacing between the two borders. Cell responses were evaluated using average response histograms. RESULTS. To predict a cell's response to spatial or temporal sequences of stimuli, the time course of excitability change due to an individual stimulus must be known. Owing to a cell's firing threshold, this could not be obtained from observed responses to single border stimuli. However, a complete picture of such excitability changes could be synthesized from experimentally-observed responses to spatial sequences of single border stimuli. Linear superposition of the synthesized excitability changes appeared to account for the cells' responses to spatial sequences of single border stimuli, but not to temporal sequences of double border stimuli.

1826 NEURONAL CIRCUITS WITH "PRESYNAPTIC DENDRITES" IN DORSAL LATERAL GENICULATE NUCLEUS (LGNd) OF MONKEYS. Pedro Pasik, Tauba Pasik and József Hámori*. Dept. Neurol., Mount Sinai Sch. Med., CUNY, New York, N.Y. 10029, and 1st Dept. Anat., Semmelweis Univ. Med. Sch., 1450 Budapest, Hungary.

A prominent feature of the synaptic organization of the LGNd is the presence of "presynaptic dendrites" exhibiting both presynaptic and postsynaptic sites. The majority of these elements are processes of Golgi type II interneurons. They enter in synaptic relations with retinal (R) or cortical (C) axon terminals, dendrites of projective neurons (P), other interneuron dendrites (Id) or axons (Ia), and still other elements of undetermined origin. The present study has used the technique of serial sections of the LGNd from mature monkeys (M. mulatta) to analyze the various synaptic arrangements with Id participation. Three basic prototypes were found, namely triadic, serial and reciprocal synapses. In the triad, the Id element is postsynaptic to element #1 and presynaptic to element #3 which is also postsynaptic to element #1. Since element #1 and #3 can be R, C, P, Id or Ia in nature, 8 different kinds of triads involving these profiles may exist in the LGNd. So far, 4 of them have been found as follows:

The triad with retinal participation is by far the most common. In the serial synapses, the Id element is postsynaptic to element #1, and presynaptic to element #3. Seven of the 8 possible combinations have been already identified, namely:

R → Id → P R → Id → Id C → Id → P C → Id → Id

Ia → Id → P Ia → Id → Id Id → Id → P

In the reciprocal synapses, the Id element is presynaptic and postsynaptic to another element of similar nature. This type, although rare, is also present in the LGNd: Id ⇄ Id. In addition to these basic prototype circuits, there are also linkages at a distance between, for example, a triadic and a serial arrangement, the linking element being the same Id profile. The most frequent of these combinations is a triad with retinal input where the Id profile is also presynaptic to a distant P element, probably belonging to a different projective neuron:

The existence of triadic, serial and reciprocal synapses offers multiple possibilities for the processing of sensory information dealing with both spatial and temporal properties of stimuli. Additional knowledge is needed, however, on the operational features of the interneurons as well as a direct physiologic evidence for their assumed inhibitory nature. Aided by N.I.M.H. Grant MH-02261.

1827 VISION OF CATS REARED IN STROBOSCOPIC ILLUMINATION. Tatiana Pasternak, William H. Merigan and John Lott Brown. Center for Visual Science, University of Rochester, Rochester, NY 14627.

Cats were reared from birth to at least 12 mo. in a room illuminated only by a short flash (3 μsec) every 1.5 sec. This environment provided patterned visual stimulation but precluded the perception of movement. Single unit studies of these animals have shown normal responses in the optic tract but some reduction in orientation selectivity and highly significant reduction in directional selectivity of cortical cells (Levitt, Emerson, Brown, 1977). Behaviorally, upon removal from the stroboscopic environment, the cats showed no visual following, no startle to a looming object, poor visually guided placing and severe deficits in visually guided reaching (serrated edge test). The cats locomoted on bent legs, bumped into barriers in an obstacle course and would not jump down from a height of 30 cm. Optokinetic nystagmus was present. After several months in a normal environment, the animals showed improvement in some tests, but they remained deficient in visually guided reaching, showed no startle response to a looming object and did not jump normally.

Quantitative behavioral measurements of the spatial modulation transfer function have been undertaken on three experimental and three control cats following at least two months of adaptation of the experimental animals to a normal environment. In a two-alternative forced-choice procedure, the cats are presented with a vertical sinusoidal grating and a blank field of equal mean luminance displayed on two CRTs. The position of the grating is varied at random from left to right on successive trials. The cats are rewarded for a nose pressing response towards the grating. Results indicate a reduction in the high frequency cut-off and reduced sensitivity to intermediate spatial frequencies for the strobe-reared cats as compared to the normal animals. (Supported by NIH Grant EY 00680-05)

1828 LOCAL NOREPINEPHRINE PERFUSION AND EFFECTS OF MONOCULAR DEPRIVATION IN 6-OHDA-TREATED KITTENS. John D. Pettigrew* and Takuji Kasamatsu. Beckman Labs. of Behav. Biol., Calif. Inst. of Tech. Pasadena, CA 91125.

We have adopted a regime of 6-OHDA treatment which produces significant catecholamine depletion in the cortex of kittens after intraventricular administration. The doses of 6-OHDA required are proportionately much larger than those which appear to be adequate for rodents. In addition, these doses do not produce significant depletion of catecholamines from brainstem regions.

As described previously, we find that visual cortical neurons in 6-OHDA-treated kittens do not respond in the usual way by changing ocular dominance after monocular occlusion. Recordings from normally-reared kittens treated with 6-OHDA following a period of monocular deprivation are consistent with the hypothesis that cortical plasticity, as measured by the change in ocular dominance, is dependent upon the presence of catecholamines.

To test this hypothesis further we have developed a technique of local cortical perfusion of norepinephrine from a fine cannula attached to an osmotic mini-pump (Alzet). Virtually complete ocular dominance shifts are observed in 6-OHDA-treated kittens amongst those neurons in the cortical region close to the infusion site following one week of monocular closure simultaneous with one week's delivery at 1 μl/hr of a solution containing 0.4% ascorbate in saline (pH=3) whose initial concentration of norepinephrine was 0.1 μg/μl. Such ocular dominance shifts appeared to be confined to cortex which was reached by norepinephrine. High proportions of binocular neurons, without a bias for one eye, were observed in the opposite visual cortex of the same kittens, in the regions surrounding control cannulation sites which had been perfused with the acidic vehicle solution alone.

(Supported by Spencer Foundation and NIH Grant MH25852).

1829 CALCIUM SPIKES EVOKED IN TURTLE CONES BY PERIPHERAL LIGHT STIMULATION. M.Piccolino* and H.M.Gerschenfeld*(SPON:E.Marder). Lab.Neurobiol., Ecole Normale Supérieure,75005 Paris,France.

Cones of the turtle Pseudemys scripta elegans, when illuminated with a bright light on the periphery of their receptor field during light stimulation of its center, show a synaptic depolarization (Baylor, Fuortes and O'Bryan, J.Physiol.,214, 265,1971) which in some cases may give rise to a spike-like response of 10-20 mV (Fuortes,Schwartz and Simon, J.Physiol. 234,199,1973; O'Bryan, J.Physiol. 235,207,1973).

We have found that injecting long pulses of outward current the feed-back synaptic depolarization can be converted to a 15-30 mV spike. Sr^{++} ions (4-6 mM) facilitate the appearance of these spikes either with or without current injection.

In many cones the feed-back depolarization disappears spontaneously or is never observed. In this case, peripheral light stimuli, or the proper combination of central or peripheral stimulation can evoke spikes of 30-45 mV after prolonged application of Sr^{++} or Ba^{++} ions (6 mM). 4-aminopyridine(4-AP) facilitates the appearance of the Sr^{++}-induced spikes. The application of Ba^{++} or of both Sr^{++} and 4-AP evokes Ca-spikes appearing at the off of the cone responses, similar to those described in the toad rods (Fain,Quandt and Gerschenfeld,ARVO Meeting,1977).Atropine (5 mM), which hyperpolarizes the horizontal cells and block their responses, as well as glutamate ions (50 mM), which depolarize the horizontal cells and block their responses, both block preferentially the synaptically evoked spikes. These are not affected by 10 μM tetrodotoxin, but are blocked by Co^{++} ions and D-600 (0.5 mM).

These experiments suggest that stimulation of the periphery of the receptor field of turtle cones can facilitate through a synaptic mechanism a regenerative Ca^{++}-conductance.

1830 CLASSIFICATION OF RECEPTIVE FIELD PROPERTIES OF CELLS IN THE VISUAL CORTEX. Karl H. Pribram, Maryse Lassonde and Maurice Ptito. Psychology, Stanford Univ., Stanford, CA 94305

Quantitative analyses of receptive field properties of cells in the visual cortex were performed using spots, single lines, double lines and multiple lines (gratings). Results were classified on the basis of whether the properties examined varied independently or covaried. Independently varying properties were found to delineate stimulus parameters while the covarying properties described the cells' response. However, an intermediate level that defines the interactive dimensions of the dendritic field of the cell was distinguished because two classes of covariation were identified. The interactive dimensions were examined especially in the two-line experiments. The results of these experiments showed that simple receptive fields are characterized by definitely separate "zones" of excitation and inhibition with a neutral region between. Complex receptive fields, on the other hand, display inhibitory interactions over a wider region. The independently varying properties were especially clearly delineated by exposure to gratings. First, these characteristics confirm the stimulus orientation and direction of movement selectivity of cells in the visual cortex as described by single and double line experiments. Second, an additional stimulus parameter is added: spatial frequency. There is no covariation of spatial frequency selectivity in our results with any other parameter investigated, nor is there covariation between the bandwidth of the spatial frequency selectivity and these other parameters. Additionally, two classes of covarying interactive properties of the receptive field were distinguished by the use of stationary sine wave gratings when phase angle was reversed and by sine wave gratings drifted across the field in the preferred orientation and direction. Enroth-Cugell and Robson (1966) using these techniques described two populations of retinal ganglion cells which they labeled "X" and "Y". In our experiments, the same criteria defined populations which were practically coordinate with those defined by hand held and computer controlled single-line stimuli as "simple" and "complex" (only 2 out of 47 cells failed to match). Most investigators have assumed an equivalence between sustained response and "X" characteristics and between transient response and "Y" characteristics and between transient response and "Y" characteristics. Our results clearly show that the X-Y and sustained-transient classes are orthogonal to each other and not coordinate. Our data suggest further that the sustained/transient classification reflects basic output (axonal) properties of visual cells while the X-Y, simple-complex classification appears to reflect input (dendritic) properties.

1831 EFFECT OF PRENATAL UNILATERAL EYE ENUCLEATION ON THE FORMATION OF LAYERS AND RETINAL CONNECTIONS IN THE DORSAL LATERAL GENICULATE NUCLEUS (LGd) OF THE RHESUS MONKEY. Pasko Rakic, Dept. of Neuropathology, Harvard Med. Sch. and Dept. of Neuroscience, Children's Hospital Medical Center, Boston, Mass. 02115

Single eye enucleations were performed in two fetal monkeys exteriorized from the uterus at E63 (63rd embryonic day) and E91. The fetuses were replaced in utero and carried to full term (165 days). At 3 months of age, the remaining eye of each monkey was injected with a mixture of H^3-proline and H^3-fucose. Fourteen days later, the animals were fixed by perfusion and their brains processed for light microscopic, autoradiographic and electron microscopic analysis.

In the 3-month-old monkey in which one eye was enucleated at E63, the LGd is positioned normally and retains its usual size and "knee-like" shape, but it is totally devoid of layers. Therefore, the presence of retinal axons from both eyes around or after E63 may be essential for the development of LGd layers. In the 3-month-old monkey in which one eye was enucleated at E91, LGd is slightly smaller and discernible layers emerge only at the caudal pole of the nucleus. This incipient lamination is comparable to that attained in the fetus at the time of eye removal. Thus, even after being initiated, lamination does not proceed to completion if one eye is absent.

In each monkey, radioactive tracers are transported equally to both LGd's. In the animal enucleated at E63, grains are distributed uniformly over the entire nucleus; thus even neurons situated at the periphery, which normally receive input from the contralateral eye are surrounded by ipsilateral projections. Electron microscopy displays an abundance of retinal synapses in these areas which would normally be occupied by terminals from the enucleated eye. Thus, retinal axons form synapses with LGd neurons which they do not contact normally. In the monkey enucleated at E91, the presence of small, irregular and less densely labeled territories at the posterior moiety of the LGd suggests that the separation of fibers from the two eyes has stopped at the level achieved at the time one eye had been removed. Since projections from the two eyes initially overlap in the fetal monkey (Rakic, P., Nature, 1976, 261: 467) terminals from the remaining eye do not have to invade new neuronal territories. Rather, they may fail to retract to monocular domains.

On the basis of these experiments, it appears that both the development of laminae as well as the segregation of afferent connections in the primate LGd depend on prenatal competition between retinal projections from the two eyes.

1832 FUNCTIONAL ANALYSIS OF GO-NO GO RELATED (ATTENTION) UNITS IN THE ROSTRAL BRAINSTEM. Constance L. Ray* (SPON: Allan F. Mirsky). Div. Psychiatry, Sch. Med., Boston University, Boston, MA 02118

Bakay Pragay and Mirsky (Neurosci. Abstr. #1556, 1976) used the Evarts' method to analyze neuronal correlates of performance on a go-no go visual discrimination task. Using rhesus monkeys, most of the rostral brainstem was explored. The monkeys learned to press a 'hold' button for two seconds. Then, either a red or a green light appeared on another response button above the hold button. If the light was red (go), the monkey had to lift its hand from the hold button and press the upper response button within one second to receive a juice reward. If the light was green (no go), the animal was reinforced for continuing to hold for 1 second. Many of the task related units were related to parallel events in both types of trial, i.e. 1) the onset of the cue stimuli and 2) the offset of the cue stimuli/delivery of the reinforcers.

In this work these task related changes in firing rate were studied to determine their relation to 1) the physical sensory configuration of the event, 2) the behavioral significance of the event and 3) event-evoked eye movements. When a task related unit was detected, it was first recorded during the task. Then with the task off, a series of cue stimuli (stimulus only condition) and a series of juice reinforcers (reinforcement only condition) were presented separately to the animal. (The animal's responses in the stimulus only condition had been extinguished previously.) Stereotyped saccadic eye movements were monitored continuously with Beckman minature electrodes.

The units which displayed peri-stimulus on responses during the task differed in their responsiveness to the physically identical stimuli presented during the stimulus only condition. Some units (type A) continued to respond to the stimuli in both contexts, suggesting a relation to the physical qualities of the stimuli. Other units (type B) responded to the stimuli only during the task. The B units which tended to be found in non-visual areas may be related to the reward value of the event. The peri-reinforcement responses could be due to the offset of the stimuli or to the delivery of the reinforcers; these occur almost simultaneously. We have been able to identify whether a given response is due to one or both of these events.

Analysis of EOG as well as unit recordings from the oculomotor complex during task performance suggest that eye movement evoked changes seldom occur in parallel in both trials. In general task evoked saccades occur most regularly in the positive trial during the go response.

1833 A REDEFINITION OF PULVINAR SUBDIVISIONS IN THE MACAQUE MONKEY: EVIDENCE FOR THREE DISTINCT SUBREGIONS WITHIN CLASSICALLY DEFINED LATERAL PULVINAR. Michael Rezak and L. A. Benevento. College of Medicine, University of Illinois at the Medical Center, Chicago, Illinois 60680.

Traditionally the lateral pulvinar (PL) of the macaque thalamus has been considered a single anatomical and functional entity. Our previous and ongoing autoradiographic studies (Brain Res., '75; '76; '77 and Anat. Rec., '77) have shown that this traditional view is incorrect and that this may be a source of the discrepancies among recent anatomical reports. Thus, as a result of placing discrete microinjections (.1µl) of tritiated leucine and proline along the dorsal-ventral and rostral-caudal axes of classically defined PL of 15 macaque monkeys and observing the cortical projection targets we propose to redefine PL in terms of 3 subregions i.e., PL_α, PL_β, and PL_γ. PL_α forms a narrow band approximately 2-3mm wide surrounding the inferior pulvinar dorsally, ventrally and laterally. PL_α contains a precise map of the visual hemifield and projects this map to layers I-II of striate cortex and layers III, IV and I of prestriate cortex. PL_β lies dorsal to PL_α and has as its cortical target layers III, IV and I of the parietal lobe (areas 5 and 7) as well as dorsal portions of the temporal lobe. Finally, the lateral portion of the caudal pole of the pulvinar forms PL_γ and has as its cortical projection site layers III, IV and I of inferotemporal cortex (areas 20 and 21). Neither PL_β nor PL_γ project to striate cortex. Based on the results of injections of tritiated amino acids into occipital cortex we have found that all three subregions of PL receive input from these visual cortical areas, however, only PL_α receives an input which is clearly organized with respect to visual hemifield representation. In addition it should be noted that PL_β is the target of projections from retinorecipient portions of the pretectum (Brain Res., '77) thus forming an important link in visuomotor function. (Supported by NSF Grant BMS 75 07349)

1834 VISUAL RESPONSES DURING SACCADIC EYE MOVEMENT: A COROLLARY DISCHARGE TO SUPERIOR COLLICULUS. Barry J. Richmond and Robert H. Wurtz. Lab of Neurobiology, National Institute of Mental Health, Bethesda, Md. 20014

Some cells in the superficial layers of the monkey (Macaca mulatta) superior colliculus respond to rapid stimulus movement across the stationary receptive field but fail to respond when a saccadic eye movement sweeps the stimulus across the receptive field. The differentiation between real stimulus movement and self-induced stimulus movement resulting from the eye movement is not due to visual stimulation since it persists when the background light is reduced. In addition a suppression of discharge rate occurs following eye movements made in total darkness indicating that the suppression is not visual in origin (Robinson and Wurtz, 1976). To determine whether this extra-visual input was dependent on the movement of the eye (a proprioceptive input or mechanical shearing of the retina) or resulted from input from the oculomotor system (a corollary discharge) we paralyzed the eyes in two monkeys and used the suppression of the discharge rate during attempted spontaneous eye movements as an indicator of extra-retinal input. Retrobulbar injections of 1% xylocaine produced complete paralysis of extra-ocular movements lasting 15 to 20 minutes; no eye movement greater than 3 minutes of arc (the smallest we could resolve) was observed during the period of complete paralysis. Attempted eye movements by the monkey were indicated by integrated multiple unit activity recorded from a chronically implanted macroelectrode in the oculomotor nucleus. The discharge of 17 cells which showed the suppression of background discharge with normal eye movement continued to show the suppression during the complete paralysis. For several cells, the suppression was observed before, during, and after the period of paralysis. Since the suppression, and therefore the extra-retinal input, was just as pronounced when the proprioception and shearing factors were eliminated, the elimination of visual response must result from a potent corollary discharge to the monkey superior colliculus.

1835 FUNCTIONAL PROPERTIES OF POSTERIOR PARIETAL CORTEX OF THE MONKEY. I. SENSORY RESPONSES. David Lee Robinson and Michael E. Goldberg. Behavioral Sciences Department, Armed Forces Radiobiology Research Institute, Bethesda, Maryland 20014.

On the basis of clinical observations and experimental studies, posterior parietal cortex has been thought to associate information from the visual and somatosensory modalities with behavior, such as limb movements and eye movements. By recording from several hundred movement-related single neurons in areas 5 and 7 of three awake, trained monkeys, we have found that such cells respond to passive visual and/or somatosensory stimulation. In addition, the responses of some of these cells can be modulated by behavioral conditions which are the subject of the subsequent abstract.

Passive visual stimuli were presented while the monkey fixated a spot of light on a tangent screen; the animal was not required to make any movement toward the visual stimuli. Posterior parietal cells have very large receptive fields. These frequently include a whole visual quadrant; on occasion the fields include a whole hemifield and can be bilateral. These visual fields can include the fovea. Some cells have tonic responses to stimuli whereas other respond phasically; the activity of these cells during eye movement tasks is determined by these visual properties, i.e., tonic cells discharge during fixations and tracking eye movements, phasic cells discharge with saccadic eye movements. Parietal cells are not sensitive to the orientation of stationary stimuli. Most parietal cells respond very well to large stimuli and less well to small spots of light. The visual responses of these cells can be modulated by the intensity of the stimulus. Many cells respond equally well to all directions of stimulus movement although a subset of neurons are directionally selective.

Passive somatosensory stimuli were delivered while the animal sat quietly in his chair and could not see his limbs. Somatic receptive fields of posterior parietal neurons are similar to the visual receptive fields in that they are quite large. Somatic receptive fields frequently include whole limbs, either the forelimb or hindlimb. Some cells respond to passive somatosensory stimulation of the ipsilateral or contralateral limb while others respond best to simultaneous bilateral stimulation. Although many posterior parietal neurons are excited by somatic stimulation, some can have their spontaneous activity inhibited.

We believe that our data support the association hypothesis for the function of posterior parietal cortex, and we suggest that this area, in conjunction with other parts of the visual and somatosensory systems, helps to determine a sensory environment in which movement might be appropriate.

1836 THE SYNAPTIC ORGANIZATION OF TERMINALS TRACED FROM INDIVIDUAL LABELED RETINO-GENICULATE AXONS IN THE CAT. J.A. Robson* and C.A. Mason* (SPON: A.W. Clark). Dept. of Anatomy, Univ. of Wisconsin, Madison, WI 53706

The synaptic organization of different terminals of individual retino-geniculate axons labeled with horseradish peroxidase (HRP) was studied in the dorsal lateral geniculate nucleus. HRP was injected into the optic tract and the tissue was prepared as described by Mason and Robson (this volume). However, sections were not soaked in $CoCl_2$ since this appears to detract from the quality of tissue preservation. After the sections were incubated in diaminobenzidine, they were osmicated and embedded flat between plastic slides. Individual axons in lamina A were drawn with a camera lucida and 5µm sections were cut through the drawn axons. After the labeled axons in the 5µm sections were matched to the drawing, the sections were thin-sectioned. Ultrastructural examination revealed that labeled axons contain an electron-dense reaction product distributed throughout the cytoplasm. This reaction product tends to coat membranes and consequently, the cytoplasmic surfaces of synaptic vesicles and mitochondria are densely outlined. However, the synaptic vesicles are seen to be round and the mitochondria are pale with widely spaced cisternae. Specialized synaptic zones are also discernable and the labeled terminals have never been seen to be postsynaptic. Thus, all of the labeled terminals are classifiable as RLP-terminals, previously identified as arising from retino-geniculate axons. One of the most striking results of this study is the variation in the number of synaptic contacts made by different terminals of the same axon. That is, a terminal may be small and contact only a few process (1-3) while another terminal of the same axon may be large and contact many processes (20 or more). The largest terminals (7-10µm) are always the central process in a glomerulus containing numerous postsynaptic profiles. These profiles often indent the central, labeled terminal giving it a crenulated appearance also seen light microscopically (Mason and Robson, this volume). Smaller, intermediate sized terminals (3-7µm) often participate in glomeruli but may also form solitary contacts onto dendritic shafts. The smallest terminals (1-2µm) are round and are most often found to contact dendritic shafts outside glomeruli. Furthermore, several terminals from one axon may contact the same dendrite and a single dendritic stem may be contacted by some labeled and some unlabeled retino-geniculate terminals. This method provides a new way of identifying retino-geniculate axons and their terminals and demonstrates that a surprising number of these terminals form synaptic contacts outside of glomeruli. (Supported by USPHS Grants NS11869, NS06662 and NS05407).

1837 GENICULATE PROJECTIONS TO STRIATE CORTEX (AREA 17) IN THE SQUIRREL MONKEY AS DEMONSTRATED BY TRANSNEURONAL AUTORADIOGRAPHY. M. H. Rowe, M. Rezak and L. A. Benevento. College of Medicine, University of Illinois Medical Center, Chicago, Illinois 60680.

The pattern of geniculo-striate projections has been examined in the squirrel monkey by means of transsynaptic autoradiography, and compared to the patterns reported in certain other primates. 1 mCi of tritiated fucose and 1 mCi of tritiated proline were injected into the vitreous chamber of the left eye of one adult monkey. The animal survived 3 weeks and the brain sections were exposed to Kodak NTB-2 emulsion for 6 weeks. First-order grains were visible to the naked eye in the superior colliculus, pretectum and dorsal lateral geniculate nucleus (DLG). With the aid of darkfield microscopy second-order grains were readily apparent in structures such as the inferior pulvinar and striate cortex, presumably due to transsynaptic transport from the superior colliculus and DLG, respectively. No grains were apparent in area 18, suggesting that the DLG does not project to this cortical area. The grains in area 17 were seen only in layer IV and ended abruptly at the border between areas 17 and 18. In area 17, layer IV can be cytoarchitecturally subdivided (as in the macaque) into 3 sublayers i.e., IVa, IVb and IVc. In striate cortex of both hemispheres the grain density was highest in layer IVc. Both layer IVa and the lower half of IVb contained a moderate amount of grains, while the upper half of layer IVb was relatively free of grains. Thus, in this respect the laminar distribution of grains was essentially identical to that seen in the macaque monkey. However, at these survival and exposure times grains were apparently present throughout the horizontal extent of layer IV in both hemispheres. The only difference between the two striate cortices was that the overall density seemed slightly lower on the ipsilateral side. Although there were some horizontal variations in grain density apparent in layer IV on both sides, these variations did not seem to form any systematic pattern. Whether or not these variations represent a relatively undeveloped system of ocular dominance columns like those reported in the cat, is not yet clear. (Supported by NSF Grants BNS 75-07349 and 75-17890)

1838 RETINAL DEVELOPMENT IN THE LAMPREY, PETROMYZON MARINUS. K. Rubinson, H. Ripps, P. Witkovsky and M.C. Kennedy. Dept. Physiol. and Biophysics, NYU Sch. Med., Dept. Anat., SUNY at Stony Brook, and Dept. Biol., NYU, New York, NY 10016.

Morphological and physiological studies were conducted on retinas of larval and transforming sea lampreys. Electrical activity, spectral absorption measurements and tissue for electron microscopic observation were obtained from the same retinas.

In larvae less than 1 year old, the neural retina is divided into nuclear zones, but plexiform layers and short, receptoral outer segments are only visible in a small region surrounding the optic disc. Nevertheless, in these animals, no ERG can be recorded and absorbance spectroscopy fails to demonstrate the presence of any photolabile pigment. This appearance of the retina, compacted, yet differentiated centrally, is seen in larvae of all stages. It is connected with the brain and the central projections have been described.

At stage IV of transformation, outer segments and plexiform zones are seen throughout the retina. The photoreceptors are of 2 types, long and short, but both possess pedicle-like terminations as demonstrated by Golgi impregnation. The outer segments, throughout the retina, are longer than those of the larvae and contain well-ordered discs. All fully-impregnated bipolar cells possess Landoldt's clubs.

Stage V is similar to stage IV with a slight increase in outer segment length. ERG responses can be evoked, as they can be in stage IV, and absorbance spectroscopy of the isolated retina reveals the presence of a photolabile pigment whose absorption maximum is at 510 nanometers.

The inability to measure either photopigment or electrical responses in larval stages whose retinas possess substantial numbers of outer segments suggests that the presence of visual pigment is not essential to the maintenance of disc integrity.

1839 BRIEF PERIODS OF BINOCULAR PARALYSIS IN THE ADULT CAT PRODUCE REDUCTIONS IN ENCOUNTER RATES FOR SELECTED CELLS IN THE LATERAL GENICULATE NUCLEUS. W.L. Salinger, P.R. Wilkerson*, and M.G. MacAvoy*. Psych. Dept., Univ. N. Carolina, Greensboro, 27412.

Binocular paralysis produces substantial changes in the electrophysiology of the lateral geniculate nucleus (LGN) in the adult cat. These effects do not appear to arise from accidental surgical trauma, since in producing the paralysis, neither the orbit nor the meninges are penetrated, and the bone covering over the optic nerve and optic chiasm remained intact. The nature and time course of the effects of binocular paralysis therefore should reflect functional changes in the visual system.

To assess such functional change, single units were recorded from the LGNs of adult cats which had bilateral transections of cranial nerves III, IV, and VI for four days or less at the time of recording. The latency of response to optic chiasm shock (OX latency) was measured for each unit. Within four days following paralysis, the LGN contained significantly fewer cells with OX latencies in the X-cell range than is the case in normal animals.

This rapid change in the electrophysiology of the LGN after binocular paralysis may have parallels in the rapid "release" of cortical cells from the effects of monocular deprivation; produced in the adult either by ennucleation of the non-deprived eye, (Kratz, Spear, and Smith, J. Neurophys., 1976) or by the administration of bicculline or ammonium acetate (Duffy, Burchfiel, and Snodgrass, Neuroscience Abst., 1976). Whether or not these parallels obtain, the effects of binocular paralysis reaffirm that the organization of the adult visual system is extremely responsive to modifying environmental influences. Moreover, the extent of this continuing sensitivity exceeds what one would expect based on earlier work on sensitive periods for development and maintenance of orientation selectivity and ocular dominance properties of cortical cells.

1840 PYRAMIDAL CELLS IN THE OPTIC TECTUM OF A TURTLE, PSEUDEMYS SCRIPTA ELEGANS. P.B. Schechter and P.S. Ulinski. Departments of Ophthalmology and Anatomy, University of Chicago, Chicago, Ill. 60637.

Pyramidal cells are characteristic of the optic tecta of many nonmammalian vertebrates. They are likely to play an important role in the tectum's vertical organization, including integration of multisensory information, because their apical dendrites extend radially, often throughout the thickness of the tectum. Therefore, we have examined turtle pyramidal cells in detail in Golgi-Kopsch preparations. Pyramidal cells are positioned with their somas in the strata griseum periventriculare (SGP) and griseum centrale (SGC). Those in the SGP form several substrata, each one cell thick. Both sets of pyramidal cells have basal dendritic fields, and apical dendrites which terminate in the stratum opticum (SO). Although the apical dendrites of SGC pyramidal cells are shorter than those of SGP cells, both pass through the strata griseum et fibrosum superficiale and intersect retinal afferents. The apical dendrites of the two types of pyramidal cells do not differ systematically, but both vary in several ways. First, some dendrites are smooth and nearly appendage-free, others have elaborate specializations, and others bear many classic spines with thin necks and round heads. Second, some dendrites do not branch at all, others branch only once, and others have three or four branches. Finally, some dendrites end in SO with round enlargements, others have complex specializations similar to those present on some dendritic shafts, and others run parallel to the pial surface for 40 or 50 μ before terminating. In conclusion, pyramidal cells in SGP and SGC both receive retinal input, but those in SGP probably receive additional inputs on their somata and the proximal parts of their apical dendrites. The existence of morphological subcategories of cells in both strata implies the existence of still undetermined functional subcategories. (Supported by PHS grants EY 05134 and NS 12518.)

1841 DISTRIBUTION OF CELLS CONTAINING CYTOPLASMIC LAMINATED BODIES (CLB) IN THE LATERAL GENICULATE NUCLEUS OF THE CAT. M.L.Schmidt* (SPON: Helen Ghiradella). Biology Department, Union College, Schenectady, New York 12308.

The distribution of neurons containing CLBs was examined in the lateral geniculate nucleus (LGNd) and the perigeniculate nucleus (NPG) in adult cats. Formalin fixed, Paraplast embedded tissue, sectioned at 6mμ or 8mμ, was stained with Luxol fast blue and counterstained with Nissl stain. Neurons containing CLBs could be identified readily using this procedure. At present, over 10,000 cells have been counted of which approximately one third contained CLBs.

The distribution of cells in the LGNd which contained CLBs was found to be qualitatively, but not quantitatively, similar to that described previously (LeVay, S. & Ferster, D., J.Comp.Neurol. 172, 563-584, 1977): the highest proportions of cells containing CLBs were found in laminae A and A1 near the projection of the area centralis. Fewer neurons containing CLBs were found in the other layers (NIC,B) near the projection of the area centralis, however, significant numbers of cells containing CLBs were clearly present in these layers. The monocular segment of the LGNd was found to contain relatively more cells with CLBs than had been reported previously, perhaps only a few percent less than were found in the binocular segment of the LGNd. Cells containing CLBs were also present in the medial interlaminar nucleus (NIM) and in the NPG but in smaller numbers than in the laminated regions of the LGNd.

It was observed that the distribution of cells containing CLBs was not uniform in any regions of the structures that were studied: cells of this type were clustered together in groups of varying size. As a result, the variability in the proportion of cells containing CLBs is great, even between adjacent 300mμ wide segments of the same section. A precise quantitative description of the distribution of cells containing CLBs, thus, requires that large samples of cells be examined: the techniques used in this study make this a feasible undertaking.

Assuming that CLBs are present only in X-cells, then the proportions of neurons containing CLBs found in this study suggest that physiological sampling procedures are not adequate to determine the absolute proportions of different cell types. They may suffice, however, for determining relative distributions in regions of the nervous system. (Support provided by USPHS Research Grant RO1 EY-01268 to H.V.B.Hirsch)

1842 AFFERENT GEOMETRY IN THE PRIMATE VISUAL CORTEX AND THE GENERATION OF NEURONAL TRIGGER FEATURES. Eric L. Schwartz Brain Research, Dept. Psych., N.Y.U. Med. Sch. N.Y. 10016 N.Y.

The retinotopic mapping of the primate striate cortex may be mathematically represented by the complex logarithmic (conformal) mapping (1). The present work demonstrates that dendritic summation of an anisotropic cortical afferent input which recapitulates (on the scale of a cortical hypercolumn) the global retinotopic mapping, accounts for the existence of sequence regularity (1,3). Intra-cortical lateral inhibition may then flow uni-directionally, yet still create 'rotating' excitatory and inhibitory receptive field structure (3). The direction of this lateral inhibition operator is suggested to lie parallel to the boundaries of the ocular dominance slabs, (i.e. horizontally in the visual field). Since the left and right eye projections differ mainly in their horizontal component, this intra-cortical lateral inhibition would tend to enhance binocular disparity, at the cortical level. The fact that the left and right eye projections differ, in general, in their size and rotational aspects, is a serious problem for a putative role of cross -convolution in stereopsis; however, the complex logarithmic pre-processing of the visual scene provides a size and rotation invariant cortical image (1,3). This fact is discussed in the context of a spatial frequency model of stereopsis. The ocular dominance column boundaries are the approximate images, under the complex mapping log(z+1), of horizontal straight lines in the visual field. This map is regular at the fovea (z=0), is roughly linear for the central 1-2 degree's, and is essentially identical to the complex logarithm for the remainder of the field. The binocular trigger features of the primate cortex follow from the same geometrical model (3). The developmental plausability of this model is supported by noting that the 'smoothest' possible mapping of two arbitrary neural surfaces is represented by some conformal mapping which will depend entirely on the boundary conditions (shape) of the respective tissue surfaces. This is discussed in the context of the goldfish and the primate visual systems (2). The amount of genetic coding (and chemo-specificity) is minimized in this model. Finally, the fact that the local(3), global (1), and developmental (2) neurophysiology of the cortex may be succinctly described in terms of geometric function theory suggests that 'computational geometry',rather than 'neuronal feature extraction', may provide a workable paradigm for the study of visual information processing.

1843 EFFECTS OF BINOCULAR DEPRIVATION ON VISUAL DISCRIMINATION. Sheila A. Scoville*, John A. Jane, and Mary D. Guthrie . Depts. of Neurosurgery and Anatomy, University of Virginia School of Medicine, Charlottesville, VA 22901.

Considerable attention has recently been given to the effects of monocular and binocular visual deprivation. This study was undertaken to determine visual behavioral deficits in binocularly deprived rats. Hooded rats were chosen for the subjects of this experiment: Three were normal (NR), and four were binocularly deprived (BDR), one of which had a visual cortex ablation. Animals were tested for performance on flux and acuity. The subjects were water deprived and were tested by means of an apparatus in which animals viewed a closed circuit T.V. monitor, and were reinforced by a spurt of water for licking a tube beneath the appropriate stimulus pattern. The major deficit observed in the BDR's was that an increased number of trials was required to achieve criterion performance. The BDR with ablated cortex required significantly more trials to achieve criterion performance than either the NR's or BDR's. The battery of more refined stimuli in the present experiments give results that expand previous results obtained with less sensitive stimulus discrimination; i.e., only black versus white and only one set of horizontal versus vertical gratings. Recent electron microscopic studies of BDR cortex which quantifies abnormal intracortical connections, and confirms earlier light microscopic results, suggest a possible anatomical basis for the deficits. At least part of the difficulty in interpretation and comparison of the behavioral results between this and previous studies lies in differences between species and testing procedures. Nevertheless, consistent interpretations relating the behavioral and anatomical evidence can be made.

1844 DIRECTIONAL SELECTIVITY OF STRIATE NEURONS IN THE SIAMESE CAT. Michael S. Shansky* and Yuzo M. Chino*. Division of Visual Science, Illinois College of Optometry, Chicago, IL 60616. W.J. Pizzi. Dept. of Psychology, Northeastern Illinois University, Chicago, IL 60625. (SPON: D.I. Hamasaki)

Directional selectivity of cortical neurons in area 17 of Siamese cats was measured and compared to similar properties in normal domestic cats. After classifying cells as simple, complex, or hypercomplex, a rectangular stimulus was positioned (using a dove prism and X/Y positioner) over the receptive field and moved at various velocities via a mirror galvanometer driven by a function generator. The direction of movement was perpendicular to the stimulus orientation, which was varied over 180 degrees. Directional preference was determined by analyzing average response histograms accumulated by a PDP-11 computer. If the peak firing rate in the non-preferred direction was less than 20% of that in the preferred direction, a unit was classified as directionally selective (Goodwin and Henry, 1976). Our data indicate a reduction of directionally selective striate Siamese units compared to normal cats. This reduction is not exclusive to either simple or complex cells alone, and may reflect the lack of Y-cells in the Siamese cat retina (Chino, Shansky, and Hamasaki, 1977).

1845 REARRANGEMENT OF GENICULOCORTICAL AND CORTICOCORTICAL CONNECTIONS IN BOSTON SIAMESE CATS. Carla J. Shatz and Simon LeVay. Dept. of Neurobiology, Harvard Medical School, Boston, Mass. 02115.

In Siamese cats, a genetic mutation causes some fibers from the temporal half of each retina to cross erroneously in the chiasm and innervate lamina A1 of the opposite lateral geniculate nucleus (LGN). This misrouting is orderly, so that in each LGN corresponding positions in laminae A and A1 come to represent mirror-symmetric points in the contralateral and ipsilateral visual fields, but only in the contralateral eye.

How does this abnormal organization in the LGN affect the geniculocortical and intracortical connections in these animals? Previous physiological recordings from the visual cortex of the Boston variety of Siamese cat suggested that there is an orderly rearrangement in the geniculocortical projection (Hubel and Wiesel, 1971). Here, this rearrangement is examined anatomically by means of the retrograde transport of horseradish peroxidase (HRP) following an injection through a recording micropipette. In the common cat, an injection of HRP anywhere in the visual cortex labels LGN cells at a single locus in laminae A and A1. When HRP was injected at the 17-18 border in a Siamese cat, however, labeled cells were found only in lamina A1. Receptive fields recorded at the injection site were located in the ipsilateral visual field, roughly 20 degrees away from the vertical midline, indicating that this animal was a Boston cat. In another Boston cat, an injection was made at the cortical region representing the mirror-symmetric visual field position (20° into the contralateral field); labeled cells were found in LGN lamina A only. This pattern of HRP labeling confirmed the physiological results.

In view of this rearrangement, we next checked to see if intracortical connections were also rewired, by injecting tritiated proline at the 17-18 border. In 3 Boston Siamese cats, we found a projection from the border to the cortical regions within areas 17 and 18 on the same side which represent the mirror-symmetric visual field position (20° into the contralateral field). This projection was remarkable in two ways: it does not exist in the common cat, and it is functionally useless, since it links up cortical regions representing different (though mirror-symmetric) visual field positions in the same eye.

We conclude that the preservation of visual field continuity may be an important principle governing the formation of geniculocortical connections. Further, in the formation of corticocortical connections, neurons may seek out others in the same hemisphere which receive innervation from a common locus in the lateral geniculate nucleus.

1846 SOME IPSILATERAL VISUAL CONNECTIONS IN THE ALBINO RAT. C.L.Shen* and R.H.Baisden* (SPON: C.H.Anderson) Dept. of Anat., Univ. of Illinois Medical School, Chicago, Ill. 60680.

Early investigations using silver stains to selectively impregnate degenerating boutons indicated an ipsilateral projection into nuclei of the accessory optic fiber system (Nauta and VanStraaten,1947), however, more recent anterograde studies have not confirmed projections to these centers in a variety of mammalian species (e.g. Cavalcante, et al., 1975; Giolli, 1961; Heyhow, et al., 1960; Thorpe and Herbert, 1976). As part of a project concerning the effects of unilateral enucleation on projection patterns of the remaining eye, ^{3}H-Fucose was injected into the vitreous of the rt. eye of normal controls and 1 yr. old albino rats which had the left eye removed 4 mos. prior to injection. Animals were sacrificed 1 day post-injection in order to minimize transneuronal spread of the label. Analysis of the ipsilateral projections indicated an accumulation of silver grains over the Medial Terminal Nucleus (MTN) of the accessory optic fiber system. The grain density over the ipsilateral nucleus was not as great as over the contralateral nucleus,however, it appeared to be increased in unilaterally enucleated animals as compared to controls. No evidence for ipsilateral projections to other of the accessory optic nuclei was noted. It remains to be determined if this finding is indiginous to rodents or may be generalized to other mammalian species. These results will be discussed with respect to further findings concerning ipsilateral visual connections in mature rats enucleated either neonatally or as adults.

1847 THE CAT'S PARABIGEMINAL NUCLEUS: VISUAL FIELD TOPOGRAPHY AND CELL RESPONSE PROPERTIES. Helen Sherk. Dept. of Psychology, Massachusetts Institute of Technology, Cambridge, Mass. 02139.

The parabigeminal nucleus, a small midbrain cell group, is known to receive a dense input from the upper layers of the cat's superior colliculus. This nucleus was studied using single unit recording techniques to determine the response properties of its cells to visual stimuli, and the topographic organization of their receptive fields.

Cells in the parabigeminal nucleus were found to respond vigorously and consistently to visual stimuli. Their properties, studied quantitatively with a computer-driven optical system, appeared to be similar to those of cells of upper collicular layers, the most notable difference being the high rate of spontaneous firing common among parabigeminal cells. The population as a whole was dominated by the contralateral eye, although, as in the superior colliculus, many cells were driven equally well by both eyes. Receptive fields were, on the average, larger than those found in superficial colliculus: within 10 deg of the area centralis the mean receptive field diameter was 2.3 deg, and for fields lying 10-20 deg from the area centralis, the mean diameter was 4.4 deg. Inhibitory surrounds similar to those of collicular neurons depressed the responses of most cells to large stimuli. The majority of parabigeminal neurons responded briskly to stationary as well as moving stimuli, and such responses tended to be quite transient. Most cells responded preferentially to a particular axis or direction of stimulus movement, and there was a tendency for the optimal axis to coincide with the meridian through the cell's receptive field and the cat's fixation point on the tangent screen.

The topography of the visual field formed by parabigeminal cell receptive fields was surprisingly orderly for so small a structure. The entire extent of the visual field represented in the superior colliculus also appeared to be represented in this nucleus. Horizontal movement from ipsilateral visual fields to the contralateral periphery coincided approximately with the rostro-caudal axis of the nucleus. Movement from upper to lower visual fields corresponded to progression from dorsolateral to ventromedial in the parabigeminal nucleus.

Preliminary recording in the pargbigeminal nucleus of the monkey (Macaca mulatta) indicates that cell response properties are similar in this animal, except that cells selective for the axis or direction of stimulus movement have not been found. An orderly map of the visual field also appears to exist in the monkey's parabigeminal nucleus.

1848 DEOXYGLUCOSE MAPPING OF THE ORIENTATION COLUMN SYSTEM IN THE STRIATE CORTEX OF THE TREE SHREW (Tupaia glis). L.C. Skeen, A. L. Humphrey, T.T. Norton and W.C. Hall. Departments of Anatomy, Psychology and Physiology, Duke University, Durham, N.C. 27710.

Electrophysiological studies of the striate cortex in tree shrews have revealed a columnar system tuned for optimal stimulus orientation which is similar to that reported for cats and monkeys. To better visualize the topographic organization of this system, we employed an autoradiographic method for localizing stimulus-induced alterations in cerebral deoxyglucose consumption (Science, 187: 850, '75). Paralyzed tree shrews were given i.v. injections of tracer ^{14}[C]-2-deoxy-D-glucose (250μCi/kg) and monocularly exposed to a moving pattern of vertically oriented black and white stripes for 45-70 min. Their brains were subsequently processed for x-ray film autoradiography.

Autoradiographs of coronal sections contralateral to the stimulated eye revealed two patterns of increased deoxygluxose consumption in the striate cortex: 1) a continuous, horizontal strip of increased optical density restricted to layer IV, and 2) alternating radial zones of high and low optical density running through the cortical laminae perpendicular to the pial surface. The radial zones of increased optical density are approximately 150-200μm wide and probably reflect the increased activity not only of cells which responded maximally to the vertically oriented stimuli, but also that of adjacent cells having slightly different "preferred" orientations which responded at reduced rates to these stimuli. Serial reconstructions of these zones produced a map of continuous, albeit wavy, iso-orientation lines which are arranged roughly parallel to one another. They are restricted to the striate cortex and intersect its lateral border.

As suggested by previous anatomical and electrophysiological studies, these experimentally-induced radial zones of increased deoxyglucose consumption are not artifacts of monocular stimulation. They are present in identical form in the striate cortex of awake, unrestrained tree shrews which viewed vertically oriented stimuli either monocularly or binocularly, and they are not present in animals monocularly stimulated with lines of many orientations. These results reveal the topographic relationships of iso-orientation lines in the striate cortex of Tupaia. They also allow predictions concerning the organization of the stimulus orientation system which can be further examined with electrophysiological methods (see abstract by Humphrey et. al., these meetings). 1849 TEXTURE VIEWING, DURING DEVELOPMENT IN KITTENS, MODIFIES THE FUNCTIONAL PROPERTIES OF SINGLE CELLS IN VISUAL CORTEX. D.N. Spinelli, Dept. of Psychology and Computer Science, Univ. of Mass., Amherst, MA 01003.

Natural scenes present the visual system with information consisting of colors, edges and textures. In the cat's visual cortex Hubel and Wiesel have discovered cells that are especially sensitive to lines and edges of specific orientations. Hirsh and Spinelli have shown that if kittens are raised while viewing discordant lines with the two eyes, e.g. vertical and horizontal, binocularity of cells, in area 17, is lost and that cells with sharply tuned receptive fields have only vertically or horizontally elongated receptive fields, that can be mapped only through the eye that saw vertical or horizontal lines respectively. This powerful method can then help to answer the question of how the visual system detects textures, i.e. by first analyzing the microstructure of the texture or by processing it as an elementary feature. To this end kittens were raised in a dark room and exposed daily through their critical period for four hours, to two textures which were viewed through goggles. The two textures had identical microstructure, but appeared macroscopically quite different. The expectation was that, if the visual system first analyzes the microstructure, binocularity of cells in area 17 should not be lost and that receptive fields should be sharply tuned to the orientation of the microstructure; conversely if textures are analyzed as elementary features then binocularity should be lost and the receptive fields should not be sharply tuned. The results show that, in these kittens, cells in area 17 have lost binocularity and that the receptive fields exhibit the properties of complex receptive fields. Simple cells were not found. The implications that these findings have for visual perception and pattern recognition will be discussed.

1850 ENERGY, QUANTA AND VISION IN DROSOPHILA. William S. Stark, Robert M. Greenberg*, and Austina M. Ivanyshyn*. Department of Psychology, Johns Hopkins Univ., Baltimore, MD 21218

Drosophila eyes have 750 facets with 8 photoreceptors each. RI-6 are 6 cells/facet with peripheral rhodopsin-containing rhabdomeres. Cyclindrical rhabdomeres have packed microvilli and are ∿ 200μ by 1.5μ (diameter). Microvilli are ∿ .05μ (diameter). We calculate (1) rhodopsin optical density (OD) in vivo, (2) electroretinographic (ERG) and phototactic quantal thresholds, and (3) rhodopsin conversion adaptation intensity.

Microvilli have ∿ 4217 freeze-fracture bumps/μ^2; vitamin A deprived flies have $\frac{1}{4}$ this count (Harris, Ready, Lipson, Huspeth and Stark, Nature 266, 648, 1977). Thus, most or all bumps in controls are rhodopsin molecules. There are up to 990 molecules/microvillus=8.3×10^{7} molecules/rhabdomere=3.94×10^{-4} moles/liter. Substituting length and extinction for rhodopsin conversion at the 470nm absorption and sensitivity peak (3.3×10^{4} cm^2/mole, Harris, Stark and Walker, J. Physiol., 256, 415, 1976), OD=.26; 45% of incident light is absorbed. This density is higher than for human rods (Hecht, Schlaer and Pirenne, J. gen. Physiol., 25, 819, 1942), but rhabdomeres are longer. Other data and observations support a high OD, which causes a slight flattening of spectral sensitivity near the peak. In vitro (Harris et al.) and computed (from extinction and in vivo concentration) Δ OD's for rhodopsin conversion agree.

Drosophila ERG's are as large as 30mV. As few as 10^{10} quanta/cm^2·s or 80 quanta absorbed/rhabdomere·s elicit a 3mV receptor potential at 470nm. The absolute ERG threshold can be 2.5 log units lower for <1s, i.e., less than 1 quantum absorbed/receptor. RI-6 phototaxis thresholds are also low, about 10^{10} quanta/cm^2·s (from Schümperli, J. comp. Physiol., 86, 77, 1973). To convert half the rhodopsin with 470nm, 9.32×10^{7} incident quanta/rhabdomere =5.26×10^{15} quanta/cm^2 would be required. This agrees with physiologically assayed values (e.g., Stark and Zitzmann, J. comp. Physiol. 105, 15, 1976; Harris and Stark, J. gen. Physiol., 69, 261, 1977). Despite rhodopsin level differences, control vs. vitamin A deprived Drosophila should require similar adaptation levels for a half sensitivity decrease as was reported by Harris and Stark (1977).

Thus: rhabdomeric OD is high, ≥45%; ERG threshold is low, <1 absorbed quantum/rhabdomere; intensities ∿ 8 log units above ERG threshold elicit substantial rhodopsin conversions.

1851 NOCICEPTIVE REPRESENTATION IN THE SUPERIOR COLLICULUS. Barry E. Stein and James Dixon* Dept. Physiology, Medical College of Virginia, Richmond, VA 23298.

Visual, somatic and acoustic representations in the hamster superior colliculus (SC) were studied with single-unit recordings. All animals (n=26) were anesthetized with urethane, and in selected experiments animals were also paralyzed with gallamine triethiodide and artificially respired. The upper layers of the SC (stratum opticum and above) contained cells activated only by visual stimuli. Deeper laminae, however, contained cells which were excited by visual, somatic or acoustic stimuli alone (unimodal), as well as individual cells which responded to more than one sensory modality (multimodal). A topographical register between visual and somatic representations was also noted.

Of the forty-six deeper laminae somatic cells studied, twenty-three responded either optimally (nonspecific nociceptor = 12/23) or solely (specific nociceptor = 11/23) to such stimuli as noxious pinch, pin-prick and/or elevation of skin temperature > 45° C. An additional twenty-four (of 39 somatic cells) cells found in adjacent tissue (subjacent tegmentum and central gray) had nociceptive properties similar to those of cells within the SC. Many nonspecific nociceptors also had low threshold mechanoreceptor properties, with the nociceptive and the low threshold receptive fields partially separated. Responses to nociceptive stimuli were blocked by etorphine (.1 mg/kg) and reinstated by naloxone (1 mg/kg) in both specific and nonspecific nociceptors. A few SC cells were also found which could be activated by both nociceptive and visual stimuli. In one cell tested, etorphine selectively blocked responses to nociceptive stimuli (responses were later reinstated by naloxone), but was without effect upon responses to visual stimuli.

The presence of nociceptive representation in the SC may account for the aversive effects of intense, yet localized, electrical stimulation of this structure in awake cats and humans. In addition, the loss of this representation may contribute to the deficits in localizing noxious stimuli which are induced by SC lesions.

1852 ORIENTATION COLUMNS IN THE CAT'S VISUAL CORTEX M.P. Stryker, D.H. Hubel, & T.N. Wiesel Dept. Neurobiology, Harvard Medical School, Boston, Massachusetts 02115

The cells of the cat's primary visual cortex are arranged into columns according to the orientation of the bar or edge stimulus which drives the cells optimally; these columns are arranged so that preferred orientation changes gradually and progressively across the cortical surface (Hubel & Wiesel, J. Physiol. 165:559, 1963, & J. Comp. Neur. 158:267,1974). To demonstrate the shape and arrangement of the orientation columns, we used Sokoloff's histochemical method for determining local cerebral glucose uptake (Kennedy et. al., Proc. Natl. Acad. Sci. USA 73:4230,1976). One would expect when the cortex is stimulated binocularly by contours of only one orientation to see a distribution of activity which is columnar in cross section and consists of swirly or parallel bands in tangential section.

The eyes of a prarlyzed, anesthetized cat were aligned on a point in the plane of a pattern of moving vertical stripes. ^{14}C-2-Deoxyglucose was injected intravenously and visual stimulation continued for 50 to 90 minutes. Autoradiograms showed bands of label over most of areas 17 and 18. In cross section, these orientation columns were seen to extend through all layers of the cortex, with the probable exception of layer I. Density of the label was greatest, however, below and just above layer IV. Consistent with physiological differences between monkey and cat, the bands were visible in the cat's layer IVc, unlike the monkey in which this layer is labelled uniformly (W, H & S, this meeting). The mean spacing between the iso-orientation bands was 870 μm ± 70 μm SD. The pattern of these bands was irregular and sometimes discontinuous near the crest of the lateral gyrus but formed less swirled, almost parallel stripes on the medial bank of this gyrus and on the tentorial surface of area 17. In the three hemispheres examined there was a common tendency for these bands to run generally from posterior-dorsal to anterior-ventral over the greatest part of the medial bank.

1853 NEW ASPECTS OF SPATIO-TEMPORAL ORGANIZATION OF GANGLION CELLS. V. G. Sutija. U. of Miami, Miami, FL 33152.

Recordings were made extracellularly from optic tract fibers of cats with lacquer coated tungsten electrodes in a conventional set-up. Isolated units were classified into on-center and off-center, and then segregated into X and Y using linearity of spatial summation criteria. A 3 degree bipartite field of continually reversing contrast at mesopic adaptation level was used for that purpose. A 1 degree spot of light, frequency and amplitude modulated, was then positioned over the receptive field (RF) center, while the periphery received steady light of low luminance. On-center and off-center X cells responded similarly to the reversed contrast stimulus, with a pattern of responses that were mirror images of each other. Both subgroups had a null position, showing linear spatial summation, and a sustained pattern of responses at positions on either side of the null.

In the processing of time-varying stimulation, there were evident difference. Although both subgroups responded with a spike discharge that was sinusoidally modulated in response to sinusoidally modulated light, when firing rates were plotted against stimulus frequency for each modulation depth and constant average luminance, the on-center X had overall higher firing rates at all contrast levels, higher peak frequency, higher cut-off frequency and less attenuation at low frequencies, than the off-center X. The differences were statistically significant. Also off-center X had a typically higher spontaneous discharge rates at same adaptation levels and their RF centers were larger on the average at corresponding retinal locations.

The findings are consistent with recent morphological evidence (Famiglietti and Kolb, Sci., 194:193; Nelson et al., Invest.Ophthalm. 15:946) showing different anatomical pathways for on-center and off-center ganglion cells, strongly suggesting that the less direct off-center pathway is rod derived, while the more direct on-center pathway is cone derived. In cat, both, rod and cone inputs are always mixed, which makes it very difficult to separate the scotopic from photopic sensitivities. The difficulty might be resolved, if different time constants of the off- and on-center systems are also taken into account.

1854 PHOTON COUNTING AND ENERGY DETECTION: THE EXPERIMENT OF HECHT, SHLAER, AND PIRENNE REVISITED. Malvin Carl Teich and Paul R. Prucnal*. Columbia University, New York, NY 10027.

Following the work of Hecht, Shlaer, and Pirenne in 1942, it has been widely assumed in the vision literature that the photon counting distribution of thermal light is Poisson. We indicate that the correct statistical distribution of photons is negative binomial, which reduces to the Poisson under certain conditions, such as those used by Hecht, Shlaer, and Pirenne. Under other conditions, however, the negative binomial reduces to the Bose-Einstein which is quite different in character from the Poisson.

Using signal detection theory, we obtain the optimum processor for an arbitrary photon counting distribution (a wide class of noise counting distributions will do). For a specified decision criterion (e.g., Neyman-Pearson), it is found that the simple counting processor, forming a comparison against a stored threshold count, is optimum. This is identical to the energy detection scheme proposed by McGill in 1967 for the processing of neural counts in audition. The optimum test is simple; it is the antithesis of complex information processing in which the observer is thought to abandon threshold ideas and sense likelihood ratios.

We present probability of detection curves for the specific case of generalized thermal light and show that they can differ substantially from the Poisson case. Even in the Poisson limit of the negative binomial photon counting distribution, these curves are not identical to those used by Hecht, Shlaer, and Pirenne because of the presence of noise, which manifests itself most directly in the non-zero experimental false-alarm rate. However, the curves we derive in the Poisson limit may not be distinguishable from those used by Hecht, Shlaer, and Pirenne within the accuracy of current experiments.

1855 UPTAKE OF NEUROTRANSMITTERS BY SYNAPTOSOMAL FRACTIONS FROM RETINA. Thomas, T.N., and Redburn, D.A., Dept. of Neurobiology and Anatomy, Univ. Tex. Med. Sch., Houston, Tex. 77025.

Rabbit retina were homogenized in isotonic sucrose and subjected to differential centrifugation. Low speed centrifugation (800g for 10 min) produced a P_1 fraction containing the photoreceptor cell synaptosomes (PCS). A P_2 fraction was obtained by centrifuging the resultant supernatant at 25,000g for 12 min. The P_2 fraction contained many small, conventional synaptosomes. Analytical electron microscopic techniques (C. Cotman and D. Lansburg, 1970, Br. Res. 22:152) were used to evaluate the purity of various retina fractions. The large photoreceptor cell synaptosomes (3-4 μ diameter) showed invaginations into which processes from horizontal and bipolar cells normally project. Also the PCS exhibited the characteristic synaptic ribbon.

The uptake of putative neurotransmitters dopamine, glutamic acid and aspartic acid was studied in the retinal fractions. All three transmitters showed high affinity uptake which was temperature dependent and saturable. The P_2 fraction showed the highest rate of uptake. The P_1 fraction had very little dopamine uptake, whereas the aspartic acid uptake was relatively high. Kinetic analysis of the data showed that the Km for retinal uptake is consierably lower than that of the brain.

	Km (μM)		
Fraction	Dopamine	Aspartic Acid	Glutamic Acid
Homogenate	3.35	3.36	2.52
P_1	0.15	0.94	0.51
P_2	0.96	1.70	0.86

Fractionation of retina thus yields two morphologically distinct populations of synaptosomes derived from different cell types. The fractions also showed differences in uptake patterns. Studies are underway to further characterize the uptake systems in order to identify and localize the functional neurotransmitter of the retina. Supported by USPH Grant EYO 1655-02 (DAR) and NIH Training Grant E4-07024-02 (TNT).

1856 HARDWARE SIMULATION OF CONE CELL PHOTORESPONSES. S. Vallerga*, R. Covacci*, F.W. Pottala* (SPON: M.G.F.Fuortes). NIH, Bethesda, MD, 20014.

It is well known that the vertebrate photoreceptors are connected by complex synaptic endings to both horizontal and bipolar cells, and that the horizontal and bipolar cells synapse onto one another. However, the anatomy of the retina does not reveal the direction and the polarity of the synapses. These characteristics must be inferred from the membrane potential changes recorded when the photoreceptors are stimulated by different light patterns (e.g. flashes, steps, flashes on steps, etc.).

A hardware modeling system of a limited portion of the retina could be helpful in making these inferences about the actual features of the retinal synapses.

For this purpose a hardware model of a cone cell has been designed and fabricated according to the Baylor - Hodgkin - Lamb theoretical model (J.Physiol. 242, 685-791, 1974). The model parameters have been adjusted to best fit the actual photoresponses recorded intracellularly from cones in the retina of the larval tiger salamander (Ambystoma tigrinum tigrinum, and Ambystoma tigrinum mavortium). Stimuli consisted of flashes and steps of light. The responses of the model and the real cone were matched visually and were in good agreement for 10 msec. flashes and 0.7 sec. steps of light whose intensities ranged over 2.5 log units with the intensity of the unattenuated light $1.5 * 10^{17}$ photons/sec * cm^2.

This model cone is the first step of a project involving the design and fabrication of hardware models of the retinal photoreceptor cells and second order neurons, namely the horizontal and bipolar cells. A simple network of retinal cells (10 to 12 hardware models) driven by a minicomputer should permit a fast test of all the possible synaptic connections, thus enabling us to choose the configuration more likely responsible for the observed photoresponse, and eventually design the proper electrophysiological experiment to verify it.

The project has been undertaken jointly by the Laboratory of Neurophysiology, NINCDS and the Laboratory of Applied Studies, DCRT at NIH.

1857 PLASTICITY OF PRESYNAPTIC PROTEINS IN THE RABBIT VISUAL SYSTEM. John A. Wagner*, Amy Schick Kelly* and Regis B. Kelly. Dept. Biochem., U. Cal., San Francisco, CA 94143, and Dept. Neurol., Stanford Med. Sch., Stanford, CA 94305.

We have developed a procedure that allows us to identify specific proteins in presynaptic nerve terminals, and have used it to study the presynaptic proteins appearing in the lateral geniculate nucleus (LGN) and superior colliculus (SC) of the rabbit. ^{35}Proteins were labelled by making use of axonal transport. ^{35}S-Methionine was injected into the eye. Animals were sacrificed after 36-48 hours, and the LGN, SC and optic chiasm were quickly removed and homogenized. The proteins in these tissues were then analyzed by two-dimensional gel electrophoresis. This procedure, which separates proteins on the basis of both molecular weight and isoelectric point, is capable of resolving more than a thousand protein species. Autoradiography of the gels allows labelled nerve terminal proteins to be identified even though such proteins are a small fraction of the total proteins in the regions examined. Control experiments showed that at least 90% of the radioactivity in the LGN, SC and optic chiasm is due to transported proteins.

Analysis of the two-dimensional gels from normal rabbits demonstrates that at least 160 proteins are transported to the nerve terminals in the LGN and SC. Although the majority of these proteins are transported to both, there is a small set of proteins that is transported only to the LGN and a second small set of proteins which is found only in the SC.

Visual deprivation has been shown to cause electrophysiological changes in the LGN and SC of rabbits. We sutured the eyelids of young rabbits before eye opening, and injected ^{35}S-methionine into the deprived eyes at 35 days of age. Normally open eyes of littermates were injected as controls. The results showed that visual deprivation prevents the synthesis of a single protein of the approximately 160 which are transported to both the LGN and SC of the normal rabbit. Because this protein is found in the optic chiasm of animals that have been visually deprived, we believe that this protein is a component of the nerve terminal, and not a postsynaptic protein. This protein is not present in adult animals, and thus appears to be expressed only transiently during the development of the visual system.

In summary, we have demonstrated that this type of analysis has the capability of providing an insight into the biochemical basis of the development and modification of the visual system, as well as other neural pathways. Supported by NIH grant NS09878. JAW is an NIH Postdoctoral Fellow (NS05092).

1858 A RETINOTOPIC MAP OF MOUSE EXTRASTRIATE VISUAL CORTEX. Earl Wagor, Nancy Mangini* and Alan L. Pearlman. Dept. Physiol. and Neurol., Washington Univ. Med. Sch., St. Louis, MO 63110.

Retinotopic maps of area 17 and the visual cortex surrounding it laterally and rostrally (area 18a) have been constructed for the C57BL/6J mouse using electrophysiological mapping techniques. Area 17 contains a complete representation of the visual field, with the nasal field located laterally and the upper field representation located caudally. In area 17, lines representing elevation and azimuth of the receptive field positions are everywhere approximately orthogonal, with azimuth lines running from rostromedial to caudolateral and elevation lines running from caudomedial to rostrolateral. At least two additional representations of the visual field are located in area 18a. These extrastriate visual representations are not simple mirror images of the area 17 map. In 18a, the azimuth and elevation lines are represented on the cortex in a complicated manner, and in several places are not orthogonal. The azimuth lines of 18a run roughly parallel to the line of the vertical meridian, which demarcates the lateral boundary of areas 17 and 18a. The lines of elevation, although parallel within area 17, diverge into two groups as they pass from 17 to 18a. One group consists of the lines representing elevations higher than 25° above the horizontal meridian, and the other group consists of the lower elevation lines. In area 17 the upper elevation lines are located caudally. As they pass over the 17-18a border, they curve around to head in a caudolateral direction and provide a representation of the upper part of the visual field in the most caudal 1/3 of 18a. The lines of elevation representing the lower part of the visual field are located in the more rostral and medial parts of area 17. As they pass over the 17-18a border, they turn to run in a rostromedial direction, and provide a representation of the middle and lower visual field located in the part of 18a rostral to 17. Together these two subareas provide a complete representation of the visual field. An additional complete representation of the visual field is found in the rostrolateral portion of 18a. Elevation lines located at 20° and at 30° above the horizontal meridian delineate areas of special functional significance. The cortical areas that represent the nasal visual field 20° to 30° above the horizontal meridian are expanded in both area 17 and in some regions of 18a, and one such expanded area overlaps the vertical meridian in a manner reminiscent of the expanded foveal representations found in other species. In addition, the 20° to 30° division can be effectively used to demarcate subregions of 18a, much as the horizontal meridian figures importantly in the demarcation of the boundaries of visual areas in other species. (Supported by NIH research grant EY 00621)

1859 EFFECTS OF LARGE INTEROCULAR ROTATIONAL DISPARITIES ON THE DEVELOPMENT OF BINOCULARITY IN KITTEN VISUAL CORTICAL NEURONS. Ida M. Washington*, Michael R. Isley* and Paul G. Shinkman. Univ. North Carolina, Chapel Hill, N.C. 27514.

In a recent report (Shinkman & Bruce, Science, 1977) we showed that when kittens' early visual experience consisted of left- and right-eye visual fields optically rotated in opposite directions about the visual axes (8° of rotation in each eye, giving 16° of net torsional disparity between the two eyes), the distribution of interocular differences in visual cortical cells' preferred stimulus orientations was found subsequently to be centered about the rotation experienced during early development.

The present experiment was designed as a first step towards testing the limits of plasticity in the development of interocular matching of receptive-field orientations. Awake kittens were placed in a restraining device while viewing black-white gratings that moved back and forth over the entire visual field. Each eye was exposed to a variety of grating orientations and speeds of movement, but the orientation of the gratings differed by a constant amount between the two eyes, either 45° (experimental condition) or 0° (control condition). Kittens received six 4-hr. exposures between the ages of 28-53 days. Subsequently, receptive-field organization of visual cortex was studied by conventional means.

The 45° disparity condition differed from the 0° disparity condition in three principal ways: (1) the proportion of binocular cells was significantly less in the 45° condition (58%) than in the 0° condition (79%); (2) among binocular cells, the proportion exhibiting orientation specificity in both eyes (strongly binocular) was significantly less in the 45° condition (65%) than in the 0° condition (97%); and (3) among strongly binocular cells, the variance of the distribution of interocular differences in preferred orientation was significantly greater in the 45° condition than in the 0° condition ($F = 28.24$, $p < .001$). The mean interocular difference in preferred orientation matched the kittens' experience in the 0° condition ($\bar{X} = 1.2°$) but not in the 45° condition ($\bar{X} = 13.5°$). These results are interpreted as reflecting a general disruption of binocularity produced by early visual experience in which the inputs to the two eyes have 45° of interocular rotational disparity about the visual axes.

1860 CONNECTIONS OF THE LATERAL GENICULATE NUCLEUS (LGN) OF THE SQUIRREL MONKEY. J.T. Weber, J.H. Kaas, M.F. Huerta*, and J.K. Harting. Dept. of Anat., Univ. of Wis., Madison, 53706 and Dept. of Psych., Vanderbilt Univ., Nashville, Tenn. 37232.

The LGN of Saimiri consists of three pairs of layers, a dorsal parvocellular, a ventral magnocellular and a ventral, more poorly developed S pair. Following injections of ^{3}H-proline into one eye, label fills the dorsal parvocellular, the ventral magnocellular and the more dorsal S layer contralaterally, and the three remaining layers ipsilaterally. Label is also present bilaterally within the interlaminar zone between the magnocellular and the parvocellular layers.

Following injections of ^{3}H-proline into the superior colliculus, label is present within (1) the S layers, (2) the interlaminar zone between the two magnocellular layers, and (3) the interlaminar zone between the magnocellular and parvocellular layers.

The organization of geniculocortical projections has also been analyzed. Transsynaptic transport (TTP) studies reveal that the distribution of label is similar within both hemispheres. A dense, continuous band fills layer IV and the adjacent portion of layer IIIc, with the density being greater within layer IV. A second, much thinner band of label lies within the ventral portion of layer IIIb. Sparse label was also apparent within layers IIIa, II and I and labeled axons were present within layers V and VI. No type of ocular segregation, either vertical or horizontal in orientation, is evident in the TTP experiments.

Injections of ^{3}H-proline which involve all layers of the LGN result in a pattern of cortical labeling which differs from that present in the TTP experiments. First, label within layer IV is fine grain in appearance and evenly distributed, while that in layer IIIc appears to outline the individual fiber elements of a course plexus. Second, puffs of transported protein are present within layer IIIb immediately dorsal to the thin band within ventral IIIb. Following injections of only the parvocellular layers, label fills layer IV but not IIIc. A thin band is apparent in IIIb, but no puffs are present within the dorsal regions of IIIb. 1861 EVIDENCE FOR SELECTIVE LOSS OF X-CELL INPUT TO THE DORSAL LATERAL GENICULATE NUCLEUS OF MONKEYS WITH LONG-TERM ABLATIONS OF STRIATE CORTEX. R. E. Weller* and J. H. Kaas. Depts. Psych. and Anat., Vanderbilt Univ., Nashville, TN 37240

Retinal projections were studied autoradiographically with H^3-proline injections in two adult macaque monkeys in which most of striate cortex had been removed soon after birth. As a result of the cortical lesions, most portions of the lateral geniculate nuclei (LGN) were severely degenerated. Yet, small marginal sectors of each LGN were preserved reflecting regions of intact striate cortex. Thus, we were able to compare intact and degenerated portions of the LGN for concentrations of silver grains indicative of retinal terminations. The dense deposits of silver grains were in distinct laminar patterns. In the intact portions of the LGN, and in some of the degenerated geniculate layers, the laminar distribution of input appeared to be normal. For each magnocellular layer, label continued as an equally dense band from the intact segments across the degenerated segments of the LGN. Thus, the distribution of silver grains was not greatly affected by almost total neuronal loss. Similarly, in the degenerated portions of the LGN, silver grains reflect a normal pattern of input to a thin superficial layer, S, located between the external magnocellular layer and the optic tract. This suggests that S layer input does not depend on the presence of LGN neurons. Other input to the degenerated segments of the LGN was to the interlaminar zones. In contrast to the above regions of the LGN, the distribution of silver grains in parvocellular layers differed greatly between the intact and degenerated segments. At the junction of the parvocellular layers with the degenerated zone, the concentration of silver grains dropped off sharply. However, a thin scattering of silver grains extended the laminar pattern into the degenerated segments for a short distance. The remaining portions of the degenerated parvocellular region were free of input except for narrow concentrated bands of silver grains in some sections that may represent interlaminar input. Thus, the pattern of input to the parvocellular layers was severely disrupted by the loss of LGN neurons, while input to other regions was not. Since electrophysiological experiments indicate that X-cell retinal input is to the parvocellular layers, the results suggest a selective loss of these neurons from the retina. Indeed, examination of sections from one retina indicate a substantial loss of ganglion cells in agreement with previous studies of ganglion cell distribution after long-term cortical lesions.

1862 UNUSUAL BIPOLAR-RECEPTOR CONTACTS IN THE GRAY SQUIRREL RETINA R.W. West. Dept. of Psychology, Memorial Univ. of Newfoundland, St. John's, Newfoundland, Canada

Previous research on mammalian retinas has shown that bipolar cells contact receptor terminals in one of two ways--as simple "flat" contacts which have little junctional specialization other than a prominent presynaptic thickening or as participants in a synaptic complex which includes a ribbon-like organelle in the receptor cytoplasm. Golgi-EM of the cat and primate retinas has shown that the bipolars make exclusively flat or ribbon-related contacts only onto cones or exclusively ribbon-related contacts only onto rods.

Golgi-EM of the gray squirrel retina now shows that this pattern is not universal among the mammals. While the gray squirrel bipolar cells also make flat and ribbon-related receptor contacts, two out of five bipolar subtypes do so in an unusual way. One bipolar cell subtype, which contacts rods exclusively, simultaneously makes flat as well as ribbon-related junctions. The unusual flat junctions may be identical to those previously described in the squirrel retinas as prominent presynaptic thickenings on rod terminals. A second unusual bipolar subtype, which makes flat contacts onto cones, makes a small number of flat contacts onto rods as well. The presence of these unusual bipolar-receptor contacts may be related to the many cone-like morphological and physiological features which characterize the squirrel rods.

1863 ORIENTATION COLUMNS IN MONKEY STRIATE CORTEX AND THEIR RELATIONSHIP TO OCULAR DOMINANCE COLUMNS T.N. Wiesel, D.H. Hubel, and M.P. Stryker. Dept. Neurobiology, Harvard Medical School, Boston, Massachusetts 02115.

The ^{14}C 2 deoxyglucose method recently developed by Sokoloff and his group (C. Kennedy et al., Proc. Natl. Acad. Sci. USA. 73: 4230, 1976) was used to visualize orientation columns in the macaque monkey striate cortex, following stimulation with vertical lines. Two weeks before the experiment we injected one eye with ^3H-proline to label by transneuronal transport the geniculate terminals in the ocular dominance columns corresponding to the injected eye (Wiesel, Hubel and Lam, Brain Res. 79:273, 1974). At the time of the experiment we stimulated the anesthetized monkey for 45 minutes after the deoxyglucose injection, moving back and forth a large screen consisting of vertical white stripes on a black background. Both eyes were open and aligned with a prism so as to superimpose the foveal projections on the screen. The ^{14}C autoradiographs of striate cortex showed vertical bands of label extending through the full cortical thickness, except possibly for layer I, which was only faintly labelled. Label was most intense in layers IV b (line of Gennari) and VI. Layer IV c was labelled uniformly throughout striate cortex, as expected given the lack of orientation specificity of units recorded in this layer. The pattern seen in tangential sections was complex, consisting of swirling stripes with many bifurcations and blind endings, but with occasional more regular regions of roughly parallel stripes. Interstripe distance was rather constant at 570 μm. Eye dominance stripes in layer IV c from the eye injection were revealed by washing the fixed sections for some hours in water to remove the deoxyglucose, dipping them in emulsion, and exposing them in the dark for several months. These stripes had a period of 770 μm and were simpler in their pattern, with fewer bifurcations and swirls. A comparison of the two sets of columns in the same area showed extensive intersections, without however any strict or consistent relationship: angles of intersection were distributed as expected for any two randomly superimposed sets of lines. Tangential sections from a second monkey stimulated with vertical stripes, with only one eye open, and injected with deoxyglucose showed regular rows of patches except in IV c, where the rows were uniformly stained. Again this pattern of labelling is predicted from, and confirms, the physiological studies.

1864 MONOCULAR AND BINOCULAR PARALYSIS PRODUCE DIFFERING PATTERNS OF CHANGE IN THE LATERAL GENICULATE NUCLEUS OF THE ADULT CAT. P. R. Wilkerson*, W.L. Salinger, and M.G. MacAvoy* (SPON: M.R. Harter). Psych. Dept., Univ. N. Carolina, Greensboro, 27412.

Data collected in cortex of adult cats (Maffei and Fiorentini, Brain Research, 1976) indicate that binocular paralysis (abnormal and symmetric loss of ocular motility) has no effect on ocular dominance distributions of cortical cells. Monocular paralysis (abnormal and asymmetric loss of ocular motility), however, produces a clear loss of binocularity in the visual cells of the cortex. The study reported here was conducted to determine if the effects of monocular and binocular paralysis on cortex are mirrored in the electrophysiology of the lateral geniculate nucleus (LGN) of the adult cat.

LGN is known to undergo substantial electrophysiological change following monocular paralysis (Salinger, Schwartz, and Wilkerson, Brain Research, 1977). In contrast to reports on visual cortex, changes in LGN following binocular paralysis were in evidence as well. Binocular paralysis, like monocular paralysis, induced selective losses, indicated by decreases in the relative frequency of encountering LGN cells with response latencies to optic chiasm shock (OX latencies) in the X-cell range. These changes were, however, different from those seen in the LGN following monocular paralysis. The losses induced by binocular paralysis occur more quickly than is the case following monocular paralysis. Moreover, cell losses produced by binocular paralysis were relatively more uniformly distributed across LGN laminae than was the case following monocular paralysis. With monocular paralysis, the losses were more concentrated in, but not limited to, the lamina served by the mobile eye.

In the LGN it appears that abnormal oculomotor innervation in the adult, with or without asymmetry of motility, is effective in altering the normal organization; while according to Maffei and Fiorentini, in cortex, only asymmetrically abnormal innervation is sufficient to alter the normal organization. We have no explanation for the apparent failure of LGN and visual cortex to respond to binocular paralysis in a parallel fashion.

1865 CONNECTIONS BETWEEN THE DORSAL LATERAL GENICULATE NUCLEUS AND VISUAL CORTEX IN THE MACAQUE AND SQUIRREL MONKEY. J.R. Wilson, A.E. Hendrickson, and M.P. Ogren. Dept. of Ophthalmology, University of Washington, Seattle, Washington 98195.

Projections between the dorsal lateral geniculate nucleus (dLGN) and visual cortex were studied in Macaque and squirrel monkeys using the techniques of orthograde and retrograde axonal transport by either a direct injection of a mixture of radioactively labeled amino acids and horseradish peroxidase (HRP) into the dLGN or injections of H^3 proline and fucose into one eye. We found no convincing evidence for any connections between the dLGN and prestriate area 18 in Macaque or squirrel monkey by either experimental method. In all cases radioactive label in area 17 declined abruptly at the 17/18 border to remain at background levels throughout area 18. We also looked closely in area 18 for HRP-labeled neurons but only a few scattered cells were found.

In contrast to area 18, a large number of neurons in layer VI of area 17 were labeled with HRP. Direct injection of parvocellular layers resulted in autoradiographic labeling of terminals in layer IVCβ and IVA while labeled magnocellular terminals were found only in IVCα. Large injections involving several layers of the dLGN of Macaques frequently showed regularly repeating autoradiographic labeled/non-labeled patches within layer IVC resembling the ocular dominance columns reported by Hubel, Weisel and co-workers. Within each patch, layer IVCα and/or IVCβ were homogeneously labeled while layer IVA often had 2 or 3 small, intense areas of label. Squirrel monkeys had homogeneous labeling in layers IVA and IVC with no sign of any banding patterns. In some animals, layer VI also appeared lightly labeled. One Macaque showed orthograde transport of HRP from the dLGN into layer IVC of area 17 which again formed regularly repeating patches. HRP positive neurons were found in layer VI under these labeled patches suggesting that the cortical feedback is to the same layer(s) of dLGN which are projecting to the patches of layer IV; i.e., a geniculo-cortical loop dominated by one eye.

Our results show that monkeys, unlike cats, have no direct dLGN input to area 18. There is also additional separation of inputs from the dLGN to layer IV of monkeys which is not seen in cats. Finally, there appears to be a basic difference in organization between the visual geniculo-cortical pathways of Old and New World monkeys; Old World monkeys have a separation of the ocular inputs within layer IV of 17, while New World monkeys have a mixed input. 1866 PERFORMANCE OF 4-CHOICE BRIGHTNESS DISCRIMINATIONS BY CATS WITH LESIONS OF THE SUPERIOR COLLICULUS. J.M.S. Winterkorn and T.H. Meikle, Jr. Anatomy Dept., Cornell U. Med. Coll., N.Y., N.Y. 10021

The superior colliculus (SC) has been implicated in several aspects of attention. Goodale and Murison (Brain Res.88:243,1975) have reported that rats with lesions of the SC follow more direct paths to the correct stimulus than intact rats in a multiple choice brightness discrimination and are less distracted by novel stimuli than intact rats. They concluded that deficits in attention following ablation of the SC are reflected in decreased distractibility.

In the present experiment, cats were trained for food reward in a visual discrimination, in which 4 stimulus panels were presented along one wall of a 6-ft. square open field. The path of approach to the correct one of the 4 stimulus panels was recorded for each cat (a) when learning a brightness discrimination and (b) when presented with a distracting visual stimulus after the cat had learned the discrimination to a high performance criterion. Four cats were trained and tested before and after bilateral ablation of the SC and 3 cats were trained and tested only postoperatively.

All intact cats and cats with lesions of the SC learned the 4-choice brightness discrimination to the same high levels of performance. Contrary to Goodale and Murison's results with rats, cats with lesions of the SC followed longer paths in approaching the correct stimulus panel even after attaining criterional performance. In addition, both intact cats and cats with lesions of the SC were distracted by novel stimuli, but both groups quickly habituated to the distracting stimuli. These results do not support the hypothesis that lesions of the SC produce deficits in attention as measured by distractibility to novel stimuli.

1867 SYNAPTOGENESIS IN THE OUTER PLEXIFORM LAYER OF THE RETINA OF THE CLAWED TOAD XENOPUS LAEVIS. Paul Witkovsky and Frank D.H. Chen* Dept. Anat. Sci., SUNY Stony Brook, N.Y. 11794

The initial appearance and subsequent development of synapses in the outer plexiform layer of the Xenopus tadpole have been examined by electron microscopy. Photoreceptor synaptic ribbons with a halo of agranular vesicles first appear at Nieukoop-Faber stage 37/8 but at this stage often are not aligned with postsynaptic processes. E-PTA staining revealed that the arciform density and adjacent membrane specializations of post-synaptic profiles were barely visible at stage 37/8, thereafter increasing in both density and extent. Serial section reconstruction established that the post-synaptic element associated with the photoreceptor synaptic ribbon was invariably a horizontal cell (HC) dendrite. A few en passant ribbon synapses made onto HC dendrites at the base of the photoreceptor cell were noted, but the main synaptic input to the HC was within the receptoral invagination where 4-9 ribbons made contact with the several lobules derived from a single HC dendrite. Additional HC membrane specializations away from the ribbon were noted.

Bipolar cell (BC) dendrites made only basal junctions with the photoreceptor in the tadpole stages 37/8 - 46 studied. The basal contact was characterized by a wide synaptic cleft containing transverse bars. With E-PTA staining, basal junctions were trilaminar, the photoreceptor paramembranous material appearing somewhat denser than that of the BC dendrite. The third line of electron-dense material was located in the synaptic cleft. Although BC basal junctions were first noted at stage 37/8, their numbers increased markedly after stage 42.

No conventional synapses were found in the outer plexiform layer of the retina in stages 37/8 - 46, but they were encountered in a late-stage, pre-metamorphic tadpole.

The data indicate (a) that the morphological substrate of photoreceptor to HC, and photoreceptor to BC, transmission differ substantially, and (b) that there is a sequential appearance of specific synapses in the retinal outer plexiform layer during tadpole development.

1868 3',5'-GUANOSINE MONOPHOSPHATE AND THE IN VITRO PHYSIOLOGY OF FROG PHOTORECEPTOR MEMBRANES. Michael L. Woodruff and Deric Bownds. Dept. of Zoology and Laboratory of Molecular Biology, Univ. of Wisconsin, Madison, Wisconsin 53706.

A cyclic nucleotide system may be important in photoreceptor function. It is now well established that 3',5'-guanosine monophosphate (cGMP) is found at high levels in dark-adapted retinal rod outer segments (ROS), and that illumination decreases the cGMP concentration. The experiments reported here measured directly (by radioimmunoassay) the levels of cGMP in freshly isolated frog ROS to establish light sensitivity, kinetics and correlations with plasma membrane permeability. The data suggest that cGMP may mediate light-induced permeability changes.

Illumination can decrease the concentration of cGMP from approximately .015 moles cGMP/mole rhodopsin to .007 moles cGMP/mole rhodopsin. The light-dependent cGMP decrease is rapid and reversible. A significant decrease is observed 200-400 ms after the onset of illumination, and after brief light exposures the concentration returns to near the dark value within 60 seconds. The decrease on illumination represents a substantial amplification. The capture of a single photon can reduce the cGMP level by 2×10^4 molecules.

Light suppression of ROS permeability and the light-dependent cGMP decrease become larger as illumination is increased and vary with the logarithm of light intensity at levels which bleach between 5×10^2 and 5×10^5 rhodopsin molecules/outer segment-second. The correlation between cGMP and permeability is maintained through three pharmacological perturbations. The phosphodiesterase inhibitor papaverine increases both cGMP levels and permeability; β,γ-methylene adenosine triphosphate or calcium increases the effectiveness of light in reducing both cGMP and permeability.

1869 MEMBRANE CURRENT RECORDING FROM SINGLE ROD OUTER SEGMENTS. King-Wai Yau*, Trevor D. Lamb and Denis A Baylor. Dept. of Neurobiology, Stanford Univ. Sch. of Med., Stanford, CA 94305

Vertebrate photoreceptors respond to light with a reduction in the steady sodium current which in darkness flows inward across the membrane of the outer segment. We have developed a method for recording membrane current across single rod outer segments in the toad retina. The method was to draw an outer segment projecting from a piece of isolated retina into a close-fitting glass suction electrode filled with Ringer solution and connected to a current-to-voltage transducer. Flashes of visible light evoked slow outward membrane current with properties generally similar to voltage responses recorded with an intracellular electrode; the initial spike on the voltage response to bright flashes has, however, not been seen in the current recordings. The maximum photocurrent obtainable from a cell corresponded closely to a complete suppression of its inward dark current. Dim light evoked fluctuations in the membrane current which were apparently composed of single photon effects having peak amplitudes of about 0.5 pA and a slow time course similar to responses to brighter flashes. The smooth form of the elementary photon effects suggests that many ion channels or carriers may be blocked by one photoisomerization. A dark current noise suppressed by bright light has also been observed. This dark noise is composed of faster elementary events than the photon noise.

1870 SPECTRAL OPPONENCY AND ASYMMETRY BETWEEN CONE MECHANISMS IN THE CAT ELECTRORETINOGRAM (ERG). Eberhart Zrenner* and Peter Gouras. National Eye Institute, NIH, Bethesda, Md. 20014

In the d.c.-ERG of the isolated perfused cat eye two cone mechanisms (λmax=450 and 555nm) can be identified by their action spectra obtained by constant response criteria with monochromatic Ganzfeld-stimuli in the presence of intense chromatic adaptation (12 experiments).

At the onset of the light stimulus and in the presence of strong yellow adaptation both cone mechanisms appear to sum their contributions to the negative on-response (P III) producing a broad, flat single peaked action spectrum, fitting a summation of 450 and 555nm Dartnall-nomograms when corrected for lens absorption. Under the same conditions they appear to oppose each other in their contribution to the positive on-response (b-wave) producing a double peaked action spectrum (peaks near 450 and 555nm) with a large sensitivity loss near 500nm, fitting a subtraction of both nomograms. This double peaked function cannot be due to interaction between a 555nm cone mechanism and rods because the short wavelength branch remains unaltered over a 16-fold increase in yellow adaptation, whereas the long wavelength branch follows the Weber-Fechner law.

When isolated, the sigmoidal intensity-response function for the 450nm-mechanism has a lower slope and saturates at several μV maximum amplitude; that of the 555nm-mechanism is steeper and cannot be saturated with our maximum intensity. The intensity response function for the former could be made to approximate the latter by multiplying it by a factor of at least 10, possibly the ratio of 555 to 450nm cones.

At the offset of the light, both cone mechanisms generate a slow negative response but only the 555nm-mechanism produces a quick positive response also. The action spectrum of the negative off-response resembles that of the negative on-response (P III), whereas the action spectrum of the positive off-response shows no participation of the 450nm-mechanism at all. We interpret this on-off assymmetry to mean that the positive off-response is generated by a quick return of the 555nm cone receptor potential, not present in the 450nm cones.

We conclude that there are at least two cone types in cat retina: One more numerous, more long wavelength sensitive and more rapid in its response; the other less numerous, more short wavelength sensitive and slower in its time course resembling in some respects rods. At a point beyond the receptor level (P III) but before (or at) the site of b-wave generation opponency between these two cone mechanisms seems to occur.
