1 MEDIAL GENICULATE NEURONS OF THE UNANESTHETIZED SQUIRREL MONKEY: PROCESSING OF SIMPLE AND COMPLEX ACOUSTIC STIMULI.
G. E. Alexander, D. Symmes and J. D. Newman. BBBr., NICHD-NIH, Bethesda, Md. 20014.

The activity of single neurons was recorded from the main subdivisions of the medial geniculate nucleus of awake unanesthetized squirrel monkeys (Saimiri sciureus). The sample was composed of 269 cells tested with a variety of acoustic stimuli. Sustained increase in spike discharge was the most frequently encountered response pattern to tone bursts, noise bursts, and taped Saimiri vocalizations. Approximately 98% of the neurons tested responded to clicks, 92% to broad band noise bursts, and 91% to tone bursts in the range between 0.5 and 21 KHz. Sixty percent of the units were driven most effectively when the stimuli were presented binaurally with matched intensity, 29% were driven best by contralateral stimulation, and the remaining 11% were most sensitive to ipsilateral stimuli. About 25% of the cells were characterized by a variety of non-monotonic spike vs. intensity curves, including transitions from activation to suppression of firing with increasing stimulus intensity. In the other 75% of cells which had monotonic spike vs. intensity curves, the relationship between firing rate and stimulus intensity was in each case best described by a power function. In the ventral subdivision of the medial geniculate approximately 90% of the cells had definable best or center frequencies, whereas this was true of only 30% of cells in the magnocellular subdivision.

Responses of individual medial geniculate neurons to tape recorded Saimiri vocalizations were predictable from each cell's response to artificial stimuli, in terms of frequency vs. intensity tuning curves, spike vs. intensity functions, and binaural interactions. In comparison to neurons in the primary and secondary auditory cortices, medial geniculate cells showed less selectivity in their responsiveness to a standard set of species-specific vocalizations.

2 THALAMOCORTICAL, CORTICOTHALAMIC AND CORTICOTECTAL PROJECTIONS TO AND FROM PHYSIOLOGICALLY IDENTIFIED LOCI WITHIN THE AUDITORY CORTICAL FIELDS AAF, AII AND AI. R.A. Andersen*, H. Patterson*, P. Knight*, B. Crandall* and M.M. Merzenich* (Spon. R. Nicoll). Coleman Lab., Univ. of Calif., San Francisco, Ca. 94143.

We entertain the possibility that different cortical fields encode or represent different aspects of auditory sensation. We have studied the thalamocortical, corticothalamic and corticocollicular connections of 3 of these auditory cortical fields in the cat, the anterior auditory field (AAF), AI and AII. After initially mapping the representation of the cochlea over a part of one or more of these fields using microelectrode recording techniques, tritiated leucine and/or horseradish peroxidase were injected at physiologically defined loci. Thalamocortical and corticothalamic projections to and from restricted AAF and AII loci were found to be purely ipsilateral and precisely reciprocal. A similar reciprocity has been previously described for the complex connections of AI and the medial geniculate body (MGB) (Colwell and Merzenich, Anat. Rec. 181:336, 1975), suggesting that such thalamocortical-corticothalmic reciprocity is the rule for auditory cortical fields. The principal reciprocal projection of a restricted AAF locus is to and from a column of neurons extending throughout the deep dorsal division of MGB. This reciprocal projection continues into the posterior group, where it breaks into several discrete columns, and into the caudal MGB, where it extends out to the lateral margin. AAF-deep dorsal MGB connections are ordered, consistent with a basal-to-apical cochlear representation within the lateral-to-medial dimension of the deep dorsal MGB. There was a less dense but restricted reciprocal projection to the rostrolateral part of MGB. With AII injections, a complex and diffuse reciprocal array restricted to the caudal MGB was observed.

Neurons at any AI locus projected to the caudal region of the inferior colliculus (IC), where their terminals formed restricted sheets within the pericentral and the central nuclei. A physiologically identified sector of the cochlear partition represented within AI always projected bilaterally to the same cochlear place represented within the two central nuclei. The corticotectal projection from an AII locus formed a layer of grains within the pericentral nucleus. No projections from AAF to IC have been observed.

Comparisons of the projections of these 3 fields onto the thalamus and IC show structural similarities suggesting certain developmental as well as functional commonalities. However, the overall connectional organization of each cortical field is unique, implying functional segregation and parallel processing of information ultimately giving rise to various aspects of auditory sensation. Supported by NIH Grant NS-10414.

3 **FORWARD AND BACKWARD MASKING OF CLICKS AND BRAINSTEM EVOKED RESPONSE CORRELATES.** **Rüdiger D.Brinkmann*,and Michael Scherg* (SPON: E.Pöppel). Max Planck Institut für Psychiatrie,8000 München 40 Fed.Rep.Germany**

The superior olive is the first waystation of the auditory system,where inputs of the two ears converge onto the same neurons and comparisons of differences in time of arrival and intensity are performed for the first time. Since wave III of the auditory brainstem evoked response has been related to the superior olive,we were interested to see,whether this wave contributes to our understanding of temporal masking.Under conditions of sequential dichotic presentation the masking click was held constant at 55 dB SL,while the probe click was presented with 55,45,35,25,and 15 dB SL either leading (backward masking) or lagging (forward masking). In the psychophysical part of the experiment subjects had to respond to the probe click as soon as it could be heard. The subjects then entered the electrophysiological part of the experiment. They were exposed to the combinations of intensities as mentioned above and the clicks were temporally separated according to the psychophysical findings. The brainstem evoked responses correspond closely to the stimulus conditions applied,in the sense,that a superimposition of the two brainstem evoked responses can be demonstrated. The latencies of the observed positive deflections coincide with the expected peaks due to each of the two clicks. Moreover,the temporal interval necessary for the detection of the probe click can be predicted from the latency of wave III for each of the conditions under investigation. This temporal interval (Δt) is a function of the difference between the latencies of wave III of the probe and the masking click ($LatIII_P - LatIII_M$) plus a constant time interval (C) of 1.4 ms in forward masking and .7 ms in backward masking with respect to the given intensities. in general Δt can be described by the following model: $\Delta t = f(LatIII_P - LatIII_M) + C$

This model allows to evaluate the consistency of the psychophysical judgements of subjects engaged in a temporal masking task. The different values for 'C' in forward and backward masking are in good accordance with reports on comparable psychophysical data.

4 TRAVELING WAVE PARAMETERS IN THE KITTEN COCHLEA ESTIMATED FROM RESPONSE PROPERTIES OF NEURONS IN ANTEROVENTRAL COCHLEAR NUCLEUS. John F. Brugge, Eric Javel and Leonard M. Kitzes*. Dept. Neurophys. and Waisman Cntr., Univ. Wisconsin, Madison, WI 53706

Response areas, which plot discharge rate vs stimulus frequency at various SPLs, were obtained from AVCN cells of kittens during the first month postpartum. They are compared with similar data from AVCN of adult cat (Gibson et al, Psychophysics and Physiology of Hearing) and auditory nerve of adult monkey (Anderson et al, J. Acoust. Soc. Am. 49:1131). Most cells recorded in kitten AVCN had characteristics frequencies (CF) below 4 kHz, indicating that they were excited by basilar membrane motion primarily in the apical half of the cochlea, a region which may undergo structural changes during this time. After the first postnatal week the shapes of the response areas closely resemble those of response areas of auditory nerve fibers and AVCN neurons having the same CF in the adult. For CF below 1 kHz the response area is skewed toward high frequencies; around 1 kHz the curves become symmetrical; at higher CF there is an abrupt high-frequency cut off and shift of the curves toward lower frequencies. Measurements of the frequency interval between CF and high-frequency cut off, at 20 dB above threshold, agree well with adult values. Intervals were converted to distance along the basilar membrane using Greenwood's function relating distance to frequency. This distance may be taken as an estimate of the length of the apical segment of the traveling wave envelope at various locations along the basilar membrane given by the neuron's CF. Results indicate that in kittens as young as 6 days of age the basilar membrane supports a traveling wave along most of its length and that the dimension of the apical segment is similar to that in the adult cochlea. At the cochlear apex this length is about 3 mm; it decreases to a somewhat constant average value, less than 0.5 mm, in the basal half of the cochlea. During the first postnatal week, AVCN neurons are also responsive within a restricted frequency-intensity domain. However, the curves are broader than those in older animals and may spread for considerable distances in the high frequency direction. Period histograms were constructed for AVCN cells whose discharges are locked to cycles of low frequency tones. From the histograms a straight line phase-vs-frequency plot is constructed. The slope of the line is a time delay from which can be determined mechanical travel time along the basilar membrane. Cochlear propagation time in kittens in the third and fourth postnatal weeks approaches that in adults at all CFs. Travel time appears slightly lengthened in animals younger than two weeks of age. While mechanical properties of the kitten cochlea mature at an early age, many response properties of AVCN neurons are delayed for several weeks after birth. NIH Grants NS12732, HD03352.

5 SOME ASCENDING PROJECTIONS OF THE MEDIAL NUCLEUS OF THE TRAPEZOID BODY IN CAT. Judy Brunso-Bechtold, K. K. Glendenning, and R. B. Masterton. Dept. Psych., Florida State University, Tallahassee, Fla. 32306.

Because the cells of the medial nucleus of the trapezoid body (MTB) are scattered among the fibers of the trapezoid body, its projections have been difficult to study. Nevertheless, MTB projections to the ipsilateral lateral superior olive have been deduced with degeneration techniques. The present investigation confirms this deduction by showing that small electrophoretic injections of HRP in the lateral superior olive result in a large number of backfilled neurons in MTB.

However, the projections of MTB are not restricted to bulbar structures. Following electrophoretic injections of HRP in the nuclei of the lateral lemniscus, a significant projection from the ipsilateral MTB is found. Furthermore, occasional backfilled neurons in ipsilateral MTB are found after small injections of HRP in the central nucleus of the inferior colliculus. Thus, MTB in addition to being part of the LSO system, is also part of a separate system that ascends to pontine and midbrain levels. (Supported by NIH:NS-7726)

6 GLYCINE EFFECTS ON RESPONSE PATTERNS OF NEURONS IN THE COCHLEAR NUCLEI. D.M. Caspary and D.C. Havey*. Division of Neurobiology, Department of Medical Sciences, Southern Illinois University School of Medicine, Springfield, IL 62704.

Glycine has been found in varied concentrations in different regions of the cochlear nuclei (Godfrey et al., J. Histochem. Cytochem., in press, 1977). Godfrey et al. reported that glycine levels in the cochlear nuclei (CN) are similar to those reported for spinal cord gray matter, where evidence exists for its role as a possible inhibitory transmitter (Aprison et al., Handbook of Neurochemistry, 1970, Vol. 3). The present study examined changes in both auditory evoked and spontaneous single unit activity in response to iontophoretic application of glycine. All neurons were studied at their best frequency, 20-30dB above the unit's threshold. A summating or current balancing channel, or a separate current barrel was used in all experiments. Post-stimulus time histograms (PSTH's) and interspike interval histograms (ISIH's) were obtained before, during, and after application of glycine onto CN neurons of the anesthetized chinchilla. Selective effects of glycine were observed on area-specific response patterns and spontaneous activity. Pauser and build-up type neurons from the dorsal cochlear nucleus (DCN) occasionally exhibit increased latency of onset response in PSTH's with iontophoretic application of small amounts (0.5-50 nA) of glycine (0.5M). Other pauser and build-up neurons exhibited a generalized inhibition of driven and spontaneous activity. Primary-like neurons typical of ventral cochlear nucleus (VCN) did not show a specific effect on the initial portion of the response. Glycine-responsive neurons showed either generalized depression of activity, or a striking inhibition of spontaneous activity with little reduction of driven activity. Frequently, glycine application caused total cessation of all spontaneous activity even in neurons with moderate to high rates of control spontaneous activity. Increasing doses of glycine progressively increased the selective effect in all glycine-sensitive neurons examined. In certain VCN neurons, increased glycine resulted in a response decrement resembling the reduction in response associated with a decrease in stimulus intensity.

Preliminary findings indicate that GABA also has an inhibitory effect on some CN neurons, but seems less effective than glycine. Further studies of the glycine and GABA effects on area-specific response patterns may suggest relationships with a specific cell type, i.e., small cells or interneurons, or neurons receiving descending inputs.

7 AUDITORY NERVE PROJECTIONS TO COCHLEAR NUCLEUS DEMONSTRATED BY ANTEROGRADE TRANSPORT METHODS. J.H. Casseday and D.R. Jones*, Depts. Surgery and Psychology, Duke University, Durham, NC 27710

To investigate the possibility that projections of the auditory nerve could be studied by methods utilizing anterograde axonal transport, tritiated leucine (250-1500 μCi) was injected through the round window into the cochlea of cats. After a survival period of 6-7 days, standard autoradiographic methods were used to show transport of the labeled amino acid to the cochlear nucleus. The result showed that variations in overall density of silver grains in the cochlear nucleus were consistent with recent reports on the projection pattern of the auditory nerve obtained by degeneration methods. For example, the density of labeled fibers was greatest in the ventral cochlear nucleus and least in the dorsal nucleus, where only a few labeled fibers were found in the molecular layer.

The most interesting finding concerned variations in the proximity and density of silver grains around cell bodies within each subdivision of the cochlear nucleus. These variations suggested marked differences in the innervation pattern of different cell types. In general cells of similar morphology had similar patterns of silver grains around their somas. For example in the anterior part of the anteroventral cochlear nucleus, spherical cells were most often totally surrounded by silver grains; whereas in both anteroventral and posteroventral cochlear nucleus, fusiform cells were never surrounded by grains, and when present, the grains were clustered at the poles of the cell. In the central area of the posteroventral nucleus the soma and proximal dendrites of octopus cells were encrusted with silver grains. The pattern of label around an octopus cell is shown in darkfield and lightfield illumination in Figs. 1 and 2 respectively. (Supported by NIH grant NS 12322)

8 ONGOING HAIR CELL PRODUCTION, MATURATION, AND DEGENERATION IN THE SHARK EAR. Jeffrey T. Corwin, Neurobiol. Unit, Scripps Inst. Oceanography, and Dept. Neurosciences, Sch. Med., Univ. Calif., San Diego, La Jolla, CA 92093.

In carcharhinid sharks the macula neglecta is an auditory epithelium which contains thousands of aligned hair cells and forms part of the lining of the posterior canal duct. It is a highly differentiated structure, but inspite of this, surface counts of its hair cells indicate that great numbers are added post-embryonically.

The origins of these cells were investigated by pulse injection of juvenile sharks with 3H-thymidine. In animals with the shortest survival time autoradiography demonstrated the label within the nuclei of relatively undifferentiated basal cells in a stratified marginal epithelium which forms a nonsensory zone extending 250 μm outside the edge of the sensory epithelium. With longer survival times the label progressed into the surface strata within this marginal epithelium and eventually entered the hair cell population in the peripheral sensory epithelium. While in the stratified marginal epithelium some of the cells develop certain cytological characteristics of hair cells. At this time they also develop associations with neurites even though they may be 200 μm peripheral to the edge of the sensory epithelium.

In correspondence with the above, scanning electron microscopy of ears from juvenile and mature adults has shown a gradation of hair cell surface form from the periphery to the center in each sensory epithelium examined. Peripheral cells have small surface outlines, short stereocilia, and a kinocilium which in some cells is shorter than normal. However, these cells possess a full complement of cilia arranged in a miniature version of the geometrical array found in central hair cells. There is a gradual change in these characteristics as one progresses inward to the central portion of the epithelium which is mainly composed of large, mature hair cells. In the adult ears in addition to the large cells a third type of hair cell was sparsely distributed in the central region. The small size, the lack of geometrical form, and the reduced number of cilia of this third cell type suggest that they may be senile or degenerating.

These results clearly show that the possibility of post-embryonic hair cell addition and turnover should not be ruled out simply on the basis of the high structural differentiation found in epithelia of many acousticolateralis organs.

(Supported by grants to Dr. T.H. Bullock from NSF and NIH and grants to Mid-Pacific Marine Laboratory from ERDA.)

9 ROLE OF NEOCORTEX IN INTERAURAL INTENSITY AND PHASE-ANGLE DISCRIMINATION: DETECTION VS. IDENTIFICATION. Jerry Cranford, Makoto Igarashi, Ronald DeWitt,* Dept. Otorhinolaryngology & Communicative Sciences, Baylor College of Medicine, Houston, Texas, 77030

At the present time, a major issue concerning the effects of auditory decortication on sound localization is whether or not operated animals retain a normal capacity for discriminating the small interaural differences in arrival time (phase) or intensity which result from the spatial separation of sound sources relative to the head. Heffner & Masterton (1975) have suggested that the deficit seen with cortical lesions, rather than reflecting a disruption of the animal's normal perception of the location of sounds, may be the result of an "auditomotor or associative" deficit involving the animal's inability to act appropriately on the basis of its normal perception. Neff & Casseday (1977), on the other hand, believe that the auditory cortex is necessary to allow animals to recognize that the stimulus to one ear differs in some respect (intensity, time of arrival, sequential arrangement of sounds) from the stimulus to the opposite ear.

The present experiment was designed to provide data relevant to this controversy. Using earphones and an active avoidance training procedure, the effects of auditory cortex ablations on the cats' ability to detect reversals in the interaural phase-angle or intensity relations of binaural 1-kHz tones were studied with seven cats. For both auditory decorticate (ablation of AI, AII, Ep, SII, I-T) and unoperated cats the detection thresholds for interaural intensity and phase-angle were found to be close to 1-dB and 5^{o} respectively. In addition, we found that both operated and unoperated cats transferred at above chance levels from the original lateralization task involving the detection of interaural reversals of phase-angle or intensity to a new paradigm which required the cats to identify, in an absolute sense, which ear received the leading or louder signals. Thus, the present investigation provides additional evidence that the neocortex has no primary sensory role in sound localization.

10 QUANTITATIVE ANALYSIS OF CLICK ELICITED RESPONSES IN ANTEROVENTRAL COCHLEAR NUCLEUS NEURONS. John W. Dickson, Mario A. Ruggero and Robert E. Wickesberg*. Dept. of Neurophysiology, University of Wisconsin, Madison, WI 53706.

We have studied the post-stimulus time histograms of the responses to clicks of 111 anteroventral cochlear nucleus (AVCN) neurons in barbiturate-anesthetized cats. Most units were stimulated with clicks of both polarities at a variety of intensities; characteristic frequencies (CF's) were determined for 93 units. As in the cochlear nerve (N. VIII), the click-evoked histograms from low-CF units were multimodal. The "time" of each peak was defined as the arithmetic mean of the times of the spikes in the peak. Using statistical and graphical methods, we studied the relationship of mean interpeak interval to CF, the interdigitation of the peaks elicited by the two polarities, the consistency of the mean interpeak intervals measured at different polarities and intensities, and peak latency shifts with intensity changes. Most of our results confirm the similarity of AVCN and N. VIII click responses. Results not previously reported for click responses in AVCN include occasional systematic changes in interpeak interval within a single histogram and, for low-CF units, similarity of peak times for units of similar CF. The former, seen most often at high intensities, is reminiscent of nonlinear effects seen in the basilar membrane and in N. VIII. The latter suggests a uniformity of AVCN responses which may be important for processing of temporally encoded signals by higher centers (e.g. for sensing interaural phase differences). (Supported by N.I.H. grants NS12732, NS02024, NS51561 and a NSF Graduate Fellowship (R.E.W)).

11 COCHLEAR NUCLEUS UNIT RESPONSES IN CONSCIOUS RABBITS. John F. Disterhoft, Scott Evans* and Leslie Sargent Jones*. Dept. Anat., Northwestern Univ. Med. Sch., Chicago, IL 60611.

Responses of single neurons in the cochlear nucleus of young adult male albino rabbits to pure tones were characterized. The rabbit's head was fixed to a stereotaxic by 4 restraining bolts. A visual approach to the cochlear nucleus was achieved by opening the foramen magnum and removing enough of the occipital bone to visualize the cochlear nucleus below the cerebellum. The cerebellum was sometimes gently retracted to allow a better view. The area of incision was thoroughly infiltrated with Xylocaine after initial preparation. The animal was paralyzed with Flaxedil and respirated through a tracheostomy tube. Pure tone stimuli, 50 msec in duration, were gated on with a 2.5 msec rise-time at a repetition rate of 1/1.4 second and delivered free field in a sound attenuating chamber. Etched tungsten microelectrodes coated with Epoxylite, with impedances of 1-4 megohms, were introduced into the cochlear nucleus by a remotely controlled hydraulic microdrive. Extracellular potentials from 200 μV to 2 mV were recorded.

Thus far 62 single units in DCN and AVCN have been studied. Response latencies varied from 4 to 10 msec from tone onset at the ear for most units. Most tuning curves have been rather broad. The prominent response pattern recorded has been a "primarylike" response, with the neuron responding with increased firing throughout the tone burst. Some of these neurons have also shown a suppression in firing at tone offset. A smaller group of neurons have shown more complex patterns as have been commonly recorded from DCN in unanesthetized preparations by previous investigators: inhibition throughout the tone; no response during the tone with a burst of spikes at tone offset; excitation at certain tone frequencies and inhibition at others; long latency excitatory response continued well after tone offset. Neuron location as judged from depth of electrode penetration from the cochlear nucleus surface and histological location of electrode tracks indicated that a large proportion of the neurons studied have been in DCN. But the predominant response type which has been seen is that usually recorded in AVCN. Ongoing studies, with more precise reconstruction of electrode tracks, are being done to accurately correlate response type with neuron location in cochlear nucleus.

12 CYTOARCHITECTURE OF THE TORUS SEMICIRCULARIS IN THE RED-EARED TURTLE, CHRYSEMYS SCRIPTA ELEGANS. T. FACELLE and R. BROWNER. Dept. of Anatomy, New York Medical College, Valhalla, N.Y. 10595.

The normal cytoarchitecture of the torus semicircularis (TS) was analyzed in eleven turtle brains stained with cresyl violet or impregnated by the Golgi-Kopsch method. Golgi sections of 120μm thickness were studied in the three standard planes. The TS is a midbrain nucleus which caudally bulges on the dorsal mesencephalon and extends rostrally, laterally, and dorsally where it is ventral to the tectal ventricle (TV) at a mid-tectal level. The TV consists of two nuclei: a larger central nucleus (CN) and a laminar nucleus (LN) interposed between the CN and the TV.

The CN has a small neuron population of ovoid-spherical soma ranging from 6.5-14.0μm with one to five primary dendrites. The dendrites radiate from the cell soma without a consistent pattern. This neuronal population has occasional secondary and tertiary dendritic branches with spines. There is a large cell population (16.0-26.0μm) of either ovoid (one-five primary dendrites), or fusiform (two-four dendrites). The large ovoid cells often show secondary and tertiary dendrites with spines seen frequently on the distal dendrites, and infrequently on the primary dendrites and soma. The primary dendrites form different patterns: radiate, bipolar, or perpendicular where two dendrites emerge from the soma at a 90^{o} angle to each other. The fusiform cells have dendrites emerging at opposite poles of the soma and show distal branching, but no dendritic spines. The only notable distribution is the encapsulation of the CN borders by the dendrites of the large ovoid cells at the CN periphery.

At the caudal TS the LN cups the ventromedial CN, more rostrally the LN is medial and then dorsomedial to the CN, and at the rostral pole caps the CN dorsoventrally. In Golgi sections there are three cell types in the LN: ovoid (16.0-19.5μm) with one-three primary dendrites; fusiform neurons (23.0-26.0μm) with two or three primary dendrites; and stellate (20.0μm) with four primary dendrites. All LN cells lack spines but many display an extensive, branching dendritic field with dendrites up to 550μm long. The dendrites of the LN neurons form a criss-crossing grid in three directions: dorsomedial to ventrolateral (from the TV into the CN), dorsolateral to ventromedial (along the dorsal CN border), and anterior to the CN the LN fibers run rostral to caudal.

13 THALAMIC PROJECTIONS TO THE POSTERIOR AUDITORY CORTICAL FIELD IN CAT. K. A. FitzPatrick, T. J. Imig* and R. A. Reale. Dept. of Neurophysiology, Waisman Center, Univ. of Wisconsin, Madison, WI 53706.

Electrophysiological mapping experiments currently in progress in this laboratory have deomonstrated the presence of a secondary auditory field buried within the posterior ectosylvian sulcus in the cat (Reale and Imig, this meeting). This field, called the posterior auditory field, occupies the posterior bank of the sulcus and contains a complete representation of the cochlea. In the present study injections of horseradish peroxidase were made into selected regions of the posterior field after constructing a detailed tonotopic map of this region. The location of labeled cells in the medial geniculate body was analyzed in order to determine the sources of thalamic input to the posterior field. Following injections confined to this field, labeled cells are found primarily in restricted portions of the principal and dorsal nuclei of the medial geniculate. Additional labeled cells appear in the ventrolateral nucleus of the geniculate and an occasional cell is seen in the magnocellular nucleus and nucleus of the brachium of the inferior colliculus.

Supported by NIH Program Project Grant NS12732, Core Grant HD-03352, and NSF grant BNS 76-19893, Postdoctoral Fellowship NS-05232-01.

14 EFFECTS OF HAIR CELL LOSS IN THE WALTZING GUINEA PIG ON THE SYNAPSES OF THE SPIRAL GANGLION CELLS IN THE ROSTRAL AVCN. R.L. Gulley and R.J. Wenthold. Dept. of Anatomy, Case Western Reserve University, Cleveland, Ohio and LNO, NIH, Bethesda, MD.

In the NIH strain waltzing guinea pig, there is a progressive loss of hair cells in the organ of Corti beginning 10 days after birth. By 60 days, all hair cells have degenerated. Between days 30 and 90, 60 to 80% of the spiral ganglion cells degenerate. After 90 days, a stable population of both type I and II spiral ganglion cells remains. There is no further loss of ganglion cells during the next 6 months. The terminals of the ganglion cells in the rostral AVCN, the end bulbs of Held, are normal through 20 days of age. In animals older than 90 days, the synaptic junctions are flattened but the terminals otherwise are normal. In these older animals, all stages of granulofilamentous degeneration can be identified in these terminals following surgical destruction of the ganglion cells that remain after hair cell loss. In freeze-fracture replicas, the postsynaptic membranes of the end bulbs before hair cell loss are identical to those in normal guinea pigs. However, the postsynaptic membrane opposite end bulbs in animals older than 90 days have a greater density of nonaggregate particles on the external leaflet than this membrane in animals before hair cell loss. Moreover, in older animals there are no perisynaptic aggregates on the external leaflet of the membrane. The number and distribution of junctional aggregates is identical to that in animals before hair cell loss. The similarity of the changes in the principal cell membrane following hair cell loss to those seen immediately following deafferentation of the principal cell suggests that synaptic activity may be important for maintaining the postsynaptic membrane. Moreover, there is a clear implication that the presence of intact spiral ganglion cells following hair cell loss does not necessarily imply the existence of functionally competent synapses in the CNS.

15 ALLOXAN - INDUCED DIABETES CONFERS PROTECTION AGAINST KANAMYCIN OTOTOXICITY. Paul S. Guth*, Juan Garcia-Quiroga and Charles H. Norris*. Dept. Pharm., Sch. Med., Tulane Univ., New Orleans, LA 70112.

The clinical utility of the aminoglycoside antibiotics is hampered by their well-known capacity to cause labyrinthine damage. The pattern and time course of the damage produced have been extensively described by many researchers, but the ototoxic mechanism remains unclarified. Our attention was focused on the aminosugar moieties of these antibiotics by the finding of Owada (Chemotherapia 5, 227, 1962) that 3-aminoglucose, the aminosugar of kanamycin is itself ototoxic. It is known that aminosugars compete with glucose for transport systems across membranes. As a first test of the hypothesis that the aminoglycoside antibiotics produce their ototoxicity by reducing glucose transport in the organ of Corti we attempted to prevent kanamycin-induced ototoxicity by making animals hyperglycemic. One group of rats were made diabetic with alloxan and were injected with kanamycin (400 mg/kg i.p.) daily. A second group received kanamycin alone at the same dose. Blood and urine glucose levels were monitored periodically. The status of the cochlea was determined once weekly by electrocochleographically measuring the visual detection at 1,2,4,6,8,10,12,14,16, and 32 KHZ. When the non-diabetic animals showed a threshold shift greater than 30db at two frequencies both groups of animals were sacrificed and their cochleas examined by the surface preparation technique. The diabetic group of animals were clearly and dramatically protected against kanamycin ototoxicity as evidenced both by electrocochleography and histological examination. The extent of the protection correlates very clearly with the blood glucose concentration. (Supported by grant 71-6 from the V.A.)

16 EFFECT OF AUDITORY CORTEX ABLATION ON THE PERCEPTION OF MEANINGFUL SOUNDS. Henry E. Heffner. Bureau of Child Research, University of Kansas, & Parsons State Hospital and Training Center, Parsons, KS 67357

Dogs were tested on their ability to classify meaningful sounds before and after auditory cortex ablation. The animals were trained to classify sounds chosen from two well-defined categories of sound. The first category was that of "dog" sounds and the sounds used were dog vocalizations, such as barks, whines, and howls, which had been recorded from over 50 different dogs. The second category was that of "non-dog" sounds and the sounds used consisted of the vocalizations of animals ranging from crickets to elephants as well as the sounds of objects ranging from clocks to steamboats. The sounds were carefully chosen to reduce the possibility that the dogs could classify them simply on the basis of physical characteristics such as frequency spectrum and temporal pattern.

Using a two-choice procedure, the animals were trained to make one response when a dog sound was presented and a different response when a non-dog sound was presented, a task which normal dogs readily learned. The ability of the animals to classify the sounds was tested in two ways. First, the dogs were presented with new sounds and their ability to transfer their training to these sounds was determined. Second, the animals were given an equivalence test in which their response to additional new sounds was determined in the absence of any feedback concerning the correct response. Again, normal dogs were easily able to learn these tasks and could successfully classify as many as 100 new sounds in a single one-hour session.

Bilateral ablation of primary auditory cortex (AI) had no significant effect on the ability of the dogs to classify the sounds. However, bilateral ablation of both primary and secondary auditory cortex resulted in a temporary inability of the animals to discriminate between the sounds as well as to classify them. This disability diminished with time and after several months the animals were able to discriminate and classify the sounds at normal or near-normal levels.

It appears, then, that auditory cortex is not necessary for the discrimination of meaningful sounds. Furthermore, the evidence suggests that bilateral ablation of auditory cortex may result in no more than a transient disruption of the ability to perceive meaningful sounds. (Supported by NIH Grants NS 12 992 and HD 02528, Bureau of Child Research, University of Kansas.)

17 NEUROLOGICAL EVALUATION OF THE AUDITORY SYSTEM IN NONVERBAL SEVERELY RETARDED CHILDREN. Rickye S. Heffner. Bureau of Child Research, University of Kansas, Lawrence, KS 66045.

Recently, we have considered the possibility that the language disorders of nonverbal mentally retarded children may be due in some cases to an inability of auditory input to reach the cortical speech areas of the brain despite normal pure tone sensitivity. To investigate this possibility, nonverbal severely retarded children with normal hearing were tested for their ability to localize sounds. The reason for choosing a sound-localization test was that ablation-behavior experiments have indicated that animals are unable to localize brief sounds if the input from the ear is completely severed from the cortex at any level in the auditory pathway. Therefore, a sound-localization test would constitute a test of the integrity of the auditory pathway from the ear up to and including auditory cortex.

Fifteen nonverbal severely retarded children were tested on their ability to localize single clicks emitted by loudspeakers located to the left and right of midline. The children were trained to respond by touching a screen covering the loudspeaker from which the sound had come. Despite severe cognitive and motor impairments, twelve of the children were able to localize single clicks with normal or near-normal thresholds while only three were unable to localize single clicks at all.

Since disruption of auditory input to the cortex is known to disrupt the localization of brief sounds, it appears that the auditory system of these twelve children is at least sufficiently intact to enable them to localize sounds. Therefore, the inability of these children to learn language cannot be due to gross disconnection of the ears from the cortex. Further work is presently being conducted to determine if the inability of the other three children to localize single clicks is due to an auditory incapacity or to some cognitive, emotional, or motor problem.

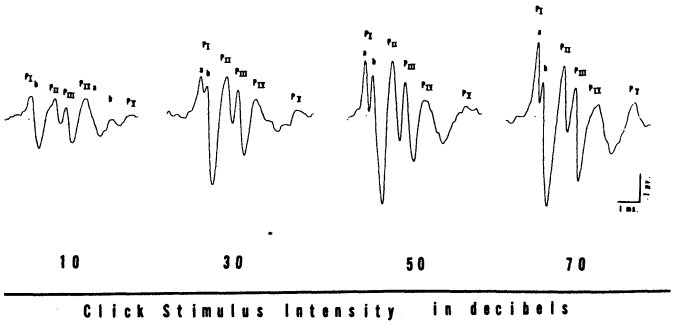
18 DIFFERENTIAL SENSITIVITY OF PERIPHERAL AUDITORY VOLUME CONDUCTED RESPONSES OF THE C57BL/6 MOUSE TO ACOUSTIC STRESS. Kenneth R. Henry. Dept. Psychol., U. of Calif., Davis, 95616.

Volume-conducted inner ear and auditory brainstem responses to a click centered at 2 kHz were obtained from the C57BL/6 mouse. By using a vertex-to-mouth electrode configuration, and maintaining a constant ear temperature (37.5 ± .1°C), it was possible to simultaneously obtain recordings representing cochlear microphonics (CMs) and the negative summating potential, in addition to the auditory nerve and brainstem (P_I to P_V) far field measurements previously described by Jewett. Rarefaction clicks produced a larger CM amplitude and a shorter CN8 (P_I) latency than did condensation clicks. Dual P_I peaks were observed, separated by an interval which approximated the period of the click center frequency. Although P_{Ia} and P_{Ib} showed parallel latency decreases as the click was increased from 30 to 70 db, P_{Ia} amplitude increased while P_{Ib} amplitude decreased as stimulus intensity increased over this range. After exposure to 5 min of 110 db asynchronous noise centered at 5 kHz, all the measures described above showed a decrease of amplitude, and condensation and rarefaction clicks no longer produced differential effects on CMs and P_I measures. One week postexposure, P_{Ib} continued to show an amplitude decrement from 10 to 70 db, while P_{Ia} was only decreased in amplitude at 70 db. Hypothermia and barbituates interacted with noise in these postexposure changes. The hair cell loss due to this acoustic stimulus was greatest in the apical region of the organ of Corti, and it was postulated that P_{Ib} reflects activity which is generated at or near the apical portion, while P_{Ia} represents synchronous activity generated nearer the base of the auditory transducer.



19 A PRELIMINARY STUDY ON THE EFFECTS OF THE HYPEROXIA AND HYPOCAPNIA TO THE 8TH NERVE ACTION POTENTIAL IN CHINCHILLA. S.-M. Hou and D. M. Lipscomb*. Noise Research Laboratory, Dept. of Audiology & Speech Pathology, The University of Tennessee, Knoxville, TN. 37916.

Hyperoxic breathing at 1 atm was found to produce two types of neural depressions in the action potential of the cochlear nerve. A rapid depression of the AP immediately upon flushing the chamber with 100% oxygen was observed. Complete recovery of the AP takes place within 10 seconds of introducing trace amount of carbon dioxide into the inhalant. The second type of neural condition developed over 2 hours of pure oxygen breathing and consists of a prolonged AP depression and latency shift. Recovery from this effect was achieved 6 hours after returning to air. The short term effect was found due to carbon dioxide deprivation during the 100% oxygen inhalation and the long term effect was found to be result from the development of intracellular oxygen toxicity by prolonged hyperoxic breathing. The possible role of the superoxide radical in the auditory oxygen toxicity will be discussed.

20 THE ABILITY OF SINGLE CELLS AND EVOKED POTENTIALS FROM THE CAT'S BRAIN STEM TO RESPOND TO REPETITIVE ACOUSTIC STIMULATION. Chi-Ming Huang* and Jennifer S. Buchwald, (SPON: Lowell E. White, Jr.) Dept. Physiology, Univ. of S. Alabama, College of Medicine, Mobile, AL 36688 and Dept. Physiology, BRI, Mental Retardation Research Ctr., UCLA School of Medicine, Los Angeles, CA 90024.

The classical brain stem auditory relay pathway contains a chain of relay neurons. They appear to make monosynaptic contact with relay neurons in the structure to which they project, thereby establishing a fast conduction pathway with minimum synaptic delay. Their sequential activation provides a basis for the current interpretation of brain stem evoked response (BER). The short response latencies suggest that the synaptic conduction is secure and the axons are probably the fastest-conducting axons in the auditory pathway. Since, in a given brain stem structure the initial discharges of these relay neurons are usually highly synchronized, it also suggests that these neurons may have similar synaptical as well as morphological features such as diameters of axon, types of synapse, etc. This report deals with single neurons in the brain stem of anesthetized adult cats and evoked potentials from the brain stem of anesthetized cats and awake cats. Short (45 ms) tones at the neuron's best frequency were delivered at rates from 1/sec to 20/sec. In a given brain stem structure, depending upon the level, approximately 20 to 50% of all the neurons sampled were short-latency cells. (e.g. 50% in the cochlear nucleus and 20% in the inferior colliculus). The response plasticity of neuronal discharges was analyzed and compared in different neurons. The response plasticity of BER was also analyzed. In the same neuron, the response was broken down in segments of time and analyzed. The data suggested that (1) the initial discharge (within 5 ms of tone stimulus) of short-latency cells demonstrated identical response plasticities as that of the BER. The later discharge of short and long-latency cells demonstrated the same response plasticity. (2) In awake cats, the response plasticity of BER components 1-4 were similar to that measured when the cat was anesthetized. (3) Evoked potentials from the inferior colliculus showed a peculiar enhancing effect in the awake state when the repetitive acoustic stimuli were separated by approximately 500 msec.

These data suggested that the BER may also be under central control.

21 THE ORIGINS AND TARGETS OF CORTICOCORTICAL CONNECTIONS RELATED TO TONOTOPIC MAPS OF CAT AUDITORY CORTEX. T. J. Imig* and R. A. Reale (SPON: A. L. Berman). Dept. of Neurophysiol. and Waisman Ctr. on Mental Retardation, Univ. of Wisconsin, Madison, WI 53706

Within the auditory region of the cat's cerebral cortex are located several complete and orderly frequency representations. In the experiments reported here, we have employed microelectrode mapping techniques to study the frequency organization of the primary auditory field (AI) and two adjacent auditory fields. Adjoining AI caudoventrally is a posterior field (P) which occupies the caudal bank and part of the rostral bank of the posterior ectosylvian sulcus. Bordering AI rostrally is an anterior field (A) located on the anterior ectosylvian gyrus and extending onto the caudal bank of the anterior limb of the suprasylvian sulcus. Within each field is a complete and orderly frequency representation with a narrow band of frequencies represented along a cortical strip. During experiments in which the frequency organizations of these fields were mapped, tritiated (3H) proline was injected at one or more locations into a restricted portion of the frequency representation of AI, A or P. From histological sections processed for autoradiography, maps of the frequency organization of auditory cortex and the distribution of labeled protein were reconstructed. Following an injection of 3H proline into AI, labeled protein is found in both A and P. Following an injection of 3H proline in either A or P, labeled protein is found in AI. Furthermore, frequencies represented at the injection site correspond closely to frequencies represented at target sites. These data indicate that similar portions of the frequency representations in fields AI and P and fields AI and A are reciprocally connected. When projected upon the cortical surface, the heavily labeled region produced by a single injection of 3H proline in field AI, A or P occupies a circular region centered at the injection site. On the other hand, the distribution of labeled protein found at the target sites, when projected upon the cortical surface, occupies an area elongated in a direction parallel to isofrequency contours. 22 AUTORADIOGRAPHIC DEMONSTRATION OF PRIMARY PROJECTIONS TO CAT COCHLEAR NUCLEUS. Eileen S. Kane and John W. Conlee.* Dept.Anat. University of Chicago, Chicago, Illinois 60637

Manual injections of small volumes (0.15-0.7 µl) of tritiated leucine (25-70 µC) directly into the fenestra rotunda of adult cats, followed by 24-48 hour survivals, perfusion-fixation, frozen-sectioning, and routine processing of mounted sections for light microscopic autoradiography showed clear grain distribution in the ipsilateral cochlear nucleus only. Significant grain counts (above background) occurred in all major regions of ventral cochlear nucleus or VCN (500-600 grains/100 μm^2) with fewer grains (150-300 grains/100 μm^2) in dorsal cochlear nucleus or DCN. Liquid scintillation counts (LSC) of cochlear nerve roots showed significantly greater uptake by experimental vs. control roots (average dpm's = 30:1 after 48 hours) in all cases. Similar results were obtained with and without blockage of the cochlear aqueduct. Specifically, our autoradiographic studies showed more dense and uniform labelling of all major regions of the ventral than the dorsal cochlear nucleus, predominantly perisomatic distribution of label in the anteroventral (AVCN) and posteroventral (PVCN) cochlear nuclei and in the fusiform cell layer (FCL) of DCN plus a dense-to-sparse gradation of grain density from deep to superficial layers of DCN. Heaviest labelling occurred in the nerve root zone and lightest in the superficial DCN. Both bright and, particularly, dark-field illumination, revealed clear grains in emulsion over somata of PVCN (both PA and PP) and in AVCN (both AA and AP), over "giant" and small cell somas of deep DCN, and several grains consistently over fusiform cell somata. Octopus cells were notably covered with nearly uniform grain populations; frequently, linear grains (suggesting incoming axons) could be followed directly into these perisomatic grain clusters. Our observations have confirmed findings of numerous prior investigations of cochlear inputs and have provided the basis for further study of (1) primary synaptic terminals in specific cochlear nucleus regions and (2) primary neurotransmitter substances, now under study. (Supported by University Chicago, Deafness Res. Fdn. and USPHS Grants NS-12071 & NS-00008 (RCDA) to E. S. K.).

23 DISCRIMINATION OF LEFT-RIGHT VS RIGHT-LEFT CLICK PAIRS FOLLOWING LESIONS OF AUDITORY CORTEX IN THE RAT. Jack B. Kelly Department of Psychology, Carleton University, Ottawa, Canada, K1S 5B6.

Lesions of auditory cortex in cats result in severe deficits in the ability to localize sounds in space. Even unilateral lesions produce impairments in localization if the animals are tested with left and right sounds presented in pairs separated by small time intervals, that is,the precedence effect (Cranford, Ravizza, Diamond and Whitfield, 1971). Because the precedence effect is a very sensitive test in the cat, we have employed discriminations of small time intervals between spatially separated loudspeakers to assess the effects of auditory cortical lesions in the rat. In our tests the animals were trained by the conditioned suppression procedure, first, to discriminate a train of left clicks from a train of right clicks emanating from loudspeakers separated by 180°. When the animals had learned this simple left vs right discrimination, they were given further tests with paired clicks in which they had to discriminate left-right from right-left sequences. The temporal separations (Δt) between left and right clicks ranged from 8 msec to 250 microseconds. In spite of the apparent complexity of this stimulus situation, rats with bilateral lesions of auditory cortex could still perform the discrimination with both large and small Δt values. Unilateral lesions also produced no obvious impairment. We have concluded that,for rats,auditory cortex is not essential for discrimination based on the precedence effect. The apparent difference between rats and cats is possibly based upon the nature of the response required by the testing procedure.

24 AUDITORY RECEPTIVE FIELDS IN THE OWL. Eric I. Knudsen and Masakazu Konishi. Div. Biology, California Institute of Technology, Pasadena, CA 91125.

The influence of sound location on the responses of auditory neurons in the barn owl (Tyto alba) were studied using noise, clicks, tones and FM stimuli delivered by a movable speaker under free-field, anechoic conditions. Three types of units have been found: 1. space-independent, 2. space-preferring, and 3. space-dependent. Space-independent units were not selective for sound location. Space-preferring units responded strongly to sounds from a particular area of space and sporadically to sounds from outside this area, but their responsive areas expanded with increasing sound intensity. Space-dependent units demonstrated well-defined receptive fields that were relatively independent of sound intensity, expanding by less than 20° in azimuth and 45° in elevation to a 20 dB increase in sound intensity. The typical receptive field was vertically elongate, although some circular and irregular fields were found. The smallest receptive fields subtended as little as 8° in azimuth and 20° in elevation. Just as with space-preferring units, the vigor of space-dependent unit responses increased as the sound stimulus approached the center of their receptive fields.

All three unit types were found in the telencephalon (space-preferring > space-independent > space-dependent). In contrast, only space-dependent units with small receptive fields were found in a small region of the midbrain. These units all shared similar characteristic frequencies (5.5-8.5 KHz) and responses to noise and click stimuli. The single attribute found, in which they differed, was the location of their receptive fields which moved systematically as a function of electrode position. These response properties argue strongly for this midbrain region being involved in sound localization. Furthermore, the distribution of receptive fields in this midbrain region was heavily biased toward a limited area directly in front of the owl, suggesting that within this frontal area of "expanded representation" the owl attains maximal spatial acuity.

25 RESPONSES OF INFERIOR COLLICULUS NEURONS TO INTERAURAL TIME DIFFERENCES IN THE CAT. S. Kuwada*, T.J. Buunen*, J. Syka* and R. Wickesberg* (Spon. H. Sobkowicz) Dept. of Neurophysiology, Univ. of Wisconsin Med. School, Madison, Wisconsin 53706.

Several studies have reported the existence of inferior collicular neurons whose responses vary cyclically as a function of interaural time delay. The interval between peaks of this cyclic function equals the period of the stimulating frequency. Many of these cells repond maximally or minimally to a specific time delay independent of the stimulating frequency or intensity. Neurons which have the above properties are said to exhibit "characteristic delay". The present experiment describes a population of inferior collicular neurons which display cyclical properties but for which the interaural time delay resulting in maximal firing changes as a function of frequency and intensity. A computer system was employed for stimulus generation and data collection. Our protocol was as follows: 1) Isolation of a unit that responds cyclically to interaural time delays. 2) Binaural presentation of pure tones of the same frequency and intensity while varying the interaural time delay. Both the ipsilateral and contralateral stimuli were systematically delayed covering two periods of the stimulating frequency in steps of no more than .1 of a cycle. This procedure was continued until the frequency range of a particular cell was adequately sampled for a given SPL level. For any particular presentation the stimuli to both ears were identical in frequency and intensity. 3) Time permitting, we set several intensity differences between stimuli and repeated the time delay sequences. 4) Finally, monaural and binaural response areas were determined. All the units studied displayed a frequency related delay: more specifically, the maximal response of a neuron occurs at delays which were an orderly function of frequency. Within this population, there was a small number of cells which responded optimally to a particular phase difference between the binaural stimuli across frequencies. We termed such a response "characteristic phase". The interaural delay resulting in maximal firing could be shifted as much as 1/5 of a period as a function of intensity difference between the binaural stimuli.

We conclude that: 1) The delay eliciting maximal firing can be frequency dependent; 2) For some cells, the maximal response occurs at a particular phase difference independent of frequency; 3) Interaural intensity differences at a given frequency can shift the delay at which maximal response occurs.

26 CLICK-EVOKED NEAR- AND FAR-FIELD POTENTIALS AND MULTIPLE UNIT ACTIVITY RECORDED FROM MONKEY SUPERIOR TEMPORAL PLANE AND SUBCORTICAL STRUCTURES. Alan D. Legatt, Joseph Arezzo*, and Herbert G. Vaughan, Jr.* Dept. of Neuroscience, Albert Einstein College of Medicine, Bronx, New York 10461.

Short latency far-field click-evoked potentials have been recorded in several species, including man. Based in part on depth studies in cat and rat, these potentials are believed to reflect neuronal activity in subcortical structures which precedes cortical activation. We examined this issue in the primate by intracranial mapping of gross potentials in monkeys, and by comparison of the far-field activity to the near fields and multiple unit activity generated in the primary auditory cortex.

Following 100 μsec 95 dBSPL peak clicks delivered at 10 per second monaurally to the anesthetized monkey, a series of seven positive deflections are seen at the vertex (reference = mastoid ipsilateral to the stimulated ear) which resemble the human far-field potentials, although with a shorter time course. The peak latencies are 1.6, 2.6, 3.4, 3.8, 4.4, 6.1, and 7.8 msec. Other electrode placements give complex waveforms which may have additional peaks; topographic analysis of these data provides information about the locations and orientations of the generators.

Of the seven waves recorded at the vertex, the first five precede activity in the superior temporal plane, and can be recorded in the vicinity of the latter structure as far fields. Topographic analysis confirms that these are generated in subcortical structures; amplitude increases of greater than 300-fold are seen as the recording electrodes are moved from the vertex through the brain stem. Inferences about the sources of the latter two components are more difficult, however, as they overlap in time with fields generated in the superior temporal plane. Brain stem structures show activity patterns which begin with latencies as short as those of the far-field potentials but continue well into the cortical response.

Multiple unit activity recorded in the superior temporal plane remains at the prestimulus baseline level until 5.0 msec after the stimulus, when it begins to increase sharply. It peaks at 5.8 msec at a level 22% above baseline, and then declines, almost reaching the baseline at 6.1 msec. Subsequently the multiple unit activity increases to more than twice the baseline level, followed by a decline to below baseline. The initial increase in multiple unit activity, which partially overlaps the sixth wave of the early evoked potential, may represent geniculocortical activity as well as the initial activation of cortical neurons.

27 AUDITORY DYSFUNCTION FOLLOWING HUMAN HEAD INJURY: EVALUATION OF MONAURAL VERSUS BINAURAL AUDITORY FAR FIELD POTENTIALS. Barbara White Navari*, Richard P. Greenberg and Donald P. Becker. Div. of Neurosurg., Medical College of Virginia, Richmond, VA 23298.

To determine the accuracy with which auditory far field evoked potentials (Jewett, Brain 94:681-696, 1971) could localize auditory system dysfunction in comatose head injury patients we obtained both monaural and binaural auditory far field potentials from 33 patients with severe head trauma and correlated the evoked potential data with the patients clinical auditory status 3 months or more after head injury. (Greenberg, J. Neurosurg. 46, 1977). All patients were unresponsive when studied (mean day 3 post-injury) and the presence or absence of auditory dysfunction was clinically unknown. When the auditory far field data was evaluated it was noted that the evoked potentials generated by monaural stimulation of the ears significantly associated with the presence or absence of auditory dysfunction in the 33 patients ($p<.001$; Fisher's Exact Test) while the auditory far field evoked potentials generated with binaural stimulation did not. Therefore, the monaural and binaural evoked potential data were examined to determine the basis for this disparity.

If the waveforms and latencies of the first VII positive potentials generated after monaural stimulation of the left and right ear were similar the data generated by binaural stimulation correlated with the presence or absence of auditory dysfunction in the patients. However, when latency differences were present after monaural stimulation, comparing the left to the right ear, the binaurally produced data in the same patient did not correlate with auditory dysfunction. Latencies of the binaural far field potentials in these cases were found to have intermediate values between the latencies of each ear stimulated monaurally. For example, stimulation of one patients' left ear produced a wave V latency of 6.7 msec while the wave V latency following right ear stimulation was 5.8 msec. With binaural stimulation wave V latency in this patient was 6.2 msec.

These data suggest that binaural stimulation is unnecessary for adequate evaluation of auditory function following head injury and that it may actually be misleading. (Supported by N.I.H. grant NS 12587 and a Southern Medical Association Training Grant).

28 A COMPARATIVE SCANNING ELECTRON MICROSCOPIC STUDY OF THE OTOLITHIC ORGANS IN FISHES. Arthur N. Popper. Lab. of Sensory Sciences and Dept. of Zoology, University of Hawaii, Honolulu, Hawaii 96822.

Investigations have been conducted on the hair cell orientation patterns of the otolithic organs in the ears of more than 30 species of fish. Species were selected for study on the basis of diversity in acoustic behavior, habitat, and taxonomic relationship.

Inter-specific variation in hair cell orientation pattern is wide, particularly in the presumed auditory regions, the sacculus and lagena. Considerably less inter-specific variation is found in the utriculus where the patterns are very similar to those found in tetrapods.

In most non-ostariophysines (species not having a direct mechanical coupling between the swim bladder and inner ear) the sacculus is divided into four 'regions' with all of the hair cells in each region oriented in the same direction. Generally the cells on the dorsal side of the posterior half of the saccular macula are oriented with the eccentrically placed kinocilium on the dorsal side of the cell while the cells on the ventral side of the posterior half of the macula are oriented ventrally. Cells on the anterior half of the macula are divided into two groups, one oriented anteriorly and one posteriorly. The relationship between the anteriorly and posteriorly oriented groups varies considerably in different species. There is also considerable inter-specific variation in the relationship between the sensory region and overlying otolith, with the otolith, in many species, not covering the whole sensory area.

The hair cells on the lagena are generally divided into two groups oriented in opposite directions. The relationship between these groups varies in different species, but variation is not as extensive as in the sacculus.

The functional and taxonomic significance of the diversity of hair cell orientation patterns among fishes is not yet clear. However, it is possible that the different patterns relate to inter-specific variation in the method of sound detection and initial processing of acoustic signals. It is also likely that fishes can perform detection of sound source direction (sound localization) and the hair cell patterns may have evolved in relationship to such mechanisms in at least some non-ostariophysines. Thus the different patterns, particularly in the sacculus, may represent different approaches taken in the evolution of various teleosts for making maximum use of sound directional information. 29 AN ORDERLY FREQUENCY REPRESENTATION IN THE POSTERIOR ECTOSYLVIAN SULCUS OF THE CAT. Richard A. Reale and Thomas J. Imig*. Dept. of Neurophysiology, Waisman Center on Mental Retardation and Human Development, Univ. of Wisconsin, Madison, Wis. 53706.

On the basis of electrophysiological and cytoarchitectural evidence the auditory cortex of cat has been divided into a primary field (AI) and several surrounding secondary fields. These auditory fields are not confined to the gyral surfaces but are also located within the three major sulci in this region. We have undertaken a microelectrode investigation of one secondary area which we call the posterior field (P). P lies on the banks of the posterior ectosylvian sulcus (PES) where it is bordered dorsorostrally by AI. This field covers approximately 40 mm^2 of cortical surface, an area nearly equal to that occupied by AI. Electrode penetrations directed into both the anterior and posterior banks of the PES were aligned nearly parallel to these sucal walls. The responses of single neurons or neuron clusters to tone pips were studied at intervals of 300 micron or less. Best frequencies, latencies of responses at several stimulus intensities and occassionally binaural interactions were determined at each location. These data together with the histological reconstruction of each animal's brain revealed a complete and orderly frequency representation in P. Low frequencies in this field are located dorsorostrally contiguous with the low frequency representation in AI. High frequencies in P are located caudoventrally occupying a portion of the posterior bank of the PES and often extending upon the posterior ectosylvian gyrus. Thus the frequency organization of P is a mirror image of the frequency organization in AI. Often isofrequency contours extend from the posterior bank of the PES across the bottom of the sulcus onto the anterior bank. In the anterior and middle portions of P, neuronal responses to near threshold stimulation consist of a short latency (15-30 msec) burst of firing confined to a restricted frequency range. In the posterior portion of P, responses latencies of 50-150 msec are often seen in addition to the short latency component. These long latency discharges occur over a broad range of the frequency spectrum, making a determination of best frequency difficult or impossible. Supported by NIH Program Project Grant NS-12732, Core Grant HD-03352, Postdoctoral Fellowship NS-05459-01 and NSF Grant BNS 76-19893.

30 THE ROLE OF AFFERENT FIBER SYSTEMS ON THE DEVELOPMENT AND DIFFERENTIATION OF THE INFERIOR COLLICULUS. D.K. Ryugo. Dept. Anatomy, Univ. Vermont, Burlington, Vt 05401.

The present study investigates the role played by afferent fiber systems in the formation and differentiation of the nuclear subdivisions within the inferior colliculus(IC) of the rat. It has previously been reported that deafferentation of the central nucleus(CN) of the IC on post-natal day 1(PN 1) produces a delamination of the CN principal neurons and their dendrites, a shrinkage in CN volume and an apparent expansion of the pericentral nucleus(PcN)(Killackey and Ryugo, Anat. Rec., 187:624, 1977). Deafferentation of PcN was performed by auditory cortex ablations on PN 1 in an attempt to detect shrinkage in PcN with a corresponding expansion of CN; however, no effect on either PcN or CN was observed following such lesions. Golgi examination of CN on PN 1 showed the presence of lateral lemniscal fibers and a laminar arrangement of the immature principal neurons and their dendrites; electron microscopy at this age revealed only the start of synaptogenesis within the neuropil. In the adult, Fink-Heimer analysis following spinal cord hemisections, dorsal column nucleus lesions and auditory cortex ablations revealed terminal degeneration converging in PcN and the external nucleus(XN). A small amount of degeneration was also observed in CN. Sections of the IC commissure resulted in heavy degeneration in the dorsal medial nucleus(DM), PcN, XN and the dorsal portion of CN; the ventral portion of CN was entirely free of commissural projections. Sections of the lateral lemniscus produced heavy degeneration in CN, moderate degeneration in DM, PcN and XN, and sparse degeneration in the contralateral DM, PcN and XN.

These observations prompted the following conclusions: 1) the principal neurons and their dendrites of CN are oriented in a laminar pattern as early as PN 1; 2) CN lamina initiation does not appear to be dependent upon synaptic contacts; 3) the maintenance of CN lamination does depend upon the presence of lateral lemniscal fibers, at least for the age group studied; 4) since the entire CN is laminated, the differential distribution of commissural afferents within CN indicates that they probably do not play a crucial role in the formation or maintenance of the laminae; 5) the lack of shrinkage in PcN following auditory cortex ablations may be attributable to the sustaining influence of the remaining fiber systems.

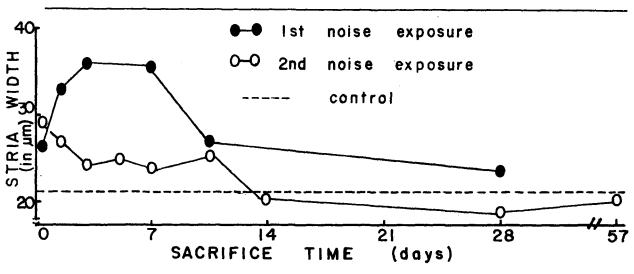
31 STRIA VASCULARIS PATHOLOGY AND RECOVERY FOLLOWING NOISE EXPOSURE. P.A. SANTI AND A.J. DUVALL*. Dept. Otolaryngology, Sch. Med., U. Minn., Minneapolis, MN 55414.

Duvall et al., 1974 (Ann. Oto-Rhino-Laryng. 83: 498) previously described stria vascularis pathology and recovery following a noise exposure of 700-2800 Hz at 123dB SPL for 15 min. The purpose of this research was to obtain quantitative data on the time course of stria pathology and recovery following 1 or 2 equivalent noise exposures. The second noise exposure was given 28 days after the first when stria morphology appeared to have returned to normal.

Sixty-one chinchillas were noise exposed and their right cochleae processed for transmission electron microscopy at sacrifice times of 0,3,6,24 hr, 3,7,10,14,28 days following the noise exposures. Each cochlea was bisected mid-modiolar and a segment of the stria removed from each of the three cochlear turns. Stria damage, consisting primarily of intercellular edema, was measured, using a light microscope eyepiece micrometer, from 2 µm epon sections. The results of these data are shown in the figure below. Although both noise exposures were equivalent and stria morphology appeared normal before the second noise exposure was given, stria edema was significantly less after the second noise exposure. Twenty eight days after the second noise exposure stria thickness had still not returned to normal. An additional group of animals were sacrificed 57 days post second exposure and showed that stria thickness was slowly returning to normal.

Six chinchillas have also been injected i.v. with horseradish peroxidase (Sigma type II, 0.1 mg/g body weight) to demonstrate stria blood vessels. These animals were sacrificed three days following a single noise exposure. Surface preparations revealed that stria damage was 1) diffusely distributed, 2) began in the lower basal turn near the supra strial region, and 3) progressively increased towards the cochlear apex. Presently, thin sections of selected tissues are being examined electron microscopically.



32 NON-PRIMARY AFFERENTS IN THE ROSTRAL AVCN OF THE GUINEA PIG. A.M. Schwartz* and R.L. Gulley (SPON: K.E. Alley). Dept. of Anatomy, Case Western Reserve University, Cleveland, Ohio 44106.

About 50% of the soma of the principal cell of the rostral anteroventral cochlear nucleus (AVCN) in the adult guinea pig is covered by large, primary terminals, the end bulbs of Held. In addition to the end bulb, 3 other axosomatic boutons have been identified in thin sections and freeze-fracture replicas. These boutons are non-primary, since all 3 types have been identified in animals 30 days following complete unilateral cochlear ablation, when all end bulbs have degenerated. Four percent of the principal cell soma is covered by small, angular boutons which often occur singly. Typically, these boutons are not surrounded by glial processes. These boutons contain small, round synaptic vesicles. The long, flat synaptic junction is undistinguished except for symmetric densities lining the cytoplasmic surface of the membranes. These boutons are more commonly found forming axo-dendritic synapses in the neuropil. About 12% of the soma is covered by small to medium-sized boutons containing oval synaptic vesicles. Single boutons of this type are isolated on the soma by astrocytic processes. In freeze-fracture replicas, each of these boutons has one to three crescent-shaped synaptic junctions. Accordingly, the size and shape of the junctions in thin sections is variable. The cytoplasmic density lining the postsynaptic membrane at the synaptic junctions is slightly thicker than the corresponding region of the presynaptic membrane. About 6% of the soma is covered by small boutons containing distinctly flattened synaptic vesicles. These boutons frequently occur in clusters which are ensheathed by astrocytic processes; however the individual boutons within the cluster are not separated by glial processes. These boutons have a flattened, oval-shaped synaptic junction. In thin sections, the cytoplasmic surface of the membranes at the synaptic junction are lined symmetrically by dense material. In freeze-fracture replicas, there is no specialization of the post-synaptic membrane opposite any of the non-primary boutons. Boutons containing flattened vesicles, in animals kept in a sound deprived environment for one hour prior to sacrifice, have a greater number of synaptic vesicle attachment sites, indicative of synaptic vesicle release, than these boutons in animals in a noise enriched environment. This observation suggests that this population of terminals on the principal cells may be active in the absence of sound. Since the other non-primary terminals can be easily distinguished using the criteria described above, it is hoped that further studies using the freeze-fracture technique under well defined physiological conditions, will elucidate the role of the other inputs to the principal cell of the rostral AVCN.

33 OTOTOXICITY AS MEASURED BY THE AUDITORY BRAINSTEM RESPONSE AND THE SCALP RECORDED COCHLEAR MICROPHONIC IN GUINEA PIGS. Vincent L. Schwent*, John S. Williston, and Don L. Jewett (SPON: A.S. Gevins). Dept. Ortho. Surg., Sch. Med., UCSF, San Francisco, CA. 94143.

The ability of the ABR (Auditory Brainstem Response) and the SRCM (Scalp Recorded Cochlear Microphonic) to reflect the ototoxic effects of kanamycin sulfate (s.c.) was assessed using adult guinea pigs. Twenty-one albino guinea pigs were studied with one third receiving 400 mg/kg/day for 7 consecutive days, one third receiving 200 mg/kg/day for 14 days and the remaining third receiving no drug. ABRs were recorded from vertex to stimulated ear by standard response-averaging methods using 50μsec clicks at 40 and 80 dBSPL at both 10 and 80 Hz repetition rates. Responses were obtained before, during and after drug administration with recording from most animals continuing for at least 2 months after the kanamycin treatment. At the termination of the study additional intensities were also recorded. SRCMs were continuous pure tones were recorded from the vertex referenced to the neck or throat by a special modification of our averaging techniques (see Neuroscience Ab. 2:25, 1976). SRCMs were obtained to 500 Hz (90 dBSPL), 2 KHz (90 dBSPL) and 8 KHz (90 and 100 dBSPL) with continuous tones. Hair cell counts of representative cochleas are pending.

Several guinea pigs in both the high dose (400 mg/kg) and low dose (200 mg/kg) groups evidenced varying degrees of change in the ABRs after kanamycin administration, usually by increased component latencies. The time course of these latency increases and their interaction with stimulus intensity produced widely varying patterns of auditory system change among those animals evidencing ototoxicity. The relative amplitude of the SRCM to the three frequencies of tonal stimulation showed differential frequency effects in some animals. The implications of employing the ABR and SRCM to monitor ototoxicity in non-communicative patients receiving potentially ototoxic drug (e.g. premature infants) and in animal studies on the effects of such drugs will be discussed.

34 DETECTION OF THE PRIMARY AFFERENT AUDITORY TRANSMITTER USING BIOLOGICAL ASSAY. William F. Sewell and Paul S. Guth*. Dept. Pharmacology, School of Medicine, Tulane University, New Orleans, La. 70112

The junction between the auditory hair cells and the primary afferent nerve has the morphological and electrophysiological characteristics of a chemically transmitting synapse. Although several candidates, including gamma-aminobutyrate and acetylcholine, have been put forward as the primary transmitter (PAT) of audition, none has been supported by the evidence. On the contrary, there is evidence that acetylcholine is not the PAT. Unsuccessful attempts at blocking transmission at this synapse with standard pharmacological antagonists have led to the conclusion that the PAT may not be one of the standard transmitters. Consequently, a research strategy which could detect the presence of the transmitter, even though its identity was unknown, was required in order to allow purification and characterization of the transmitter. Frogs were immobilized with d-tubocurarine and the posterior branch of the VIII nerve and the perilymphatic sac surgically exposed. Single unit activity in VIII nerve fibers from the basilar or amphibian papillae was monitored and the units identified by their characteristic frequencies. The frogs were stimulated with white noise or kept in silence while the perilymphatic space was perfused by a push-pull cannula containing artificial perilymph. The collected fluid was then reinfused in silence and the firing pattern of the single unit fiber was monitored and recorded. In several instances, the reinfusion in silence of fluid collected during white noise stimulation resulted in an increase in the firing rate of the single unit being investigated. By this means, the PAT can be collected and attempts at concentration and purification can be monitored by following the effect upon the firing rate of VIII nerve single units. (This work was supported by Grant 71-6 from the Veterans Administration).

35 MAPPING OF THE TONOTOPIC ORGANIZATION OF THE AUDITORY SYSTEM BY UPTAKE OF RADIOACTIVE METABOLITES. M.S. Silverman*, A.E. Hendrickson, B.M. Clopton* Dep't of Otolaryngology and Opthalmology, Univ. of Washington, Seattle, Washington 98195.

Recent studies have shown that neuronal activity within the central nervous system is closely associated with the uptake of deoxyglucose (DG) (Kennedy et al, PNAS, 1976). We have used this association in conjunction with autoradiographic techniques to study tonotopic organization within the auditory system. Pentobarbital-anesthetized rats or guinea pigs were exposed to a pulsed tone for 45 minutes following an intravenous injection of C^{14} or H^3-DG. Immediately following exposure to the tone the brain was removed and frozen in liquid nitrogen-chilled freon and sectioned at 10μ in a cryostat maintained at -20°C. The sections were heat-treated and autoradiographed using X-ray film. Examination of the autoradiographs revealed distinct, localized variations in silver grain density throughout the auditory nuclei. These regional variations of grain density and their relative positioning in a given auditory nucleus are dependent on the exposure tone frequency used following the DG injection. In addition, the autoradiography patterns agree with classical tonotopic mapping as determined by electrophysiological techniques. The use of radioactively labeled DG in conjunction with autoradiography can produce a pictorial and spatial representation of the tonotopic organization of the auditory system that is a powerful alternative to electrophysical techniques. The localization of C^{14} DG in central auditory nuclei will be compared with autoradiographic labeling of auditory pathways after injection of H^3 amino acids. (Supported by grants EY01208 and NS13052-02).

36 DENDRITIC STRUCTURE IN N. LAMINARIS OF THE CHICKEN. D. J. Smith* and E. W Rubel, Depts. of Otolaryngology and Physiology, Univ. of Virginia Medical School, Charlottesville, VA., 22901.

In the avian brain stem, n. laminaris (NL) is composed of a monolayer sheet of 3rd-order auditory neurons receiving spatially segregated binaural input from corresponding regions of the ipsilateral and contralateral magnocellular nuclei. Previous studies have described the functional and structural organization of inputs to NL as well as its tonotopic organization. The present investigation examines the normal morphology of NL cells as a function of their position along the tonotopic dimension of the nucleus in 5-day-old hatchling chickens. Rapid Golgi, Golgi-Cox and Golgi-Kopsch methods were used, the latter providing the most reliable impregnation with little background staining. In the anteromedial portion of NL, which is responsive to high frequencies (2.5-4 kHz), many (16+) short, stubby, unbranched dendrites extend about 16μ from each side of the cell body, giving it a two-sided "thistle" appearance. In the central (1.5-2.5 kHz) region, similar cells have fewer (10-16) primary dendrites which extend further (33μ) from the cell body and are more branched. Toward the posterior pole (below 1.5kHz), 3-8 longer processes branch profusely after extending 50-80μ from the cell body. Quantitative analyses of dendritic lengths were made of 81 neurons sampled from all parts of NL. Camera lucida tracings made down the center of each individual dendritic process were measured with an electronic planimeter. Dorsal, ventral and total dendritic lengths were related to the position of the cell within the rostrocaudal and mediolateral nuclear dimensions. Regression analyses yielded a highly reliable ($p<.001$) 2.5-fold increase in dendritic lengths from the anteromedial to the posterolateral pole of NL. Mean dorsal and ventral dendritic lengths over nuclear regions were also highly correlated ($r= .62$). These results indicate that there is a systematic variation of dendritic morphology coincident with the tonotopic organization of NL. In addition, there is surprising uniformity of dorsal and ventral dendritic lengths within each region of NL.

37 TIME DOMAIN ANALYSIS OF SINGLE UNITS IN THE INFERIOR COLLICULUS. E. E. Sutter, H. L. Hosford* and B. Dawson*. Hearing and Speach Sciences, Stanford Medical Center, Stanford, CA 94305.

The technique developed by Lee and Schetzen (Int. J. Control 2: 237, 1965) for the determination of transfer characteristics was employed in a study of the response of single units in the inferior colliculus. Recordings were obtained from three chronic awake cats binaurally stimulated with uncorrelated Gaussian white noise. So far, only first order processing has been performed on the data. The first order correlation provides information concerning latencies, "memory", and tuning. Since the response is a spike train, the first order correlation is represented by the spike locked average of the noise stimuli. Averages of the input signals to the ipsilateral and contralateral ear over approximately 10,000 spikes were obtained for each unit. For 75% of the cells these averages agreed well with tuning curves obtained by means of pure tone bursts. The absence of strong signal averages for 25% of those cells which responded strongly to tone bursts suggest poor phase-locking of the spikes. In those cases, higher order analysis of the data can be expected to yield valuable information.

38 PERCEPTUAL CONSTANCY FOR VOWEL CONTRASTS IN NORMAL AND LANGUAGE DELAYED CHILDREN. P. Tallal* and R.E. Stark* (SPON: M.S. Preston). Dept. Neurol., Johns Hopkins Med. Sch. Baltimore, MD 21205.

The ability to generalize phonemes across various vocal tracts is an essential aspect of normal speech perception. The child must learn that, although acoustically different, a speech sound produced by different individuals is still the same speech sound. Kuhl (1976, JASA, 60, S90A) has recently demonstrated that infants as young as six months old are able to generalize phonetically similar speech sounds across various size vocal tracts.

Ten children 7½ to 8½ years old with specific developmental language delay and ten normally developing children matched for age, I.Q and socioeconomic status were presented with the vowel /a/ spoken by a man, a woman and a child. Subjects were trained to press the bottom button on a response panel to each presentation of this vowel, regardless of which speaker produced it. Next, subjects were presented with the vowel /ɛ/ spoken by the same man, woman and child and trained to press the top button on the response panel to each presentation of this vowel. Finally subjects were presented with the two vowels produced by the three different speakers in random order and they were required to press the appropriate button on the response panel. No verbal instructions were given at anytime to any of the subjects. Knowledge of results and correction of errors were given and correct responses were rewarded after each trial until a criterion of 20 out of 24 consecutive trials correct had been reached or 48 trials had been given.

Results showed that there was no significant difference between the language delayed and normally developing children's ability to learn to press the appropriate button for each vowel when they were produced by a single speaker. Thus, both groups of children were able to discriminate between the two vowels and learn to associate them with the correct button. However, when the same vowels were produced by various speakers and presented randomly the performance of the two groups was significantly different ($p < 0.05$). Whereas nine out of ten of the normally developing children learned the concept underlying this task and reached the criterion within the 48 trials given, only four out of ten of the language delayed children were able to meet this criterion. The importance of perceptual constancy for normal language development will be discussed.

39 BRAINSTEM PATHWAYS MEDIATING HEAD ORIENTATION TO SOUND. G. C. Thompson and R. B. Masterton. Dept. Psych., Florida State Univ., Tallahassee, Fla. 32306.

The neuroanatomical pathways responsible for the reflexive head-turn toward the source of an unexpected sound have been traced with the ablation-behavior method. Postoperative measurements of latency and accuracy of the orienting response have been made in cats with unilateral lesions of either the lateral lemniscus and pathways medial and rostral to it, the brachium of the inferior colliculus, the midbrain pathways lying medial and ventromedial to the brachium, the superior colliculus, or auditory cortex.

The results show: 1) lesions transecting the lateral lemniscus and nearby pathways (e.g., the dorsal acoustic stria) completely abolish head orientation toward a sound source in the contralateral auditory field; 2) lesions confined to the lateral lemniscus itself disrupt the accuracy of alignment toward a contralateral sound source without affecting the latency or direction of the response; 3) lesions at the level of the brachium of the inferior colliculus including the pathways medial and ventromedial to it abolish the accuracy of the orienting response toward the contralateral field and lengthen the latency of the response; 4) lesions confined to the brachium of the inferior colliculus and the pathways medial to it have little effect on the orienting response except to increase its latency bilaterally; 5) lesions of the superior colliculus including its deepest layers that completely abolish head-orientation to a visual stimulus do not affect head-orientation to a sound stimulus; 6) lesions of auditory cortex including the most ventral auditory fields reduce the probability but not the parameters of orientation to sound in the contralateral field. Comparisons of midbrain lesions that affect the accuracy of orientation with lesions in the same vicinity that do not affect orientation suggest a critical pathway through the midbrain tegmentum ventromedial to the brachium of the inferior colliculus and ventral to even the deepest layers of the superior colliculus. 40 COMBINED GOLGI, HORSERADISH PEROXIDASE (HRP), AND ELECTRON MICROSCOPIC STUDY OF BUSHY CELLS IN THE COCHLEAR NUCLEUS. Leslie P. Tolbert and D. Kent Morest. Depts. Anat., Harvard Medical Sch., Boston, MA 02115, and U. Conn., Farmington, CT 06032.

Golgi impregnations of the posterior part of the cat's anteroventral cochlear nucleus (AVCNp) reveal two types of neurons, bushy cells with short bush-like dendrites and stellate cells with long, tapered processes; Nissl stains reveal globular neurons and multipolar neurons with dispersed and clumped ribosomal patterns, respectively. The present findings indicate that bushy cells are globular neurons that project to the contralateral medial nucleus of the trapezoid body (MNTB). After HRP injections in the MNTB or transected trapezoid body, two types of HRP labelling were observed: diffuse and granular. In the ipsilateral AVCNp, retrograde diffuse labelling of neurons yielded Golgi-like profiles of bushy cells with thick axons projecting toward the trapezoid body. Anterograde diffuse labelling of thick fibers demonstrated typical calyces in the contralateral MNTB. The diffusely filled bushy cells were examined in the electron microscope to establish correlations between ultrastructural observations and Golgi and Nissl findings. Bushy cell bodies were found to have the dispersed ribosomal pattern of globular neurons and to receive several types of synaptic endings, including the large terminals indicative of endbulbs from cochlear nerve axons. In the contralateral AVCNp, cell bodies were labelled with a granular reaction product, presumably due to HRP uptake at synaptic endings; they were Nissl-stained and seen to be globular neurons. It is concluded that bushy cells typically correspond to globular cells, which receive endbulbs from the cochlea and send thick axons to the contralateral MNTB, where they form calyces on principal cells. Principal cells, in turn, project to the nucleus of origin of the crossed olivocochlear bundle, which feeds back to the cochlea. Thus, an anatomical circuit can be defined in terms of specific cell types and kinds of synaptic endings at the ultrastructural level. In this circuit, correlations between particular synaptic patterns and certain physiological signal transfer characteristics are suggested. 41 THE TEMPORAL PATTERN OF DISCHARGES ELICITED FROM LATERAL SUPERIOR OLIVE UNITS WITH ACOUSTIC STIMULATION. Chiyeko Tsuchitani. Sensory Sciences Center, Univ. of Texas Health Sciences Center, Houston, TX, 77025.

The temporal characteristics of the discharges of lateral superior olivary units to acoustic stimulation were examined in barbiturate anesthetized cats. Gold-plated, stainless steel microelectrodes with platinum-blacked tips were used to record extracellularly from units confirmed histologically to be located within the lateral superior olive.

With monaural tone burst stimulation of the ipsilateral ear lateral superior olive units with characteristic frequency, (CF: the frequency to which a unit is most sensitive), greater than 2 kHz produced discharges that were time-locked to stimulus onset (chopper pattern). The initial peaks of the chopper-type poststimulus time (PST) histograms of these units are narrow and are separated by short interpeak intervals. The chopper pattern is not maintained for the duration of a 60 msec tone burst and may be produced by only the first 3 to 13 spikes of the elicited discharges. The discharges following this initial, transient chopper response may drop to very low rates, producing an almost phasic-type PST histogram, or may be maintained at high levels with an irregular temporal pattern. The interspike interval (ISI) histograms of the tone burst elicited discharges are often bimodal in distribution, with a short interval peak formed by the initial chopper response, and a second, longer interval peak formed by the later discharges.

Increasing stimulus level increases the duration of the chopper response and narrows the peak widths and interpeak intervals of the chopper response. With increases in stimulus level the two peaks of the bimodal ISI histograms become indistinguishable and often fuse at high stimulus levels to form a unimodal, symmetrical distribution. Stimulation with tone bursts at frequencies other than unit CF elicite discharges similar to those elicited by CF tones at lower stimulus levels. Simultaneous stimulation of the contralateral ear, which is inhibitory,disrupts the chopper pattern and produces an irregular discharge pattern.

42 AUDITORY NEURONS OF THE MOUSE SELECTIVELY RESPONSIVE TO LONG DURATION STIMULI. James F. Willott and Gregory P. Urban*. Dept. Psychol., Northern Illinois Univ., DeKalb, Ill. 60115.

Obvious means by which the auditory system could encode the duration of acoustic stimuli are the duration of sustained evoked discharges and phasic on-off responses signalling the beginning and end of a stimulus. Both involve changes in neural activity closely following the onset and termination of the stimulus. In addition to these, we have observed a different type of response in neurons of the mouse inferior colliculus (IC). These responses had latencies of 100 msec to over 200 msec and required tone bursts of such relatively long durations in order to significantly respond. In a sample of more than 300 IC neurons of mice tranquilized with chlorprothixene and only minimal barbiturate, 8 units of this type were observed. None appeared to be located in the ventrolateral (central) nucleus. Since optimal responding required stimuli of particular minimal durations, these units appear to "filter" out short duration sounds. Such responses are fundamentally different from previously mentioned sustained and on-off responses which follow the temporal course of stimuli over wide duration ranges. For the units described here, relatively long duration is an obligatory stimulus "feature," and the very fact that a response occurs provides information about duration.

43 CHANGES IN ENDOGENOUS REACTIVITY TO DIAMINOBENZIDINE IN BRAIN STEM AUDITORY NUCLEI SUBSEQUENT TO THE "SILENCING" OF THE AUDITORY NERVE. Margaret Wong-Riley, Michael M. Merzenich* and Patricia A. Leake*. Dept. Anat. and Coleman Lab., Univ. Calif., San Francisco, Ca. 94143.

In previous studies (Wong-Riley, Brain Res., 108 (1976) 257-277, and unpublished observations), neurons and/or neuropil in various relay nuclei of the auditory pathway (cochlear nuclei, superior olivary nuclei, nuclei of the lateral lemnisci, inferior colliculi) were found to be highly reactive to the diaminobenzidine-H_2O_2 medium at pH 9.0. This was interpreted to be due largely to a higher concentration of heme-enzymes, most likely of the cytochrome system, within these regions. In order to test the possible relationship of such oxidative enzyme activity to the functional state of these nuclei, experiments were carried out in cats whose auditory nerves were unilaterally "silenced" for periods of 1-10 months. These cats (implanted with long silastic scala tympani inserts; Schindler and Merzenich, Ann. Otol. Rhinol. Laryngol., 83 (1974) 202-216) were totally deaf in one ear, while the auditory nerve fibers of that side were determined histologically to be largely intact. When the brain stems of these cats were reacted with the DAB-H_2O_2 medium, neurons or neuropil that received their major excitatory input directly or indirectly from the deaf ear exhibited decreased reactivity. Thus, the level of reactivity was significantly reduced within both neurons and neuropil of the ipsilateral anteroventral and posteroventral cochlear nuclei, and of the ipsilateral lateral superior olives (which receive excitatory input from the ipsilateral ear, and inhibitory input from the contralateral ear). Neurons of the contralateral medial nucleus of the trapezoid body, and neuropil of the contralateral ventral nucleus of the lateral lemniscus and at least the caudal (monaural) portion of the contralateral central nucleus of the inferior colliculus also exhibited markedly reduced reactivity. By comparison, there was relatively little difference in reactivity between the dorsal cochlear nuclei, the medial superior olives (which receive excitatory input from both ears) and the dorsal nuclei of the lateral lemnisci of the two sides.

The decrease in presumed oxidative enzyme activity within major auditory nuclei seen to the level of the midbrain in unilaterally deafened cats reflects a sensitive response of neurons to the elimination of their primary excitatory input(s) one to several synapses away.

(Supported by NIH Grants NS-12995, NS-11804 and NS-10414).

44 THE ANATOMIC AND ELECTRONIC FACTORS IN THE PRODUCTION OF COCHLEAR MICROPHONICS OR THE WEVER-BRAY PHENOMENON. M. Wharton Young*, Emeritus Professor of Anatomy, (SPON: James A. Holloway). Howard University, College of Medicine, Washington, D.C., 20059

When Wever and Bray first demonstrated the cochlear microphonic effects in 1930, they theorized that the anatomical basis for this physiological activity was "..a cochlear structure acting as a special receptor and transmitter" hence a true microphone. Numerous studies have reconfirmed these electrical effects, even in the post-mortem state but the anatomic and the electronic bases have remained somewhat obscure and speculative. The labyrinthine structure of the inner ear presents many gross and molecular problems. Throughout the prenatal period, the amniotic fluid exerts a constant and equal pressure on the developing organs which approximates that of the cerebrospinal fluid of the mother. After birth, the persons own cerebrospinal fluid pressure upon the endolymphatic sac is transmitted through its duct to balloon the membranous labyrinth and force (propel) its endolymph across the ultra thin vestibular (Reissner's) membrane into the perilymphatic space thus generating a streaming membrane potential, DC. The perilymph does not drain through its duct into the subarachnoid space but this duct ends in a terminal 'perilymphatic sac' similar to the endolymphatic duct and sac. This newly discovered sac lies in the jugular fossa above the carotid sheath. The perilymph makes its exit through the 'fistula ante fenestram' into the tympanic lymph channel that grooves the promontory and drains into the tubal tonsils. The retina and organ of Corti have a similar embryonic development and each individual hair cell develops a protoplasmic outgrowth (projection) of a different length that forms a dorsal cuticular border on Corti's organ that grows and expands to form the pennant-shaped tectorial membrane attached medially to the individual auditory (Huschke's) teeth on the limbic lip, adjacent to the highly charged vestibular membrane. Each individual hair cell with its outer tectorial segment and 'tooth' forms a 'cochlear rod' (as retinal rods) whose specific length renders it as a selective resonator sensitive and responsive to a particular sonic frequency (cps): like radio antennae. Chemicophysical experiments indicate that the cytoplasmic sound-sensitive macromolecules are helical in shape and linearly arranged hence harmonious sonic vibrations cause ionic derangements (migration) that generate displacement potentials, CM, that initiate the local nerve impulse, NP, which is relayed to definite brain centers and specific cortical areas (Place Theory). Obviously each one of the twenty some thousand 'cochlear rods' is needed "..a cochlear structure acting as a special receptor and transmitter" and is thus a transducer and microphone.

45 AUDITORY FEATURE DETECTORS IN THE CANARY FOREBRAIN AND THEIR RESPONSE TO SONG. Malcolm D. Zaretsky*. Dept. Zoology, Univ. of Iowa, Iowa City, IA 52242.

The auditory areas of the canary forebrain contains single units which respond to various optimal stimuli: pure tones over a narrow band, pure tones over a wide range, FM signals, clicks. There are phasic and tonic units, on units, off units and units which respond with long latency.

The song of the roller canary consists of several phrases in succession, each formed by repetition of a distinctive syllable. The spectral composition of each syllable can be analyzed by means of the sound spectrograph. Auditory units respond to elements of natural song which have spectral characteristics similar to those of artificial optimal stimuli.

AUTONOMIC FUNCTION

46 INCREASED DEPRESSOR RESPONSES TO CENTRALLY ADMINISTERED NOREPINEPHRINE & EPINEPHRINE IN SINOAORTIC DENERVATED RATS. Natalie Alexander* and Charles K. Haun* (SPON: Bertha Newman) Depts. of Med. and Anat., Sch. of Med., USC, Los Angeles, CA 90033.

Resection of carotid sinus and aortic depressor nerves in the rat produces moderate, labile hypertension associated with elevated plasma dopamine beta hydroxylase activity (Life Sci. 18:655, 1976). Intra-arterial pressure recordings from conscious sinoaortic denervated (SAD) rats show wide oscillations of 25-50 mm Hg lasting 2 to 5 min with superimposed large pressure dips of 1-30 sec duration. The same occurs in SAD rabbits (PSEBM 121: 766, 1966). We hypothesized that SAD not only eliminates a major source of neural inhibition to the cardiovascular system, thereby raising systemic pressure, but also causes a "central denervation supersensitivity" to neurotransmitters. To test this idea, a 23-gauge canula extending into the fourth cerebral ventricle was implanted 10-12 mm posterior to the bregma in adult rats. A week later SAD or a sham operation was performed. Four to 21 days later a femoral artery was canulated (under ether or Innovar) and 3 hours later with the rat sitting in a restrainer, arterial pressure (AP) and pulse rate (PR) were recorded continuously before and after intraventricular injections of 1,2,4,8 and 16 µg (base) of l-norepinephrine bitartrate (NE) or l-epinephrine bitartrate (E) dissolved in saline. Each dose was in a volume of 1 µl and injected at 10-15 min. intervals. Both amines caused reductions in AP and PR. In some studies a NE and E dose-response curve was obtained in the same rat with an interval of 2-18 hrs. between the 2 tests. If this was done with an interval of only 1 hr. between tests, responses to the second amine were clearly attenuated suggesting that NE and E occupy some of the same central receptor sites to produce AP lowering. Both NE & E caused greater reductions of AP in SAD rats than in shams so that dose-response curves of SAD rats were shifted to the left. In contrast, PR reductions in response to NE or E were the same in both groups. SAD rats also had greater AP reductions than shams under urethane anesthesia where starting pressures were equal. One interpretation of these results is that pressure lability and pressure dips in SAD rats are due to intermittent release of adrenergic amines acting on brain stem vasomotor neurones which are supersensitive to neurotransmitters following interruption of neural input from baroreceptor nerves. Neurons involved in reflexes that affect PR did not show this supersensitivity to NE or E.

47 THE EFFECT OF GUANIDINE ON TRANSMISSION AT THE CHICK CILIARY GANGLION. Floyd W. Banks. Dept. of Physiol., Univ. of Colo. Sch. Med., Denver, CO 80262.

Guanidine hydrochloride (CH_5N_3-HCl) has been shown to increase the size of the end-plate potential at the neuromuscular junction and also to cause hyperexcitability in axons (Matthews, G., and Wickelgren, W.O. J. Physiol. 266, 69-89, 1977). The effect of guanidine was tested on the chick ciliary ganglion to see if the increase in transmitter release could be accounted for by an increase in amplitude or duration of the presynaptic action potential or whether the drug had an effect on the release mechanism itself. When 0.5 mM guanidine was perfused into the bath and a presynaptic terminal (calix) was impaled, the calix spike showed a transient increase in amplitude and broadening and, occasionally, subsequent failure. This failure was probably due to a measured decrease in input resistance of the calix which enhanced the impedance mismatch between the small presynaptic axon and the large caliciform terminal. When the ganglion cell was impaled and guanidine applied, there was an increase in average amplitude of evoked e.p.s.p.'s. To test if this increase was associated with the broadening of the presynaptic spike, only ganglion cells with coupling potentials were impaled. After recording control e.p.s.p.'s, guanidine (0.5 mM) was perfused into the bath. Records were taken one every 4 sec for at least 5 min. A graph of the average amplitudes of the electrical coupling potential and chemical e.p.s.p. showed that the increase in chemical transmission preceded any changes in electrical transmission by 2.0 - 2.5 min. The time course of the change of electrical transmission closely followed the time course of broadening of the presynaptic spike when the calix was impaled directly. Amplitude histograms were made of evoked responses in control solution and in guanidine. The mean amplitude of the responses was larger and the coefficient of variation smaller in the guanidine solution. The decrease in the coefficient of variation is consistent with the idea that the increase in amplitude was due to an increase in quantal content and not due to increased sensitivity of the postsynaptic membrane. Supported by NIH grant # NS 09660 and Fellowship # NS 05554.

48 TONIC SYMPATHOINHIBITION OF NON-BARORECEPTOR ORIGIN. Susan M. Barman and Gerard L. Gebber. Dept. of Pharmacology, Michigan State University, East Lansing, Michigan 48824.

Experiments were performed on Dial-urethane anesthetized cats to determine whether neural inhibition of non-baroreceptor origin functions tonically to depress naturally occurring sympathetic nervous discharge (SND). The effects on renal SND produced by bilateral electrolytic lesions (5 mA for 15 sec) of the nucleus of the tractus solitarius (NTS) and of medial medullary structures were compared in baroreceptor intact and denervated animals. In the intact animal, NTS lesions 1 mm rostral and 1 mm caudal to the obex produced a significant ($p<0.05$) increase in renal SND (154±13% of control) and abolished the baroreceptor reflex. Loss of the baroreceptor reflex was evidenced by the disruption of the phase relations between SND and the cardiac cycle. NTS lesions increased SND in only 1 of 5 cats in which the carotid sinus, aortic depressor, and vagus nerves were bilaterally sectioned. These results suggest that sympathoinhibitory elements within NTS usually are not tonically active in the baroreceptor denervated cat.

Lesions in the midline of the medulla 0-2 mm rostral to the obex produced a significant increase in renal SND (142±11% of control) without affecting the baroreceptor reflex in intact cats. These lesions destroyed portions of nucleus raphe obscurus and the paramedian reticular nucleus. Midline medullary lesions in the baroreceptor denervated cat produced an equivalent increase in renal SND (161±13% of control). Section of the spinal cord at the first cervical segment essentially eliminated renal SND after medial medullary lesions. These data support the contention that inhibition mediated through midline structures in the caudal medulla is tonically active in the absence of baroreceptor nerve discharge and functions to suppress SND emanating from supraspinal structures. Furthermore, sympathoinhibition mediated through midline medullary structures is transmitted over a pathway distinct from that which receives baroreceptor input.

In contrast to the results obtained in animals with an intact neuraxis, midline medullary lesions failed to produce an increase in renal SND in baroreceptor denervated cats which were decerebrated at the midcollicular level. These results suggest either that sympathoinhibition mediated through midline medullary structures is of forebrain origin or that the increase in SND produced by midline lesions in cats with an intact neuraxis emanates from forebrain structures. (Supported by PHS grant HL 13187 and by a grant from the Michigan Heart Association.)

49 EFFECT OF CLONIDINE AND CHLORPROMAZINE ON ELECTRODERMAL RESPONSES AND REFLEXES AND THEIR INTERACTION WITH YOHIMBINE. Patricia J. Bernthal* and Michael C. Koss. Dept. Pharmacology, Univ. Okla. Sch. Med., Okla. City, Oklahoma 73190.

Adult cats were anesthetized with either sodium pentobarbital (36 mg/kg) or α-chloralose and urethane (35 mg/kg and 500 mg/kg). Electrodermal responses were evoked by electrical stimulation of the posterior hypothalamus at a constant submaximal frequency (10-16 Hz). Electrodermal reflexes were elicited by stimulation of the afferent common peroneal nerve in intact and spinal preparations. Peripheral electrodermal responses were evoked by stimulation of the efferent ulnar nerve. Graded i.v. doses of both clonidine and chlorpromazine reduced the amplitude of the centrally evoked responses. The ED_{50} for clonidine was approximately 5 µg/kg and that for chlorpromazine was about 1 mg/kg. Yohimbine pretreatment (0.5 mg/kg) antagonized the effects of clonidine but did not alter the action of chlorpromazine in inhibiting these responses. Both clonidine and chlorpromazine also reduced the amplitude of the electrodermal reflexes in a dose-related fashion. The ED_{50} for clonidine was approximately 1 µg/kg in the intact preparations and 2 µg/kg in the spinal cats. The ED_{50} for chlorpromazine was about 0.1 mg/kg and 0.03 mg/kg respectively in these two types of preparations. As with the centrally evoked responses, pretreatment with yohimbine effectively blocked the actions of clonidine but not that of chlorpromazine. None of these agents had any significant effect on the peripherally evoked responses. The results demonstrate that both clonidine and chlorpromazine inhibit central reactivity of this sudomotor system and that they can exert their action at several levels including the spinal cord. In addition, the observation that yohimbine selectively blocks the action of clonidine but not chlorpromazine suggests that these two agents depress the central reactivity of this sympathetic-cholinergic system by different mechanisms. (Supported by USPHS grant MH 25792)

50 TRANSIENT LOCAL ALTERATIONS IN CEREBRAL MICROVASCULAR BLOOD VOLUMES AND FLOWS INDUCED BY HYPOTHALAMIC STIMULATION. Baruch Blum*, Tamar Yashin*, Villi Benari*, and Stephan Friedland*. (SPON: W. A. Alter III). Dept. Physiol. & Pharmacol., Tel Aviv University, Tel-Aviv, Israel.

Evidence has been accumulated for neurogenic control of regional cerebral blood (RCB) supply. This includes anatomical data on rich autonomic innervation of various components of leptomeningeal vasculature and pharmacological data suggestive of neural control. This report presents physiological evidence on fast local changes in RCB supply at middle and posterior syprasylvian gyri (SSG) following lateral hypothalamic (LH) stimulation. Data were obtained from 24 chloralose-anesthetized cats. Application was made of silicon semiconductor detector for measurement of radioactive krypton (Kr) clearances after its bolus injection into internal carotid artery. This permitted computation of baseline RCB flow during stationary conditions and also comparison between microvessel blood volumes in stationary vs dynamic states induced by LH stimulation. The Zierler stochastic method and compartmental analysis used gave values agreeing in the low and medium ranges but diverged in the high flow ranges. Compartmental analysis revealed two gray-matter compartments within SSG: a fast one with a low weight(average f_{fast} = 220 ml/100g/min and average W_{fast} = 16% and a slow one with a high weight(average f_{slow} = 37 ml/100g/min and average W_{slow} = 84%). The fast compartment showed greater response to LH stimulation. Heat-clearance method calibrated by simultaneously applied Kr clearance was used to measure flow for stationary control periods and for dynamic conditions induced by LH stimulation. This method proved very sensitive for measurements of small changes. It was thus established that LH stimulation induces local RCB supply changes--either increases or decreases--with flow rates and microvessel volumes changing even independently, at latencies often shorter than 1 second. Phenomena of adaptation, recruitment, and oscillation were also observed. Microscopic observations, aided sometimes by fluorescein, enabled locating sites of maximal effects and observation that LH stimulation induced opening of capillaries that were previously closed and of widening of microvessels that were only partially open. Based on the shortness of latencies for changes and specificity of stimulation site, it was concluded that the data support a neurogenic control mechanism for gray-matter RCB blood supply.

51 MODULATION OF SOMATO-VAGAL REFLEXES BY SEPTAL STIMULATION IN THE RABBIT. A. L. Brickman, G. J. Mogenson and F. R. Calaresu, Dept. of Physiology, Univ. of Western Ontario, London, Canada N6A 5C1.

It has been suggested that limbic forebrain structures are involved in cardiovascular integration by altering mechanisms lower in the neuraxis so that cardiovascular adjustments are appropriate to sensory inputs (Calaresu, Faiers and Mogenson, Prog. Neurobiol. 5: 1-35, 1975). Since it is well documented that electrical stimulation of somatic afferents elicits cardiovascular responses (Sato and Schmidt, Physiol. Rev. 53: 916-947, 1973), a series of experiments was done to investigate the role of the septum in the cardiovascular response elicited during somatic nerve stimulation.

Electrical stimulation of histologically verified sites in the lateral septum consistently elicited decreases in heart rate (HR) and mean arterial pressure (MAP). These responses were observed in rabbits anesthetized with either sodium pentobarbital (22 sites) or alpha-chloralose (20 sites). They were not due to changes in somatic activity since all rabbits were paralysed with decamethonium bromide (4 mg/kg, i.v.) and artificially ventilated. Stimulation of the sciatic nerve in rabbits anesthetized with chloralose elicited an immediate and pronounced drop in HR as well as a decrease in MAP. The HR response was shown to be due to vagal excitation as it was abolished by either bilateral vagotomy (n=8) or the administration of atropine methylbromide (3 mg/kg, i.v.; n=4). In order to investigate the influence of septal stimulation on the sciatic response, the lateral septum and sciatic nerve were stimulated simultaneously. The current intensities used during simultaneous stimulation were determined by stimulating either the sciatic nerve or the lateral septum individually using the threshold stimulus for a cardiovascular response. Combined threshold stimulation elicited a significant decrease in both HR and MAP (n=8). These findings suggest that the septum may participate in modulating cardiovascular responses elicited during somatic nerve stimulation.

52 MECHANISMS INVOLVED IN THE CARDIOVASCULAR AND BEHAVIORAL CHANGES EVOKED BY CHOLINERGIC STIMULATION OF THE POSTERIOR HYPOTHALAMUS. J. J. Buccafusco* and H. E. Brezenoff. Dept. Pharmacol. CMDNJ, New Jersey Medical School, Newark, N. J., 07103.

We have demonstrated previously that stimulation of cholinergic receptors specifically localized in the posterior hypothalamic nucleus (PH) via microinjection (0.5µl) of carbachol produces a dose-dependent increase in blood pressure and a marked increase in motor activity in conscious, freely-moving rats (Fed. Proc. 36: 950, 1977). Dose-related changes in heart rate accompanied the consistent pressor and behavioral responses, however, the direction of the change was variable; increases and decreases in heart rate occurring with equal probability. Prior microinjection of the muscarinic antagonist atropine (6 nmole) inhibited the hypertensive (+40±3 mmHg) and bradycardic (-57 ±5 beats min^{-1}) response to 3 nmole of carbachol injected into the same site. In contrast neither the tachycardia (+71±7 beats min^{-1}) nor the increase in motor activity (405±45 movements per 15 min) evoked by carbachol were affected by atropine. Prior microinjection of the nicotinic antagonist mecamylamine (6 nmole) produced no effect on the cardiovascular changes to 3 nmole of carbachol but significantly reduced the increase in activity. Atropine and mecamylamine produced no cardiovascular or behavioral changes of their own when injected into the PH.

In anesthetized rats intravenous injection of 2 mg/kg of phentolamine produced a 60% reduction in the pressor response to electrical stimulation of the PH. This dose of the α-adrenergic blocking agent administered i.v. to unanesthetized rats also reduced the pressor response to chemical stimulation of the PH with carbachol by a similar amount.

These results indicate that a cholinergic mechanism exists in the PH which mediates a rise in blood pressure and a fall in heart rate through muscarinic receptors; and an increase in motor activity through nicotinic receptors. The nature of the receptors mediating the tachycardic response to carbachol is unknown. The pressor response evoked by carbachol appears to be mediated at least in part through an increase in sympathetic nervous outflow.

53 SYMPATHOADRENAL MEDULLARY ACTIVITIES IN SPONTANEOUSLY HYPERTENSIVE RATS AND WISTAR KYOTO RATS FOLLOWING RESTING, HANDLING, RESTRAINT, COLD STRESS AND FOOT-SHOCK STRESS. C.C. Chiueh*, R. McCarty and I.J. Kopin. NIMH, Bethesda, Md. 20014.

Blood (0.5 ml) was obtained from undisturbed spontaneously hypertensive (SHR) and the normotensive Wistar Kyoto (WKY) rats through a chronic indwelling tail arterial cannula and assayed for plasma norepinephrine (NE) and epinephrine (EPI) by a modified radioenzymatic paper chromatographic method. The plasma levels of NE and EPI are a good index of the sympathoadrenal medullary activities because the increments of plasma catecholamines are found to be dependent upon the degree of stress (Chiueh et al., Pharmacologist 18:135, 1976). There was no significant difference in 'basal' plasma levels of NE and EPI in blood obtained from the conscious and undisturbed SHR and WKY rats 24-48 hours after cannulation despite the fact that blood pressures of SHR rats were 25-50 mmHg higher than those of WKY rats. Several experimental manipulations, i.e., transfer of rats into a new 20x40x40 cm^3 cage (handling), confinement of rats in a 6.5x6.5x20 cm^3 restrainer of the tail cuff procedure for indirect measurement of blood pressure (restraint) and cold stress at 4°C, increased plasma NE and EPI in both WKY and SHR rats. The increments in plasma NE and EPI in SHR rats were not significantly different from those of WKY rats during handling or after 20-240 min. at 4°C. However, there was a greater elevation of plasma catecholamines, mainly, EPI, in restrained SHR rats than in restrained WKY rats. In the restrainer, the blood pressures of SHR rats increased approximately 25 mmHg while those of WKY remained unchanged. Hyperadrenergic responsivity in SHR rats was also noted during and after 5 min. foot-shock stress (2mA, 0.1 Hz, 0.4 sec). During the 5 min. intermittent foot-shock period, a 4-7 fold increase in plasma levels of NE and EPI was found in WKY rats and an 8-21 fold increase in SHR rats. Fifteen minutes after the shocks, when the rats still remained in a freezing posture suggesting an emotional stage of fear of shock, elevated levels of EPI and NE were found in SHR rats but not in WKY rats. In conclusion, while there was no difference between WKY and SHR rats in basal sympathoadrenal medullary activities, hyperadrenergic responses were found in SHR rats during restraint, foot-shock and possible emotional stress but not during other stresses.

54 DO SOME CARDIOINHIBITORY AXONS ORIGINATE IN THE EXTERNAL CUNEATE NUCLEUS? J. Ciriello* and F. R. Calaresu, Dept. of Physiology, University of Western Ontario, London, Canada N6A 5C1.

The external cuneate nucleus (ECN) has been shown to receive an input from the aortic depressor nerve (Am. J. Physiol. 215: 269-276, 1968) and from a cardioacceleratory area in the posterior hypothalamus (Ciriello and Calaresu, in preparation). These findings suggest a role for this nucleus in central regulation of the cardiovascular system and have prompted the following experiments.

Electrical stimulation of 78 histologically verified sites in the ventral ECN in 15 chloralosed, paralyzed and artificially ventiled cats, consistently elicited a marked decrease in heart rate, with a threshold current of 5-25 μA and an optimal frequency of 20 Hz when using 0.2 ms pulses. This response was shown to be due to vagal excitation as it was not affected by propranolol (1.5 mg/kg, i.v.) but was abolished by ipsilateral vagotomy and by the administration of atropine methylbromide (2 mg/kg, i.v.). The possibility that the bradycardia observed was due to activation of cardiovascular afferents terminating at or near this nucleus was investigated in seven chloralosed cats by studying the effect of administration of progressively larger doses of pentobarbital, a barbiturate known to depress synaptic transmission, on the magnitude of the bradycardia elicited by stimulation of a known site of termination of baroreceptor afferents (n. tractus solitarius, NTS) and that elicited by stimulation of either a known site of origin of cardioinhibitory neurons (n. ambiguus, AMB) or the cervical vagus. Bradycardic responses to stimulation of the ECN, the AMB and the cervical vagus were of the same magnitude and were affected by the barbiturate significantly less than the response from the NTS, suggesting that the ECN may be a site of origin of cardioinhibitory axons. In six additional experiments the possibility that the bradycardia observed during ECN stimulation was due to activation of cardioinhibitory axons originating in the AMB was tested by making unilateral lesions of the AMB and, after sufficient time had passed for the fibers originating in the AMB to degenerate (11-23 days), the magnitude of the bradycardia elicited by stimulation of sites in the ECN ipsi- and contralateral to the lesion was compared. Stimulation of the ECN on either side in these animals still elicited a marked bradycardia which was abolished by cutting the ipsilateral cervical vagus. These results suggest that the ECN is a site of origin of cardioinhibitory axons in the cat and must therefore be considered an important component of reflex arcs leading to cardiac slowing.

55 EFFECT OF BIOFEEDBACK INDUCED CHANGES IN SKIN TEMPERATURE ON NON-INVASIVE REGIONAL CEREBRAL BLOOD FLOW IN NORMAL SUBJECTS. James L. Claghorn*, Roy J. Mathew*, John W. Largen*, John S. Meyer* (SPON: Beng T. Ho). TRIMS, Houston, Tx. 77030

A study to ascertain the effects of biofeedback induced skin temperature changes on regional cerebral blood flow was undertaken at the Texas Research Institute of Mental Sciences, in accordance with the hypothesis that such techniques may be utilized in the treatment of migraine headache syndrome. Migraine has been characterized as a stress related syndrome, with painful cephalic dilation during the headache phase which may be precipitated by excessive sympathetic activity; hand warming through biofeedback temperature training may result in a decreased sympathetic outflow to the cephalic vessels, an alteration in the vasomotor state, and a consequent abortion of the headache phase.

Subjects are 12 normal female volunteers, aged 19-35, randomly assigned to either a hand warming or hand cooling temperature feedback group. Each participant was trained to elevate or lower her hand temperature in a series of 9 biofeedback sessions, over a period of approximately 30 days. At the conclusion of training, all subjects underwent 2 measurements of non-invasive regional cerebral blood flow(nrCBF) via the ^{133}Xenon inhalation technique(pre and post skin temperature manipulation); this phase of the research was conducted in a carefully controlled laboratory setting.

The authors will present data comparing regional intracerebral and extracerebral blood flow measures at pre and post skin temperature manipulation; comparison between subject groups (hand warming or hand cooling) will be made, and correlations of change in nrCBF parameters with biofeedback induced skin temperature changes will be offered.

56 EFFECTS OF INDORAMIN ON CENTRAL SYMPATHETIC REACTIVITY. Meredith A. Davison and Michael C. Koss. Medical Biology Division, Okla. College of Osteopathic Medicine, Tulsa, Ok 74101.

Indoramin has been shown to reduce blood pressure in both humans and experimental animals (Royds et al., Clin. Pharmacol. Therap. 13: 380, 1972; Baum and Shropshire, European J. Pharmacol. 32: 30, 1975). Many features of the complex pharmacological profile of this agent suggest that its antihypertensive effect may be due in part to central actions (Baum and Shropshire, European J. Pharmacol. 32: 30, 1975). We have previously reported that the sympathetic-cholinergic electrodermal response (EDR) is an effective model system for studying the effects of drugs on central sympathetic reactivity, and that clonidine inhibits central reactivity in this system in a manner analagous to its action on other sympathetic systems (European J. Pharmacol. 37: 71, 1976). The present experiments used the electrodermal response system to investigate the possible action of indoramin on central autonomic activity. In anesthetized cats (pentobarbital, 36 mg/kg, ip) EDR were evoked centrally by stimulation of reactive loci in the posterior hypothalamus and peripherally by stimulation of the distal portion of the sectioned ulnar nerve. Indoramin (0.33-10 mg/kg, iv) significantly reduced the amplitude of the EDR evoked by stimulation of the hypothalamus at a constant submaximal frequency (10-16 Hz) is a dose-related manner. Indoramin had no effect on the peripherally evoked responses. As has been previously reported indoramin also caused a similar dose-dependent reduction in both blood pressure and heart rate. Unlike clonidine, indoramin did not induce mydriasis. Preliminary results indicate that the effects of indoramin on the EDR appear to be at least partially antagonized by yohimbine pretreatment (0.5 mg/kg, iv). The results of these investigations suggest that indoramin reduces central sympathetic reactivity elicited by hypothalamic stimulation.

57 EFFECTS OF TRH AND SOMATOSTATIN ON CENTRAL REGULATION OF BLOOD PRESSURE. Bernard Delbarre*, Danielle Senon* and Henry Schmitt* (SPON: Marthe Cohn). Lab. Ch. Exp. Fac. Med. 37032 Tours Cedex, Dep. Pharm. Broussais Hotel-Dieu Paris, France.

Thyrotropin releasing hormone (TRH) has been shown to be widely distributed in the central nervous system and has been proposed as a neurotransmitter. The effects of this agent on blood pressure and heart rate has been looked for after intracerebroventricular administration. Cats of either sex were anaesthetized with chloralose. Blood pressure, heart rate and splanchnic discharges were recorded. The injection of TRH (1 $\mu g/kg^{-1}$) into the lateral ventricle or the third ventricle of the brain induced a significant and long lasting increase in blood pressure, heart rate and splanchnic discharges. Similar results have been shown in pentobarbitalized dogs. Injection of TRH into the cisterna magna in the same dose, has no effect. Somatostatin (1 $\mu g/kg^{-1}$) injected by the same route in cats induced a slight but significant decrease in blood pressure and in addition antagonized the effects of TRH when injected before or after the latter hormone. TRH has been shown to activate the adenylate cyclase and somatostatin to reduce the level of adenosine 3':5' monophosphate (cyclic AMP) in the brain. As cyclic AMP has been shown to increase blood pressure after intracerebroventricular administration (Delbarre and all., Abst. 6 Int. Congr. Pharmacol 227, 1975-Clin. Exp. Pharm. Phys., 1977. In press) there is a possibility that cyclic AMP might be involved in the effect of TRH and somatostatin.

58 LATERALIZATION OF PRESSOR AND CARDIOACCELERATORY RESPONSES IN THE ZONA INTERMEDIA OF THE CAT SPINAL CORD. A. I. Faden*, M. Woods*, T. P. Jacobs* and C. F. Tyner (SPON: F. J. Manning). Department of Medical Neurosciences, Walter Reed Army Institute of Research, Washington, D.C. 20012.

Pressor and cardioacceleratory responses to electrical stimulation of the thoracolumbar spinal cord were studied in 19 anesthetized, vagotomized, paralyzed cats following low cervical spinal cord transection. Arterial pH, arterial blood gases and rectal temperature were closely monitored and maintained within normal limits. Pressor and cardioacceleratory sites were mapped using trains of constant current and stimulating at 0.25 mm intervals throughout the spinal cord.

Blood pressure and heart rate responses were very well localized within the zona intermedia and could be obtained with currents as low as 40 microamperes. Maximal response sites were demonstrated histologically to correspond to the intermediolateral nucleus. Both pressor and cardioacceleratory responses could be elicited throughout the longitudinal extent of the intermediolateral nuclear column (T_1-L_4), with the largest responses found in the upper thoracic region. The lumbar cardioacceleratory responses could be obtained after bilateral transection of the sympathetic chain at T_{11} but were abolished by spinal cord transection at T_{11}. Lumbar pressor responses could still be generated after T_{11} spinal cord transection, but were substantially reduced in magnitude. Cardioacceleratory and pressor responses were remarkably well lateralized at all levels of the spinal cord between T_1 and L_4, with significantly greater changes in heart rate and blood pressure obtained from right intermediolateral column stimulation as compared to the left. Change of anesthetic agent (alpha chloralose, sodium pentobarbital) and adrenalectomy failed to alter this lateralized responsiveness.

59 RELATION BETWEEN EXPIRATORY DURATION AND ROSTRAL MEDULLARY EXPIRATORY NEURONAL DISCHARGE. J.L. Feldman and M.I. Cohen, Dept. Physiol., Albert Einstein Col. Med., Bronx, N.Y.

In order to understand the central neural events that control expiratory duration (T_E), the responses of expiratory (E) neurons in the rostral medulla to various types of cycle triggered lung inflations were studied. Experiments were performed on decerebrate cats, gallamine paralyzed, with pneumothorax, and ventilated via a tracheal cannula with a cycle triggered pump (CTP; Feldman et al., Brain Res. 104, 341, 1976). The CTP inflated the lungs coincidentally with the period of the phrenic nerve burst, which served as indicator of the central inspiratory (I) phase. E unit activity was recorded with glass microelectrodes in the region of the nucleus of the solitary tract (NTS) and in the rostral part of the nucleus retroambigualis (rNRA). Changes in T_E were produced either by withholding inflations during the I phase or by applying maintained or phasic inflations during the E phase. Two major types of E neurons were observed: 1) Early expiratory: These began firing immediately after I cutoff, reached peak frequency shortly thereafter, and then declined in frequency throughout the remainder of the E phase. During the lengthened E phase which followed the lengthened I phase due to withholding inflation (Breuer-Hering I-inhibitory reflex), these neurons had a higher initial frequency and their discharge decayed more slowly. E inflations produced increased firing of these neurons together with lengthening of the E phase (Breuer-Hering E-facilitatory reflex). Many of these neurons were located in the NTS, which is thought to be a prime component of the I pattern generator. The responses of these neurons suggest that they control T_E by exerting inhibitory actions on I-facilitatory systems. 2) Late expiratory: These neurons, found predominantly in the rNRA, began firing with different delays after I cutoff, gradually increased their firing throughout the E phase, and stopped firing near the time of onset of the I phase. Withholding inflation did not markedly affect the initial discharge of these neurons but caused a prolongation of firing. In contrast, E inflations produced a marked inhibition of their discharge. These neurons could be involved in either: a) the control of the E musculature; or b) the control of T_E, by promoting the onset of the next I phase. (Supported by USPHS Grant HL-20800.)

60 CONVERGENCE OF INPUTS ONTO INTERNEURONS OF BARORECEPTOR REFLEX ARC. Gerard L. Gebber, Robert B. McCall and Susan M. Barman. Dept. Pharmacol., Michigan State Univ., East Lansing, MI 48824.

In a previous report from this laboratory (McCall and Gebber, Fed. Proc. 36: 488Abs., 1977) neurons whose discharges were interrupted within a heart beat upon bilateral occlusion of the common carotid arteries (BLCO) in vagotomized cats were located in the nucleus of the tractus solitarius (NTS), and in the vicinity of the intermediomedial spinal nucleus (IMM). These neurons were presumed to be interneurons in the baroreceptor reflex arc and additional evidence was offered that the units in IMM mediated spinal sympathoinhibition. In the present investigation, the spontaneous discharge patterns of BLCO-sensitive neurons in NTS and IMM of vagotomized cats were analyzed by constructing post-R wave time interval histograms (post-R wave TIH's). Six units in NTS exhibited unimodal histograms with peak probability of discharge occurring 70-80 msec after the R wave. The timing of this peak is consistent with the possibility that rhythmically-active input to these neurons was solely of carotid sinus baroreceptor origin. In this regard, the pulse synchronous component of carotid sinus nerve discharge began 68-71 msec after the R wave. The post-R wave TIH's of other units (n=11) in NTS and in IMM were multimodal. The timing of the second peak (70-80 msec), but not that of the earlier or later peaks, in the multimodal histograms was consistent with that of pulse synchronous carotid sinus baroreceptor discharge. Since the vagus and aortic depressor nerves were sectioned in these experiments, it is concluded that medullary and spinal interneurons of the baroreceptor reflex arc receive auxiliary afferent input from sources in addition to the IX and X cranial nerves. These auxiliary inputs apparently are responsible for the early (<50 msec) and late (>100 msec) peaks in the multimodal post-R wave TIH's of unitary discharge.

One source of auxiliary input is provided by sympathetic afferents in the inferior cardiac nerve. Single shocks applied to the inferior cardiac nerve elicited early and late orthodromic discharges in IMM neurons which exhibited multimodal post-R wave TIH's. The latency of the early discharge (5 msec) was shorter than that (8 msec) for activation of IMM units by NTS stimulation. This observation suggests that the early discharge was mediated over a spinal pathway. The latency of the late discharge (12 msec) of IMM neurons was consistent with activation over a supraspinal reflex pathway. Indeed, NTS units exhibiting multimodal post-R wave TIH's were activated with a latency of 6 msec by single shock stimulation of the inferior cardiac nerve. (Supported by PHS Grant HL 13187 and a grant from the Michigan Heart Association.)

61 EFFECTS OF PULMONARY AFFERENTS ON RESPIRATORY MODULATION OF SYMPATHETIC DISCHARGE. P.M. Gootman, J.L. Feldman, and M.I. Cohen. Depts. Physiol., Downstate Med. Ctr., SUNY, Brooklyn and Albert Einstein Col. Med., Bronx, N.Y.

Experiments were performed on decerebrate or urethane-anesthetized, gallamine-paralyzed cats with pneumothorax and intact vagi. Efferent splanchnic and cervical sympathetic nerve discharges were recorded monophasically (0.2-1000 Hz). Phrenic (PHR) nerve discharge served as an indicator of respiratory center output. Lung inflation was applied coincidentally with PHR discharge during control cycles by means of a cycle triggered pump (CTP; Feldman et al., Brain Res., 104: 341, 1976). Changes in the timing of CTP inflations were used to evaluate effects of pulmonary afferent (PA) activity from lung stretch receptors on central respiratory modulation of sympathetic (SYMP) discharge (Cohen and Gootman, Am. J. Physiol., 218: 1092, 1970). When inflation was not applied for one inspiratory (I) phase, the Breuer-Hering I-inhibitory reflex occurred: I prolongation with no change in slope of the integral of PHR activity, as measured with an average-response computer. In contrast this test produced an increase in slope of the integrated SYMP discharge. This indicates that inflations during the control I phases inhibited SYMP discharge. The striking difference in the slope changes of PHR vs. SYMP activities implies that this inhibition of SYMP activity was acting via circuits different from but related to those of the Breuer-Hering reflex. Lung inflation also inhibited SYMP discharge during the expiratory (E) phase, since inflations applied during the E phase reduced SYMP discharge, concomitantly with lengthening of the E phase (Breuer-Hering E-facilitatory reflex). The latency for SYMP inhibition from the onset of inflation was of the order of 100-200 msec for both I and E inflations. Vagotomy abolished these effects and resulted in an increased respiratory modulation of SYMP discharge. These results indicate that PA activity exerts an important influence on the central respiratory modulation of SYMP discharge. (Supported in part by NIH grants HL-20800 and NS-12031.)

62 EFFECTS OF DRUGS WHICH PRODUCE SYMPATHECTOMY ON THE RETROGRADE TRANSPORT AND ACCUMULATION OF NGF. Eugene M. Johnson, Jr., Roger Y. Andres, Richard A. Macia and Ralph A. Bradshaw. Depts. of Pharmacology and Biochemistry, Washington U. Med. School, St. Louis, MO 63110 (Spon: J. A. Ferrendelli).

Work by Hendry, Thoenen and co-workers has shown that nerve growth factor (NGF) is transported from the periphery to the cell body of sympathetic neurons by a retrograde axoplasmic flow. Since the cytotoxicity of drugs which destroy sympathetic neurons (6-hydroxydopamine, guanethidine, vinblastine) can be suppressed by concomitant administration of NGF, we have explored the possibility that these agents may all ultimately kill the cell by a common mechanism: prevention of the retrograde transport, accumation or utilization of NGF. Administration of high specific activity NGF (6-10 ng, ∿500,000 cpm) into the anterior eye chamber of adult rats resulted in a maximal accumulation (∿ 1000 cpm) of ^{125}I-NGF (confirmed by gel electrophoresis) in the ipsilateral superior cervical ganglion (SCG) about 16 hrs after injection. Very few counts (<30) were found in the contralateral ganglion. This system was "half-saturated" when 30-40 ng of NGF were injected into the eye chamber. Administration of NGF (200ng) systemically to adult (i.v.) or 5 day old animals (s.c.) resulted in maximal accumulation in SCG in about 8 hours. Administration of guanethidine (50 mg/kg/day i.p.) to adult rats resulted in a 50-60% decrease in accumulated NGF within 3 days of starting treatment. A single injection of 6-hydroxydopamine (100 mg/kg s.c.) or vinblastine (0.4 mg/kg s.c.) 16 hours prior to systemic administration of ^{125}I-NGF to 5 day-old rats prevented the accumulation of radioactivity in SCG. Administration of 6-hydroxydopamine to adult rats did not effect the accumulation of NGF during the first 6 hours after ^{125}I-NGF administration (i.v.), but accumulation ceased at that time rather than continuing for another 3 hours as in controls. These results support the notion that, although their initial interaction with the neuron may be very different, all of the drugs ultimately kill sympathetic neurons by "depriving" them of NGF. (Supported by Nat. Fdn., March of Dimes, NIH Grant HL20604 and NS10229, R. Y. A. is a fellow of the Swiss National Foundation.)

63 Gastric secretion and hyperglycemia provoked by cytoglucopenia in the nuclei of the solitary tract. M. Kadekaro, C. Timo-Iaria and M.L. Mendes Vicentini. Dept. Physiology and Pharmacology, Inst. Biomedical Sciences, Univ. of Sao Paulo, Cx. Postal 4365, Sao Paulo, S.P., Brazil.

Previous reports showed that cytoglucopenia induced by intravenous injection of 2-deoxy-D-glucose (2-DG) in cats increases gastric secretion by activation of several parallel mechanisms (J. Physiol. 1972, 221:1-13; J. Physiol. 1975, 252:565-584; Nerves and Gut, ed. F.P. Brooks, 1977, in press). 1. The first mechanism involves a neuronal chain whose afferent and efferent limbs are in the medial forebrain bundle (MFB) area; 2. The second circuit consists of glucoreceptors in the MFB area with the efferent limb in the globus pallidus; 3. The third reflex arc involves afferent pathways arising in the liver and efferent pathways in the lower brain stem; 4. The fourth loop is mediated by afferent and efferent pathways located in the lower brain stem. This latter circuit was first disclosed by injection of 2-DG (60 mg/kg) in the left vertebral artery of cats previously subjected to midcollicular transection of the brain stem and also in cats subjected to pontomedullary electrolytic transection. The present work shows that rhombencephalic receptors located in nuclei of the solitary tract are responsible for gastrosecretory and hyperglycemic responses to local cytoglucopenia but that gastrosecretory responses produced by microinjection into vagal nuclei is nonspecific. The identification of the rhombencephalic glucoreceptors was accomplished through microinjection of 3.3 µl/min of 2-DG (50 mg/ml) by means of a glass micropipette in several medullary structures of cats with midcollicular transection of the brain stem. At the end of the experiment a very low anodal current (10 µA x 10 sec) was passed through a microelectrode carried by the micropipette and the histological identification of the lesion (Prussian blue reaction) enabled us to locate the site of microinjection. Local microinjection of 2-DG within the boundaries of the nuclei of the solitary tract caused intense gastric secretion. Saline microinjection in the same areas failed to increase gastric secretion, showing that the effect is specific to glucorecepetor activation. Injection of either 2-DG or saline in the dorsal nucleus of the vagus caused an increase in gastric secretion which was apparently due to the mechanical stimulation of the nucleus. No secretory response was obtained by microinjection of 2-DG or saline into surrounding areas. Activation of the glucoreceptors involved in the gastrosecretory effect of cytoglucopenia also provoked a hyperglycemic response.

64 NATURAL SUPPRESSION OF FEVER IN THE NEAR-TERM EWE: A CENTRAL PHENOMENON? Norman K. Kasting*, Warren L. Veale, Keith E. Cooper, Division of Medical Physiology, University of Calgary, Calgary, Alberta, Canada T2N 1N4.

The production of fever involves an interaction between an exogenous pyrogenic factor (bacterial pyrogen - BP) and cells of the reticulo-endothelial system to elaborate endogenous pyrogen (EP). It is thought that EP enters the central nervous system to initiate responses leading to fever. It is well-known that the newborn human often does not become febrile even though it may be seriously infected. We have shown that the newborn lamb does not respond to either EP or BP immediately after birth. In our efforts to obtain more information regarding this phenomenon, we have examined the ability of the pregnant ewe near term to become febrile. Twenty-two pregnant ewes were injected intravenously with a bacterial pyrogen derived from Salmonella abortus equi (SAEP) several days before and immediately following parturition. The most commonly injected dose of SAE was 30 µg, an amount sufficient to produce a fever of 1.3 $\pm$0.15°C in a non-pregnant adult sheep. Endogenous pyrogen was made in vitro by incubating peritoneal exudate macrophages with SAEP. Amounts of EP were injected which produced a fever of 1.85 $\pm$0.10°C in the non-pregnant adult sheep. During these experiments rectal temperature was monitored continuously and the general physiological state of the animal was assessed.

The febrile response to SAEP was diminished or absent from 4 days prior to and 1 day after parturition. Similarly, the animals failed to become febrile following intravenous injection of EP over a similar time course. Since fever to both EP and BP are inhibited, it is suggested that this phenomenon is not associated with the elaboration of endogenous pyrogen by cells of the reticulo-endothelial system, but is more likely to be an inhibition of the action of EP on the central nervous system.

65 SENSORY AND MOTOR PATHWAYS OF THE PULMONARY VAGUS: SIMULTANEOUS VISUALIZATION BY HRP TRANSPORT. David M. Katz* (Spon: A.D. Rosen) and Harvey J. Karten, Depts. of Biology (DMK) and Psychiatry (HJK) S.U.N.Y., Stony Brook, N.Y. 11794.

The dorsal motor nucleus of the vagus nerve (DMN) contains cells of origin of vagal efferent fibers in both birds and mammals. Nucleus solitarius (NS), which lies immediately lateral and dorsal to DMN in the floor of the fourth ventricle, receives sensory input from vagal afferent fibers. Numerous subdivisions have been recognized within both nuclei, but the relationship of those subdivisions to the individual peripheral structures innervated by the vagus is unknown. Horseradish peroxidase (HRP) labelling techniques were used in the pigeon to determine the topographic representation of the pulmonary branch of the vagus in both DMN and NS.

An HRP-filled cuff was placed on the cut end of the right pulmonary vagal branch in otherwise intact animals. Following various survival times HRP granules were observed in 1) cell bodies in the nodose and jugular-superior ganglia, 2) the tractus solitarius (TS), 3) the neuropil of the posterior ventrolateral nucleus of NS, parasolitarius lateralis (Pl) and 4) DMN and the ventral motor nucleus of the vagus (VMN). Labelled cells were found in several subdivisions of DMN, ipsilateral to the transected nerve, and were most heavily concentrated in a ventrolateral subdivision of the caudal portion of the nucleus. Bilateral labelling was observed in both Pl and TS. The rostro-caudal extent of labelling in Pl corresponded to the rostro-caudal levels at which labelled cells were found in DMN.

The distribution of HRP granules in the neuropil of Pl correlates well with the recent finding in mammals that Pl contains respiratory neurons receiving a vagal afferent input (ref.: von Euler, Br.Res., 1973). HRP appears to have been transported anterograde from nodose and/or jugular-superior ganglion cells whose central processes terminate in Pl, and whose peripheral processes extend into the pulmonary vagus. Pl was not labelled in similar experiments involving other vagal branches. These findings suggest that 1) pulmonary vagal afferents project centrally to the lateral parasolitary subdivision of NS; 2) the cells of origin of pulmonary vagal efferent fibers lie in several subdivisions of DMN, corresponding, perhaps, to different effectors within the lung receiving a vagal input and 3) the pulmonary vagus is generally represented at corresponding rostro-caudal levels in both DMN and NS.

66 ROLE OF SUBTHALAMUS IN MEDIATION OF BRADYCARDIA RESPONSES IN RABBITS. Marc P. Kaufman, Robert B. Hamilton*, Guy K. Petrik* and Neil Schneiderman. Dept. Psychol., Univ. of Miami, Coral Gables, FL 33124.

In barbiturate anesthetized rabbits electrical stimulation (100 pulses/sec, 0.5 msec pulse-width, 10 sec train, <250μA) of 20 sites in the lateral zona incerta of the subthalamus (LZI) elicited bradycardia (M=94 bpm, SE=±8 from a baseline of 220 bpm) and a small decrease in mean arterial pressure (M=6 mmHg; SE=±2 from a baseline of 80 mmHg). In contrast, comparable stimulation of 17 sites in the medial zona incerta and H fields of Forel in the subthalamus evoked a small bradycardia response (M=-16 bpm, SE=±8) and an increase in mean pressure (M=17 mmHg, SE=±2). Bilateral section of the vagus nerves converted the bradycardia response to a slight heart rate increase and transformed the vasodepressor response into a small pressor response. Low frequency (25 pulses/sec) stimulation of LZI attenuated the bradycardia response (-94 vs. -13 bpm). Extracellular recordings from 7 units in the vicinity of the bradycardia responsive area of the LZI indicated that they received barosensory input. Onset latency for these 7 cells to single-pulse stimulation of the aortic nerve averaged 68 msec (SE=±20).

Fifteen neurons were observed in the nucleus of the tractus solitarius or in the dorsal vagal nucleus that were activated by single-pulse stimulation of sites in LZI previously shown to elicit bradycardia to train stimulation. The units were also activated by either single-pulse stimulation of aortic nerve, or were found to fire in synchrony with the EKG. In addition, 3 of the 15 cells were also antidromically invaded from the cervical vagus nerve and were therefore preganglionic and probably cardioinhibitory. Onset and peak latencies of the responses to LZI stimulation averaged 6 msec (SE=±.5) and 9 msec (SE=±.9), respectively. When the LZI was stimulated with a train of 10 pulses at a frequency of 100 pps, the probability of discharge was greatly increased as compared to single-pulse stimulation.

The results suggest that (a) train stimulation of LZI elicits primary bradycardia accompanied by a secondary fall in blood pressure, (b) neurons within the LZI receive barosensory input, (c) LZI neurons project with short latency onto cardioinhibitory neurons in the dorsal medulla, and (d) the discharge rate of these neurons is importantly influenced by temporal summation (Supported by NSF Grant BMS 75-10967 and by a grant from the Heart Association of Greater Miami).

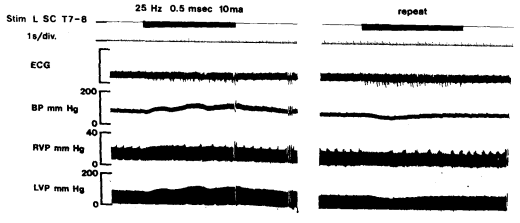
67 NEUROANATOMICAL SUBSTRUCTURE OF MEDULLAR RESPIRATORY NEURONS. Gary W. King* and Charles K. Knox. Laboratory of Neurophysiology, Department of Physiology, University of Minnesota, Minneapolis, MN 55455.

Neuroanatomical tracing studies were performed in cats, utilizing retrograde axonal transport of horseradish peroxidase (HRP) and anterograde axonal transport of 3H-amino acids to delineate the medullar-pontine pathways involved in the neural control of respiration. The results show that two major groups of neurons in the medulla project to the parabrachial nucleus (NPB) of the dorsolateral rostral pons: 1) the medial nucleus of the solitary tract and dorsal motor nucleus of the vagus, which project topographically to NPB, and 2) lateral tegmental field (FTL) neurons. The FTL neurons are arranged in four longitudinal sheets which, on a frontal section, appear as groups of cells aligned radially with respect to the fourth ventricle. The sheets of FTL neurons are about 100μ thick and lie at the level of the obex near nucleus ambiguus, about 0.5mm apart. Furthermore, microscopic examination has revealed four longitudinal sheets of arterioles which coincide with the sheets of neurons projecting to the pontine respiratory areas. The neurons are thus interdigitated and closely juxtaposed to the arterioles. The most dorsal of the arteriolar sheets corresponds to nucleus retroambigualis, and extends from the spinal cord level C1, through n. ambiguus, and beyond the dorsal aspect of the seventh cranial nerve nucleus (c.f. Merrill, Brain Res., 24:11, 1970).

Preliminary electrophysiological studies have shown that respiratory-modulated neurons of the FTL are also found preferentially in these four sheets. Thus, the vascular system would appear to determine a topographical organization for respiratory neurons in the medulla. Also, if central chemosensitivity is located in deeper FTL regions (Lipscomb and Boyarsky, Resp. Physiol., 16:362, 1972), then these arteriolar sheets would provide a rapid sampling of arterial blood for the chemoreceptors.

68 SYMPATHETIC DEPRESSOR REFLEX ELICITED BY STIMULATING THE SYMPATHETIC CHAIN IN THE CANINE AND PRIMATE. David R. Kostreva, Fran A. Hopp* and John P. Kampine*. Depts. Physiol. and Anesthesiol., Med. College of Wisconsin and Wood VA Ctr., Milwaukee, WI 53193

Electrical stimulation of the left or right sympathetic chains (SC) after sectioning of the ventral and dorsal ansae subclavia and the SC below T12 resulted in a depressor reflex response in the canine and primate. Mongrel dogs and pigtail macaque monkeys (*Macaca nemestrina*) were anesthetized using phencyclidine hydrochloride, 2 mg/kg i.m., and sodium pentobarbital, 35 mg/kg i.v. The animals were placed on positive pressure ventilation, and the second through seventh ribs were removed from the left and right sides along with the adjacent sternum to allow unimpeded access to both SC. Right ventricular pressure (RVP), systemic arterial blood pressure (BP), and left ventricular pressure (LVP) were monitored from a femoral vein and arteries, respectively. The electrocardiogram (ECG) was monitored from leads placed in a lead II configuration. A representative response to stimulation of the left SC after section of the left ventral and dorsal ansae subclavia is shown in the left panel of the figure. With stimu-



lation of the left SC between T7 and 8, increases in BP, RVP and LVP were observed. However, when the left SC was sectioned at T12 and the SC stimulation repeated, as shown in the panel on the right, BP and LVP decreased with little or no change in RVP. Similar responses were observed when the upper (T1 or 2) and lower segments (T11 or 12) were stimulated on either the right or left SC in both the canine and primate. This study has provided some evidence for the existence of a sympathetic depressor reflex that can be elicited by stimulation of thoracic and abdominal sympathetic afferents.

69 NEURAL RELATIONSHIPS BETWEEN THE CELIAC PLEXUS AND COLONIC MOTILITY IN THE GUINEA PIG. David L. Kreulen* and Joseph H. Szurszewski. Dept. Physiol., Mayo Med. Sch., Rochester, MN 55901.

Experiments were performed to determine the relationship between synaptic input to neurons in the celiac plexus and colonic motility. In vitro preparations were dissected from guinea pigs and consisted of the celiac plexus attached to the whole colon by its vascular supply and nerve trunks. Intracellular electrical activity was recorded and nerve trunks were stimulated with external electrodes. Repetitive stimulation (5-15 Hz) of nerve trunks between the ganglia and the colon resulted in a 0.5 to 1.5 sec after-train hyperpolarization, a marked decrease in the level of synaptic input from receptors located in the colon and a decrease in colonic intraluminal pressure. In the superior mesenteric ganglion (SMG), only 5 of 77 neurons tested received synaptic input from a greater splanchnic nerve. In the celiac ganglia (CG), less than 10 percent of the neurons received synaptic input from both the ipsilateral greater splanchnic nerve and from the periphery. Thus in both the SMG and CG there was subganglionic organization of input. Neurons with a particular pattern of input appeared to be localized in specific regions. When the colon was connected to the ganglia 60 percent of the neurons tested in the SMG had continuous excitatory synaptic input. In the CG only 20 percent of the neurons received continuous excitatory synaptic input. In the neurons in both ganglia that did receive input, distention of the colon resulted in an increase in the level of synaptic input. However, all of these neurons did not receive synaptic input from all regions of the colon. For example, when the terminal colon was distended there was an increase in synaptic input to some neurons while there was no change in others. These results demonstrate subganglionic organization of neurons in the CG and SMG and that neurons in the CG and SMG receive mechanosensitive synaptic input from the colon. 70 EFFECT OF MESENCEPHALIC LESIONS ON THE CEREBROVASCULAR RESPONSE TO ELEVATED ARTERIAL PCO_2. J.H. Ovelmen Levitt and C.E. Rapela*. Depts. Neurology and Physiology-Pharmacology, Bowman Gray School of Medicine, Winston-Salem, North Carolina 27103

The CNS has been implicated by others as having a role in cerebrovascular control. The possibility that a mechanism located in the mesencephalon, influencing the cerebrovascular response to alterations in partial pressures of arterial carbon dioxide ($PaCO_2$) has been studied acutely in 22 dogs anesthetized with Chloralose. In 16 of these experiments midbrain lesions were made. Descending mechanisms influencing systemic blood pressure, ascending fibers from the locus coeruleus, the raphe nuclei, pathways associated with pain, as well as portions of the reticular activating system, and elements related to the limbic system are located in the midbrain and were involved in the lesions. In 6 animals no lesions were made in order to evaluate the effect of experimental time on sequential cerebrovascular responses to altered $PaCO_2$. During hypercapnia autoregulation by cerebral vessels is lost and cerebral blood flow (CBF) is highly dependent upon the level of the perfusion pressure. In order to separate the effect of lesions on the CBF from a concommitant effect on blood pressure, perfusion pressure-cerebral blood flow (PP-CBF) curves were obtained during normocapnia (N) and hypercapnia (H) twice during the control experiments; and in N and H before and after midbrain lesions in the lesion experiments. Cerebral PP changes were obtained by graded compression of the common carotids (CC) with the vertebral (V) arteries occluded. The mean of the CC pressure distal to the compression and the V wedged pressure was taken as cerebral PP. The BCF was recorded by the supratentorial venous outflow method. PP-CBF curves obtained before and after mesencephalic lesions, either during ($NPaCO_2$ = 35.1±5.25 mm Hg) or H($PaCO_2$ = 75.4±10.34 mm Hg) did not show significant differences. The mean post-lesion CBF response [CBF(H) - CBF(N)] was found to be 0.83 of the pre-lesion response (Conf. Lim. = 0.87-0.72). In the non-lesion control experiments, the second CBF response was 0.86 of the first (Conf. Lim. = 0.95-0.77). These CBF response ratio values for the lesion and control experiments were not significantly different. The results indicate that these midbrain lesions did not have a significant effect on the cerebrovascular response to increased $PaCO_2$ (75 mm Hg) within 60 minutes of lesion production. Supported by NIH Grants NS 11953, H1 5392, and NS 06655.

71 EFFERENT PROJECTIONS FROM NUCLEI OF THE SOLITARY TRACT IN THE CAT A.D. Loewy and H. Burton. Dept. Anat. & Neurobiol., Wash. Univ. Sch. Med., St. Louis, MO 63110.

Previous studies have shown that afferent fibers from the cardiovascular, respiratory and other visceral systems terminate in the commissural (Com), medial (Sm) and ventrolateral (Svl) solitary nuclei. The solitary complex may be further subdivided to include a lateral (Sla) and an intermediate (Int) nucleus. The close proximity of these small nuclei and the heterogeneity of the cell types in some of them (e.g. Svl) make it difficult to analyze the efferent projections from this region with degeneration techniques.

By using retrograde and anterograde labeling techniques we have begun a systematic analysis of some efferent projections from the solitary complex in the cat. Small quantities of concentrated solutions of tritiated amino acids (50μCi/μl of leucine and proline) were injected into portions of the solitary complex through glass micropipettes. Our investigations have been confined to those regions from which activity related to respiratory or cardiovascular functions have been recorded. Following a survival of 7 days and subsequent autoradiographic processing, several of the efferent projections from the solitary complex have been observed. After an injection centered over Svl, descending fibers can be traced to the region of the phrenic motor neurons in the C5-C7 segments of the spinal cord and to the ventral tip of the thoracic ventral horn. Bilateral projections could be traced to the ventral and lateral funiculi surrounding the ventral horn. Ipsilateral projections were greater. Connections could also be traced in the medulla bilaterally to the retroambiguus, ambiguus, and retrofacial nuclei and contralaterally to the dorsal aspects of the paramedian reticular nucleus. Projections were traced to the ipsilateral medial accessory olive, rostral aspects of the dorsal motor nucleus of the vagus, contralateral Com, Sm, and Int nuclei of the solitary complex. Ascending connections were seen bilaterally in the medial and lateral parabrachial nuclei and Kölliker-Fuse nucleus.

The location of retrogradely labeled neurons in the solitary complex was also studied after injections of a 25% horseradish peroxidase solution. Following injections into the lower cervical and upper thoracic segments, medium sized neurons were labeled bilaterally in Svl, Sm and Int. HRP injections centered in medial accessory olive retrogradely label ipsilateral Sla, whereas, injections in the region of n. ambiguus label medium and large neurons in Svl. (Supported by USPHS Grants NS09809 and NS12751)

72 MEDULLARY AND SPINAL LATERAL HORN NEURONS RESPONSIVE TO STIMULI WHICH FORCE A CARDIOVASCULAR STATE-CHANGE. J. W. Manning and S. J. Putnam.* Dept. Physiol., Emory U., Atl., GA 30322.

Little or no information is available on the concurrent behabior of repetitively firing single units (RFNs) in the medullary reticular vasomotor area and in the intermediolateral cells column following stimulation of one or more of the following systems: anterior hypothalamus, posterior hypothalamus and carotid sinus nerve as well as stretch activation of baroreceptors by intravenous administration of noradrenaline (1μg/kg). Experiments were performed on ether induced, α-chloralose anesthetized cats paralyzed with Gallomine triethiodide; activity of brainstem medullary and lateral horn neurons was monitored extracellularly by tungsten μ-electrodes (7-11μF). Following suitable amplification arterial pulse pressure, ECG, unitary responses and respiratory event were stored on magnetic tape. The RFNs studied at the medullary level were in and around the stereotaxic coordinates P - 10, L-3, 2mm below floor of fourth ventricle, those in the lateral horn were at the T-1 level and identified as sympathetic preganglionic through antidromic activation by stimulation of the common vagosympathetic cervical trunk. The typical behavior of medullary RFNs has been reported previously; spinal RFNs do not fire with the characteristic burst pattern exemplified by many medullary units. The spontaneous activity of spinal units (ave. 6 per sec) has a lower frequency than that of medullary RFNs (ave. 13 per sec). Interspike interval analysis as well as post-stimulus histograms reveal a coupling of medullary and spinal unit response behavior. Correlation analysis will be sought between medullary and spinal RFNs with cardiac cycle. (Supported by NIH Grant HL 16648-13).

73 FUNCTIONAL CATEGORIES OF UNMYELINATED FIBERS IN RAT VENTRAL ROOTS. C.W. Maynard,* R.E. Coggeshall and T.B. Stubbs, III. Marine Biomedical Institute and Department of Anatomy, Univ. of Texas Medical Br., Galveston, Texas 77550.

We have previously identified large numbers of unmyelinated fibers in rat ventral roots T1-L2 and L6-S1, the same segments that contain large numbers of the smallest myelinated fibers. The present experiments are aimed at determining the functional categories of the unmyelinated axons in the L6 and S1 ventral roots. Ventral rhizotomies were performed on rats at the L6 or S1 segments. After three days the animals were sacrificed and the proximal and distal stumps of the cut root and the intact ventral root from the opposite side of the animal were taken for electron microscopic examination. To date, we have found in seven rats that the proximal stumps of the L6 or S1 ventral roots contain 70-80% as many unmyelinated axons as are found in the normal root. These are assumed to be unmyelinated preganglionic fibers. Thus 20-30% of the unmyelinated axons are missing from the proximal stump. We are in the process of determining the functional categories of these axons, one possibility being that they arise from dorsal root ganglion cells and are sensory in nature.

This work is supported by grants DHEW GM 45916, NS 11255, and NS 10161.

74 ATTENUATION WITH ATROPINE IN THE BRAIN OF FEVER PRODUCED BY INTRA VENOUS PYROGEN: EFFECT OF SYMPATHECTOMY OF THE EARS OF THE RABBIT. B.J.C. Mutch*, K.E. Cooper and W.L. Veale, Division of Medical Physiology, Faculty of Medicine, University of Calgary, Calgary, Alberta, Canada T2N 1N4.

Atropine injected into a lateral cerebral ventricle and the posterior hypothalamus of rabbits has been shown to attenuate fever produced by intravenous injection of pyrogen or intracranial prostaglandin E_1. Atropine has been postulated to block the febrile response by activation of heat loss mechanisms, such as vasodilatation and an increase in respiratory rate. The present investigation was undertaken to examine the effect of removal of sympathetic innervation from the ears of rabbits, and hence eliminate their ability to vasoconstrict, on fever production and its attenuation by intracerebral atropine.

Male New Zealand rabbits were anaesthetized, and fitted stereotaxically with headplates or cannulae, to serve as guides for microinjection into brain tissue or a lateral ventricle. In half of the animals the auricular nerves were isolated and cut. Several days later the animals were injected i.v. with endotoxin derived from Salmonella abortus equi (SAEP) and atropine sulphate was given in a lateral ventricle (200 µg/0.1 cc CSF) or in the posterior hypothalamus (50 µg/µl). Body temperature was measured by means of a rectal probe, and ear temperature was recorded using a disc thermistor attached to an ear.

For a non-denervated rabbit, ear temperature during a 1.5°C fever dropped from 36.5 ±1.5°C before the onset of fever, to 23 ±1.5°C just prior to the peak of the fever, at which point the ears rewarmed to their pre-fever temperature. However, for a rabbit with sympathectomized ears, the ear temperature accompanying a similar fever remained 35.5 ±2.0°C, without any correlation with stages of the fever. In the non-denervated rabbit, the ear temperature increased rapidly within 5 minutes following the injection of atropine to 37.0 ±1.5°C, and remained relatively constant for the duration of the action of the drug. When atropine was injected in conjunction with i.v. SAEP, the changes in ear temperature reflected the influence of both in relation to their relative time of injection. However, in denervated rabbits the ear temperature remained stable at 35.5 ±2.0°C throughout the experiment, apparently independent of heat loss or heat gain mechanisms which others have proposed to accompany fever.

It appears, therefore, that denervation of the ears of rabbits does not prevent fever, or the attenuation of fever by atropine.

Supported by the Medical Research Council of Canada. B.J.C.M. is a predoctoral trainee of the Medical Research Council of Canada.

75 LOCALIZATION OF THE SACRAL AUTONOMIC (PARASYMPATHETIC) NUCLEUS IN THE SPINAL CORD OF CAT AND MONKEY BY THE HORSERADISH PEROXIDASE TECHNIQUE. I. Nadelhaft, C. Morgan, T. Schauble* and W.C. de Groat Dept. Neurosurg. & Pharmacol, Univ. of Pittsburgh School of Med. and Veterans Administration Hospital, Pittsburgh, PA 15261

A 25% aqueous solution of horseradish peroxidase (HRP) was applied to the central end of the transected whole pelvic nerve or to the branch going to the urinary bladder. In some experiments both nerves (bladder on one side, pelvic nerve on the other) were exposed to HRP. The animals were kept under anesthesia during the entire process which lasted between 24 and 48 hours, after which they were sacrificed and perfused with fixative. Frozen sections were processed using either diaminobenzidene or benzidene as the enzyme substrate, mounted, and examined under dark field illumination. The neurons belonging to the nucleus formed a long, narrow band lying mainly along the lateral edge of the grey matter. The highest concentration of labelled cells was in the second sacral segment but the longitudinal distribution had long tails on either side of the peak making its total length 7-8 mm. When the entire pelvic nerve was labelled, the cross-sectional aspect of the nucleus appeared as a band 100-150 microns wide extending for a length of about 1 mm from below the ventral extent of the central canal to just under the dorsal horn, at which point the band turned medially for about 300 microns. This medial extension was absent when only the bladder portion of the nerve was exposed to HRP. When diaminobenzidene was used, the cells and some of their dendritic extensions appeared with white granules in the dark field microscope. However, the benzidene substrate brought out additional features. In this case even the axons were visualized. These were seen to come from the ventral rootlets and pass near the edge of the ventral gray matter. The labelled cells were either spindle shaped (30-50 microns long, 12-15 microns wide) or multipolar (15-30 micron diameter). Frequently their dendrites could be followed for many cell widths in the 42 micron thick sections. These extensions for the most part followed the direction of the band (as seen in the cross section) but were sometimes observed to extend far into the white matter. The number of labelled cells varied in different cats from 700 and 1500. In the rhesus monkey preliminary results indicate that the nucleus is smaller in cross-sectional size (200 micron diameter) and much longer (13 mm) than in the cat. It is located at the lateral edge of the grey matter just under the dorsal horn. The cells were similar in shape and size to those found in the cat.

76 RELATIONSHIP BETWEEN BARORECEPTOR SENSITIVITY AND CLASSICAL CONDITIONED ARTERIAL PRESSURE RESPONSES IN CATS. Marc A. Nathan, Walter H. Severini*, Lewis W. Tucker*, and Donald J. Reis. Lab. of Neurobiol., Dept. of Neurol., Cornell University Medical College, New York, NY 10021.

A common observation is that the magnitude of conditioned arterial pressure (AP) responses is highly idiosyncratic. We recently found enhanced conditioned pressure responses after abolishment of baroreceptor reflexes produced by lesions of the nucleus tractus solitarii (NTS) (Circulation II:144, 1976), indirectly suggesting that the idiosyncrasy of conditioned AP responses may relate to differences in baroreceptor sensitivity. To test this hypothesis, we examined the correlation between baroreceptor sensitivity and the magnitude of conditioned pressure AP responses. Since lability of AP is also increased in cats deprived of baroreceptor function (Circ Res 40:72-81, 1977), the relationship of lability to baroreceptor sensitivity was also examined. Lesions were placed in the NTS in 5 of 11 cats tested. Baroreceptor sensitivity was assessed by calculating the slope of the curve relating the rise in AP, elevated by norepinephrine, to the reflexively induced increase of cardiac interbeat interval. Lability was measured by the standard deviation of a frequency histogram distribution of AP recorded when the cats were not being conditioned. The cats were classically conditioned by presenting two tones of different frequency for 10-60 seconds duration. One tone was immediately followed by delivery of electrical shock and the other tone was never followed by shock. There was a significant decrease in baroreceptor sensitivity in the cats with NTS lesions ($p<.05$). However, within the group the effect of the lesions was variable. When all cats were grouped, correlations could be computed over a wider range of baroreceptor sensitivities than would be normally possible. We found a significant inverse correlation between baroreceptor sensitivity and the magnitude of the conditioned AP response ($p<.05$). A significant inverse correlation was found between baroreceptor sensitivity and the lability of AP ($p<.05$), and lability was positively related to the size of the conditioned AP response ($p<.01$). The high correlation of baroreceptor sensitivity and the magnitude of the conditioned AP response suggests that baroreceptor sensitivity may be an important factor governing the size of conditioned AP pressure responses. The correlation of lability to the conditioned AP response is probably a reflection of the close correlation between lability and baroreceptor sensitivity.

77 EDINGER-WESTPHAL NUCLEUS: PROJECTIONS TO MEDULLA AND SPINAL CORD. C.B. Saper*, N.D. Yamodis*, and A.D. Loewy (Spon: H. Burton). Depts. Anat. & Neurobiol. and Neurosurg., Wash. Univ. Sch. Med., St. Louis, MO 63110.

Recently we reported that neurons in the Edinger-Westphal (EW) nucleus may be retrogradely labeled with horseradish peroxidase (HRP) after injections in the medulla or spinal cord (Anat. Rec., 187: 640). We now present the results of an autoradiographic study tracing these efferent projections from the EW nucleus. Small injections of a mixture of tritiated amino acids were made in the region of the EW nucleus and after 5 to 7 days survival the brains and spinal cords were processed using the autoradiographic method. Combined with the results of the previous HRP experiments, these new data have allowed us to trace the distribution of some of these fibers and their terminal fields in the medulla and spinal cord. It appears that the main region of termination in the caudal medulla is in a well defined zone between the gracile and cuneate nuclei, which has been previously shown to project to laminae I, IV and V of the spinal cord by way of the lateralmost part of the dorsal columns and the dorsolateral funiculus of the spinal cord, adjacent to the dorsal horn (Burton and Loewy, '77). The main pathways from the EW nucleus to the spinal cord include (i) some fibers described above in the DCN which continue caudally in the ventralmost part and medial septum of the dorsal column and (ii) other fibers which continue caudally along the ventrolateral aspect of the spinal trigeminal nucleus in the zone of the subtrigeminal nucleus and then through the region between the dorsal horn and lateral cervical nucleus to curve around the lateral surface of the dorsal horn. These EW fibers appear to terminate primarily in laminae I and V at least as far caudally as the lower thoracic spinal cord. These experiments indicate that the traditional view of the EW nucleus as merely a parasympathetic preganglionic nucleus should be seriously questioned.

78 CRYOGENIC BLOCKADE IN THE THALAMIC GATING SYSTEM PREVENTS VENTRICULAR FIBRILLATION IN THE ISCHEMIC MYOCARDIUM OF THE CONSCIOUS PIG. J. E. Skinner and J. C. Reed*. Physiology Dept., Baylor College of Medicine, Houston, TX 77030.

Previous work has shown that the psychologic stress of unfamiliar laboratory surroundings is necessary to initiate ventricular fibrillation (VF) in the conscious pig following left anterior descending coronary artery (LADCA) occlusion (Skinner, et al., Circulation, 51:656-667, 1975). Recent evidence has shown that a tone reinforced by cutaneous shock will evoke slow potentials in the frontal cortex, thalamic reticular nucleus and mesencephalic reticular formation of the conscious cat (Skinner and Yingling, Electroenceph. Clin. Neurophysiol., 40:288-296, 1976). Cryogenic blockade in the pathway interconnecting the frontal cortex and thalamus will abolish these evoked responses to the psychologic stress (tone), but not to the physical stress (shock). The conditioned cardiac response to the tone is also abolished by this cryogenic intervention. Electrophysiological evidence indicates that the frontocortical and mesencephalic projections to the thalamic reticular nucleus, a structure which is itself inhibitory on the thalamic relay nuclei, together regulate the thalamic input to cerebral cortex (Skinner and Yingling, Prog. Clin. Neurophysiol., 1:30-69, 1977). The frontocortical-thalamic reticular system appears to mediate the selective gating associated with "attention" whereas the mesencephalic reticular-thalamic reticular system regulates the more generalized gating associated with "orienting reactions." In conclusion, a single intervention in the frontocortical-thalamic gating system will prevent the selective input to the cortex of a meaningful sensory stimulus and the consequent cardiac response to it. Our hypothesis for the present study, derived from the above neurophysiological evidence, is that intervention in the frontocortical-thalamic reticular pathway will prevent the onset of VF in the ischemic myocardium of the psychologically stressed animal. We found in the chronic pig preparation, stressed by being unadapted to the laboratory, that ventricular fibrillation will occur within 14 min following LADCA occlusion, but if the neural connections between the frontal cortex and thalamic reticular nuclei are blocked cryogenically, then the VF will be postponed or even prevented. Cryogenic blockade in control structures near the frontocortical-thalamic reticular pathway produced no effect on VF latency.

79 EFFECTS OF BICUCULLINE AND THIOSEMICARBAZIDE ON INHIBITION OF REFLEX AND SPONTANEOUS SYMPATHETIC NERVE POTENTIALS IN THE CAT. D. G. Taylor, K. A. Arbour* and M. J. Antonaccio*. Res. Dept., Pharma. Div., CIBA-GEIGY Corp., Summit, N.J. 07901.

A study was made in the α-chloralose-anesthetized cat of the effects of the γ-aminobutyric acid (GABA) receptor antagonist, bicuculline (BIC) and the GABA synthesis inhibitor, thiosemicarbazide (THIO) on the inhibition of spontaneously occurring and somatosympathetic reflex (SSR) induced potentials elicited in the splanchnic and renal nerves. SSR potentials, traveling through medullary pathways, were evoked by stimulation of afferent fibers in a sciatic nerve. Inhibition of spontaneous and SSR reponses was evaluated either during high-frequency (50 Hz) stimulation of the medial medullary depressor region (MDR) or during baroreceptor reflex activation resulting from the hypertensive response to norepinephrine (1-6 μg/kg, iv). BIC (0.1 and 0.3 mg/kg, iv) and THIO (100 mg/kg, iv) produced near total blockade of the MDR-induced inhibition of the SSR. At this time BIC and THIO did not alter baroreceptor-induced inhibition of SSR responses. Blockade of the MDR-induced inhibition commenced 2-5 mins. after injection of BIC and persisted for 30-60 mins. Effects of THIO were maximal 120 mins. after administration. Following BIC or THIO the spontaneous discharges changed from typical cardiac-locked components to sharply spiked activity of larger amplitude exhibiting no apparent relationship to the cardiac cycle. Baroreceptor reflex and MDR activation either completely inhibited these spikes or decreased the spike amplitude and/or frequency of occurrence. The results demonstrate that (1) MDR-induced inhibition of SSR potentials is markedly antagonized by two agents known to interfere with GABAergic transmission, while baroreceptor reflex effects are not changed and (2) spontaneously occurring discharges are altered by GABA antagonism; however, MDR- and baroreceptor-induced inhibition of these spikes remained functional.

80 CALCIUM DEPENDENT POTENTIALS IN THE RAT SUPERIOR CERVICAL GANGLION. Paul Yarowsky and Donald A. McAfee. Dept. Physiology and Biophysics, Univ. of Miami Sch. of Med., Miami, Fl. 33152.

Recent studies, especially in invertebrate nervous systems, have established that action potentials can trigger changes in Ca^{++} conductances which in turn alters membrane potential directly or indirectly by triggering conductance changes to other ions. Few observations have been made in mammalian nervous systems identifying similar phenomena; our studies contribute to the idea that Ca^{++} plays a direct role in control of membrane potential. Postganglionic neurons were impaled under direct visualization with KAc and KCl electrodes (40-80 Megohms). The 150 neurons in this study had an average spike height of 74mV, input impedance of 48 Megohms, time constant of 4.1 msec, and a resting membrane potential of -61mV. Following an action potential elicited synaptically or directly, an afterhyperpolarization (AHP) occured with an average peak amplitude of 8mV, total duration of 300 msec, and a 30% decrease in input impedance. The reversal potential of the AHP was -85mV. Following one second of tetanic synaptic stimulation (30Hz) the duration of the AHP was greatly increased (avg. 1700 msec) with little change in amplitude. The tetanic AHP showed the same reversal potential and resistance change as the single synaptic or direct AHP. The magnitude and duration of the AHP varied directly with the external $[Ca^{++}]$ under conditions where resting membrane potential and input impedance remained unchanged. Several divalent cations Ba^{++}, Co^{++}, & Mn^{++} (1-5mM) and D-600 (20μm) added to the normal Locke greatly reduced the amplitude and duration of the AHP without complete blockade. Tetraethylammonium (5mM) and 4-aminopyridine (3mM) increased the duration of the action potential but had little effect on the AHP. Theophylline (2.5mM) greatly augments the duration of the AHP. Ro20-1724, a non-methylxanthine phosphodiesterase inhibitor had no effect on the AHP. Prostaglandin E_1 (100ηM) depressed both the amplitude and duration of the AHP.

Depolarizing pulses in the presence of TTX elicited a regenerative depolarizing potential as well as an AHP. The amplitudes of both potentials were directly proportional to external$[Ca^{++}]$. The regenerative potential was most prominent when TEA was also present, and had a threshold of -40mV. The AHP occured with a decrease in input impedance and had a reversal potential of -87mV. Both potentials in TTX were blocked by Co^{++}, but only the AHP was blocked by Ba^{++}. The magnitude of the AHP was proportional to the strength and duration of the depolarizing pulses. It appeared that the regenerative potential but not the AHP inactivates. We support the hypothesis that post-ganglionic neurons have a potential sensitive Ca^{++} conductance and a K^{+} conductance which is mediated by Ca^{++}. Supported by USPH grants NS 7044, NS 11552, & NS 05820.

AXONAL TRANSPORT

81 AXONAL TRANSPORT OF CYTOSKELETAL PROTEINS TO THE PRESYNAPTIC TERMINALS IN THE GUINEA PIG VISUAL SYSTEM. Mark M. Black* and Raymond J. Lasek (SPON: Marcus Singer). Dept. Anat., Case Western Reserve Univ., Cleveland, Ohio 44106.

The axonal cytoskeleton, which includes microtubules, neurofilaments and microfilaments, is transported slowly from the cell body towards the axon terminals. The movement of the cytoskeleton and its turnover in the presynaptic terminals has been studied in terms of the individual cytoskeletal proteins. ^{3}H-lysine was injected into the eyes of adult guinea pigs and the animals were sacrificed 6 to 77 days later. The labeled proteins in the superior colliculus (sup. coll.) and in consecutive 3mm segments of the optic nerve and tract were resolved by SDS-polyacrylamide gel electrophoresis.

The results show that the neurofilament proteins (NFP) and the microtubule protein (tubulin) are transported in a slow component (SCa) at 0.5mm/day. The microfilament protein (actin) and its associated proteins are transported in a separate component (SCb) at 1-2mm/day. The bulk of SCb enters the sup. coll. between days 11 and 25 post injection. During this period SCb proteins accumulate in the sup. coll., (apparently within the axon terminals). These proteins then remain there for weeks, and significant amounts are found even 77 days post injection (Fig.). In contrast, SCa proteins (which begin entering the sup. coll. on days 40-45 post injection) do not accumulate (Fig.) but turnover within a few days of entering. Since actin and its associated SCb proteins reside in the axon terminals for weeks it is likely that these cytoskeletal proteins are important constituents of the presynaptic terminal and are thus involved in transmitter release.

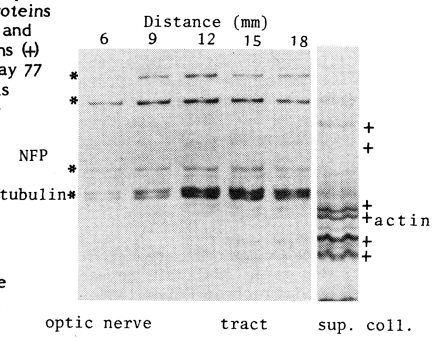

Figure. This fluorograph shows labeled SCa proteins (*) in the optic nerve and tract and SCb proteins (+) in the sup. coll. at day 77 post injection. At this time one third to one half of the total labeled SCa has entered the sup. coll., but very little remains. In constrast, a substantial amount of the labeled SCb, which had entered the sup. coll. earlier than the SCa, is still there at 77 days.

82 ANTEROGRADE AXONAL TRANSPORT OF PEROXIDASE: HOW SIGNIFICANT? R. D. Broadwell and M. W. Brightman*. NIH, Bethesda, MD 20014.

Using the neurosecretory system of the mouse hypothalamus as an example, the anterograde transport of exogenous horseradish peroxidase (HRP) in undamaged neurons has been investigated by electron microscopy under normal and experimental conditions. Cerebral ventriculo-cisternal perfusion of 10 µl of a 30% HRP mixture resulted in a rapid diffusion of the protein throughout the brain. The posterior pituitary, however, consistently appeared devoid of reaction product extracellularly at all survival times ranging from 5 mins to 48 hrs. By 12-24 hrs, perikarya of the neurosecretory neurons in the supraoptic and paraventricular nuclei were heavily labeled with HRP, due to direct pinocytotic activity of the cell bodies and dendrites and to retrograde transport in axon collaterals situated outside the posterior pituitary. Between 6 and 48 hrs post-injection, very few neurosecretory axons and terminals contained HRP-labeled organelles. These organelles consisted of tubular profiles of smooth endoplasmic reticulum (ER) and dense bodies. The latter were, like neurosecretory granules, about 2000 A-wide. The paucity of labeled organelles transported anterogradely in the pituitary stalk axons stands in sharp contrast to the large number of HRP-labeled organelles within these same axons labeled retrogradely following vascular injection of the protein.

In an attempt to increase the anterograde flow of peroxidase in the neurosecretory system, 6 mice were dehydrated by having them drink a 2% NaCl solution for 5 days prior to ventricular perfusion of HRP. The animals were then fixed 12-24 hrs post-injection. In each case, the anterograde transport of HRP-labeled organelles in the pituitary stalk axons was markedly increased. The majority of axons in the pituitary stalk and many terminals in the posterior pituitary contained numerous HRP-labeled smooth ER and 2000 A-wide dense bodies. The large number of labeled organelles in the pituitary stalk axons of NaCl-treated animals rivaled that found in retrograde transport in stalk axons of vascular injected mice. The labeled 2000 A-wide dense bodies are probably lysosomes and not neurosecretory granules. The number of these labeled organelles did not diminish and no reaction product was seen extracellularly in the posterior pituitary in response to hemorrhage, a potent stimulus for hormone release from the posterior pituitary.

These results suggest that, normally, anterograde transport of HRP in undamaged neurons is negligible. The bulk of exogenous peroxidase that enters the perikaryon remains there for eventual degradation. In instances of severe physiological stress, anterograde transport of HRP may be increased. Such an increase could reflect an added need for degradative organelles in the more distal compartments of the neuron.

83 MORPHOLOGIC ANALYSIS OF UPTAKE AND RETROGRADE TRANSPORT OF PEROXIDASES BY AXONS. Ann H. Bunt and Richard H. Haschke. Depts. of Ophthalmol. and Anesthesiol., Univ. of Wash., Seattle, WA 98195.

The retrograde axonal transport of horseradish peroxidase (HRP) in the rat visual system is highly specific. Thus, of a number of proteins examined, only the basic isoenzymes "C" and "B" but not a mixture of the acidic isoenzymes "A" of HRP are taken up by axons of retinal ganglion and dorsal lateral geniculate cells and transported retrogradely to their somata. The molecular features of the enzymes which might underlie this specificity have been examined using biochemical and morphologic techniques. Substitution of the positively charged amino groups on isoenzyme C with negative carboxyl groups by succinylation changed the isoelectric point (pI) from 8.1 to 4.0 without affecting the sugars or enzyme activity and caused noticeable depression of retrograde transport. However, a basic pI is not the sole requisite for retrograde transport since a peroxidase isolated from turnip (courtesy of Dr. G. Mazza) possessing a similar carbohydrate composition and molecular weight, with a pI of 11.6, and also cationized A isoenzymes (approximately neutral pI) were not transported. The turnip peroxidase did cause striking filling of neuronal somata and processes for long distances away from the injection sites. Peroxidase obtained recently from local horseradish roots have yielded two distinct acidic isoenzymes. The more basic of the two (A_b; pI = 4.9) shows no detectable retrograde transport, while the more acidic isoenzyme (A_a; pI = 4.2) shows weak to medium transport. Lactoperoxidase (pI = 8.0) and one batch of Sigma HRP VI (65C-9530-1) also are not transported. Removal of calcium from isoenzyme C followed by carboxyl group modification caused significant depression of enzyme activity (2400 to 300 units/mg) but did not affect retrograde transport, indicating that very low levels of enzyme activity are detectable by our light microscopic methods. E.M. of superior colliculus and visual cortex around the injection sites after various time intervals revealed the uptake of HRP isoenzymes C, A_b, and A_a, lactoperoxidase and turnip peroxidase into synaptic and coated vesicles and fine tubules of the synapses. Only HRP isoenzymes C and A_a were found in multivesicular bodies in synapses and axons, or within membrane-bounded granules in neuronal somata. The Sigma VI (65C-9530-1) did not enter any of these membraneous compartments. Thus, while many proteins enter the vesicular organelles associated with neurotransmitter recycling in synapses, only the HRP isoenzymes C and A_a enter the vesicles responsible for retrograde transport in axons. The roles played by the individual sugar moities and protein conformation in this specificity are currently under investigation. (Supported by NIH Grants EY 01756 and 01311 and GM 15991).

84 SELECTIVITY AND KINETICS OF PEROXIDASE UPTAKE BY SYNAPTOSOMES AND NEUROBLASTOMA CELLS. Kwan Y. Chan*, Ann H. Bunt, and Richard H. Haschke (SPON: W.K. Dong). Dept. of Anesthesiology, and Ophthalmology, University of Washington, Seattle, WA 98195.

To investigate further the selectivity of uptake and retrograde axonal transport of horseradish peroxidase (HRP) observed in the visual system, the uptake of various peroxidases into rat brain synaptosomes and differentiating mouse neuroblastoma N18 cells were studied. When synaptosomes were incubated with HRP isoenzyme C (HRP-C) (2 mg/ml) at 30°C for 15 to 30 min, the cytochemical reaction product of the peroxidase was observed on the surface of synaptosomes and inside synaptic vesicles, coated vesicles, multivesicular bodies, and vacuoles. When differentiating N18 cells were incubated with the same concentration of HRP-C at 37°C, peroxidase was found first on the cell surface and appeared in coated pits and endocytic vesicles (0.1 µ) within the first few minutes. By 5 min, peroxidase was found in vacuoles (0.3 to 0.5 µ), and by 15 to 20 min, in various homogeneous and heterogeneous dense bodies of similar sizes. The presence of peroxidase inside these structures was readily demonstrated in both neurites and soma of the cell. HRP isoenzyme A, succinylated HRP-C, Sigma HRP type VI (lot 65C-9530-1, which is not taken up nor transported retrogradely by the visual system), and to a lesser extent, periodate-borohydride-treated HRP-C (pb-HRP-C), were also taken up into similar structures of synaptosomes and N18 cells. However, turnip peroxidase, lacto-peroxidase and cationized ferritin were generally not incorporated into the various membraneous structures of synaptosomes and N18 cells under similar conditions of incubation. Thus, although synaptosomes took up the different HRP's, presumably through synaptic vesicle membrane recycling, while N18 cells ingested HRP's through endocytic-lysosomal activity, these two systems expressed identical membrane selectivity of peroxidase uptake in vitro. This selectivity, however, deviates from the selectivity of peroxidase uptake expressed by several axon types of the visual system in vivo with respect to Sigma HRP type VI (lot 65C-9530-1). We conclude that neuronal membranes in an in vitro environment may be altered so that subtle changes in HRP molecules may not be operant in influencing uptake, but that selectivity against uptake of proteins with greater molecular differences is still maintained.

(Supported by NIH grants EYO 1756 and 1311, and GM 15991)

85 MAYTANSINE INDUCED BLOCK OF AXOPLASMIC TRANSPORT AND MICROTUBULE LOSS. B. Ghetti and S. Ochs. Depts. of Pathology and Physiology, Indiana University School of Medicine, Indianapolis, Indiana 46202.

As part of our interest in the relation of axoplasmic transport to microtubules in a proposed transport filament model, the action of maytansine (MTS), an ansa macrolide which binds to tubulin, was studied. The action of MTS was compared with other agents, also under study, e.g. colchicine, vinca alkaloids, batrachotoxin (BTX). An investigation of the effect of MTS on both axoplasmic transport and on the axonal microtubules was carried out. Because the perineurial sheath is an effective permeability barrier, the desheathed cat peroneal nerve preparation was used (Ochs, Worth and Chan, Abst. Soc. Neurosci., this meeting, 1977). The L7 ganglia were injected with ^{3}H-leucine and 2 hours of downflow allowed before the nerves were removed, the peroneal nerve desheathed over a length from 40 to 130 mm from the ganglion and these nerves placed in flasks containing 35-70 μM MTS in lactated Ringer for 2 to 4 hours of in vitro downflow. After this period of time a 15 mm portion of nerve was removed from the end, fixed in 5% glutaraldehyde and processed for electron microscopy. The remainder of the nerve was used to determine the outflow of the labelled activity and thus to characterize the effect of MTS on axoplasmic transport.

A marked reduction of transport was found at the shorter times with 70 μM MTS while nerves exposed to 35 μM showed a smaller decrease of transport. On a comparative basis, MTS appeared to be somewhat less potent than vinblastine and vindesine in blocking axoplasmic transport and much less potent than BTX. Ultrastructural examination of myelinated axons showed a substantial decrease in the number of microtubules in the nerve fibers exposed to 70 μM of MTS. In the unmyelinated fibers, where normally microtubules are relatively more prominent, their disappearance was even more dramatic. An occasional microtubule could be seen in fibers on careful searching; however, the majority of microtubules have disappeared. Microtubules also disappeared from the Schwann cells. Within the nerve fibers, especially the unmyelinated ones, microfilaments appeared to be intermingled with a greatly increased amount of amorphous floccular material. Only a minor loss of microtubules was seen in nerves exposed to 35 μM MTS at shorter times with more loss at the longer times. To show the suggested relation of transport block to decrease of microtubules at concentrations in the range of 35-70 μM of MTS as a function of time, microtubular counts are being correlated with the degree to which the transport is diminished. Supported in part by NIH grants PHS SO1 RR 5371 and PHS RO1 NS 8706-08; and NSF grant BNS 75-03868-A03.

86 A NEW SPECIFIC, SENSITIVE AND NONCARCINOGENIC REAGENT FOR THE DEMONSTRATION OF HORSERADISH PEROXIDASE(HRP). Jacob S. Hanker, Peggy E. Yates*, Carol B. Metz*, Keith A. Carson, Alan Light and Aldo Rustioni, Dent. Res. Ctr., Neurobiol. Progr., Depts. of Anat. and Physiol. UNC, Chapel Hill, N.C. 27514

In the course of studies of the formation of artificial melanin-like polymers it was found that the peroxidation of p-phenylenediamine (PPD) was greatly accelerated by the presence of pyrocatechol (PC). The copolymer formed as a result of this oxidative coupling reaction was insoluble, conformed well to biological ultrastructure, and gave a bluish color more intense than that obtained with 3,3-diaminobenzidine (DAB). It was also osmiophilic. Peroxidation of the individual components resulted in unsatisfactory staining.

The reagent mixture (1:2 proportion of PPD to PC)[1] outperformed DAB as an indicator for the demonstration of HRP in mammalian cells including neurons and supporting cells. It is more sensitive to and specific for plant hydroperoxidases or oxygen transferases than the corresponding mammalian enzymes. Thus there is less interference due to erythrocytic hemoglobin or erythrocytic or endogenous cytoplasmic catalases and peroxidases than when DAB is employed. Its superiority for demonstrating HRP in phagosomes of many cell types including Schwann cells was shown. In proximal convoluted tubular epithelial cells, histiocytes, macrophages, osteoclasts and Schwann cells, the HRP sequestered by the limiting membranes of phagocytic vacuoles was much more clearly demonstrated with PPD-PC[1] than with DAB. In retrogradely labelled neurons of the ventrolateral nucleus of the thalamus, dorsal column nuclei and spinal cord, the reaction product was significantly more intense with 15 min. PPD-PC[1] incubation than with 30 min. DAB incubation after 30% HRP injections in motor cortex and n. ventralis posterolateralis of thalamus of cats and rats.

Likewise in single primary afferent fibers labelled by anterograde transport of intracellularly injected HRP, the reaction product produced by PPD-PC[1] was more readily visible than tissue reacted with either DAB or tissue pre-treated with $CoCl_2$ followed by reaction with DAB (J.C. Adams, Neuroscience 2, 141-145, 1976).

[1]Although these compounds are noncarcinogenic, they are skin irritants and it is advisable to use the stable premixed reagent which is available from Polysciences, Inc., Paul Valley Industrial Park, Warrington, Pa., 18976 USA.

87 BIOCHEMICAL REQUISITES OF HORSERADISH PEROXIDASE ISOENZYMES RELATED TO RETROGRADE AXONAL TRANSPORT. Richard H. Haschke and Ann H. Bunt. Departments of Anesthesiology and Ophthalmology, University of Washington, Seattle, WA 98195

The uptake and retrograde transport of exogenous proteins by axons is a selective process which may involve specific biochemical interactions between the neuronal cell membrane and the protein being taken up. The aim of this biochemical study is to determine what biochemical parameters regulate the uptake and retrograde transport of horseradish peroxidase (HRP). By studying various isoenzymes of HRP, chemically modified forms of HRP, and other similar peroxidase enzymes, we are attempting to better understand this selective recognition process. Initially a clear correlation seemed to exist between the isoelectric point (pI) and the retrograde transport of various proteins. However, more recent experiments have demonstrated that indeed one acidic isoenzyme of HRP is also transported retrogradely. The basic and acidic isoenzymes all contain essentially identical sugar moieties consisting of N-acetylglucosamine, mannose, fucose, xylose, and arabinose. Both transporting and non-transporting isoenzymes of HRP have molecular weights of ca. 44,000 and exist in the monomeric form. Amino acid analyses performed on the peroxidase isoenzymes indicate that the basic and acidic isoenzymes are similar in composition and most likely differ in the isoelectric point because of a large difference in the content of amide groups. Titrations under denaturing and non-denaturing conditions have indicated that the free carboxyl content of the two proteins differs markedly and show structural differences as based on the reactivity of the carboxyl groups. HRP has also been shown to contain two moles of bound Ca^{++} per mole of enzyme. Removal of Ca^{++} from HRP results in 50% decrease in enzymatic activity with the C isoenzyme and 90% decrease in activity of isoenzyme A. Addition of Ca^{++} free HRP results in complete reconstitution and return of enzymatic activity with the C isoenzyme. In contrast, the A isoenzyme does not recombine with Ca^{++} and does not regain enzymatic acitvity. Exchange of Ca^{++} containing HRP isoenzymes with free Ca^{++} results in rapid and complete exchange with isoenzyme C, but essentially no detectable exchange with isoenzyme A. These differences between isoenzymes C and A with respect to Ca^{++} reconstitution and exchange suggest definite structural differences between these proteins. We propose that the biochemical basis of selective recognition of certain proteins by axons may not depend simply on the presence of carbohydrate and a basic pI, but may be related to a specific conformation which exposes certain groups to the cell membrane in the proper configuration for the recognition and uptake into retrogradely transported vesicles to occur. (NIH grants EYO 1756 and 1311, and GM 15991)

88 FAST AXONAL TRANSPORT OF GLYCOPROTEINS: COMPLETE INHIBITION BY COBALT IONS. Pierre-André Lavoie* and Richard Hammerschlag. Div. of Neurosciences, City of Hope Nat. Med. Ctr., Duarte,CA 91010.

Glycoproteins labelled with [^{3}H]fucose or [^{3}H]glucosamine undergo axonal transport at the same fast rate as proteins marked with radioactive amino acids. Among a variety of preparations, this was shown in vitro in the bullfrog spinal-sciatic nerve complex (Edström & Mattsson, J.Neurochem.19:1717, 1972), and confirmed in a similar preparation in the present study. With [^{3}H]fucose and [^{3}H]glucosamine as precursors, accumulation of TCA-insoluble radioactivity proximal to a ligature 20 mm from the ganglion reached a maximum in 18 h. Maximal accumulation of protein labelled with [^{3}H]leucine was also observed at 18 h. The maximal accumulation of [^{3}H]glycoprotein at the ligature differed, however, from that seen for total [^{3}H]protein; a peak ratio (net accumulation at ligature: plateau level) of 6 was observed with carbohydrate precursors compared to 9 with [^{3}H]leucine. Given that the transport rate is similar for [^{3}H]leucine- or [^{3}H]carbohydrate-labelled proteins, this difference may suggest that relative to the total pool of protein undergoing axonal transport, glycoproteins are preferentially removed from the transport system in non-synaptic regions of the axon. The effect of cobalt on glycoprotein transport was then examined as part of our continuing study of the calcium requirement for fast axonal transport of protein (Hammerschlag, Chiu, & David, Brain Res.114:353,1976). While the amount of total [^{3}H]protein transport was blocked by 80-90% in an incubation medium containing 1.8 mM $CoCl_2$, the inhibition of [^{3}H]glycoprotein transport was essentially 100% under similar conditions. This blockage of glycoprotein transport was seen by the absence of accumulated radioactivity proximal to a ligature on the 8th spinal nerve, as well as by the lack of observable radioactivity in those segments of non-ligated 9th spinal and sciatic nerve corresponding to the plateau and crest regions of radioactivity in the contralateral control nerve. Thus, the residual protein material that is transported in the presence of cobalt does not contain fucose or glucosamine and may not be glycoprotein in nature. The effect of cobalt on glycoprotein transport seems not to be a result of inhibition of protein glycosylation as judged by the total incorporation of [^{3}H]fucose and [^{3}H]glucosamine into TCA-insoluble materials. In previous experiments, cycloheximide was utilized to show that cobalt was also not affecting transport by blocking protein synthesis. In light of the proposal of a calcium-dependent,cobalt-sensitive step in the initiation of fast axonal transport of protein, the present findings imply that this step occurs following protein glycosylation and prior to the onset of translocation of proteins via the transport system.

89 AXONAL TRANSPORT OF [^{3}H] PROTEINS IN RAT BRAIN NORADRENERGIC NEURONS. Barry E. Levin* (SPON: S.D. Cook). Department of Neurosciences, Veterans Administration Hospital, East Orange, NJ 07019 and New Jersey Medical School, Newark, NJ 07103.

Axoplasmic transport of proteins was studied in the noradrenergic pathway from the locus coeruleus (LC) to the hypothalamus of the rat using [^{3}H] leucine injected stereotaxically into the LC. [^{3}H]protein synthesized from [^{3}H]leucine was transported in four waves through the hypothalamus at rates of 96, 48, 26 and 1-2 mm/d (waves I, II, III and IV respectively). Specificity of transport within catecholamine neurons was demonstrated by 6-hydroxydopamine lesions of the LC-hypothalamic pathway which blocked transport of all four waves, while a fifth wave of uncertain origin, was not blocked. Such lesions cause a blockade of orthograde dopamine-B - hydroxylase transport as demonstrated by immunofluorescent histochemistry and a 30% decrease in enzyme activity in the ipsilateral frontal cortex without change in hypothalamic levels. Waves I and II correspond in rate to those for fucosyl glycoproteins (Brain Research, in press) and wave II, to the rate of norepinephrine transport in this model (Brain Research, 120: 303, 1977). The various waves have different properties by ion exchange chromatography suggesting the heterogeneity of transported proteins in each wave.

90 DEPENDENCE OF AXOPLASMIC TRANSPORT ON CALCIUM SHOWN IN THE DESHEATHED PERONEAL NERVE. Ochs, S., Worth, R.* and Chan, S. Y.* Department of Physiology and Medical Biophysics Program, Indiana University School of Medicine, Indianapolis, Indiana 46202.

On the basis of the transport filament hypothesis for fast axoplasmic transport, we would expect Ca and perhaps Mg to play an important role. Prior studies showed an apparent lack of effect of Ca-free media on axoplasmic transport in vitro. The perineurial sheath acts as an effective permeability barrier for a number of materials and resists changes of the ionic concentration in the extracellular fluid held within it. A desheathed nerve preparation was developed to assess the effect of different ionic compositions in the medium on axoplasmic transport. The peroneal branch of the sciatic nerve was desheathed from about 35 mm down to about 130 mm from the L7 dorsal root ganglion. This permitted a relatively long length of desheathed nerve to be exposed to a given medium for over 4 hrs of downflow in vitro. The L7 dorsal root ganglia were injected with ^{3}H-leucine and 2 hrs of downflow in vivo allowed before the sciatic nerves were removed. The peroneal branch of the sciatic nerve was desheathed and the tibial branch left intact as a control. The nerves were placed in flasks containing 20 ml of medium, either lactated Ringer, or isotonic NaCl or sucrose with or without Ca added. The solutions were vigorously bubbled with 95% O_2 + 5% CO_2 at 38°C. With Ringer or with 5 mM $CaCl_2$ present, transport in the desheathed branch compared favorably with that seen in the sheathed branch. The crest was not as prominent but otherwise the usual rate of transport of 410 mm/day was maintained. When Ca was removed from the medium, transport in the desheathed peroneal branch fell off and failed completely within approximately 2 hrs. Mg was not able to substitute for Ca in supporting transport. We consider that the removal of Ca from the medium causes the level of ionized Ca in the fibers to fall below a critical level required to maintain transport. A Ca-binding protein, sequestration of Ca in mitochondria and possibly also in the endoplasmic reticulum, Na-Ca exchange carrier and a Ca-pump in the membrane are all possible mechanisms acting to maintain free Ca at the level required for axoplasmic transport. With higher concentrations of Ca present in the in vitro medium, the rate of axoplasmic transport was gradually decreased. With isotonic Ca, block occurred within 1-2 hrs. An augmentation of Ca in the fibers could interfere with axoplasmic transport by blocking the same mechanism affected by removal of Ca, or alternatively, by some other action on the microtubules. Supported in part by the NIH grant PHS RO1 NS 8706-08 and the NSF grant BNS 75-03868-A03.

91 AXONAL TRANSPORT OF CHOLESTEROL AFTER INTRAOCULAR INJECTION OF MEVALONIC ACID. John A.P. Rostas* and Peter L. Jeffrey*, (Spon: J.C. Blosser) Dept. of Psychobiology, Univ. of California, Irvine, Ca. 92717 and Dept. of Neurology, Baylor College of Medicine, Houston, Tx. 77030.

After the injection of labeled mevalonic acid, a metabolic precursor of cholesterol, into the eye of young chickens, both the fast and the slow phase of axonaly transported radioactivity can be detected at the contralateral optic tectum. Seventy five percent and ninety two percent of the radioactivity in the fast and slow phases respectively, was recovered in the free cholesterol. After the injection of labeled cholesterol into the eye, radioactive cholesterol was axonaly transported only at the slow rate: no fast rate of cholesterol transport could be detected (Rostas et.al. (1975) J. Neurochem. 24:295-302). Therefore, in the chick optic system, cholesterol is axonaly transported in two phases, which appear to take their cholesterol from different cellular pools. The fast phase appears to be specific for newly synthesized cholesterol whereas the preformed, endogenous cholesterol can readily exchange with the transport pool for the slow phase. Because these two pools for transport phases can be selectively labeled, the retina and optic nerve provide a unique model system in which the metabolic turnover, intracellular compartmentalization, and intracellular transport of cholesterol can be studied.

92 RAPID PARTICLE TRANSPORT IN AXONS FROM DECAPOD CRUSTACEANS. Richard S. Smith. Dept. Surgery, Univ. Alberta, Edmonton, Canada.

A search has been made among the invertebrates for large diameter, non-myelinated axons in which the rapid axoplasmic transport of optically detectable particles takes place. In general, the peripheral nervous systems of the decapod crustacea provide suitable preparations.

Single "giant" motor axons were dissected from nerve trunks of the walking legs of several genera of crabs, two species of lobsters and the crayfish Pacifastacus. The axons were viewed in saline filled chambers by darkfield and Nomarski microscopy. All nerve fibers showed a sub-axolemmal system of axially oriented filaments which individually were up to 50 μm in length. These corresponded in position to the circumferential mitochondria and smooth endoplasmic reticulum seen by thin-section electron microscopy. The sub-axolemmal filaments were stationary. The core of the fibers contained long filamentous bodies, rods of a few μm length and sub-micrometer particulate bodies. All classes of bodies detected in the core of the axons showed some form of motion, however, the particulate bodies had the most regular motion and were the most rapidly moving. All nerve fibers contained proximally (somatopetally) moving particles with average velocities of about 1 μm/sec at room temperature. Values for these velocities are given as means (μm/sec) ± SD with the number of determinations in parentheses followed by the temperature in °C: Carcinus meanus, 1.08 ± 0.28 (65), 19.5-20; Homarus vulgaris, 1.01 ± 0.30 (58), 19-20; Pacifastacus trowbridgeii, 1.04 ± 0.39 (92), 21-22. The velocities of proximally moving particles in C. meanus and H. vulgaris had a Q_{10} of 2.3 and 3.0 respectively over the range of 16-27°C. Distally (somatofugally) moving particles were always fewer than proximally moving ones; their number was variable and some axons contained no detectable distally moving particles. Their velocities were less than those of proximally moving particles, these were, with the convention as above: C. meanus, 0.40 ± 0.10 (40), 19.5-20; H. vulgaris, 0.34 ± 0.12 (20), 19-20; P. trowbridgeii, 0.40 ± 0.12 (39), 21-22. The Q_{10} for the velocity of distally moving particles was, in C. meanus, 2.1 and in H. vulgaris, 1.9.

Particle transport in these axons is unique in that material moves faster somatopetally than somatofugally.

93 TWO-DIMENSIONAL MAPPING OF PROTEINS IN RAPID AXOPLASMIC TRANSPORT. George C. Stone, David L. Wilson, and Michael E. Hall. Dept. of Physiol. and Biophys., Univ. of Miami, Sch. of Med., Miami, Fl. 33152.

Rapid axoplasmic transport is thought to include proteins primarily involved in nerve terminal maintenance rather than axonal growth. Previous findings have suggested that at least 6 to 24 protein species are present in this type of transport.

Modifications of O'Farrell's (1) procedure for two-dimensional electrophoresis of proteins has allowed high resolution analysis of the protein species rapidly transported in the frog sciatic nerve.

The 7th, 8th, and 9th dorsal root ganglia were selectively labeled with ^{3}H-leucine, ^{14}C-leucine, or ^{35}S-methionine in one compartment of a lucite chamber. Transport of TCA precipitable material was monitored in the spinal roots and sciatic nerve kept in another compartment. Fastest transport rates were 75-90mm/day at 18°C. Ligation of the nerve 30mm distal to the 8th ganglion at the beginning of the experiment resulted in accumulation of label during a 24 hr period. This material was subjected to two-dimensional electrophoresis (pI 4.5-8.5; m.w. 10^4-10^5 daltons) in 3mm nerve segments. Autoradiographs or fluorographs from segments proximal to the ligature yielded a pattern of at least 60 labeled proteins. Neither actin nor tubulin were present among these rapidly transported, labeled proteins. No pattern was observed from segments distal to the ligature, ruling out the possibility of local incorporation by contamination. Blocking protein synthesis with 18μM anisomycin reduced the accumulation of label proximal to the ligature by 98%. Direct labeling of nerve segments produced patterns significantly different from the pattern of transported proteins. A comparison of proximal segment staining with labeled incorporation in the same segment following transport revealed at most 12 common species. It is concluded that at least 48 of the transported protein species are neither synthesized nor found in abundance in nerve segments. These may be destined for nerve terminals.

Supported by NIH grant NS12393 and by a Biomedical Research Support Grant. MEH is a postdoctoral trainee (NS 7044).

94 SECTIONING OF THE RAT SCIATIC NERVE PRODUCES CHANGE IN SPECIFIC PROTEINS CARRIED BY RAPID AXOPLASMIC TRANSPORT. Richard F. Theiler* and William O. McClure. Dept. of Biochemistry, Univ. of Illinois, Urbana, IL 61801, and Dept. of Biological Sciences, Univ. of Southern California, Los Angeles, CA 90007.

One sciatic nerve of a rat was exposed and sectioned. At times of 5 - 50 days after section, both the sectioned nerve with its associated dorsal root ganglion (drg), and the contralateral nerve and drg, were excised and transferred to short term in vitro culture. The drg were labelled with radioactive amino acids, after which those proteins committed to transport were detected by their acculation at a ligation placed on the nerve proximal to the cut end. Accumulation of transported proteins was allowed to proceed for 18 hr at 37° in O_2:CO_2 (95:5). Under these conditions, transported radioactivity included only material which moved at rates $\gtrsim$ 50 mm/day. The amount of transported radioactivity was compared in sectioned nerves and their contralateral controls. No statistically significant differences were observed. Similarly, no significant differences were observed in the amount of precursor incorporated into proteins of the two drg. Transported proteins were solubilized, fractionated on slabs of polyacrylamide in sodium dodecyl sulfate, and visualized by radioautography after the gel was impregnated with PPO. Several changes of individual bands occurred as a result of nerve section. One protein (MW 19000 daltons) disappeared from the transported flow following section, while a second (MW 42000 daltons) appeared. Both proteins altered their levels with a time course which followed histologically defined chromatolysis in the animals. In addition to the changes in the sectioned nerve, we also detected changes in the proteins transported by the control (unsectioned) sciatic nerve of an animal in which the other nerve was sectioned. Two proteins which are carried by axoplasmic transport in sciatic nerves of unoperated animals are not detectable in the material transported by control nerves of operated animals. The two proteins disappear for two weeks after section, and reappear at later times. These changes may be related to compensatory use of the limb contralateral to a sectioned nerve. It is possible that the rapidly transported proteins whose levels are altered in sectioned nerves are involved in the control of neuronal regeneration. Sloan Foundation, the Muscular Dystrophy Associations of America, and the Nelson Research and Development Company.

95 POLY-L-ORNITHINE IMPROVES LIGHT MICROSCOPIC VISUALIZATION OF HORSERADISH PEROXIDASE. Michael C. Trachtenberg, and Robert T. Hadley*. Neurology Svc., Boston VA Hospital, and Dept. of Neurology, B.U. Sch. of Med., Boston, Mass. 02130.

Poly-L-ornithine (ORN) mixed with horseradish peroxidase (HRP) increases the amount of HRP uptaken, greatly magnifying signal amplitude and rendering it visible for a longer time. This effect is of major importance for light microscopy where maximal resolution is ~200 nm, while vesicles containing HRP are 20-100 nm in diameter. The production of multivesicular bodies containing adequate numbers of sufficiently labelled vesicles is a time, system and direction dependent process, evident in four distinct problem areas. These are not now adequately solved by the use of different types of HRP or special fixation or reaction procedures which can only better reveal available HRP.

Paired injections of various concentrations of ORN (m.w. 200,000) with 25% HRP and 25% HRP alone were made in frontal agranular and visual cortex of Long Evans rats. After survival times of 2.5 - 100h animals were sacrificed, perfused and processed by several techniques. Four subcortical loci were examined; claustrum, ventral tier complex, lateral geniculate nucleus (LGN) and lateral dorsal nucleus (LD). Four to six times as many retrogradely labelled cells are seen in experimental as compared to control loci at post-injection times of 5-72h. Using ORN-HRP or HRP alone label is first visible and disappears at similar times. Cell counts as a function of time indicate that under test and control conditions only the number of cells and not their distribution differ suggesting an alteration in the amount of HRP transported but not in the transport rate. Anterograde terminals are seen at all times in LGN, LD and medial dorsal nucleus on the experimental side when few or none are visible on the control side.

The increased reliability of visualizing both retrograde and anterograde transport of HRP attributed to ORN allows full utilization of the entire temporal window for labelling: 5-100h vs. 16-48h by standard methods. Consequently ORN can be used advantageously to trace very long as well as short connections simultaneously in large primate brains. Four problems which appear to be ammenable to solution by this procedure are: a) inability to demonstrate by retrograde transport some known connections; b) low reliability of seeing anterograde terminals; c) inadvisability of using very small amounts of HRP to label discrete regions; d) restriction of optimal survival times.

96 PARGYLINE INDUCES CHANGES IN AXONAL TRANSPORT IN MOTOR NEURONS. D.F. Watson, J.A. Donoso and F.E. Samson. Ralph L. Smith Mental Retardation Center, University of Kansas Medical Center.

Pargyline (N-methyl-N-benzyl-2-propynylamine hydrochloride) is a monoamine oxidase inhibitor which produces numerous changes in neural and muscular functions. Because of previous conflicting reports, we have re-examined the possibility that pargyline can induce an apparent increase in the velocity of axonal transport. Male Holtzman rats, 450-550 gm, received 3 daily doses of pargyline (75 mg/kg, i.p.; controls received i.p. sterile water. Eleven of 31 rats died during the pargyline treatment. One day after the last dose, 50 uCi of 3H leucine (61 Ci/mmole) in 2.5λ of Locke's solution was micro-injected bilaterally into the L5-6 ventral horn regions under sodium pentobarbital anesthesia. After 1-4 hr for incorporation and transport, the sciatic nerves and L5 ventral roots were removed, rapidly frozen, fixed in 95% ethanol or 5% trichloracetic acid, and cleaned of connective tissue. Tritium cpm per 2 mm nerve segment were determined by digestion and liquid scintillation counting. The bulk of the transported material in the pargyline-treated rats moved at the control velocity (11.9±3.5 mm/hr and 13.3±2.2 mm/hr, respectively. However, pargyline also induced faster components of transport. In all 10 pargyline-treated nerves, a faster but smaller peak was observed, with a mean velocity of 21.4±5.1 mm/hr; in addition, 6 of 10 nerves showed a small peak at a rate of 39.9±6.8 mm/hr. Preliminary results suggest that pargyline does not cause such changes in dorsal root preparations. The observed changes in axonal transport may be a result of the accumulation of monoamines due to pargyline; however, other modes of action for pargyline cannot be excluded.

BASAL GANGLIA

97 ELECTROPHYSIOLOGICAL STUDIES OF BRANCHING NIGRAL AXONS AND THE MONOSYNAPTIC INHIBITION PRODUCED IN THALAMIC NEURONS BY STIMULATION OF THE SUBSTANTIA NIGRA. M.Anderson, M. Yoshida*, and A. Ueki*. Depts of Rehab. Med. and Physiol. and Biophys., Univ. of Wash., Seattle, and Dept of Neurology, Jichi Medical School, Tochigiken, Japan.

Anatomical studies have shown that the substantia nigra (SN) sends axons to the ventromedial thalamus (VM) and to the superior colliculus (SC). We have studied the collicular and/or thalamic destination of axons of single SN neurons and the synaptic potentials produced in thalamic neurons by SN stimulation.

Cats were anesthetized with alpha chloralose or sodium pentobarbital. In some experiments, recording microelectrodes were inserted into SN during stimulation of ipsilateral VM and SC. Extracellularly-recorded action potentials of negative configuration were identified as antidromic based on constant latency, high frequency-following and collision block criteria. Three groups of cells were activated antidromically, from (1) the thalamus only, (2) SC only, or (3) both thalamus and SC. Threshold stimulus intensities were lowest in the region of VM and in intermediate to deep layers of SC. Mean antidromic latencies were 1.17 msec from SC and 1.66 msec from the thalamus.

In other experiments, microelectrodes were inserted into the thalamus from a lateral angle of 30° and the ipsilateral SN and contralateral brachium conjunctivum (BC) were stimulated. Intracellular records from neurons in VL showed EPSPs evoked at short latencies by BC stimulation, but no response to SN stimulation. However, in VM neurons, SN stimulation evoked an IPSP at short latencies, but there was no response to BC stimulation. The short, constant latency of the nigral evoked IPSP (1.2-2.0 msec in different cells) and its constant configuration made it probable that it was produced monosynaptically. Furthermore, if the IPSP was produced by stimulating SN fibers closer to VM, the latency was reduced markedly, and if the conduction distance was extrapolated to 0mm, the delay was too short for more than one synaptic relay.

Thus, at least some SN neurons appear to send axonal branches to both VM and SC, and axons from nigral neurons inhibit VM neurons that are not directly excited by cerebellar output.

Supported by RSA grant 16 P 56818.

98 RETROGRADE AXONAL TRANSPORT OF HERPES SIMPLEX VIRUS IN BASAL GANGLIA AND RELATED NUCLEI. Il Jin Bak*, Charles H. Markham, Margery L. Cook* and Jack G. Stevens* (SPON: Hilde E. Hirsch). Dept. Neuro., Sch. Med., UCLA, Los Angeles, CA 90024.

A neurotropic virus, herpes simplex virus (HSV) wild type I, was used as a tracer in light and electron microscopic study of afferent and efferent fiber connections in the basal ganglia. Rats received microinjections (0.2-1µl) of highly concentrated HSV (10,000-40,000 plaque forming units per microliter) into the left neostriatum. Four days later substantial numbers of nuclear capsids and a few mature viruses were found in the nucleus and cytoplasm of many large neurons in the ipsilateral substantia nigra, largely in the zona compacta; in the midbrain dorsal raphé nucleus; in the medial thalamus; and in the frontal cortex bilaterally. The striatum itself showed few infected neurons. In another experiment when HSV was injected into the frontal cortex there was no virus spread to the neostriatum. The pattern of cell infection in these two experiments, plus prior knowledge of anatomical pathways, strongly suggests HSV is carried intraaxonally in a retrograde fashion in the experiments cited here.

In a third experiment, when HSV was injected into the left substantia nigra, a large number of virus labelled cells were seen in the ipsilateral neostriatum 5 days later. Most of the neurons infected by HSV were medium sized neurons measuring an average of 10-20µm in diameter. A parallel study in which the immunoperoxidase technique was employed following HSV injection into the substantia nigra confirmed the pattern of virus infection in the striatum.

99 PROSENCEPHALIC PATHWAYS RELATED TO THE AVIAN BASAL GANGLIA. Steven E. Brauth*, John L. Ferguson* & Cheryl A. Kitt* (SPON: D.I.Sommers) Dept. Psychol.,Univ of Md.,College Park,Md. 20742.

The avian basal ganglia include the paleostriatum augmentatum (PA), paleostriatum primitivum (PP), and nucleus intrapeduncularis (INP). Previous work indicated that PA was most comparable to the mammalian caudate nucleus, PP and INP to globus pallidus. The present study involves a series of anatomic experiments designed to clarify the afferent and efferent connections of these cell groups by means of horseradish peroxidase (HRP) histochemistry.

Injections of HRP into PA indicate that the source of telencephalic afferents to this structure is derived from a population of small to medium cells lying throughout the temporal-parietal-occipital area (TPO) and lateral cortical area (LCA) of the neostriatum. Some cells also appear to lie just medial to this region bounded by the dorsal archistriatal tract (DA). This result was demonstrated by both retrograde transport of HRP and by anterograde transport of the marker after injecting small quantities into the TPO area itself.

In addition to the above population of neurons, a small number of neurons in the medial part of PA project to the lateral portion. Both the medial and lateral portions of PA receive projections from cells in the TPO and LCA regions, however the lateral portion of PA receives a more extensive projection. The topography of the projection of TPO neurons onto PA is organized such that cells in the most ventral and lateral portions of TPO project upon lateral PA, and those lying dorsally and medially in TPO project upon medial PA. Nevertheless overlap in the projections of TPO and LCA neurons upon PA is present.

HRP injections in PP and INP labeled cells in PA. The majority of these retrogradely labeled cells were found in the lateral portion of PA and were scattered throughout this region. They constitute almost entirely the small cells of PA.

Subtelencephalic projections to PA are derived from the ventral portion of the nucleus tegmenti pedunculopontinus pars compacta (TPc). PP neurons receive projections from cells in the anterior nucleus of the ansa lenticularis (ALa) and in turn project extensively upon this thalamic cell group. ALa may thus resemble the mammalian subthalamic nucleus.

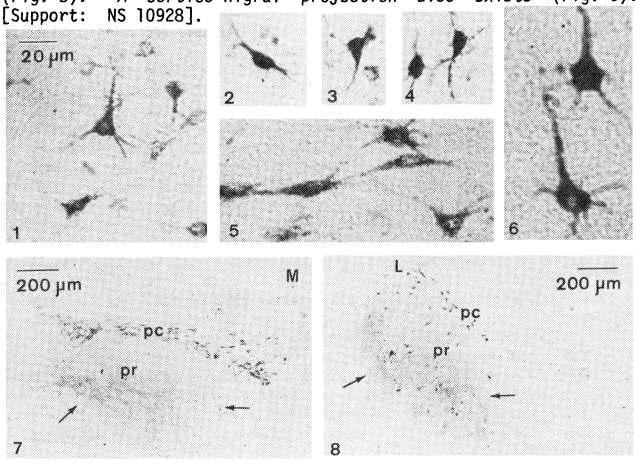
HRP injections confined to the TPO region of the telencephalon indicate that this region receives projections from the contralateral archistriatum pars ventralis (Av), and ipsilateral frontal neostriatum in areas just adjacent and also just dorsal to the ectostriatum (E). A small number of cells just ventral to PP also project into TPO ipsilaterally.

100 NIGRO-NEOSTRIATO-NIGRAL RELATIONSHIPS DEMONSTRATED BY HORSERADISH PEROXIDASE (HRP) HISTOCHEMISTRY. *LARRY L. BUTCHER*[1] *and GLENN J. GIESLER, Jr.*[2] Dept. Psychology[1,2] and Brain Research Institute[1], University of California, Los Angeles, CA, 90024, U.S.A.

HRP was infused into various regions of the rat caudate-putamen (CP) complex or substantia nigra (SN). 72 hrs later the animals were anesthetized and then sacrificed by transcardial perfusion with a glutaraldehyde-paraformaldehyde solution. After postfixation and sectioning the brains were processed according to the de Olmos o-dianisidine protocol for HRP, which demonstrates enzyme loci with greater sensitivity than other procedures for HRP. Accordingly, good cellular morphology can be obtained (Figs. 1-4: CP somata after intra-SN HRP injection; Fig. 5: pars compacta, pc, SN somata after intra-CP HRP injection; Fig. 6: cortical neurons after intra-SN HRP injection; 20 µm scale for Figs. 1-6).

Both anterograde and retrograde HRP transport were evinced consistently in our material (Figs. 7-8: SN after intra-CP HRP infusion; observe HRP both in somata in pc and in pars reticulata, pr, as well as in neuropil [arrows] in pr). Numerous CP somata, mostly in lateral regions of the nucleus, accumulated HRP after intra-SN enzyme injection. Medial (M) SN projects to medial CP, and medial CP projects to medial pr (Fig. 7). Similarly, lateral (L) SN projects to lateral CP, and lateral CP projects to lateral pr (Fig. 8). A cortico-nigral projection also exists (Fig. 6).

[Support: NS 10928].



101 AFFERENT CONNECTIONS OF THE GLOBUS PALLIDUS IN M. MULATTA AS DETERMINED BY RETROGRADE TRANSPORT OF HORSERADISH PEROXIDASE. K.W. Clausing*, M.E. Anderson and J.L. DeVito (SPON: O.A. Smith). Reg. Prim. Res. Ctr. and Depts. Rehab. Med. and Physiol. Biophys., Univ. Washington, Seattle, WA 98195

The high tonic discharge rates of globus pallidus neurons in awake monkeys make it probable that these neurons receive some potent excitatory synaptic input. Because most current electrophysiological evidence suggests that the major described pallidal afferent systems from the neostriatum and subthalamic nucleus are primarily inhibitory, we have used retrograde transport methods to identify possible additional sources of pallidal afferents.

The extent of the globus pallidus in M. mulatta was first mapped by recording the characteristic high frequency discharge of single pallidal units in awake animals. A silastic-filled stainless steel cylinder was stereotaxically implanted on the skull, and tungsten recording electrodes were inserted at a 30° angle through hypodermic cannulae into the putamen and globus pallidus. After the position of the globus pallidus was determined, a hypodermic cannula was inserted through the cortex to the outer or inner edge of the putamen and the needle of a microliter syringe was introduced through this into the globus pallidus. A 33% horseradish peroxidase (HRP) solution (0.2-0.3 µl) was injected in 0.1 µl increments and, after waiting 10-15 min, the needle was withdrawn through the cannula. The cannula was removed after an additional 30 min and proved an effective barrier to spread of HRP along the needle track.

In two animals with injections of HRP limited to the internal pallidal segment, retrograde label was seen in neurons of the ipsilateral peripeduncular pontine tegmentum, the dorsal raphe nuclei, the substantia nigra, the parafascicular nucleus, and the zona incerta. In one of the animals additional label was present in the putamen and subthalamic nucleus. A larger injection centered in the external pallidal segment, but extending medially into the internal segment and laterally into the putamen, resulted in label in the centromedian and medial pulvinar nuclei as well as in all areas listed above.

The fibers transporting HRP could be those terminating in the pallidum or damaged fibers passing through the pallidum and destined for the putamen. However, these data present the possibilities that (1) fiber systems destined for the neostriatum also have synaptic connections with pallidal neurons and (2) reciprocal synaptic connections exist between the globus pallidus and some of the sites to which pallidal axons project, such as the pedunculopontine nucleus.

Supported by NIH grant RR00166 and RSA grant 16P56818.

102 PROJECTIONS OF LOCUS COERULEUS AND RAPHE NUCLEI TO NEOSTRIATUM. James R. Couch and Glenn D. Goldstein.* Dept. Neurol., Kansas Univ. Sch. Med., Kansas City, KS 66103.

A series of 13 rats were employed to study projections from locus coeruleus (LC) and raphe nuclei to the caudatoputamen (CPU). Volumes of 2-10 µl of a 10% solution of horseradish peroxidase (HRP) (Sigma type VI) were injected into the anterior part of the right CPU employing a Gilmont microsyringe (accuracy 0.1 µl ±.04%). After 24 hrs the animals were anesthetized with with diabutal and perfused with a solution of 10% formaldehyde - 1.25% glutaraldehyde followed by 5% sucrose. Sections were cut serially at 30 microns, mounted, and incubated in 0.03% 3,3 diaminobenzidine followed by exposure to H_2O_2 and 3,3 diaminobenzidine. As controls, a sham injection into the cortex and an intravenous injection of 12 mg of 10% HRP were employed. Neurons projecting to the CPU were identified as polygonal structures with golden brown granules of reaction product in the cytoplasm.

In 7 animals given 5-10 µl injections, substantial numbers of labelled neurons were seen in both right and left LC. The labelling showed a modest ipsilateral preponderance compared to the contralateral side. On both sides labelling was somewhat heavier in the caudal, compared to the rostral LC. Ipsilateral labelling of substantia nigra (SN) neurons was seen in all animals. With 5-10 µl injections there was some spread of HRP beyond the CPU. Six additional animals were tested with 2-3 µl injections with which the HRP remained localized to the CPU. In 4 animals, there was labelling in the SN and in these, there was also labelling in the LC bilaterally. The labelling was more sparse but followed the pattern noted above. In 2 animals there was no SN and also no LC labelling.

With 5-10 µl injections, there was a modest amount of labelling in the dorsal raphe nucleus (DRN) and occasional labelling in nuclei raphe pontis and magnus. These findings were confirmed with 2-3 µl injections. No labelling of the median raphe nucleus was seen. These findings are in accord with other reports. No labelling of LC, DRN or SN was seen in control animals.

The LC, the most concentrated collection of norepinephrinergic neurons in the brain, has extensive projections, but LC-to-CPU connections have not previously been identified. The findings presented suggest there are substantial homolateral and contralateral projections from LC to CPU. The CPU contains a small but significant concentration of norepinephrine and the proposed LC-to-CPU pathway may account for much of the norepinephrine in the CPU.

103 POSTNATAL DEVELOPMENT OF THE NEOSTRIATUM IN MONKEYS (M. MULATTA). Marian DiFiglia, Tauba Pasik and Pedro Pasik. Dept. of Neurology, Mount Sinai School of Medicine, CUNY, New York, N.Y. 10029.

Paired specimens of the neostriatum of monkeys at 0, 1, 2, 4, 8, 12 weeks and 3-4 years of age were prepared for Golgi and electron microscopic studies. Wide variations in the degree of maturity of each previously described neuronal type (DiFiglia et al., Brain Res., 1976, 114, 245) are observed within the same specimen at 0 and 1 week. Some cells are not differentiated enough to be classified. General immature features of dendrites include growth cones with filopodia, other enlargements and long filiform processes. The spiny I neuron exhibits dendritic varicosities which decrease in frequency with age, and are only occasionally seen at terminal portions in the adult. The least mature cells have few dendritic spines mostly of the thin type. The most mature cells at each period show a progressively greater number of spines but their relative distribution and types (thin, stubby, mushroom) remain about the same. The spine density increases from a mean of 8.6 spines per 10µm of dendrite length at birth to 14.1 at 8 weeks, reaching maximal levels of 15-17 by 12 weeks. Concurrently, the dendritic field radius grows from 100 µm to 200 µm. The long axon of these neurons shows varicosities up to 4 weeks, and acquires mature features by 8 weeks. Beaded collaterals present from birth, continue to elaborate with age. The spiny II neuron at early ages has a dendritic field radius of up to 200 µm which may increase to 600 µm at 4 weeks. The spine density is characteristically higher at birth (7 per 10 µm) and decreases progressively down to 5 per 10 µm at 8 weeks. The long axon and its extensive collateral system are well developed by 1 week although bulbous enlargements are noted. The 3 types of short axon aspiny neurons exhibit immature dendritic features, most notably spine-like and filiform processes. Axonal arborizations vary from immature to well developed at 0 and 1 week. Four categories of presumably afferent axons are already present at birth and include: 1) thick axons branching extensively into undulating, terminal processes; 2) thick axons having grapelike clusters of large terminal boutons; 3) axons of intermediate diameter with numerous varicose branches often terminating in axonal growth cones with filopodia; and 4) thin,straight processes exhibiting short appendages with terminal boutons. All of these afferents can be correlated with similar types found in the adult.

Electron microscopic examination of striatal neuropil confirms the presence of immature dendritic and axonal features at early ages. At birth, both immature and mature synapses occur on the dendrites of aspiny and spiny (spines and shaft) neurons. Axonal profiles with features associated with dark degeneration in the adult are seen up to 4 weeks. Aided by N.I.N.C.D.S. Grant # NS-11631.

104 REVERSE TOLERANCE TO AMPHETAMINE OF MICE BEARING UNILATERAL ELECTROTHERMAL STRIATAL LESIONS: EFFECT UPON CIRCLING RESPONSE TO APOMORPHINE. Stanley D. Echols. Dept. Pharmacol. Merrell-National Laboratories, Cincinnati, Ohio 45215.

Mice bearing unilateral striatal lesions circle ipsiversively when administered amphetamine. It has previously been shown in this laboratory that such responses increase upon repeated administration of the same dose. This experiment was to determine whether such reverse tolerance to amphetamine affects the circling response to apomorphine. Mice were electrothermally lesioned, administered apomorphine, 0.4 mg/kg s.c., and circling was counted minutes 2-10 afterwards. Good responders were divided into two groups of ten matched according to response. One group received 4 doses of d-amphetamine, 4 mg/kg s.c., at weekly intervals; the other group received corresponding saline injections. The mean ipsiversive turns over 1 hour was 370 after the first dose of amphetamine and 644 after the fourth ($P < .01$), demonstrating reverse tolerance. The mean response of that group of mice to apomorphine, 0.4 mg/kg s.c., had been 33 before the amphetamine injections; afterwards it increased to 49 ($P < .01$). In the other group of mice, which had responded to the earlier apomorphine injection with 34 turns, the response after the saline injections decreased to 12 ($P < .01$). Hence, reverse tolerance to amphetamine is reflected in the response to apomorphine. Reverse tolerance to amphetamine therefore seems unlikely to be mediated solely by presynaptic changes of the nigro-striatal dopaminergic system.

105 THE ROLE OF NIGRO-TECTAL PROJECTIONS IN RELATION TO TECTO-SPINAL TRACTS AND HEAD TURNING. James E. Faber & Donald H. York, Dept. of Physiol., Sch. of Med., Univ. of Missouri, Columbia, Mo., 65201.

The anatomical projection of neurons from the substantia nigra to the superior colliculus has been demonstrated by several groups of workers. The role that this pathway may play in 1) relaying information from the basal ganglia to descending spinal cord tracts or 2) tectal integration of other inputs, is the subject of this investigation. Single unit microelectrode recordings were undertaken from the superior colliculus in male Sprague-Dawley rats (300-650 gms) anesthetized with chloral hydrate or urethane. Cells were examined in all layers of the colliculus for input from the substantia nigra (SN), neck muscles (NM), visual system (VS) and spinal cord (SC). Cells in the more superficial layers characteristically responded to visual input whereas other inputs were more diffusely spread throughout the colliculus. Of 228 neurons evaluated in the superior colliculus, 57 were antidromically identified by nigral stimulation and followed stimulus frequencies over 200/sec. About half of these tecto-nigral cells were activated by a light flash delivered to the eyes and 10 cells also received neck muscle input. In contrast, orthodromic activation of cells in the superior colliculus was obtained upon either stimulation of SN, pars reticulata (6 out of 77 cells) or SN, pars lateralis (29 out of 42 cells). Cells evoked by stimulation of the latter area (pars lateralis) were also excited by photic activation (19 out of 42) and neck muscle input (6 out of 13). Stimulation of the ventral funiculus of the cervical spinal cord also evoked these latter type of units at constant latency (~4 msec) and followed stimuli over 200/sec. Thus, of 16 tecto-spinal identified cells, all were activated by the substantia nigra (pars lateralis). These findings suggest that the superior colliculus may relay basal ganglia output to neck motoneurons in the cervical cord which results in the characteristic head turning movements and circling observed with stimulation of a variety of basal ganglia structures.

106 COBALT INJECTIONS INTO THE SUBSTANTIA NIGRA OF THE RAT: EFFECTS ON BEHAVIOUR AND METABOLISM OF STRIATAL DOPAMINE. Ruggero Fariello, Masato Shibuya*, Irene J. Farley*, Kathleen S. Price*, Kenneth G. Lloyd and Oleh Hornykiewicz. Dept. Psychopharm., Clarke Inst. Psych., Univ. Toronto, Toronto, Canada.

Small amounts of cobalt (5-12 µg in 0.5 µl) unilaterally injected into the substantia nigra (SN) of rats caused a strong, spontaneous contralateral turning which was suppressed by haloperidol. One to two days after intranigral cobalt microinjection, d-amphetamine decreased the intensity of the contralateral turning; five days after cobalt application, d-amphetamine changed the direction of the turning to the ipsilateral side. Intranigral cobalt microinjection initially caused a significant increase in the concentration of dopamine (DA), 3,4 dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) in the ipsilateral striatum. Thereafter, the levels of DA and its metabolites declined progressively to reach, 4 days after cobalt, values significantly below the control levels. Similar biochemical changes in the striatum were also seen after partial electrolytic lesions of the SN. However, in contrast to cobalt, such SN lesions produced only mild contralateral turning. Frontal hemisection completely interrupting the nigrostriatal DA pathway did not result in any increase of striatal DOPAC or HVA levels, and produced no significant turning. Thus, there was no apparent parallelism between the intensity and time course of the turning behaviour induced by the different procedures and the changes in DA metabolism in the striatum. However, within the cobalt injected SN the levels of GABA and glutamic acid decarboxylase (GAD) were decreased to 40% of the contralateral control values. The possibility is considered that the depression of a GABA mediated inhibitory influence upon the nigrostriatal or mesolimbic DA neurons may play a role in the cobalt-induced contralateral turning as well as altered striatal DA metabolism.

107 MOTOR CORTEX PROJECTIONS TO THE CAUDATE NUCLEUS. I. ELECTROPHYSIOLOGY. E. Garcia-Rill, C.D. Hull and N.A. Buchwald, MRRC, Sch. of Med., UCLA, Los Angeles, CA. 90024.

Dense afferent inputs from the frontal cortical areas have been described to project in a topographical manner onto the striatum. The experiments reported here were designed to reveal any possible differential projections to the caudate nucleus from different areas within the motor cortex. Four-pronged stimulating combs were placed within the gray matter bilaterally, spanning the precruciate cortex of the cat. The medialmost lead was generally 2 mm from the midline and within area 6aβ and the most lateral lead was usually 3 mm beyond the end of the cruciate sulcus within area 4γ. These two areas are known to correspond with the representation of the trunk or axial musculature medially, and the representation of the forelimb musculature laterally.

Intracellular recordings using potassium citrate-filled micropipettes were made from the caudate nuclei (coordinates A 18-15) of locally-anesthetized, paralyzed cats. Over 95% of cells showed EPSP-IPSP sequences, and the rest had only IPSP responses. Latencies to onset of postsyaptic potentials (PSPs) for the large majority of cells (88%) were between 5 and 20 msec (range 4-34 msec), with a mean rise time (onset to peak of PSP) of 13.4 msec (range 4-22.5 msec).

However, 72% of caudate neurons responded preferentially to stimulation of the ipsilateral medial precruciate cortex. Only 9% of cells responded preferentially to stimulation of the ipsilateral lateral precruciate area, while 7% responded best to stimulation of the contralateral medial precruciate cortex and 12% showed no response to cortical stimuli. Preferential responses involved lower threshold (usually 90-250 µA), shorter latency, higher amplutide PSPs, and the ability of the preferred input to suppress conditioning shocks to other areas during the rising phase of IPSP, and in turn not be suppressed during the rising phase of IPSPs elicited by stimulation of other leads.

Histological verification of the position of cells recorded showed that inputs from the medial precruciate area are distributed on the ventral and lateral parts of the caudate. The lateral precruciate cortex elicited preferential responses in cells located in a small region of the ventrolateral caudate nucleus. The majority of non-responsive cells were found dorsally, and those responding to the contralateral medial precruciate cortex were located in the center of the caudate nucleus.

The ipsilateral medial precruciate cortex, corresponding to the motor representation of the axial musculature, showed a potent and widespread input to the caudate nucleus. Within this projection, circumscribed regions of the caudate demonstrated preferential input from the ipsilateral lateral and contralateral medial precruciate cortex. Supported by USPHS Grants HD-05958 and MH-7097.

108 CORPUS STRIATAL (PALEOSTRIATAL COMPLEX) INTERVENTIONS AND STEREOTYPED BEHAVIORS IN PIGEONS. Irving J. Goodman and Robert E. Stitzel*. Depts. of Psychology and Pharmacology, West Virginia University, Morgantown, WV 26506.

Stereotyped pecking may be induced in pigeons by apomorphine, a dopamine agonist, and blocked by Haloperidol, a dopamine antagonist. The paleostriatum augmentatum, a component of the pigeon's corpus striatum, contains a relatively high level of dopamine. The present study attempted to determine the role of this forebrain structure in stereotyped behavior by combining several experiments: (A) Pigeons with chronically implanted stimulating electrodes within the paleostriatum provided an opportunity for tests of electrically evoked responses. Among the varied evocable responses from this structure were stimulus bound floor pecking and circling, separable responses which were usually directed contralateral to the stimulated side. These effects were observed consistently over months of testing; (B) Pigeons, acutely prepared under ether and thus quickly revived, had apomorphine (50 ug/2 ul) unilaterally administered directly to the paleostriatum. This treatment produced contralateral turning and pecking for a short period (2 - 10 min); (C) Correspondingly, unilaterally lesioned paleostriatal pigeons exhibited apomorphine-induced (2.0 - 3.5 mg/kg, IP) pecking and circling (when it occurred) markedly and consistently toward the lesioned side (30 - 60 min sessions). These effects continued through 6 months of testing; (D) Bilaterally lesioned paleostriatal pigeons exhibited a transient reduction or absence of apomorphine-induced stereotyped responding which lasted up to 10 days postoperatively. While the intact corpus striatum provides a structure from which stereotyped pecking and circling may be initiated by electrical or chemical stimulation and sustains a functional imbalance of stereotyped behavior in the unilaterally lesioned preparation, the bilaterally lesioned preparationshows only a short term disruption of apomorphine -induced stereotyped responding. These results suggest that the critical components of the total mechanism for apomorphine-induced stereotyped responding are probably located lower in the brain, within the brain stem.

109 INTERACTION BETWEEN GABA, DOPAMINE AND SUBSTANCE P IN THE RESPONSE OF NIGRO-STRIATAL SYSTEM TO ANTIPSYCHOTICS. A. Guidotti and K. Gale*. Lab. Preclinical Pharmacology, NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

Measurement of striatal tyrosine hydroxylase (TH) in the presence of subsaturating amounts of pteridine cofactor was taken as an index of activity of nigro-striatal dopamine (DA) neurons. The activation of striatal TH induced by systemic injection of neuroleptic drugs (haloperidol or chlorpromazine, 0.1-1 mg/kg) was abolished by: 1) systemic administration of DA receptor agonists (apomorphine and Trivastal); 2) systemic injection of GABA-mimetic drugs (muscimol and diazepam); 3) discrete unilateral electrolytic lesions placed anterior and lateral to substantia nigra (SN). These electrolytic lesions reduced levels of GABA and Substance P (SP) in SN by 70-90% and abolished DA-sensitive adenylate cyclase in SN. Our evidence,based on measurements of DA-sensitive adenylate cyclase and DA receptor binding, demonstrates that DA receptors in nigra are not located on DA neurons and are therefore not autoreceptors. Instead, DA receptors in SN are present on terminals of striato-nigral fibers (GABA or SP). To determine the role of these nigral DA receptors, apomorphine (10^{-9}-10^{-6}M),or haloperidol (10^{-9}-10^{-6}M) was injected into SN in rats pretreated with saline or with systemic haloperidol (0.15 mg/kg i.v.). These intranigral treatments did not significantly modify the kinetic state of striatal TH indicating that DA receptors in nigra do not constitute the critical site of neuroleptic action with respect to striatal TH. On the other hand, activation of GABA receptors in SN by intranigral muscimol (0.3 nmoles) injection blocked the neuroleptic-induced activation of striatal TH.

These experiments suggest a role (1) for striatal postsynaptic DA receptors and (2) for nigral GABA receptors,in the neuroleptic induced activation of striatal TH. We have previously demonstrated the presence of respectively independent GABA and SP neurons projecting from striatum to nigra (Fed. Proc. 30: 394, 1977). It is likely that nigral SP also may be involved in the action of neuroleptics. This is suggested by the inability of GABA antagonists alone (isoniazid, bicuculline, picrotoxin injected systemically or intranigra) to activate striatal TH.

110 ANTIDROMIC ACTIVATION OF DOPAMINERGIC AND OTHER NEURONS IN THE NIGROSTRIATAL PATHWAY. P.G. Guyenet☆ and G.K. Aghajanian, Depts. Psychiat. & Pharmacol., Yale Univ. Sch. Med., New Haven, CT 06508

The purpose of the present study was to identify nigrostriatal dopaminergic neurons by antidromic (AD) stimulation. Rats were anesthetized with chloral hydrate (400 mg/kg) and the single unit activity of neurons located in the substantia nigra (SN) was recorded while stimulating various sites in the caudate-putamen (CP) (bipolar electrodes, rectangular pulses 500 μsec, 0.3 to 2 mA). A successful search for AD-activated cells depended on the prior determination of the topography of the nigrostriatal projection; the technique of retrograde transport of horse-radish peroxidase (HRP) was used for that purpose. AD-activated cells (meeting the requirements of fixed latency and positive collision test) were found only in the area of the SN topographically related to the locus in the CP which was stimulated. The vast majority of these cells corresponded to the type described previously by Bunney et al. (1973) as being the DA-containing neurons of the nigrostriatal pathway; they are the majority of the spontaneously active cells of the SN pars compacta, have a slow bursting pattern of discharge < 7 spikes/sec, a wide action potential of 2 to 4 msec and are inhibited by low doses of the DA agonist apomorphine (APO) (10 to 40 μg/kg, i.v.). The slow conduction velocity of these neurons (0.3 to 0.6 m/sec) is characteristic of unmyelinated axons. These slow-conducting APO-sensitive neurons could also be AD-activated by stimulating the medial forebrain bundle (MFB). Many other types of neurons in the SN could also be activated by this procedure, but with much shorter latencies (0.8 to 2.9 msec instead of 4.5 to 7.5 msec). The injection of 6-hydroxydopamine (a neurotoxic agent relatively specific for catecholaminergic neurons) above the MFB (2 μl, 6 μg) selectively blocked AD-activation of the slow-conducting APO-sensitive neurons of the SN pars compacta, providing further evidence that these are the DA-containing neurons. A small minority of cells with electrophysiological characteristics completely different from the DA neurons could also be AD-activated by stimulating various areas in the CP (500 μsec pulses, 0.3 to 1.0 mA). These cells are located mainly near the ventral border of the SN pars compacta, are not inhibited by APO, have a conduction velocity of 2-3 msec and a firing rate of up to 25 spikes/sec. In conclusion these results indicate that 2 types of neurons contribute to the nigrostriatal pathway; 1) DA neurons; slow conducting and APO-sensitive, they are the most commonly encountered in the SN pars compacta; 2) fast conducting APO-insensitive neurons; less numerous, they are located in or close to the SN compacta. (USPHS Grant MH-17871, The State of Connecticut and the CNRS, France).

111 TRIGEMINAL INFLUENCES ON CAUDATE AND SUBSTANTIA NIGRA UNITS. J.A. Harper* and T. I. Lidsky (SPON: J.S. STAMM). Dept.Psych SUNY at Stony Brook, NY 11794

Trigeminal influences upon the caudate nucleus and substantia nigra were assessed in flaxidilized, chloralose anesthetized cats. Electrical stimulation was applied to two loci involved in jaw movement reflexes. Afferents from periodontal mechanoreceptors involved in reflex jaw opening were stimulated via electrodes in the inferior dental nerve (IDN). In addition, afferents from spindle receptors in jaw elevator muscles were stimulated via electrodes in the trigeminal mesencephalic nucleus (MES 5). MES 5 stimulation evokes jaw closure. A significant proportion of units in both caudate (MES 5-54%, IDN-50%) and Substantia nigra (MES 5-66%, IDN-55%) were affected by IDN and MES 5 stimuli. Both ipsilateral and contralateral stimulation were equally effective in evoking unit responses. Patterns of response to MES 5 and IDN stimulation in neurons receiving convergent input were similar; however, latency differences of unit responses served to differentiate stimulation loci.

Although the striatum is generally thought to be the major source of afferents to the substantia nigra, latency considerations suggest that most trigeminal responses recorded in the nigra are not conveyed via caudato-nigral connections. Latencies of caudate responses (mean latencies: MES 5-36 msec, IDN-48 msec) were longer than responses recorded in the nigra (mean latencies: MES 5-20 msec, IDN-28 msec). Indeed the shortest latencies of responses in the caudate (16 msec) were longer than many of the responses recorded in the substantia nigra.

Tactile stimulation of the face and mouth was also tested. Many basal ganglia neurons have peripheral receptive fields. These fields are large and often encompass two or three branches of the trigeminal nerve. (Supported by U.S.P.H.S. Biomed. Sci. Support Grant 5 So5 RR07067 to SUNY at Stony Brook).

112 MORPHOLOGICAL STUDIES ON THE POSSIBLE GLUTAMATERGIC CORTICO-STRIATAL PATHWAY. T. Hattori, E. G. McGeer, P. L. McGeer
Div. of Neurol. Sci., Dept. of Psych., Fac. of Med., Univ. of British Columbia, Vancouver, B. C., V6T 1W5, Canada.

The autoradiographic tracing technique was combined with intrastriatal injections of the neurotoxin kainic acid (KA) to provide morphological evidence bearing on the recent postulate that the cortico-striatal pathway is glutamatergic in nature. ^{3}H-Proline (20 μC) was distributed by six injections throughout the prefrontal cortex. Twenty four hours later, the distribution of axonally transported proteins in the striatum was studied by light and electron microscopic autoradiography. In some animals, degeneration was induced by an ipsilateral intrastriatal injection of KA (1.25 nm in 0.5 μl saline) ten hours before sacrifice. At the light microscopic level, the label appeared to be rather uniformly distributed in the control striatum and in unaffected areas of the KA-injected striatum. In all of the area affected by KA, grains appeared in either the same number per mm as in the unaffected areas or in patches showing much greater grain density. These clusters of grains resembled those reported in immature animals.

At the electron microscopic level, the labeled boutons in the control striatum had fairly packed round vesicles of 40-45 nm in diameter and made clear asymmetrical synaptic contacts with dendritic spines. In the KA-affected area, most of the labeled boutons made direct synapses with degenerating dendritic elements. However, the vesicle density in the labeled boutons (approximately 180 per μm^2) was the same whether they had synaptic contacts with normal or degenerating dendrites.

These results indicated that: 1) Intrastriatal injections of KA did not produce in 10 hours morphological changes in the presynaptic cortico-striatal terminals nor did it reduce the amount of axonally transported label accumulated in these terminals. In fact, the appearance of densely labeled clusters suggests that the degeneration of postsynaptic elements may have stimulated transport and/or accumulation of label in the presynaptic elements. 2) KA in 10 hours did induce massive degeneration of cell soma and dendrites in the striatum and radioactive macromolecules axonally transported in the cortico-striatal path preferentially labeled boutons in synaptic contact with KA-sensitive dendrites. In view of the evidence that this path is glutamatergic, this provides some morphological support for the hypothesis that neuronal elements carrying many glutamate receptors may be particularly sensitive to the toxic effects of KA.

113 IMPORTANCE OF THE SUBSTANTIA NIGRA IN ROTATIONAL BEHAVIOR OF RATS. Gordon K. Hodge and Larry L. Butcher. Depts. Psych., U. of New Mexico, Albuquerque, NM 87131, and UCLA, Los Angeles, CA 90024.

Many variables can affect the elicitation and assessment of rotational behavior, and since many of these factors are uncontrolled, interpretations of data and reconciliation of theories derived from such data is difficult (see Glick et al., Life Sci., 1976, 18, 889). One variable responsible for some confusion is lesion placement and extent. Our data demonstrate that relatively subtle differences in lesion placements can result in profound differences in the manifestation of rotational behavior.

Rotational behavior following unilateral radio-frequency (RF) or 6-hydroxydopamine (6-OHDA) lesions of the substantia nigra or median raphe was recorded in computerized photocell devices which counted rotations as the rat traversed an uninterrupted 360° turn around a central column. Spontaneous rotations were recorded for 7 days postoperatively. The effects of D-amphetamine (AMP; 1.5, 5.0 mg/kg) and apomorphine (APO; 1.0 mg/kg) were then noted.

The asymmetries displayed by rats varied considerably. Only rats with RF lesions of pars compacta (PC) or the raphe exhibited spontaneous rotations (contralateral). Following drug treatments, rats with 6-OHDA lesions pivoted in a very constricted manner, often wrapping themselves around the central column; animals with RF lesions typically rotated in broader circles about the column. All drugs potentiated contralateral turning in rats with asymmetrical lesions of the raphe area, but histological data indicated that the lesions involved tissue encompassing the raphe as well. Ipsilateral turning was induced by 5.0 mg/kg AMP in RF lesions of PC but APO was without effect. Both doses of AMP led to ipsilateral turning in rats lesioned with 6-OHDA, and APO to contralateral turning. Contralateral rotations to APO were also seen in rats with large lesions of the tegmentum which spared much of PC. Ipsilateral turning occurred with lesions of the medial lemniscus and adjoining areas or with lesions of pars reticulata.

Although PC appears involved in the mediation of rotational behavior, the nature of this involvement is not as straightforward as previously assumed on the basis of techniques which probably encroached upon other systems capable of affecting motor symmetry. The degree of spontaneous contralateral turning shown by rats with PC lesions seemed related to the extent of PC damage, but responses to drugs did not. Although AMP elicited ipsilateral rotations, neither quantitative nor qualitative effects of the drug appeared contingent upon the degree of PC injury. Disparities between our results and those of others are attributable to differences in lesion size and placement per se; these factors appear independent of the manner in which the lesions were made.

114 DIFFICULTY IN INITIATING ARM MOVEMENTS DURING COOLING OF THE PUTAMEN IN THE MONKEY. J. Hore and T. Vilis. Dept. Physiology, Univ. Western Ontario, London, Ontario, Canada N6A 5C1.

It was previously reported (1) that cooling in the region of the globus pallidus of Cebus monkeys did not produce a delay in the onset of prompt flexion or extension elbow movements in response to a visual GO signal, although it produced movements with decreased amplitudes and velocities. This same paradigm was used to investigate motor performance of 3 Cebus monkeys in which cooling sheaths were implanted in the ventral portion of the rostral putamen. Cooling the putamen sheath to 10°C for 10 min produced no major change in simple reaction time of the contralateral arm, as measured both to EMG and to movement onset, although such cooling usually produced a decrease in velocity of movement, due to a decrease in the phasic activity of the agonist muscle and an increase in activity of the antagonist.

However, severe putamen cooling (5° sheath ref. temp. for greater than 10 min) produced, in one monkey, a remarkable motor impairment, which was characterized by an increase in movement reaction time of up to 200 msec. Inspection of such trials revealed that there was no EMG activity in the agonist at the time that it would have occurred in the controls, but that there was a large burst of activity in the antagonist muscle shortly after this time. The result of this antagonist activity was that the monkey moved initially in the wrong direction. This incorrect movement was terminated about 100 msec after onset by movement in the correct direction. When the agonist muscle was loaded so as to increase its tonic level of activity, a small burst of EMG activity now occurred in the agonist in some cooling trials, at the same time after the GO signal as occurred in controls. This suggests that the movement disorder was due to inappropriate EMG activity in response to correctly timed descending signals.

The results from these 3 monkeys are consistent with the recent conclusion of Denny-Brown (2) that one function of the basal ganglia is to provide a preparatory facilitation or "set" in initiation of movement. Thus failure to prepare motor cortex or spinal cord for a forthcoming movement during basal ganglia dysfunction, may cause a correctly timed movement initiation command to be decoded into an inappropriate muscular response.

115 EFFECT OF KAINIC ACID LESIONS IN THE CAUDATE NUCLEUS ON MUSCARINIC CHOLINERGIC RECEPTORS: CORRELATION WITH HUNTINGTON'S DISEASE. R.E. Hruska*, J.T. Coyle, R. Schwarcz* and H.I. Yamamura (SPON: W.D. Barber). Univ. of Arizona Health Sciences Center, Tucson, AZ 85724 and Johns Hopkins Univ. Sch. Med., Baltimore, MD 21205.

The degeneration of neurons in the rat caudate nucleus after kainic acid injections resembles the neurochemical findings in the caudate nuclei of postmortem samples from patients with Huntington's Disease. Accordingly, we measured muscarinic cholinergic receptor binding in kainic acid-lesioned and control caudate nuclei using the muscarinic antagonist, [^{3}H]3-quinuclidinyl benzilate ([^{3}H]QNB). Kainic acid (2 µg in 1 µl) was injected unilaterally into the caudate nucleus. Five days after injection, the rats were sacrificed and the lesioned and contralateral, non-lesioned caudate nuclei were removed. The tissue was homogenized and washed twice before receptor binding assays were performed. We evaluated the effect of kainic acid lesions on the apparent dissociation constant (K_D) and on the total number of binding sites (Bmax). The K_D values were 11 to 13 pM for the lesioned and non-lesioned caudate nuclei, respectively, as determined from the rate of association (7×10^8 $M^{-1}min^{-1}$ for both lesioned and non-lesioned caudate nuclei) and from the rate of dissociation (9×10^{-3} min^{-1} for the lesioned and 8×10^{-3} min^{-1} for the non-lesioned caudate nuclei). The apparent K_D was also determined from saturation isotherms. The analyses of the saturation curves by Scatchard plots revealed a K_D value of 20 to 50 pM for both the lesioned and non-lesioned caudate nuclei. Therefore, the kainic acid lesions have no significant effect on the apparent K_D value. Similar findings have been reported in Huntington's Disease. However, the kainic acid lesions do decrease markedly the density of specific binding sites (Bmax), as determined from Scatchard plot analyses. The non-lesioned caudate nuclei had 1.33 ± 0.15 picomoles of [^{3}H]QNB bound per mg protein, while the lesioned caudate nuclei had 0.82 ± 0.12 picomoles of [^{3}H]QNB bound per mg protein, which is a 40% reduction in the total amount of specific binding. The decrease in [^{3}H]QNB binding effected by kainic acid lesions of the caudate nuclei parallels the decrease in [^{3}H]QNB binding found in Huntington's Disease caudate nuclei (∿50% reduction in [^{3}H]QNB binding). Since kainic acid lesions do not alter the apparent K_D value but do decrease the density of binding sites, as observed previously in Huntington's Disease, these findings strengthen the usefulness of kainic acid lesions of the caudate nuclei as an animal model for this disease. (Supported by NIH grants MH-27257 and NS-13584, fellowship NS-05585 to R.E. Hruska, and RSDA to J.T. Coyle and H.I. Yamamura.)

116 MICROIONTOPHORETIC STUDIES ON GLOBUS PALLIDUS NEURONS OF MACACA MULATTA MONKEY. Ronald D. Huffman, Leslie P. Felpel and Robert L. Polzin. Dept. Pharmac., The Univ. of Texas Health Sci. Center, San Antonio, Texas 78284.

A number of substances that are strong candidates for neurotransmitters in the mammalian CNS are found in high concentrations in the basal ganglia. These include acetylcholine (ACh), dopamine (DA), serotonin (5HT), γ-aminobutyric acid (GABA), substance P and taurine. Little is known about the effect of these substances and other putative neurotransmitters on the responsiveness of neurons of the globus pallidus. In this investigation the responsiveness of primate pallidal neurons to microiontophoretically applied (7 barrel glass micropipettes) putative neurotransmitters was studied. Macaca mulatta monkeys anesthetized with chloralose-urethane were used as the experimental animal. Pallidal neurons characteristically discharged spontaneously with rates of 150-200 spikes/sec being fairly common. Eighty pallidal cells were studied; of these 15 were located in the external pallidal segment and 6 were located in the medullary lamina between the two segments. The number of cells studied with each of the putative neurotransmitters is given in the following Table:

GABA	Glyc	Taur	Glut	DA	NA	5HT	ACh	Sub P
74	38	30	50	25	6	9	47	12

GABA, glycine and taurine depressed the spontaneous firing of neurons located in both pallidal segments. GABA was a powerful depressant and stopped spontaneous firing of many neurons with currents less than 5 nA. Only 2 of 74 pallidal cells tested did not respond to GABA. Cells located in the internal pallidal segment were generally more responsive to the depressant action of GABA than cells located in the external segment or laminar region. In general, glycine was not as effective a depressant as was GABA and currents 2-3 times those used to eject GABA were required with glycine to produce a depression of pallidal firing equivalent to that produced by GABA. Taurine was a weak depressant and many pallidal cells did not change their responsiveness in the presence of taurine. L-glutamic acid was a weak excitant and failed to excite about 50% of the pallidal neurons to which it was applied. ACh was a weak to moderate excitant of most pallidal cells although a few cells were unaffected by ACh. DA was also a weak excitant and produced a delayed and prolonged excitation of many pallidal neurons. GABA frequently caused a gradual reduction in spontaneous firing following its application; DA characteristically increased the responsiveness of the cells and restored the spontaneous firing rate to the pre-GABA level. Noradrenaline, 5HT and substance P had no effect on the responsiveness of any pallidal neurons studied. (Supported in part by NIH Grant NS-10602, USPHS.)

117 A TECHNIQUE FOR RECORDING SINGLE-UNIT ACTIVITY IN UNANESTHETIZED, RESTRAINED RATS DURING MOVEMENT. Lawrence R. Huntoon. Dept. Physiol., L.S.U. Med. Ctr., New Orleans, La. 70112.

A technique has been developed which permits single-unit recordings in restrained, unanesthetized rats during movement. Unlike other techniques, this method allows multiple microelectrode penetrations to be made in prescribed stereotaxic planes. In this manner, stereotaxic exploration of a given area can be performed on a daily basis and data can be collected over a period of several weeks. The essential features of the technique are: 1. Non-traumatic rigid head restraint 2. Body restraint which allows movement of limbs 3. Training rats to bar press by employing the operant technique of intracranial self-stimulation (I.C.S.S.).

Non-traumatic head restraint is accomplished using a 3/8" plexiglass block tailored to fit adult rats' heads, with a rectangular window to allow microelectrode penetrations. Small screws at the corners of the headpiece serve to rigidly fix the animal's head in a conventional stereotaxic frame for recording sessions, and between sessions they are used to secure a 1/16" plexiglass cap over the window. Initial surgery involves drilling a rectangular portion of the skull away and cementing the headpiece in the stereotaxic horizontal plane such that the plexiglass window is in position over the exposed area. Precautions are taken to protect dura and underlying cortex.

Appropriate body restraint is obtained using an ANIMAL HOLDER (C.H. Stoelting Co.). This restraining apparatus allows considerable freedom of movenent of body forelimbs and hindlimbs. With the addition of a bipolar electrode placed in the medial forebrain bundle (MFB) rats can be trained to bar press (I.C.S.S.) while restrained with either forelimb or hindlimb. An unexpected advantage of I.C.S.S. conditioning is the finding that following a single 2 hr. training session, rats can be placed in the restraining device without struggling or other overt signs of stress. Therefore, data can be obtained under relatively non-stressful conditions of a quality which would not exist under conditions of restraint alone.

Stainless steel microelectrodes are currently being used with this preparation in an attempt to correlate limb movement with single-unit activity in rat substantia nigra (SN). In addition to the MFB electrode, five other stainless steel bipolar electrodes are placed in the caudo-putamen to permit electrophysiological identification of cells being studied in SN. Preliminary results indicate that cells exist in rat SN which are movement related. It is concluded that this technique can be used successfully to record single-unit activity in unanesthetized restrained rats during movement, and that combined use of I.C.S.S. permits data aquisition under relatively non-stressful conditions.

118 CONDUCTION PROPERTIES OF CAUDATE EFFERENT AXONS IN THE CAT. J.D. Kocsis*, C.P. VanderMaelen*, and S.T. Kitai (SPON: G.D. Schoener). Morin Memorial Lab., Dept. Anat., Sch. Med. and Dept. Psychol., Wayne State Univ., Detroit, Mich. 48201.

Antidromic action potentials were recorded intracellularly from caudate (Cd) nucleus neurons in cats anesthetized with α-chlorolose after stimulation of the substantia nigra and the internal capsule. The antidromic nature of these spikes was determined by collision of antidromic spikes with intracellularly induced orthodromic spikes. The recorded neurons were identified as spiny neurons with intracellular injections of horseradish peroxidase. With double antidromic stimulation, the second spike shows a decrease in latency if it is induced up to 200 msec after the conditioning spike. The maximum latency shift is about 10% of the control latency. The magnitude of the latency shift is cumulative with conduction distance, suggesting that a change in conduction velocity occurs along the axon. Conditioning orthodromic spikes, either synaptic or direct, also induce a latency shift of test antidromic spikes. The latency shift is independent of somatic polarization levels and only occurs when the test antidromic spike is preceded by an action potential. Threshold measurements indicate that an increase in fiber excitability occurs during the period of increased conduction velocity. Somatic depolarization current delivered through the microelectrode will initiate spikes at the initial axon segment that show sustained firing in excess of 200 spikes per second. But, with repetitive high frequency antidromic stimulation the spikes fail to occur after an initial burst. In conclusion, the excitability and conduction velocity of a Cd efferent axon increases during the aftermath of a single action potential, and a region of low safety factor may exist along these fibers. This indicates that Cd axons may be operating not as simple relay lines, but as integrative elements responding in terms of their previous activity. (This work was supported by NIH Grants NS00405 and RR5384.)

119 PROJECTIONS FROM THE SUBSTANTIA NIGRA PARS RETICULARIS IN THE CAT USING A NEW STEREOTAXIC TECHNIQUE. K. Kultas-Ilinsky, I. Ilinsky*, L. C. Massopust, P. A. Young, and K. R. Smith. Depts. Anat. and Surg., St. Louis Univ. Sch. Med., St. Louis, MO 63104.

The purpose of this investigation was to examine the topographical organization of the efferent projections from the substantia nigra pars reticularis (SNr) employing an extremely accurate stereotaxic technique. The technique used in this study is based on intracerebral coordinates and contrast ventriculography, allowing for the placement of injections of tritiated amino acids and radiofrequency lesions into small discrete parts of the SNr without encroaching on surrounding structures. The injections of tritiated leucine and proline were made in the anterior, intermediate or posterior parts of the SNr. Nigrostriatal fibers from all three parts coursed in a rostro-lateral direction, passed around the subthalamic nucleus without entering it, crossed the internal capsule and entered the entopeduncular nucleus, putamen and globus pallidus. Terminations in these structures were sparse and diffuse. Another bundle of fibers contained within the dorsomedial part of the internal capsule coursed dorsally and entered the posterior third of the caudate nucleus forming a rather dense terminal field. When injections of tritiated amino acids were confined to the anterior two thirds of the SNr, nigrothalamic projections were also labelled. These fibers, after leaving the SNr, coursed medially towards the midline, passed around the fasciculus retroflexus, and entered Forel's field where they continued anteriorly dividing into two groups. One turned sharply dorsally, passed around the centrum medianum and entered the ventromedial thalamic nucleus (VM) from its dorsoposterior aspect. The second group of fibers continued rostrodorsally a short distance in Forel's field to enter the VM from its ventral aspect. Very dense terminal accumulations of radioactive label were found throughout the VM from both of these projections. It was noted that when neurons exclusively in the most ventral part of the SNr were labelled, terminations were also apparent in the ventral anterior and ventral lateral thalamic nuclei. Verification of nigrothalamic terminations was obtained through electron microscopy. Radiofrequency lesions were made in the SNr resulting in degeneration of synaptic boutons and medium size myelinated axons within the VM. The degenerating boutons formed symmetrical synaptic contacts on the dendrites. In some cases they were found within glomeruli where they contacted several types of profiles. In conclusion, all parts of the SNr project to the striatum, with major terminations in the posterior part of the caudate, whereas only the anterior two thirds of the SNr projects to the thalamus where the main terminal area is in the VM. (Supported by USPHS FR 05388.)

120 EFFECTS OF BASAL GANGLIA STIMULATION ON BRAINSTEM TRIGEMINAL NEURONS. T. Labuszewski* and T. I. Lidsky. Dept. Psychol., SUNY at Stony Brook, N.Y. 11794.

Basal ganglia influences upon brainstem trigeminal sensory neurons were investigated. Units were recorded in and around the trigeminal principal sensory nucleus of chloralose anesthetized cats. Cells were classified as trigeminothalamic relay neurons, trigeminal non-relay neurons and reticular formation neurons on the basis of histological location and responsiveness to electrical stimulation of the posterior thalamus and natural stimulation of the face and mouth. Stimulation of the basal ganglia was applied via electrodes implanted bilaterally in the head of the caudate and in the entopeduncular nuclei. Stimulation of the basal ganglia evoked unit responses in trigeminal relay and non-relay cells, as well as reticular formation cells. Latencies typically ranged from 15-25 msec. The effect of basal ganglia stimulation upon reticular formation neurons tended to be more pronounced than the effect upon trigeminal nucleus neurons. Stimulation of the basal ganglia also evoked changes in trigeminal neuronal response to natural stimuli. A conditioning-test (C-T) procedure was employed in which an assessment was made of the effects of conditioning stimulation of the caudate upon test responses evoked in trigeminal neurons by stimulation of the sensory receptive field. Basal ganglia stimulation resulted in primarily inhibitory effects upon test responses at C-T intervals as long as 200 msec. Control procedures demonstrated that the results reported here cannot be ascribed to current spread to the internal capsule.

121 ACETYLCHOLINESTERASE IN THE SUBSTANTIA NIGRA AND CAUDATE-PUTAMEN: PROPERTIES AND LOCALIZATION ON DOPAMINERGIC NEURONS AND TERMINALS. John Lehmann* and H.C. Fibiger (SPON: V.K. Singh). Division of Neurological Sciences, Univ. of British Columbia, Vancouver, B.C.

In order to selectively destroy neurons and terminals of the dopaminergic nigrostriatal tract, 6-hydroxydopamine (6OHDA) was administered to rats by one of two routes, intraventricular (IV) injection or unilateral stereotaxic injection into the nigro-striatal bundle (NSB). After a survival period of 4 to 5 weeks, enzymes in the 6OHDA-lesioned groups showed the following changes in activity (expressed as per cent of controls) in the substantia nigra (SN) and caudate-putamen (CP):

	Tyrosine hydroxylase	Choline acetylase	AChE
IV 6OHDA SN	10.3***	88.0	69.0***
IV 6OHDA CP	9.3***	93.6	87.6*
NSB 6OHDA SN	9.9***	99.6	56.7***
NSB 6OHDA CP	3.4***	106.0	87.9**

*p<.05; **p<.01; ***p<.001

To be certain that the observed decreases in cholinesterase activity were due to true acetylcholinesterase (AChE, EC 3.1.1.7) and not to butyrylcholinesterase (BChE, EC 3.1.1.8), several criteria were applied to tissues from the NSB-6OHDA group: 1) Substrate specificity. Acetylcholine (ACh) was replaced by either acetyl-β-methylcholine or butyrylcholine in the cholinesterase assay. SN and CP from 6OHDA lesioned rats showed 54% and 92% of control tissue cholinesterase activity respectively with acetyl-β-methylcholine as substrate, in good agreement with values found using ACh. No decrease in activity toward butyrylcholine was observed. 2) Kinetics. The decrease in cholinesterase activities at different concentrations of ACh was determined; the data showed that the 6OHDA-depleted cholinesterase was inhibited by high ACh concentrations. This is a characteristic property of AChE but not BChE. 3) Selective inhibitors. In the SN, the 6OHDA-depleted cholinesterase was inhibited by the selective AChE inhibitors BW284C51 and ambenonium with a dose-response similar to erythrocyte AChE but different from serum BChE. The selective BChE inhibitor, isoOMPA, inhibited the 6OHDA-depleted enzyme only at concentrations which inhibit erythrocyte AChE, concentrations somewhat higher than those which inhibit serum BChE. These results support the results obtained histochemically by Butcher et al. (J. Neural Transmission 37:127, 1975), and indicate that AChE is contained in dopaminergic neurons of the SN. Moreover, this is the first characterization of AChE from a homogeneous population of non-cholinergic neurons in mammalian central nervous system.

122 PHARMACOLOGIC AUGMENTATION OF ACETYLCHOLINE LEVELS IN KAINATE-LESIONED RAT STRIATUM. Edythe D. London* and Joseph T. Coyle Depts. of Pharmacology and Psychiatry, Johns Hopkins University School of Medicine, Baltimore, Maryland 21205, USA.

Stereotaxic injection of kainic acid (Ka) into the rat striatum produces neurochemical and histologic alterations in the nigro-striatal circuit similar to those seen in the neurodegenerative disorder, Huntington's Disease (HD). Ka injection causes degeneration of cholinergic and GABAergic neurons intrinsic to the striatum but leaves the nigral dopaminergic projection to the striatum intact (Coyle and Schwarcz, Nature 263:244, 1976). Since pharmacologic correction of the striatal acetylcholine (ACh) deficiency might ameliorate the dyskinesia of HD, we have examined the effects of systemic treatment with choline, dimethylaminoethanol (Deanol) and physostigmine on the levels of ACh in the striata of Ka-lesioned and control rats.

Rats received a stereotaxic injection of 3 μg of Ka in the left striatum. Four days after the lesion, the rats received the drugs IP injection and were killed by focused microwave irradiation at various times after treatment (30 min, physostigmine; 15 min, Deanol; 40 min, choline). The levels of endogenous choline, ACh and GABA were measured in Ka-lesioned, contralateral and

Treatment	Control	Contralateral	Ka-lesion
	ACh ± S.E.M. (p mol/mg tissue)		
Vehicle	56.1±3.2	51.5±2.2	14.9±0.9
Choline (100 mg/kg)	66.8±4.0	80.0±2.2	36.9±4.3
Deanol (408 mg/kg)	44.4±2.8	78.1±12.3	36.2±8.2
Physostigmine (1 mg/kg)	110. ±7.4	89.9±10.4	33.7±9.3

control striata. In Ka-lesioned striata, the levels of endogenous GABA and ACh were reduced to 46% and 27% of control respectively whereas the concentration of choline was unaffected. Choline treatment caused a 19% increase in ACh in control striata, a 55% increase in contralateral striata but a 120% increase in the lesioned striata. Although Deanol did not alter ACh in controls, it increased the levels by 52% and 114% in contralateral and lesioned striata respectively. Physostigmine caused a similar relative increase in control, contralateral and lesioned striatal ACh. These studies indicate that the deficiency in striatal ACh in the Ka-lesioned rat can be partially corrected by agents that increase precursor availability or inhibit acetylcholinesterase. Notably, choline and Deanol exhibit relatively greater effects in the Ka-lesioned striata than in controls; thus, the synthesis or storage of ACh in the surviving cholinergic neurons in the lesioned striatum may be altered. 123 COURSE OF NEOSTRIATAL EFFERENT FIBERS INVOLVED IN THE EXPRESSION OF ROTATIONAL BEHAVIOR IN RATS. John F. Marshall* and Urban Ungerstedt* (SPON: E.B. Goldstein). Karolinska Institutet, Stockholm, Sweden.

Rats given a unilateral injection of 6-hydroxydopamine along the ascending dopamine fibers of one hemisphere turn vigorously away from the side of the cerebral injection when administered apomorphine (0.25 mg/kg i.p.) 1-3 weeks later. This contralateral rotation appears due to the development of a supersensitivity to dopamine receptor stimulants in the denervated neostriatum.

Extensive electrocoagulations of the caudate-putamen performed in the same hemisphere as the prior 6-hydroxydopamine injection largely blocked the apomorphine-induced rotation. Electrocoagulations of the internal capsule during its telencephalic or diencephalic course were similarly effective in blocking this drug-induced behavior. However, extensive lesions of the globus pallidus which largely spared the internal capsule were without effect.

Knife cuts made in the coronal plane immediately rostral to the substantia nigra reduced the rotation by 54%. Knife cuts in the same plane immediately caudal to the nigra were less effective, blocking rotation by 25%.

These results suggest that neostriatal efferent fibers, in particular the strionigral projection, are involved in the expression of this dopamine-dependent behavior. (Supported in part by grant No. MH 27441 to J.F.M.)

124 CONTRAVERSIVE CIRCLING INDUCED IN THE RAT BY THE INTRANIGRAL MICROINJECTION OF MUSCIMOL. G. E. Martin, C. B. Bacino* and N. L. Papp.* Merck Institute, West Point, PA, USA, 19486.

GABA is thought to act within the substantia nigra (SN) to inhibit the firing of dopaminergic cells which project to the striatum. Accordingly, the direct unilateral application of a GABA agonist into the SN should result in the inhibition of firing of striatal dopamine neurons resulting in a preferential activation of striatal neurons on the side of the brain contralateral to the injection. It was anticipated that such treatment would evoke an ipsilateral turning response. We tested this hypothesis following the unilateral intranigral injection of muscimol, a potent GABA agonist.

A 24 ga stainless steel cannula was implanted stereotaxically in each of 38 rats at a site in the SN. As an anatomical control, microinjections were made within the caudate nucleus. To antagonize the turning evoked by muscimol, bicuculline (B) was administered i.p. or intranigrally. In addition, GABA in doses ranging from 2 to 50 μg was injected into the SN. All microinjections were delivered via a 30 ga cannula in a volume of 0.5 μl. Muscimol was administered in doses of 0.005, 0.05, 0.5 and 5.0 μg and a CSF vehicle control injection was made in each of 10 animals. The injections in each animal were spaced by an interval of one week. Turning was measured for 2-min intervals at 10 min before and at 5, 15, 30 and 60 min after the injection. At the end of the experiment, each microinjection site was verified histologically.

Muscimol, at the two highest doses, evoked a marked contralateral turning response significantly different from the response to artificial CSF. No ipsilateral turning was observed. The mean maximum turning response was observed within 30 min of the injection and reached 2.9, 2.5, 6.1 and 14.8 turns per minute (TPM) for the increasing doses of muscimol. B, administered i.p., did not diminish the turning evoked by muscimol, whereas the intranigral application of B only partially antagonized the turning response. Injected in the SN, B alone did not evoke a significant amount of turning. Neither the microinjection of GABA in the SN, nor the administration of muscimol in the striatum evoked any turning behavior.

At the doses tested, muscimol elicited turning contralateral to the injection site in the SN in agreement with the previous report of contralateral turning after the application of the putative GABA agonist, baclofen in the SN (Kelly and Moore, Pharmacologist, 1976, 18: 130). The mechanism of action of muscimol in inducing contralateral turning requires further investigation, especially in relation to the currently held views on the GABA-like action of this compound and the function of striato-nigral GABAergic neurons.

125 DESCENDING PROJECTIONS OF THE FELINE GLOBUS PALLIDUS.
Russell L. McBride* and Kenneth D. Larsen*. (SPON: J. Sutin)
Dept. Anat., Sch. Med., Emory Univ., Atlanta, GA 30322, and Rockefeller Univ., New York, NY 10021.

The external segment of the globus pallidus may influence the somatic motor system through projections to the subthalamic nucleus and substantia nigra. We have identified an additional projection which may also influence motor output.

As predicted from degeneration and autoradiographic studies, we found entopeduncular nucleus (feline homologue of primate internal segment of globus pallidus) neurons antidromically activated by stimulation in the region of the pedunculopontine nucleus. However, 8 of 105 neurons in the external segment of the globus pallidus were also antidromically activated. The latency of activation was 0.5 to 2.0 msec and the neurons were located in the caudal portion of the nucleus. Autoradiographic and horseradish peroxidase (HRP) experiments were performed to determine the terminal field and cells of origin of this descending pallidal projection. In autoradiographic experiments, 0.2 ul of ^{3}H leucine (100 uC/ul) was injected into the external segment of the globus pallidus. While a dense terminal zone was located in the subthalamic nucleus, some axons continued caudally to terminate in pars reticulata and pars compacta of the substantia nigra; some axons projected further caudally and dorsally to terminate in the caudal mesencephalon medial to the medial lemniscus, ventral to the inferior colliculus. This caudalmost terminal zone is primarily lateral to the entopeduncular nucleus projection in the pedunculopontine nucleus, but the two projections overlap slightly. In retrograde transport experiments 0.2 ul of a 50% solution of HRP (Type VI, Sigma) was injected into terminal regions of pallidal neurons. Following injections into medial substantia nigra, retrogradely labeled cells were located in the rostrolateral portions of the external pallidal segment. Injection into the lateral portions of the substantia nigra or lateral to the pedunculopontine nucleus resulted in labeled cells in the caudal ventral part of the nucleus. It appears that, in contrast to the entopeduncular nucleus, the descending projections of the external pallidal segment are topographically arranged.

126 TOXIC EFFECTS OF KAINIC ACID ON STRIATAL NEURONS: AGONISTS AND ANTAGONISTS.
Patrick L. McGeer and Edith G. McGeer. Kinsmen Lab. of Neurol. Res., Dept. of Psych., Univ. of British Columbia Vancouver, B. C., V6T 1W5, Canada

Local injections of kainic acid (KA) have been shown to destroy neurons with cell bodies in the injected area. The mechanism is not yet clear although it has been suggested that glutamate receptors may be the point of initial attach (1) and electron microscopic studies using small amounts (1-2.5 nm) of KA are consistent with this hypothesis (2). We have sought to establish what other agents might produce a similar effect and whether the KA action can be modified by concomitant injection of various drugs or prior pharmacological or surgical treatment. All injections were made into the caudate/putamen and choline acetyltransferase (CAT) and glutamic acid decarboxylase (GAD) activities in the striatum were used as indices of neuronal degeneration. Both the time and volume of injection must be kept constant to ensure reproducible results.

Significant losses in both enzymes followed stereotaxic injections of 40 nm DL-homocysteate or 50 nm L-glutamate but not after 10 nm ibotenic acid, muscazone, allylglycine or methionine sulfoximine. The effect of small amounts (2.5-5 nm) of KA were antagonized by coinjection of 50 nm of α-methylglutamate, diethyl kainate, ornithine, diaminopropionic acid, or diaminobutyric acid but not by 2-amino-4-phosphonobutyric acid, 2-amino-3-phosphonopropionic acid, 2-aminopropylphosphonic acid, proline or H966. They appeared to be increased in rats given 100 mg/kg of DOPA ip (together with an MAOI) and to be decreased in rats treated chronically with isoniazid under conditions reported to raise brain GABA levels. The effect of 2.5 nm of KA on cholinergic (but not GABAergic) neurons was significantly increased in animals where the nigrostriatal dopaminergic tract had previously been destroyed by 6-OHDA treatment. Other pretreatments tried included chronic morphine implantation, chronic reserpine, chronic haloperidol, Na di-n-propylacetate, γ-hydroxybutyric acid amantadine, aminooxyacetic acid, 5-HTP or taurine while coinjections were made with dopamine, atropine, arecoline or GABA.

127 CELL CLUSTERING IN EARLY AND LATE POSTNATAL MOUSE STRIATUM.
Patricia L. Mensah, Dept. Anat., Sch. Med., USC, Los Angeles, Ca. 90033.

Characteristics of cell clustering in the postnatal neostriatum were studied in mice from the day of birth to 6 weeks of age. Paraffin embedded material was sectioned at 10 microns in transverse, horizontal or sagittal planes and stained with either cresyl violet or with a modification of the Cajal on-the-slide silver staining procedure. Based upon earlier observations, the head of the caudate nucleus was divided into 3 zones - a central core region bordered by lateral and medial peripheral areas - and the body of the nucleus into dorsal and ventral zones. In adult mouse, the central core region of the head and ventral portion of the body contain most of the large (25-30 μ) cells of the structure. This study concentrated on studying the appearance of these areas at different postnatal times.

Neuronal cell clustering is a consistent feature of all zones at all postnatal times. Clusters range in size from a mean of 6 neurons per group at 3 days of age to a mean of 12 at 15 days or later. Even as early as day 0, only one large cell was present in the same cell grouping. Large fusiform cells occur most often in the central core area of the head or ventral area of the body of the nucleus after postnatal day 7. Cell clustering is extremely rigid in the central core zone of the head of the nucleus where both clumps and rings of clustered cells occur. Although present in other zones as well, the boundaries of individual groupings in these areas may be difficult to identify due to the tendency of some cells to occupy a position between neuronal groupings. This tendency of cells to occupy areas outside of any clearly defined cell aggregation is a developmental phenomenon that increases with advancing age.

This work was supported by a seed grant from the University of Southern California School of Medicine.

128 POSTSYNAPTIC POTENTIALS EVOKED IN DEVELOPING CAUDATE NUCLEUS NEURONS BY ACTIVATION OF THEIR AFFERENTS.
R. Morris,* E Cherubini* C.D. Hull, M.S. Levine and N.A. Buchwald. MRRC, Sch. of Med., UCLA Los Angeles, CA. 90024.

Synaptogenesis in the caudate nuclei of cats starts prior to birth and extends into the postnatal period. By thirty days (oldest age examined) adult synaptic densities have not been reached (Adinolfi, A. Brain Res. in press). To extend our extracellular single unit studies of the postnatal period of synaptogenesis we are currently carrying out an intracellular study of developing caudate neurons.

Kittens (2-72 days of age) were anesthetized with NO_2 (60-70%) O_2 (30-40%) and Halothane (1-0.5%). Stimulating electrodes were placed stereotaxically in the ventral midbrain, medial posterior thalamus (intralaminar nuclei region) and on the surface of the precruciate cortex. The cortex overlying the head of the caudate nucleus was ablated allowing direct visual placement of recording electrodes.

In animals under 15 days of age (4 animals, 10 neurons) prominent excitatory postsynaptic potentials (EPSPs) (4-10 mv) were evoked in caudate neurons by stimulation (10-15 v, 0.1-1.0 msec) of all three regions. At low frequencies of stimulation (.5-1 Hz) these EPSPs usually depolarized the cell sufficiently to result in spike initiation, however, higher rates of stimulation (above 8 Hz) the EPSPs continued to be evoked by each stimulus but few resulted in spike initiation. In four of these units the initial depolarization was followed by a period of hyperpolarization (3-6 mv, 70-90 msec duration). This is in clear contrast to responses observed in adults and older kittens (above 50 days) where EPSPs particularly those evoked by cortical stimulation are followed usually by prominent long duration hyperpolarizations (Inhibitory Postsynaptic Potentials, IPSPs). In animals 15-30 days of age (8 animals, 40 neurons) 17 of the 29 units responding to cortical stimulation showed initially an EPSP followed by a period of hyperpolarization whose magnitude and duration was closer to that of the IPSPs found in adult neurons. Typically, however, these IPSPs also tended to be smaller in amplitude and shorter in duration than those found in mature animals. Repetitive stimulation at frequencies above 20 Hz produced prolonged depolarization during stimulation, again indicating the less potent nature of the IPSPs. We have examined three animals above 45 days old (24 neurons) and here IPSPs of comparable magnitude and duration to those found in adults were observed.

These results are in agreement with our earlier extracellular data indicating the rapid postnatal development of excitatory responses in caudate neurons. In addition the current results suggest that the inhibitory processes show a slower more gradual rate of development than is true for the excitatory processes.

Supported by USPHS Grants HD-05958 and MH-7097.

129 NIGRAL DESCENDING EFFECTS ON CERVICAL AFFERENT TERMINAL EXCITABILITY AND DORSAL ROOT POTENTIALS. Fereshteh Motamedi* and Donald H. York, Dept. of Physiol., Sch. of Med. and Dalton Res. Center, Univ. of Missouri, Columbia, Mo. 65201

Previous behavioral studies have demonstrated head turning movements upon stimulation of the basal ganglia. The neural pathways mediating this behavior have not been defined. Therefore the present study was undertaken to study the effects of stimulation of the substantia nigra on changes in exciteability of neck muscle afferents at the level of the cervical spinal cord. Twelve adult male Sprague-Dawley rats (500-600 gm) were anesthetized with urethane and a cervical laminectomy was performed. Dorsal root potentials (DRP) were recorded from C_1 or C_2 dorsal roots with platinum bipolar electrodes and evoked by stimulation in the dorsal horn of the cervical spinal cord. A bipolar stimulating electrode was placed in the substantia nigra (pars reticulata), and was subsequently histologically verified. A train of conditioning pulses delivered to the substantia nigra (pars reticulata) (25-60 μA, 0.1 msec, 500/sec, 20 msec) evoked a DRP. A decline in a spinal evoked DRP was observed when a nigral train of pulses preceded the spinal evoked DRP by 5-10 msec. When the stimulating electrode was confined to substantia nigra (pars compacta), no decrease in spinal evoked DRP was observed. These results indicate that there may be a presynaptic facilitation of cervical afferent terminals by a descending nigral pathway. This suggests that such a pathway may contribute to the mechanism responsible for head turning movements during stimulation of the basal ganglia.

130 THE USE OF KAINIC ACID IN THE ANATOMICAL LOCALIZATION OF ENZYMES IN THE SUBSTANTIA NIGRA. J. Nagy*, S. R. Vincent*, J. Lehmann*, E. G. McGeer and H. C. Fibiger (SPON: S. C. Sung). Div. of Neurol. Sci., Univ. of British Columbia, Vancouver, B. C. V6T 1W5.

Kainic acid (KA) was stereotaxically injected into the substantia nigra (SN) to gain further information as to the localization of the enzymes choline acetyltransferase (CAT), glutamic acid decarboxylase (GAD), acetylcholinesterase (AChE), and dopamine-sensitive adenylate cyclase (DAC) within this nucleus. These studies were made possible by previous findings which suggest that KA, when injected intracranially in a variety of brain nuclei, destroys all neuronal cell bodies, while producing minimal damage to axonal terminals in the area of injection.

A unilateral injection of 5 nmoles of KA in a volume of 1 μl into the SN resulted 2 weeks later in virtually complete neuronal degeneration in this structure as demonstrated by histological examination. Also tyrosine hydroxylase activity (TH) in the ipsilateral caudate nucleus was almost completely depleted. The enzyme activities in the table are presented as percent of control, both per mg protein and per SN. This is desirable since the

Enzyme Activities Following Intranigral Kainic Acid

Enzyme	Per mg Protein	Per SN
TH (caudate)	6.1 ***	--
GAD (caudate)	133.8	--
GAD	51.1 ***	41.4 ***
CAT	124.5	79.0
AChE	56.0 ***	36.1 ***
DAC basal	151.2	110.8
1 μM Dopamine	146.1 *	126.8
10 μM Dopamine	172.9 *	124.8
100 μM Dopamine	166.2 **	122.2
NaF	135.5	87.3

(* $p<.05$; ** $p<.02$; *** $p<.001$; Student's t, two-tailed)

shrinkage of the SN may lead to spurious results if the enzyme activities were expressed only on the per protein basis. The persistence of DAC in the face of almost total neuronal cell loss supports the finding that DAC is not present on dopaminergic soma in the SN and establishes that this enzyme is located exclusively on nerve terminals. Similarily, the failure of KA to affect CAT activity suggests that the source of CAT is external to the SN. The partial decrease in AChE suggests both a cellular and terminal localization of this enzyme. Although unlikely, a glial contribution to these enzyme activities cannot be excluded. Finally, although an effect of DA on terminals cannot be ruled out, the partial decrease in GAD activity observed suggests that some of the GAD is contained in interneurons within the SN.

131 REGIONAL DISTRIBUTION OF DOPAMINE METABOLITES IN THE CAUDATE OF RAT AND RHESUS MONKEY. N. Narasimhachari, R.C. Smith*, T. Samorajski* and J.M. Davis (SPON: G. Pandey). Illinois State Psychiatric Institute, Department of Research, Chicago, Illinois 60612. *Texas Research Institute of Mental Sciences, Houston.

In our studies on the acid metabolites of dopamine in the caudate of rats we noticed wide variations in HVA levels depending on the size of the caudate dissected. Small samples (10-50 mg) gave values ranging from 3 μg/gm to 15 μg/gm (SEM 2.91 μg/g) and larger samples (80-140 mg) gave values from 1 to 1.5 μg/g (SEM 0.09 μg/g). This suggested differences in the regional distribution of dopamine and its metabolites in the caudate. We have now investigated HVA and 3-methoxytyramine levels in discrete areas of the caudate of rat and rhesus monkey. The amine and acid metabolite levels were determined in the right and left caudate of the rat, the tissue was also dissected to three parts, (anterior, midsection and posterior) weighing approximately 10, 20, and 10 mg respectively. Similarly eight sections each were dissected out from the right and left caudate tissue of a rhesus monkey. HVA was derivatized to methyl ester-TMS ether (1) and 3-methoxytyramine to isothocyanate-TMS ether (2) and quantitated by mass fragmentography. Significant differences in the regional distribution of HVA levels were noticed in the rat caudate and in the monkey. In the monkey the values ranged from non-detectable to 4 μg/g. Zimmerberg et al (3) reported significant asymmetry in striatal dopamine content. Further work on the neuroanatomical differences underlying the differences in dopamine metabolites in discrete areas of the two sides of the caudate is in progress.

132 MOTOR CORTEX PROJECTIONS TO THE CAUDATE NUCLEUS. II. NEUROANATOMY. A. Nieto,* E. Garcia-Rill and A.M. Adinolfi. MRRC, Sch. of Med., UCLA, Los Angeles, CA. 90024.

This study describes the distribution of fibers from the precruciate motor cortex to the head of the caudate nucleus. Discrete lesions were made by suction ablation in lateral areas (forelimb representation) and in medial areas (trunk representation). Care was taken not to involve the underlying white matter. The cats were sacrificed one week later. Serial coronal and sagittal sections, stained by the method of Fink and Heimer, were analyzed to determine the patterns of terminal degeneration. Small unilateral lesions of the medial precruciate cortex produced diffuse terminal degeneration within the lateral one-half of the rostral head of the caudate nucleus on both sides. Lateral precruciate lesions, involving only the forelimb areas on one side, resulted in bilateral terminal degeneration. However, its distribution to rostral caudate nucleus was confined to a circumscribed area immediately adjacent to the internal capsule and within the projection area of the medial motor cortex. In all animals, the medial precruciate lesions resulted in more terminal degeneration than the lateral lesions and the degeneration is always more pronounced ipsilaterally. In more caudal sections, dense terminal degeneration was found also in the nucleus accumbens.

133 HYPERACTIVITY VERSUS HYPERREACTIVITY IN FRONTAL CORTEX AND CAUDATE LESIONED CATS. Ch.E. Olmstead and J.R. Villablanca, Dept. Psychiat., Ment. Retard. Res., Ctr., UCLA, CA, 90024.

An open field room (12 ft X 12 ft) was used to evaluate and compare the behavior of normal male (INT, N=5) and oestrous female (OE, N=4) cats and animals receiving ablations of the: a) caudate nuclei (BAc, N=4), b) frontal cortices (BFr, N=5), c) one cerebral hemisphere (large lesion control) (HEMI, N=5). All lesions were performed in adult animals which were tested for three 15-min sessions at approximately one week intervals. Following the completion of the three-day baseline periods various stimuli were introduced into the unenriched environment and changes in the activity of the animals were assessed in 3-5 additional sessions. The basic data were the number of 27 in^2 squares crossed in one minute intervals. The INT were undistinguishable from HEMI animals and both groups showed decreased activity across the minutes within individual sessions ($p < .001$) and between individual days ($p < .001$) of testing. Their adaptation (habituation) to the test room was essentially complete by the end of the second testing day. Only the tendency of the HEMI animals to ipsilateral rotation distinguished them from the intact males. The BAc, on the other hand, showed less decrease of activity as a function of time both within ($p < .001$) and between sessions ($p < .006$) in the bare open field and were actually most active on the second habituation day. In contrast, BFr and OE animals were extremely active and showed increased activity as a function of days ($p < .01$). Within a session both of the latter groups showed variability far in excess of that observed in the other three groups. The introduction of olfactory, visual, auditory and somatosensory stimuli into the field had the most profound, albeit different, effects on the BAc and BFr groups. The INT, HEMI and OE cats made only cursory inspections of the stimuli and then proceeded to go to sleep. BFr cats showed an initial freezing to the onset of the stimulus followed by a somewhat sporadic approach. BAc animals, regardless of lesion size, spent the longest time inspecting the new stimuli and, irrespective of the modality, appeared to show a preference for the first objects or stimuli presented. Therefore, where BAc animals showed predominantly increases in reactivity, the animals with frontal lesions and those in active oestrous showed generalized activity increases both in the empty and in the stimulus rich open field. These data suggest that: a) the stimulus properties of the environment and their subsequent modification via conditioning might explain some of the behavioral observations previously made in acaudate cats; b) that other dynamic components, rather than just simple habituation, are operating in the adaptation of the individual groups to the open field. (Supported by USPHS Grants HD-05958, MH-07097 and HD-94612).

134 RESPONSES OF CAUDATE NUCLEUS NEURONS TO INTRACELLULAR STIMULI. R.J. Preston*, M. Sugimori* and S.T. Kitai. Morin Memorial Lab., Dept. Anat., Sch. Med., Wayne State Univ., Detroit, Mich. 48201.

Neurons in the cat caudate nucleus (Cd) which were monosynaptically excited by substantia nigra (SN) or thalamic (CM) stimulation were also analyzed for responses to direct transmembrane stimuli. Direct stimuli were applied through glass electrodes (1.5M KCl; 30-50 MΩ) which simultaneously registered intracellular potentials. Animals were anesthetized with pentobarbital, artificially respirated and paralyzed with flaxedil. The parameters of constant current, rectangular direct stimuli were adjusted to obtain data on passive electrical constants as well as spike discharge properties of the impaled Cd neurons.

Input resistance (R_O) (12 to 24 MΩ, $\bar{X}$=16.5, N=16) was determined from plateau values of membrane responses to hyper- and depolarizing stimuli. Membrane time constants were estimated from the exponential time course of responses to weak current pulses (±0.5 nA) and ranged from 7.8 to 16.9 msec (mean 11.3 msec). Since the recorded cells are probably medium spiny neurons, membrane resistance for an average cell is calculated at nearly 8000Ω·cm^2. A resistance of this magnitude would ensure efficient electrotonic spread of synaptic currents from distal dendrites to an axon trigger zone.

Single or repetitive spike discharge in Cd neurons was readily evoked by SN or CM stimuli or by suprathreshold direct depolarizing stimuli. Spike threshold was higher for direct than for synaptic activation (mean 7.2 vs 5.6 mV) and while firing frequencies were similar for either stimulus mode (100-200 spikes/second) direct stimuli were able to elicit sustained spiking with little adaptation. Neurons that showed spike properties suggesting accommodative regulation of firing threshold (e.g., short latency with rheobasic stimuli; low capacity for sustained firing) were those that appeared damaged by impalement (spike potentials less than 45 mV; membrane time constants less than 5 msec). These data suggest that the frequently noted silence of Cd neurons is more likely due to inhibitory synaptic influence than to intrinsic membrane specialization.

135 NEUROTRANSMITTER RECEPTOR ALTERATIONS IN PARKINSON'S DISEASE. T.D. Reisine*, J.Z.Fields*, E.D.Bird*, P.Schreiner*, H.I.Yamamura and S.J.Enna. Univ. of Ariz. Health Sci. Ctr., Tuc. AZ 85724; Addenbrooke Hosp., Cambridge, Eng.; Univ. of Texas, Houston, TX 77025.

Investigation of neurotransmitter levels, and related enzyme activities in human postmortem brains have helped elucidate the pathophysiology of a number of neurological diseases. Parkinson's disease (PD) is a chronic and progressive degenerative disease characterized by lesions in the dopamine (DA) containing neurons in the zona compacta of the substantia nigra. The ability of L-dopa to alleviate the symptoms of PD is thought to derive in part from a supersensitivity of the denervated DA receptors in the basal ganglia (BG). In this study we examined the BG and frontal cortex of PD and control brain samples for alterations in receptor binding using ^{3}H-spiroperidol, ^{3}H-GABA, ^{3}H-QNB and ^{3}H-5HT, respectively. Eighteen postmortem brain samples, nine with PD and nine controls were assayed for receptor alterations as well as for choline acetyltransferase (ChAc) activity.

In the putamen of PD brains we found significant reductions in ^{3}H-5HT binding (36%), ChAc activity (55%), and significant increases in ^{3}H-QNB (30%) binding. In the caudate nucleus (CN), we found significant decreases of ^{3}H-spiroperidol (30%) binding in PD samples whereas ChAc activity remained unchanged. No significant receptor alterations were found in the globus pallidus although, there was a significant lowering of ChAc activity. ^{3}H-GABA binding remained unchanged in all brain areas examined.

Our findings of the positive correlation of ^{3}H-5HT binding with ChAc activity in the putamen of PD samples may indicate that 5HT receptors might reside on cholinergic interneurons within this area. The increase in ^{3}H-QNB binding within the putamen may be a manifestation of supersensitivity of muscarinic receptors resulting from the progressive loss of the striatal cholinergic interneurons.

The affinity of ^{3}H-spiroperidol binding as determined by Scatchard analysis in control brain is unchanged in PD. Thus the decrease of ^{3}H-spiroperidol binding in the CN appears to be due to a decrease in the density of DA receptors.

After long-term treatment of PD, some patients become refractory to L-dopa therapy. The results of our studies suggest that the lack of responsiveness to L-dopa therapy may result in part from a progressive loss of striatal DA receptors. The lack of correlation between DA receptor binding and ChAc activity in the CN suggests that either DA receptors are desensitized from the chronic L-dopa treatment or that some of the DA receptors are located on non-cholinergic neurons that have degenerated. 136 AN AUTORADIOGRAPHIC ANALYSIS OF THE EFFERENT PROJECTIONS OF THE SUBTHALAMIC REGION IN THE RAT. Juarez A. Ricardo* (SPON: Walle J.H. Nauta). Dept. Psychol., MIT, Cambridge, MA 02139.

The subthalamic region seems to be innervated by several central structures, such as the cerebral cortex, the cerebellum, and various somatosensory nuclei. The study of its efferent projections, however, has been hampered in the past by the presence of a great number of fibers traversing the region. We decided to investigate this problem with the autoradiographic tracer technique, which is thought to be able to circumvent the fibers-of-passage difficulty. Small microelectrophoretic injections of tritiated proline and leucine in the zona incerta and in the nuclei of the fields of Forel in the rat revealed the existence of widespread descending and ascending projections which are mainly ipsilateral with minor crossed components. Fibers radiate dorsomedially from the injection site and lead to labeled fields in the thalamic parafascicular nucleus, extensive regions of the central gray substance (extending as far caudal as the genu of the facial nerve), interstitial nucleus of Cajal, and several of the pretectal nuclei (anterior, posterior and medial nuclei, and nuclei of the posterior commissure). Another component distributes itself to middle and deep layers of the superior colliculus, mainly in their lateral portions. A more directly descending component innervates the red nucleus (mainly its parvocellular portion) and a wide region of the midbrain reticular formation. This bundle of fibers continues caudalward, occupying a ventromedial position in the tegmentum, and at pontine levels innervates the nucleus reticularis tegmenti pontis, restricted sectors of the pontine nuclei, and the nuclei reticularis pontis oralis and caudalis; sparser labeling marks also the parabrachial region. At still more caudal levels this bundle comes to innervate the medial portions of the nucleus reticularis gigantocellularis and of the nucleus reticularis medullae oblongatae, pars ventralis, and restricted districts of the inferior olive; a smaller component of this descending bundle reaches the spinal cord. Ascending fibers lead from the injection site to labeled fields in several thalamic nuclei (ventromedial nucleus, nucleus reuniens, nucleus centralis medialis, nucleus paracentralis and nucleus centralis lateralis), in the entopeduncular nucleus, in the posterior hypothalamic nucleus, and in the lateral hypothalamic area. Preliminary evidence suggests that the subthalamic nucleus of Luys, on the other hand, projects significantly only to the substantia nigra (chiefly to its pars reticulata), to the entopeduncular nucleus, and to the external segment of the globus pallidus. (Supported by PHS Grant NS06542, by NSF Grant 7681227, and by FAPESP Grant 04-75/0167.)

137 AFFERENTS TO THE CAUDATE NUCLEUS IN THE CAT. G. James Royce. Dept. Anatomy, University of Wisconsin, Madison, WI 53706.

The horseradish peroxidase tracing method has been used to analyze the afferent connections of the caudate nucleus in the cat. Following HRP injections which were restricted to the head and body of the caudate nucleus, labeled neurons were present bilaterally throughout an extensive rostral zone of the neocortex. The most heavily labeled region of cortex was the anterior sigmoidal gyrus. Other cortical regions, which contained HRP labeled cells included the posterior sigmoidal, the anterior lateral, anterior suprasylvian, the anterior ectosylvian and the anterior sylvian gyri. Labeled cells were also apparent within the gyrus proreus, the anterior limbic cortex and the cingulate gyrus. All HRP positive cortical neurons were small to medium sized pyramidal cells. Such cells were located in layers II-VI, but were most prominent in layers III-V.

In addition to the prominent cortical regions of labeling, several thalamic nuclei also contained HRP-labeled neurons. The greatest number of labeled cells within the thalamus were located within the centromedian, the central lateral and the ventral anterior nuclei. Other thalamic zones including the central medial, the paracentral, the parafascicular, the dorsomedian, the lateral dorsal and the lateral posterior nuclei also contained labeled neurons.

Of particular interest was the presence of a significant number of labeled cells within a specific portion of the amygdaloid complex, i.e., the pars magnocellularis of the basal amygdaloid nucleus.

Finally, a large number of neurons within the pars compacta of the ipsilateral substantia nigra were densely labeled. In addition to this prominent ipsilateral projection, several scattered labeled neurons were also present within the ipsilateral pars reticularis and the contralateral pars compacta of the substantia nigra. (Supported by University of Wisconsin Graduate School Grant 135-4424).

138 IMPAIRED LEARNING AND MEMORY AFTER KAINIC ACID LESIONS OF THE STRIATUM: A BEHAVIORAL MODEL OF HUNTINGTON'S DISEASE Paul R. Sanberg, John Lehmann* and Hans C. Fibiger. Div. Neurol. Sci., Dept. Psychiat., Univ. of B.C., Vancouver, B.C., V6T 1W5

Intrastriatal micro-injection of kainic acid in rats has recently been shown to cause dramatic and permanent decreases in choline acetyltransferase (CAT) and glutamic acid decarboxylase (GAD), enzymes thought to be associated with cell bodies in the caudate-putamen (CP). In contrast, tyrosine hydroxylase (TH), an enzyme found only in nerve terminals whose perikarya are extrinsic to the CP is not affected. The selectivity of kainic acid in lesioning cell bodies but not terminals in the CP and its resulting biochemical sequelae have demonstrated that this procedure may be potentially useful as a biochemical model of Huntington's disease (HD) (Coyle and Schwarcz, *Nature 263*: 244, 1976; McGeer and McGeer, *Ibid*, 517). Clinically, HD is almost always associated with progressive intellectual deterioration and other psychological symptoms including impairments of memory and judgement. In this study the effects of kainic acid induced lesions of the CP on locomotor activity and on passive avoidance learning and memory were evaluated.

Bilateral injections of kainic acid (6 nmoles in 1 µl) into the CP of rats (n=11) resulted in impairment of both acquisition ($P < .001$) and 24 hr retention ($P < .01$) of a step-down passive avoidance task when compared to controls (n=12). Spontaneous locomotor activity measured in photocell activity cages was not significantly affected. Biochemical analysis on CP and cortical samples on behavioral subjects showed a significant reduction in CAT (22%) and GAD (25%) in the CP whereas TH activity was not significantly changed. The activities of CAT and GAD in cortical samples did not differ from controls, suggesting that the damage was confined to the CP. CP tissue weights were significantly less than controls (22%) which is consistent with previous findings in HD (Lange *et al*, *J. Neurol. Sci. 28*: 401, 1976). This decrease in tissue weight reflects shrinkage of the CP over the long survival period (75 days) and accounts for the smaller decreases in CAT and GAD reported here, compared to losses reported for shorter survival periods (McGeer and McGeer, *Nature 263*: 244, 1976; unpublished observations).

The present observation, showing that rats with these lesions also displayed marked deficits in learning and memory, indicates that this preparation may not only represent a biochemical model for HD but is a potentially useful animal preparation for studying the psychological deficits associated with this disease. Finally, because of the specificity of these lesions, it also suggests that the corpus striatum serves as an important neuronal substrate for complex psychological processes such as learning and memory.

139 SHORT-STEP LOCOMOTION RELEASED BY ANTI-CHOLINERGIC DRUGS IN THE AKINETIC, 6-HYDROXYDOPAMINE-TREATED RAT. Timothy Schallert*, Ian Whishaw*, V. D. Ramirez*, and Philip Teitelbaum. Dept. Psych., Univ. Illinois, Champaign, IL 61820.

Intraventricularly applied 6-hydroxydopamine (6-OHDA) severely depletes brain catecholamines in rats, and produces a complex set of symptoms that include akinesia or bradykinesia, and rigidity. Parkinson patients display similar disorders of movement. In both the akinetic rat and the Parkinson patient, the symptoms are thought to be related primarily to the disruption of dopamine transmission in the nigrostriatal system.

In the present study, using as a model the rat depleted of brain catecholamines by intraventricular application of 6-OHDA, we demonstrated that short-step locomotion, a form of walking strikingly analogous to the gait of Parkinson patients, can be temporarily released by anti-cholinergic drugs (atropine or scopolamine) in otherwise profoundly akinetic rats.

A radioenzymatic assay for dopamine and noradrenaline was used to confirm the effectiveness of the 6-OHDA treatment. The amount of walking was determined primarily by recording the number of revolutions in an activity wheel. Relative to control animals, the 6-OHDA-treated, catecholamine-depleted rats displayed a dose-dependent hyperkinesia when given atropine or scopolamine. The peripherally-acting anti-cholinergic drug, atropine methyl nitrate, had no significant effect.

The most profoundly akinetic rats showed the greatest amount of walking after anti-cholinergic drugs. For example, a rat that had never been observed to walk spontaneously showed nearly 3,000 activity-wheel revolutions in the eight hours following a single injection of 50 mg/kg atropine.

There were a number of interesting features in the locomotor behavior of the otherwise akinetic 6-OHDA-treated rats given atropine. For example, the walking steps released in the 6-OHDA rats were shorter than those of control rats given anti-cholinergics. To demonstrate this, we brushed the hind feet of the animals with ink and measured the distance between each of the resulting foot prints. The short-step, Parkinson-like gait of the 6-OHDA-treated animals was always quite striking.

In conclusion, our results support the long-established clinical value of anti-cholinergics in the treatment of some symptoms of human Parkinsonism, and suggest possible use to counteract akinesia. They also support the view that there is a mutually antagonistic interaction between catecholaminergic and cholinergic systems in the brain.

140 PROTEIN SYNTHESIS AND GLUTAMATE UPTAKE AND BINDING IN THE RAT NEOSTRIATUM FOLLOWING KAINIC ACID INJECTIONS. V. K. Singh, E. G. McGeer and P. L. McGeer. Kinsmen Lab. of Neurol. Res., Dept. of Psych., Univ. of British Columbia, B.C., V6T 1W5, Canada.

Stereotaxic injections of 1-5 nm of kainic acid (KA) into the caudate/putamen (CP) of a rat causes degeneration of neuronal cell soma in the injected area with concomitant losses in glutamic acid decarboxylase (GAD) and choline acetyltransferase (CAT); dopaminergic nerve endings are not destroyed and tyrosine hydroxylase (TH) activity is not reduced. These enzymic changes are comparable to those seen in Huntington's chorea. Changes in striatal proteins have also been reported in chorea. The incorporation of ^{3}H-leucine into proteins was examined at various times after the stereotaxic injections of 5 nm of KA into the CP; rats were killed 2 hours after the stereotaxic injection of ^{3}H-leucine and the amount of label in acid-insoluble material determined in the whole homogenates and in the nuclear and cytosol fractions. There was a 40-50% reduction in the total incorporation of ^{3}H-leucine at 1-2 days after the KA injection. At 3 days, however, the incorporation was increased to about 160% of control and was maintained at elevated levels until 5-10 days following the KA lesion. The reduction in incorporation at 1-2 days was limited to the cytosol fraction, whereas the increased accumulation at 3-10 days was in the nuclear pellet.

The binding of ^{3}H-colchicine to the cytoplasmic supernatant was decreased 30% and 60%, respectively, at 1 and 5 days after KA injections suggesting the loss of microtubular filaments of the neurons at the injection site.

Binding of ^{14}C-glutamate to the crude synaptosomal membrane fractions was reduced by 40-60% at 5 days after KA injections; this reduction is consistent with the existence of glutamate receptors on the affected neurons. High affinity, sodium-dependent uptake of glutamate into a synaptosomal preparation was not reduced in the CP of rats receiving 2.5 nm of KA and was increased significantly (to 137%) at a time (2 days) when GABA uptake was decreased to 57% of control, GAD to 64% of control and CAT to 62% of control. Since there is evidence that much of the high affinity uptake of glutamate in the striatum is into terminals of the cortico-striatal tract, this result is another indication that KA does not lesion primarily axon terminals. The increased uptake, like the increase in TH observed in KA-injected striata, suggests that the activity in the presynaptic boutons may be increased by either a presynaptic effect of KA itself or as a secondary response to degeneration of the post-synaptic elements.

Supported by grants from the MRC of Canada, the W. Garfield-Weston Foundation and the Huntington's Chorea Fdn. of the U. S.

141 MOTOR AND BEHAVIORAL CHANGES IN CATS FOLLOWING CHOLINERGIC STIMULATION OF THE CAUDATE AND ENTOPEDUNCULAR NUCLEI. Paulette Springer* and Russell E. Dill. Dept. Anat., Baylor Coll. Dent., Dallas, Tx. 75246.

An electromyographic (EMG) study using fine wire electrodes was made of tonic activity of neck extensor muscles in cats following injection of carbachol (0.5-2 µg) into the head of the caudate nucleus and entopeduncular nucleus. Intracranial injections were made unilaterally via chronic cannulae implanted bilaterally.

Changes in muscle tone were recorded and quantitated by means of standard EMG equipment and spike counters with digital-to-analog converters. One second histograms were made of motor unit activity both ipsilateral and contralateral to the drug injection site prior to and at 10-20 min after drug injection. Similar records were made of saline injections in the same sites and compared with records obtained during carbachol treatment. All cannula sites were verified histologically.

Injection of carbachol in the caudate produced an eight fold increase ($P < 0.001$) in motor unit activity on the contralateral side and a three fold increase ($P < 0.001$) on the ipsilateral side as compared with saline effects. Carbachol injected into the entopeduncular nucleus produced a 560 fold increase ($P < 0.001$) in motor unit activity contralaterally and a 2.3 fold increase ipsilaterally. These EMG records verify the behavioral changes seen after injection of carbachol into the caudate and entopeduncular nuclei. These were circling and neck torsion respectively.

Other injection sites (internal capsule, cortex and nucleus accumbens septi) did not produce these effects.

142 DENDRITIC INHIBITION OF THE CAUDATE SPINY NEURON. C. P. VanderMaelen*, J. D. Kocsis* and S. T. Kitai (SPON: J. A. Rafols). Morin Memorial Lab., Dept. Anat., Sch. Med., and Dept. Psychol., Wayne State Univ., Detroit, MI 48201.

Intracellular recordings were made in the caudate (Cd) nucleus in cats anesthetized with α-chlorolose (80 mg/kg). Glass microelectrodes were filled with 2 M KCl and had DC resistances of 30 to 50 MΩ. In some instances the electrode was filled with 4% horseradish peroxidase (HRP) in 0.2 M KCl in order to intracellularly stain the recorded neuron. All identified neurons were medium sized, with aspiny somata and proximal dendrites, and spine laden distal dendrites. Stimulating electrodes were placed in the substantia nigra (SN) and the centro-median-parafascicular complex (CMP) of the thalamus. Stimulation of SN induced a short latency monosynaptic EPSP of low amplitude, designated C1; and a longer latency monosynaptic EPSP of large amplitude, designated C2. The C2 EPSP arose from the falling phase of the C1 EPSP. CMP stimulation always resulted in a slow monosynaptic, large amplitude EPSP similar to C2, but occasionally a C1-like response was also observed. Double stimualtion of SN or CMP resulted in amplitude reduction or elimination of the test C2 EPSP, while C1 remained unchanged. The reduction in the test C2 EPSP followed an orderly time course, beginning at conditioning-test interstimulus intervals (ISIs) of about 12 msec, and lasting up to 300 msec. With ISIs less than 12 msec, summation of C2 EPSPs occurred. In some cases IPSPs were observed following the C2 EPSP. The time course of the C2 reduction followed that of the IPSP. But even when no IPSP was seen, C2 reduction still occurred. In field potential analysis, SN stimulation evoked a negative-positive potential in the Cd nucleus. The positivity corresponded in time with the C2 EPSPs. Double stimualtion of SN resulted in a reduction of the positive field potential, with a time course paralleling that for the C2 EPSP reduction. These data indicate that in the Cd spiny neuron inhibition may be operating distally on the dendrites, "shunting" the C2 EPSP which is induced in the distal dendrites and the spines. The C1 EPSP may be generated on the proximal dendrites and/or on the soma, and is virtually unaffected by the dendritic inhibition. (This work was supported by NIH Grants NS00405 and RR5384.)

143 CATS WITH LESIONS OF THE CAUDATE NUCLEI ARE BEHAVIORALLY HYPER-REACTIVE. J.R. Villablanca and Ch.E. Olmstead, Dept. Psychiat., Ment. Retard. Res. Ctr., UCLA, CA, 90024.

We have previously demonstrated that hyper-reactivity to external stimulation is a component of the syndrome observed in adult cats receiving caudate nuclei ablations as kittens. Behavioral responses of 16 adult cats with ablations of the caudate nuclei through a midline approach (BAc, N=4), removal of the frontal cortices (BFr, N=5), and of intact cats (INT, N=7) were scored on a 6 point scale during presentation of recorded cat vocalizations or of pure tones. Twenty seven sequential 15 sec presentations of cat vocalizations were made at 1 min intervals on 2 consecutive days. One week later the animals were similarly tested using 2 kHz tone stimulus. All animals showed initial distinct behavioral responses to both vocalizations and tones. On day 1 of call presentations all INT animals, 3 BAc and 1 BFr showed the maximal response. During the first day's presentation INT animals showed the most rapid decrement followed by BFr and BAc cats. Where the BFr were readily distinguishable from BAc animals on day 1, on day 2 of call presentations they both showed very little savings from previous days and habituated similarly. On the first day of tone presentation INT animals showed savings from the previous habituation experience. BFr showed more savings than INT and BAc showed the least such that both lesion groups were not significantly different from day 1 of the cat call. Two additional differences were noted. First, when the INT stopped responding, no further responses were seen throughout the session, while the BFr showed periods of non-responses followed by brief bouts of responding and the magnitude of responding was in itself variable. Secondly, the response pattern of BAc animals fit well with the previously observed stereotyped behavior in BAc cats; i.e., the animals responded at the same intensity for long periods of time (i.e., runs of simple head turns). The levels of habituation described for both BAc and BFr cats remained stationary across several months. To better analyze behavioral responsiveness, some animals were tested using "conspecific" vocalizations and artificial laboratory sounds. This demonstrated that behavioral reactivity per se and its habituation are quite different depending upon the classes of stimuli used. These results show that, both by the criteria of initial responsiveness and habituation of that responding, animals receiving lesions of the caudate nuclei or the frontal cortices as adults are distinctly different, i.e., much more hyper-reactive, than either intact cats or those receiving comparable lesions as kittens. The rank ordering of groups, however, still remains, i.e. INT showed the most rapid habituation followed by BFr and, finally, by BAc. This seems to confirm that both frontal areas and the caudate nuclei are involved in the regulation of behavioral reactivity. (USPHS Grants HD-05958, MH-07097 and HD-94612).

144 OBSERVATIONS ON THE INTRINSIC ORGANIZATION OF THE RAT SUBSTANTIA NIGRA. C. J. Wilson*, S. J. Young* and P. M. Groves. Dept. Psych., Univ. Colo., Boulder, CO 80309.

Light and electron microscopic observations, and auto- and cross-correlational analyses of extracellularly recorded spontaneous neuronal activity have been used to investigate the intrinsic organization of the rat substantia nigra.

Most of the neurons of the substantia nigra, pars compacta are of medium size. Each possesses two sets of dendrites, one which descends into pars reticulata, and one which forms a disk-like dendritic field within the pars compacta, where it overlaps extensively with those of other pars compacta neurons. Auto-correlation histograms computed from spontaneous spike trains of pars compacta neurons are characterized by an 80-250 msec. period of low firing probability which follows generation of an action potential. Cross-correlations between simultaneously recorded pars compacta neurons indicate that nearby cells inhibit each other with a similar time course. A possible substrate for both of these phenomena is suggested by electron microscopic investigation of material taken from animals treated with 5-hydroxydopamine, which reveals the presence of monoaminergic dendro-dendritic synapses in the pars compacta.

In contrast, neurons of pars reticulata show a much shorter (15-45 msec.) post-firing inhibitory period. The majority of these show a tendency toward regular firing, and no tendency to inhibit each other. They probably correspond to the medium- and large-sized pars reticulata neurons seen in Golgi-stained preparations. A third less common neuron firing in a bursty pattern may correspond to the nigral interneuron. Cross-correlations between these and the more common pars reticulata neurons suggest that they may be arranged in a recurrent inhibitory network.

BRAIN METABOLISM AND NUTRITION

145 REHABILITATION FOLLOWING MALNUTRITION: MORPHOLOGICAL STUDIES OF THE RAT CEREBRAL CORTEX. Ana G. Angulo-Colmenares. Department of Anatomy, Boston University School of Medicine, Boston MA 02118

The effects of protein malnutrition and the possibility of rehabilitation have been studied in the somatosensory cortex of the rat. Animals were malnourished by giving their mothers an 8% casein diet beginning on day 10 of gestation and continuing until 20 days after birth. At this time rehabilitation was attempted by: a) feeding the animals a 24% casein diet, b) leaving the pups with their mother until they were 40 days old and c) reducing the litter size from 8 to 4 pups. Control animals were fed a 24% casein diet throughout the experiment. Observations were made on tissue from animals 20, 40 and 70 days old fixed by vascular perfusion of aldehydes. For 20 and 40 day animals the somatosensory cortex from one hemisphere was embedded in Araldite, and that from the contralateral side was processed for Golgi staining. Previous work (Colmenares, Neuroscience Abstracts, 2: 210, 76) on 20 day animals showed a reduction in the size of the cerebral hemispheres, in the thickness of somatosensory cortex, and in the proportion of tissue occupied by neuropil. In the latter case the difference was greatest in the upper half of layer II, less in the lower part of layer II and not statistically significant in layers III and IV. I now report on further analysis of 20 day old animals and observations on rehabilitated 40 and 70 day animals. At 40 days the length and width of the cerebral hemispheres, although nearer control values than at 20 days, are still significantly different. The thickness of the cerebral cortex is no longer significantly reduced and neither is the percent neuropil in layer II. The cell body volume of layer II neurons was measured in 1 μm plastic sections. In the 20 day old animals it is reduced by 23% ($P<.05$) and at 40 days a 12% difference in the rehabilitated animals is no longer statistically significant. In Golgi preparations the thickness of the apical and basal dendrites of layer II pyramidal neurons was measured at a distance of 20 μm from the center of the cell body. At 20 days of age the thickness of both apical and basal dendrites is reduced in the malnourished animals by 13% ($P<.025$) and 16% ($P<.005$) respectively. At 40 days, following rehabilitation, the thickness of both kinds of dendrites has improved to 12 and 13% respectively and the differences were still statistically significant ($P<.05$ and $P<.01$). At 70 days, figures are available only for cerebral hemisphere measurements. The length in the rehabilitated animals is 99% of controls, the width 98% and the height 100%. None of these differences is statistically significant. **These observations suggest the possibility that a normal structure of the cerebral cortex may be achieved following early malnutrition if adequate rehabilitation is provided following the stage of deprivation.**

146 **THE COMPARATIVE EFFECT OF HYPO- AND HYPER-OSMOTIC BLOOD PLASMA UPON BIOCHEMICAL CHANGES IN BRAIN TISSUES.** **Claude F. Baxter and Roger A. Baldwin*. Neurochemistry Laboratories, V.A. Hospital, Sepulveda, CA 91343, and Dept. of Psychiatry, UCLA School of Medicine, Los Angeles, CA 90024.**

Hypo- and hyper-osmotic changes in the blood plasma of the toad (Bufo boreas) in vivo are accompanied by corresponding depression and elevation of most "nonessential" amino acids, some "essential" amino acids, some amines, urea and ammonia in the brain tissues. In general, hypo-osmotic plasma conditions decreased and hyper-osmotic plasma conditions increased amino acids and their related compounds. Exceptions to this rule are methionine, isoleucine and leucine, which are elevated, and 3-methylhistidine, the level of which is depressed by osmotic changes in either direction; phenylalanine, lysine and to some extent histidine are elevated under hypo-osmotic and depressed by hyper-osmotic plasma conditions. The most striking change in brains of the hypo-osmotic toads is the depression of tyrosine levels to approximately one-third of their normal values. The patterns of changes in brain tissues indicate that different mechanisms regulating steady-state levels of amino acids and related compounds are affected by hyper- and hypo-osmotic conditions in the toad. These results have provided clues for biochemical mechanisms in brain, liver and other organ systems that may be susceptible to direct or indirect osmotic regulation. Some of these mechanisms have been or are being tested, and the results of these experiments will be presented.

147 EXTRACELLULAR POTASSIUM CHANGES DURING ISCHEMIA IN GERBILS. William F. Blank. NIH, Bethesda, MD 20014.

Extracellular potassium concentration (Ko) was measured continuously in gerbil cortex during ischemic insults caused by occluding one or both carotid arteries. Exponential increases in Ko were seen which resembled cortical spreading depression and which usually reached valves in excess of 100 mM. The fall in potassium after reversal of the insult occurred in two stages. A slow initial component occurred which may represent washout of Ko during re-establishment of blood flow. Following this the fall of Ko accelerated and could be described by a single exponential equation with a rate constant of about 0.03 per second. Undershoots of Ko of up to 0.5 mM below control levels (mean 3.0 mM) were frequently seen after reversal. With repeated or prolonged insults, the maximum rates of Ko rise decreased; the rate constants of the fall decreased; the Ko equilibrated at higher levels after reversal of the insult; and the undershoots disappeared.

Portions of the gerbil cortex were frozen with a dry-ice/acetone mixture in order to produce gliosis. Neurons were not present within the areas of astrocytic proliferation. Ko changes during ischemia were measured in the gliotic cortex and in normal cortex nearby. The changes of Ko in the normal portions of the cortex were similar to those described above. The Ko rise in the gliotic cortex was linear. The mean rate of rise was 3.7 mM/min. The kinetics of the fall following reversal was similar to that seen in intact cortex, however, undershoots were not seen and the rate constants were greater.

It is postulated that the presence of neurons is necessary for the occurrence of the exponential rise of Ko and the undershoot of Ko following reversal. The exponential rise probably occurs because of increased neuronal membrane permeability due to massive transmitter release. The linear rise in gliotic cortex is probably due to inhibition of Na^+-K^+ ATPase of the astrocytes (see Blank, W. F. and Kirshner, H. S., Brain Research 123: 113-124, 1977).

148 A GENETIC PREDISPOSITION TO THIAMINE DEFICIENCY IN FOUR PATIENTS WITH THIAMINE-DEFICIENCY DEMENTIA. John P. Blass and Gary E. Gibson. UCLA Medical School, Los Angeles, California 90024.

The Wernicke-Korsakoff syndrome is a well-characterized neuropsychiatric disorder associated in its chronic form with dementia, deficient short-term memory, and confabulatory psychosis. It is known to be due to a lack of dietary thiamine, but the rarity of this syndrome and its ethnic distribution suggest that genetic factors also play a role in its pathogenesis. We therefore studied the properties of transketolase (EC 2.2.1.1), a thiamine-dependent enzyme which is known to be affected early in thiamine deficiency, in cultured skin fibroblasts from four patients with typical chronic Wernicke-Korsakoff syndrome and six controls. Cultured fibroblasts are known to maintain the genome of the individual from whom they were derived during serial passages in culture which dilute out the material in the original biopsy by several million-fold. Thus abnormalities which persist in culture are presumably genetic rather than consequences of the disease or of malnutrition, alcohol abuse, etc. Transketolase activity was measured by a standard spectrophotometric coupled enzyme assay. Endogenous thiamine pyrophosphate (TPP) was removed from the enzyme by precipitation with $(NH_4)_2SO_4$ at pH 3.5.

Transketolase from all 4 patients showed an apparent K_m for TPP about one order of magnitude higher than for controls, although activity in the presence of saturating amounts of TPP was comparable to controls.

	K_m for TPP (μM)	Activity (Saturating TPP) (nmol/min per mg protein)
Controls	16 ± 2	17 ± 1
Patients	195 ± 31	22 ± 3
#1	281 ± 79	15 ± 3
#2	196 ± 45	22 ± 4
#3	156 ± 40	24 ± 1
#4	146 ± 45	27 ± 5

These results suggest that the patients have an inherited aberation in transketolase which would be a benign polymorphism on an adequate diet but predisposes them to developing thiamine deficiency on a diet marginal in thiamine. This "vitamin insufficiency syndrome" is an example of an inborn predisposition to the development of a neuropsychiatric disorder.

149 EFFECT OF INSULIN INDUCED HYPOGLYCEMIA ON CEREBROSPINAL FLUID PRODUCTION. E. Fritschka*, M. E. Carey*, A. R. Vela*, J. J. Spitzer* (SPON: G. H. Ojemann). Dept. Physiol. and Neurosurg., L.S.U.M.C. Sch. Med., New Orleans, LA 70112.

The choroid plexus is thought to be the major source of CSF. Choroidal CSF is produced by an active secretory process involving $Na^{+}K^{+}$ ATPase. The choroid plexus also actively accumulates glucose and galactose from the CSF, perhaps by means of a low capacity sugar pump. (Progress in Brain Res 29:147,1967). No data are available concerning the effects of insulin induced hypoglycemia on CSF production (Vf).

Acute ventriculocisternal perfusion using mock cerebrospinal fluid containing blue dextran was used to measure CSF production in the anesthetized dog. Twelve mongrel dogs weighing approximately 10 kg were divided into two groups of 6 animals each. After an equilibrium period of 2 hrs to allow homogenous distribution of blue dextran in CSF basal control rates of cerebrospinal fluid production were obtained for 60 min. Following this control period the experimental animals received a constant intravenous insulin infusion of 1.5, 2.0 and 3.0 U/kg/hr. Blood samples and ventriculocisternal perfusate samples were collected on ice at 20 and 40 min for glucose and insulin determinations. Vf was estimated at a frequency of 20 min over the experimental time of 240 min. The control group was treated likewise, but received no insulin infusions.

Our experiments show that severe insulin induced hypoglycemia reduced CSF production. The Vf decreased significantly in all experimental animals and averaged after 240 min 40% of the control value. The Vf of the control group did not change significantly as determined by two way analysis of variance. The Vf in the experimental animals could be expressed as a logarithmic function of the glucose concentration of both the blood (r^2=.71) and the perfusate V (r^2=.83). Vf is approximately constant between blood glucose levels of 100 mg% and 20 mg%. Below 20 mg% a rapid decrease was observed. A linear regression of the mean Vf in each experimental period could be best fitted with a curve according to the formula Vf = .05 - .01x, x being the time in hours (r^2= .87). The mechanism of the Vf decrease remains to be elucidated.

150 EFFECTS OF VARIOUS PERIODS OF FOOD DEPRIVATION ON 5-HYDROXYTRYPTAMINE TURNOVER IN THE LATERAL HYPOTHALAMUS. K.M. Kantak,* M.J. Wayner and J.M. Stein*. Brain Res. Lab., Syracuse Univ., Syracuse, NY 13210.

The results from a recent study (Pharmac. Biochem. Behav., Kantak, et al, 1977) indicate a faster 5-hydroxytryptamine turnover rate in the lateral hypothalamus of 24 hr food deprived rats than in non-deprived rats. There was significantly more ^{3}H-5-hydroxyindoleacetic acid and ^{3}H-5-methoxytryptamine formed from ^{3}H-5-hydroxytryptamine in the 24 hr food deprived rats. In the present study, the periods of food deprivation were extended to include 48 and 72 hr food deprived rats. One hr following an infusion of ^{3}H-5-hydroxytryptamine, the lateral hypothalamus was perfused with physiological bacteriostatic saline for 40 min. Samples, which corresponded to 75-90 min post-infusion of ^{3}H-5-hydroxytryptamine, were analysed by thin layer chromatography for estimation of ^{3}H-labelled 5-hydroxytryptamine, 5-hydroxyindoleacetic acid, 5-methoxytryptamine, 5-methoxytryptophol and 5-methoxyindoleacetic acid. These results show that 5-hydroxytryptamine turnover is still enhanced as a result of food deprivation up to 72 hr. There was significantly more ^{3}H-5-hydroxyindoleacetic acid and ^{3}H-5-methoxyindoleacetic acid (the acid metabolite of 5-methoxytryptamine) in the 72 hr food deprived rats.

151 EFFECT OF AN 8% CASEIN DIET ON THE DEVELOPMENT OF NEURONS IN SUBCORTICAL FORMATION. Thomas L. Kemper* and Shelley Drazen* (SPON: W. Bruce Warr). Dept. Neuropathology, Boston City Hospital and Worcester Foundation for Experimental Biology, Boston, Mass. 02113.

Numerous studies have shown an effect of a low protein diet on the growth and maturation of the cerebral cortex. However little attention has been paid to the subcortical formations. In the present study the effects of dietary protein restriction was determined on rapid Golgi-impregnated neurons of the striatum, an example of a nucleated formation, and the nucleus of the diagonal band of Broca, an example of reticular formation.

Albino rats were conceived and suckled by mothers on an 8% Casein diet and controls on an isocaloric 25% Casein diet. After weaning the pups were maintained on their respective diet ad libitum. Six animals from each group were sacrificed at 90 days of age and the brains perfused in situ with 10% formalin, blocked and post fixed in rapid Golgi solution. Following silvering they were dehydrated, imbedded in LVN, and serially sectioned. Dendritic length and spine density measurements were made with an ocular reticle. In the striatum the spine-rich neurons of the 8% casein diet animals, as compared to controls, showed 9% decrease in spine density (1.96± 0.13 S.D.M. vs 2.16± 0.05 S.D.M. spines/micron) and a 2% decrease in dendritic length (141± 9 S.D.M. vs 144± 5 S.D.M. microns); the spine-free and spine-poor stellate cells showed a 4% decrease in dendritic length (110± 7 S.D.M. vs 115± 21 S.D.M. microns); and the large neurons a 3% decrease in dendritic length (253± 36 S.D.M. vs 262± 53 S.D.M. microns). The diagonal band neurons showed a 3% decrease in dendritic length (288± 15 S.D.M. vs 298± 15 S.D.M. microns). As compared to our previous study of dendritic and synaptic spine development in the visual cortical and cerebellar neurons (Brain Res. 103: 221, 1976) these phylogenically older and more conservative subcortical formations showed a correspondingly less striking effect of the 8% casein diet.

152 INCREASED CEREBRAL BLOOD FLOW ELICITED BY STIMULATION OF FASTIGIAL NUCLEUS OF CEREBELLUM. Eric MacKenzie*, Masahiro Mori*, and Donald J. Reis (SPON. D. Park). Lab. of Neurobiol., Dept. of Neurol., Cornell University Medical College, New York, NY 10021.

Electrical stimulation of the rostral medial pole of the fastigial nucleus (FN) of cat, monkey, and dog elicits a marked elevation of arterial pressure (AP). the fastigial pressor response (Miura and Reis, Am J Physiol 219:1330, 1970). We sought to establish if FN stimulation would also increase cerebral blood flow (CBF), as previously proposed (Doba and Reis, J Physiol 227:729, 1972). Focal CBF in the parietal cortices was measured by a hydrogen clearance technique in 42 normocapnic rabbits anesthetized with urethane, paralyzed and ventilated. Variations in AP produced by phenylephrine or controlled bleeding demonstrated an autoregulatory curve in rabbit comparable to that of other species. Electrical stimulation of FN at 5X current threshold for an elevation in AP substantially increased CBF. The increase was linearly dependent on the final AP. Thus, at a mean AP of 120 mmHg, for example, the CBF in unstimulated animals (AP elevated by phenylephrine) was 93±5 ml/100 g.min, during FN stimulation it increased to 148±15 ml/100 g.min (n=20, P<0.01). The increase in CBF was elicited only from pressor zones of FN and exhibited comparable stimulus frequency and response characteristics to the pressor response. Elevation of AP produced by electrical stimulation of pressor areas in the medullary tegmentum did not increase CBF. Abolition of the increase in AP by spinal cord transection did not inhibit but rather enhanced the response. Cervical sympathectomy did not affect it. We conclude that the cerebellum contains a neural system, not previously recognized, which can elicit profound vasodilatation of the cerebral circulation, probably through an intrinsic neuronal system of the brainstem.

(Supported by NIH grant HL18974 and the MRC).

153 HISTIDINE-INDUCED ELEVATION OF BRAIN CYCLIC ADENOSINE 3',5'-MONOPHOSPHATE ASSOCIATED WITH ELEVATED BRAIN HISTAMINE IN RATS. T.M. McMurray*, E. Orr*, A. Qureshi*, and B. Eichelman. (SPON: R.F. Keesey). Laboratory of Behavioral Neurochemistry, Dept. Psychiat., Univ. Wisconsin and VA Hospital, Madison, WI 53705.

Recently, we have reported that feeding rats an L-histidine supplemented diet causes a decrease in lipogenic enzymes (Eichelman et al., 1977) and an induction of cholesterol biosynthesis(Qureshi et al., 1977) in both brain and liver. Previous work on liver lipogenic enzyme systems suggested that these effects might be mediated by increases in cyclic adenosine 3',5'-monophosphate(cAMP) levels. The present studies describe the effect of different nutritional states(employing histidine loading) on the levels of brain cAMP.

Rats were maintained acutely for three days and chronically for twenty-one days on a diet enriched 5% with L-histidine. To maximize enzyme levels under study, the rats were fasted for two days and refed for three days prior to sacrifice. In both the acute and chronic studies there was an increase of brain cAMP levels to 60-100% over control levels in groups fed a histidine enriched diet. Rats injected with L-histidine (500 mg/kg, ip) showed 100% increases in brain cAMP levels after two to three hours. Decreases in brain lipogenic enzymes were proportional to the increases in brain cAMP levels over the three hour period.

Findings that histamine plays a role as a putative neurotransmitter and has also been shown to increase intracellular cAMP through H2 receptors in vitro(Busse & Sosman, 1976) suggested a mechanism whereby brain cAMP might be increased following histidine loading. Our results showed that histamine levels under the above conditions were increased similar to the cAMP increases.

Brain levels of cAMP following three day feeding and three hour injections of urocanic acid(an irreversible histidine metabolite) showed a slight increase.

These results are compatible with the hypothesis that histidine induced changes in brain lipogenic enzymes and cholesterol biosynthesis are mediated through histamine induced increases in brain cAMP. (This work was supported by grants from the Medical Research Service of the Veterans Administration Hospital and intramural grants from the University of Wisconsin.)

154 PRESENCE OF DIHYDROFOLATE REDUCTASE IN RAT BRAIN DURING EARLY DEVELOPMENT. J.C. Mendible* and L.A. Ordóñez. Lab. Neuroquimica y Comportamiento. I.M.E. Apdo: 50587. Sabana Grande. Caracas-Venezuela.

Folates are involved in metabolic processes which seem to be essential during early mammalian brain development, as shown by increased total folate levels (L.D. McClain and W.F. Bridgers, J. Neurochem 17:763, 1970), increased serine-tetrahydrofolate 5,10-hydroxymethyl transferase activity (W.F. Bridgers, J. Neurochem 15:1325,1968) and increased methylene reductase activity (L.A.Ordóñez and O. Villarroel, J. Neurochem 27:305,1976) in developing brain when compared to adult tissue. These changes could reflect the involvement of folates in the generation of thymidine requiered for deoxyribonucleic acid synthesis. In thymidine synthesis, tetrahydrofolic acid (THFA) is oxydized to dihydrofolic acid and it must be reduced back to THFA by Dihydrofolate Reductase (DR) before being able to participate again in metabolism. This enzyme has been reported to be absent from adult brain (D.R. Makulu, et al, J. Neurochem 21: 241,1973); we have studied the activity of this enzyme in rat brain and liver from five days before birth (-5 days) to adult. DR is present in fetal brain (-5 days; S.A: 0.414 ± 0.034 umol/h.mg) and decreases continuosly until becoming non-detectable in the adult. The enzyme is still detectable at 20 days of age (S.A. 0.045 ± 0.009 umol/h.mg). In contrast, the liver enzyme shows a constant activity from -5 days until adult (~0.27 umol/h.mg). At 0 days of age cerebellum DR activity is lower (0.084 ± 0.007 umol/h.mg) than that of the rest of the brain (0.120 ± 0.011 umol/h.mg) but in the former area this activity remains relatively constant until day 20 while in the rest of the brain it decreases rapidly with time. In both brain areas no activity is detectable in the adult.

These result support the importance of folates during early brain development probably through their involvement in thymidine synthesis and could explain the neurological disorders reported in humans and other animals associated with folate deficiencies during early development.

155 BRAIN AND PERIPHERAL UTILIZATION OF LABELLED TRYPTOPHAN IN PROTEIN MALNOURISHED RATS. Maravene Miller*, Oscar Resnick*, J. Patrick Leahy* and Peter J. Morgane. Worcester Foundation for Experimental Biology, Shrewsbury, Ma. 01545.

The utilization of IP injected ^{14}C-tryptophan (^{14}C-trp) for incorporation into protein in brain and peripheral tissues from birth to 21 days was examined in rats fed a normal (25% casein) or a low protein (8% casein) diet. The malnourished group, whose dams received the low protein diet 5 weeks prior to conception, showed significant alterations in the incorporation and percent incorporation of ^{14}C-trp into protein on the day of birth as compared to the normal group (table below). The lower incorporation of ^{14}C-trp into protein by the malnourished rats was also noted at the subsequent ages examined (day 5 to day 21).

This altered pattern of incorporation of ^{14}C-trp by the malnourished rats may be due, in part, to their higher concentrations of free plasma trp at these ages as reported by Miller et al. (Soc. Neurosci. p. 586, 1976). The injected trp may have less affinity for tissue incorporation due to the higher concentration of endogenous free plasma trp seen in these animals (Miller et al. Exp. Neurol., in press).

156 DEPLETION OF CYTOCHROME OXIDASE IN BRAIN MITOCHONDRIA FROM THE MOTTLED MOUSE MUTANT. Donald L. Rezek* and Cyril L. Moore* (SPON: G. A. Barr). Dept. Neurology, Albert Einstein Coll. of Med., Bronx, NY 10461.

A genetic defect prevents the male mottled mouse (Mo^{br}/+) from the normal utilization of copper. Among the enzymes most directly affected is brain mitochondrial cytochrome oxidase. Since this enzyme is essential for respiration and oxidative phosphorylation, it is noteworthy that the amount of the spectrophotometrically measureable enzyme decreases from birth to when the animal dies at about 14 days of age. In brain mitochondria of 2-4 day old animals, the ratio of the amount of cytochrome oxidase in the affected animals to that in the normal controls is 0.48; by 6-8 days of age, it is 0.43; and by 11-14 days of age, it is only 0.14. The liver, which sequesters much of the body's copper, is not nearly as affected as the brain; the respective ratios in the liver are 0.88, 1.03, and 0.73. The rate at which added cytochrome c is oxidized in brain homogenates is about 30% of normal. The study emphasizes the importance of copper as an intregal part of cytochrome a_1-a_3 in the brain and suggests that depletion of cytochrome oxidase in the mouse and in victims of the human genetic disease, Menkes kinky hair syndrome, may be related to the retardation and death caused by these diseases. (Supported by NIMH training grant MH 06418.)

157 EFFECTS OF SODIUM OCTANOATE ON BLOOD-BRAIN BARRIER PERMEABILITY.
Doris A. Trauner and Jack de la Torre. Univ. of California, San Diego, CA 92103 and Univ. of Chicago, Chicago, IL 60637.

The short chain fatty acid (SCFA) sodium octanoate causes hyperventilation, coma, seizures and electroencephalographic slowing in experimental animals. The mechanism by which this substance exerts its toxic effects is unknown. The rapidity with which octanoate produces such alterations suggests that this substance may exert some effect on blood-brain barrier (BBB) permeability. The present report describes preliminary results concerning BBB alterations in rats given intraperitoneal (IP) injections of sodium octanoate, 2 ml of a 1 M solution.

A modified glyoxylic acid histofluorescence technique (SPG method) was used to study vascular integrity in rats pretreated with octanoate and followed in 2-4 hours with injection of the monoamine oxidase inhibitor, nialamide, and L-dopa. Following L-dopa injection, there was marked diffusion of fluorescence around brain capillaries, particularly in subcortical white matter. Diffusion was also seen around brainstem neurons and was striking around cell bodies in the locus coeruleus and magnacellularis. Fluorescent diffusion was prominent around the choroid plexus as well. Diffusion of catecholaminergic terminals was also observed throughout the brain and markedly around the nucleus rotundo and stellatocellularis and the periventricular nucleus of the hypothalamus. It is of interest to note that this catecholaminergic diffusion appeared more severe in brain regions in close proximity to the ventricular system.

Fluorescence was confined within capillaries and no diffusion was seen in animals injected with nialamide and L-dopa but not pretreated with octanoate.

These data suggest that octanoic acid alters the permeability of the BBB and may produce marked cerebral metabolic changes as a result of this permeability change.

CEREBELLUM

158 FASTIGIAL UNIT ACTIVITY DURING WRIST MOVEMENTS IN PRIMATES. Antonio Bava* and Robert Grimm. Neurological Sciences Institute, Portland, Oregon 97209.

Crab-eating macaques (Macaca irus) were trained to make a series of quick (250-500°/sec), self-paced 45° flexion or extension movements of a manipulandum (stiffness: 0.86-2.9 kg. cm/rad) in order to examine the proposition that fastigial n. of cerebellum provides a fast feedback pathway to thalamus for spinal information regarding movement. Fastigial n. receives a rich supply of excitatory mossy fiber (MF) and climbing fiber (CF) collaterals carrying spinal and suprasegmental activity destined for anterior lobe. As fastigial n. also projects to ventrolateral (VL) n. of thalamus, Ia, Ib, and group II activity could reach motor cortex by this route. Accordingly, our hypothesis was that fastigial neurons participating in a voluntary movement would alter their discharge after a movement begins.

From a sample of 139 units in 20 tracks, we divided fastigial neurons into four groups: slow-firing units (1-10 Hz; 80% of the sample); tonic units (20-50 Hz; 14%); "silent" units (only recruited during a movement; 5%); and high frequency, short duration burst units (1%; presumably interneurons). Slow-firing units characteristically increase their discharge rate 200-300 msec prior to the onset of the first of a series of repeated movements (performance rate 1/sec). However, in each subsequent performance in a series, such units only discharge after force begins to rise but before handle displacement. After the last movement of a series is completed, 50% of slow-firing units discharge in concert with proximal-axial activity returning the limb to a rest position. Tonic units either increase (20%) or decrease (80%) their activity after movement begins. "Silent" units, active only with movement, always discharge before a first performance movement, thereafter decrementing as the monkey repeats the task.

These data establish that fastigial neurons are recruited before or after a movement begins depending on the context. For single movements or the first-in-a-series, "silent" and slow-firing units discharge before movement; thereafter, discharges follow (40-200 msec) the onset of similar movements serially repeated (1/sec). This rule does not apply to tonic units: they only alter their activity after a movement begins regardless of occurrence order. Where unit activity could be correlated with performance metrics, it appears that a force-velocity algorithm or changes therein and not a position measure is the work of this nucleus. The different attention given by the nucleus to single vs. repeated movements, and, tonic unit inhibition during movement are novel findings.

159 THE MORPHOLOGY OF THE FASTIGIAL NUCLEUS IN THE RAT. Alvin J. Beitz* and Victoria Chan-Palay (SPON: Nell B. Cant). Dept. Anat., Harvard Medical School, Boston, MA 02115.

The present investigation is aimed at describing the organization of the fastigial nucleus in the rat utilizing several variants of the Golgi technique and Nissl and Weigert preparations. A three-dimensional model of the fastigial nucleus was made from reconstructions of serial coronal sections stained with the Nissl method. This illustrates both the shape of the nucleus and the location and extent of the three nuclear subdivisions as described by Korneliussen (1968). The middle subdivision forms the largest portion of the nucleus and extends most rostrally while the dorsolateral protuberance and the caudomedial portion comprise smaller more caudal subdivisions of the nucleus.

In order to determine the frequency distribution of neuronal sizes within the fastigius, measurements were made of the lengths, widths and areas of 550 neurons drawn from Nissl-stained sections of the three divisions in a single animal. Two classes of neurons are present: small neurons with cross sectional areas less than 180μm^2 and larger cells with areas greater than 180μm^2. The larger neurons range in width from 10 to 22μm and in length from 18 to 35μm and are most numerous in the dorsolateral protuberance. The middle subdivision contains a mixture of large and small cells. Small neurons predominate in the caudomedial subdivision of the nucleus and range in width from 5 to 16μm and in length from 10 to 24μm. In Golgi preparations, both the small and large neurons have two major types of dendritic patterns: either the cells are truly multipolar or they have dendrites oriented in two directions. Histograms were prepared relating the numbers of neuronal perikarya in both frontal and horizontal sections with their ellipticity ratios (ER width:length). These histograms indicate that there are two basic shapes of neuronal perikarya in the rat fastigial nucleus: almost round (ER<1:1.5) and elliptical (ER>1:1.5). When the locations of round versus elongated cells were charted, three distinct rostrocaudal zones became evident within the nucleus: a medial and lateral zone with predominantly elliptical neurons and an intermediate round cell zone. All impregnated neurons in a set of horizontal Golgi-Kopsch serial sections were drawn to study cellular organization in detail. Elongated neurons in the medial and lateral zones of the nucleus are fusiform with their cell bodies and dendrites oriented predominantly in a rostrocaudal direction. The rounded cells of the intermediate zone are multipolar with their perikarya and dendrites arranged in a more mediolateral direction. Elongated neurons in the caudomedial subdivision displayed a distinct rostromedial-to-caudolateral orientation. (Supported by Neuroanatomy Training Grant NS 05591 to Dr. S. L. Palay and NIH Postdoctoral Fellowship NS 05688.)

160 OLIVARY UNIT ACTIVITY AND EFFECT OF MICROSTIMULATION DURING LOCOMOTION. C. C. Boylls, Jr., Biomed. Res. Lab., E. E. Dept., U. Maryland, College Park, MD 20742.

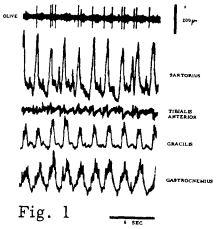

Fig. 1

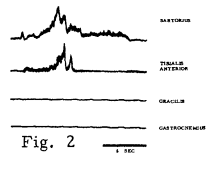

Fig. 2

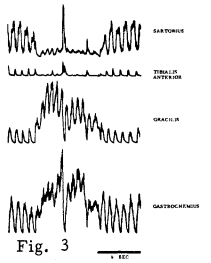

Fig. 3

Thalamic cats were prepared for slow treadmill walking (0.3-0.7 kph), with EMG's ("integrated" in records below) led from muscles of one hindlimb. Using antidromic field techniques, we then inserted tungsten electrodes into a portion of the contralateral MAO contributing climbing fibers to a parasagittal anterior lobe strip roughly 1.8 mm wide, adjacent to the midline. Here we found MAO unit activity to have but slight correlation with locomotor movements (fig. 1). However, MAO microstimulation (0.2 msec pulses, 5-30 hz), at levels just suprathreshold for cortical surface potentials (25-45 μa), was found to augment powerfully the contractions of limb flexors or extensors, with concomitant antagonist suppression (hindlimb fixed in fig. 2, walking in fig. 3). After stimulus cessation, such agonistic rebiasing required many seconds to decay.

MAO activity thus appears to affect the "carriage" of locomotion over many step cycles, hence the lack of unit activity locked to single cycles. Olivary postural biasing appears encoded in terms of multijoint, agonistic muscle groups, possibly synonymous with the agonists of spinal reflexes. Perhaps each such group is represented by a climbing fiber strip.

I thank Drs. F. E. Zajac and J. D. Cowan for the opportunity to conduct this study, Dr. N. H. Barmack for advice and encouragement, and Mssrs. D. Dungan and C. A. Twigg for expert technical assistance. Supported by NIH grant NS 11518 and postdoctoral fellowship 1 F32 NS 05568.

161 THE VENTRAL PARAFLOCCULUS: A SITE OF VISUAL CORTICAL AND TECTAL INPUT. Richard A. Burne and Donald J. Woodward. Dept. Cell Bio., Univ. Tx. Health Sci. Ctr., Dallas, Tx. 75235.

This study was undertaken with the general aim of investigating areas in rat cerebellum which receive visual information.

In this report we describe anatomical and electrophysiological evidence that the ventral parafloccculus (vpf) receives information from the visual cortex and superior colliculus via relays in the pons and inferior olive. The techniques of retrograde transport of horseradish peroxidase (HRP) and orthograde transport of tritiated L-leucine were employed to determine pathways from cortex and tectum to the cerebellum.

Injections of ^{3}H-leucine into areas 17, 18, and 18A of visual cortex resulted in overlapping terminal labeling within the rostral lateral pontine grey. In addition, two injections confined within area 17 gave labeling in a medial rostral pontine group which suggests a more detailed topography. Injections of leucine into superior colliculus gave ipsilateral labeling in lateral areas of the middle pons, and the ipsilateral medial accessory olive including the beta nucleus.

Injections of HRP in vpf yielded labeled neurons which revealed a bilateral projection (contralateral predominance) from medial and lateral neurons in the rostral pons, and a contralateral projection from medial accessory and principle olive. Experiments with simultaneous injections of HRP and leucine revealed in adjacent sections considerable overlap of leucine labeled terminals from visual cortex and superior colliculus onto HRP labeled pontine and inferior olive neurons which project to vpf.

Unit recordings and post-stimulus-time-histograms from each of 50 Purkinje cells in vpf showed evidence of mixed excitatory-inhibitory mossy fiber input (36 cells) or pure inhibitory responses (14 cells) following cortical or tectal stimulation with concentric bipolar electrodes (0.1 ms, 0.2-0.4 mA, 2-10 Hz). Mean latency to onset was 10.2 ± .4 msec for cortex and 7.8 ± .3 msec for tectum.

We conclude that the ventral parafloccculus is a cerebellar area which receives a convergence of strong visual input from visual cortex and information from superior colliculus.

162 EFFECTS OF COOLING OF THE CEREBELLAR NUCLEI ON THE MOTOR OUTPUT DURING FAST ELBOW FLEXIONS IN CATS. John E. Burton and John Kerch Engelhardt. Division of Neurosciences, City of Hope National Medical Center, Duarte, CA 91010.

Cats were trained to perform ballistically initiated elbow flexions and prepared for local cooling of individual cerebellar nuclei. The structure of the motor output following the onset of movement is characterized by a silent period in the agonist (biceps) muscle and a burst of EMG activity in the antagonist (triceps), both of which coincide with the peak of the velocity. Local cooling of the ipsilateral dentate nucleus did not alter this structure. Cooling of the interpositus nucleus, however, delayed both the decline of the biceps activity and the onset of the triceps activity relative to the onset of the motion. Also, the biceps muscle was no longer silenced and the amount of triceps activity was reduced. As a result of these changes, the acceleration was prolonged and the peak velocity and displacement attained higher values. Cooling of the fastigial nuclei (bilateral) produced either a slight advance of the termination of the biceps activity or a delay with absence of silence depending upon the position of the thermode and/or the depth of the cooling. The triceps activity was usually delayed and the amount increased. The displacement was characterized by large oscillations. It is concluded that the output of both the fastigial and the interpositus nuclei contributes to regulate the amount and timing of the motor output during fast movements in cats. The results will be discussed in terms of the behavior of neurons of the cerebellar nuclei, red nucleus, and lateral vestibular nucleus during such movements. (Supported by NIH research grant number NS 11798 from NINCDS and by the Jerry Rosen Research Fund)

163 THE SOURCE OF CLIMBING FIBERS TO THE VESTIBULO-CEREBELLUM OF THE TADPOLE. S.L. Cochran and J.T. Hackett. Dept. Physiology, Univ. of Virginia Medical School, Charlottesville, Virginia, 22901.

Current research suggests that the inferior olive is the exclusive source of climbing fibers(CFs). However, an extra-olivary origin of CFs has been reported in the frog to project from the periphery to the auricular lobe("vestibulo-cerebellum") via the VIIIth cranial nerve. Our own experiments upon the frog (Cochran and Hackett, 1977) have failed to locate any extra-olivary source of CFs. This failure could be due to difficulties in sampling the minute auricular cerebellum of the frog. According to Larsell (1923,1967), the tadpole cerebellum is predominantly auricular. Therefore, we have investigated the source of CFs to this cerebellum. Electrophysiological experiments were performed upon isolated brains of premetamorphic Rana pipiens and Rana catesbeiana tadpoles. Purkinje cells(PCs) were recognized electrophysiologically by their characteristic antidromic, CF, and mossy fiber(MF) evoked responses. This recognition was anatomically verified by subsequently processing the tissue histologically following ejection of horseradish peroxidase(HRP) from the recording microelectrode. Direct CF-evoked responses were identified by their fixed latency, by their all-or-nothing character, and by their interposition between the directly-evoked antidromic response and the disynaptically-evoked MF response in the PC. Furthermore, intracellular recordings in evoked PCs uncover a single, large, fixed latency, all-or-nothing EPSP, the polarity of which could be reversed by depolarizing current injection. By repositioning the stimulating electrode, individual CFs could be traced along their trajectory through the brain. A linear correlation($r>0.9$; $p<0.001$)existed between the latency to PC activation and the distance of the stimulating electrode from the cerebellum, thereby demonstrating direct CF activation. CF activation could be found only along the lateral edge of the brain, past cranial nerves VII, VIII, and IX. At the level of the Xth cranial nerve, a CF's path could be traced caudally, ventro-medially and across the midline where large latency shifts in activation suggested other than direct CF stimulation. Some axons appeared not to cross the midline. Electron microscopic observations of the cerebellum reveal a cellular association characteristic of that attributed to the CF and PC in the tadpole(Cajal, 1911). We therefore conclude that the tadpole indeed possesses a CF afferent system and that even in a limbless, finless vertebrate, the caudal medulla has a unique relationship with the cerebellum in that only it innervates the PCs with CFs. The demonstration of this unique source of CFs in all vertebrates suggests that the functional contribution of the CF to cerebellar action is, to some extent, fixed in phylogeny. (Supported by NSF Grant BNS 74-01423 A02)

164 PONTINE PROJECTION TO CEREBELLAR CORTEX AND NUCLEI. J. Courville and G. Coulombe. Centre de Recherche en Sciences Neurologiques, Université de Montréal, Montréal, H3C 3T8

The distribution of the pontine projection onto the cerebellar cortex and nuclei was studied with methods of anterograde degeneration and tritiated amino acid transport. Multiple large injections of L-leucine in cats demonstrate the course of the fibers and a terminal distribution appearing as roughly circular grain accumulations and restricted to the granular layer. The projection is abundant in the contralateral, lateral portion of the anterior lobe, in lobules VI, VII, simplex, paramedian and in Crus I, Crus II and paraflocculus. For vermian lobules VI and VII, an abundant bilateral distribution originates from each side of the pontine gray. The central region of the anterior lobe comprising the vermis and part of the intermediate zone is practically devoid of pontine afferents. After small localized injections in the pons, the grain accumulations are much less abundant. However, they always appear widely distributed to different cerebellar regions. Anterograde degeneration experiments confirm these data except for the quantitative differences for each side. This is interpreted as a result of a destruction of crossed fibers which occurs with unilateral lesions. Concerning a projection to the cerebellar nuclei, the evidence obtained is that grain counts are significantly augmented in the dentate nuclei, the difference being greater in the nucleus contralateral to the injection. Degeneration studies confirm this distribution and support the conclusion of a rather sparse distribution. In addition, it appears that this projection originates mostly if not exclusively, from the nucleus reticularis tegmenti pontis. Injections of horseradish peroxidase in the nuclei have yielded inconsistant results. Medially situated injections were not followed by any retrograde labeling of pontine cells. Laterally localized injections either showed few labeled cells or widespread distributions of a large number of labeled elements. These vagaries are attributed to variations in the uptake by fibers of passage and to differences in the degree of fixation among cases.

165 TOPOGRAPHIC ORGANIZATION OF PROJECTIONS FROM THE DENTATE AND INTERPOSITUS NUCLEI IN THE RHESUS MONKEY: AN AUTORADIOGRAPHIC STUDY. K. Kalil. Dept. of Anat., University of Wisconsin, Madison, WI., 53706.

Injections of (^{3}H) proline were made into the dentate and interpositus nuclei of rhesus monkeys. Several different approaches were used to inject either an entire cerebellar nucleus or selected regions of the dentate and interpositus nuclei. All efferent pathways from the nuclei to the brainstem and thalamus were traced but particular attention was focused on the topographic organization of cerebellar projections to the inferior olivary complex and the ventral tier nuclei of the thalamus. The dentate nucleus projects upon the principal inferior olivary nucleus in a precisely ordered topography such that the ventral dentate terminates upon the ventral lamella of the olive and the dorsal dentate projects upon its dorsal lip. Moreover, these connections follow an exact and non-overlapping mediolateral topography. By contrast, when regions of the interpositus were injected with minimal encroachment into the dentate only the dorsal and medial accessory olivary nuclei were labeled and not the principal nucleus. Preliminary results suggest that this projection is also topographically organized. For example, when the entire interpositus was injected the entire medial accessory olive was covered with silver grains, but injections of only the dorsal or ventral regions of the interpositus resulted in selective labeling of the dorsal and medial accessory olive. Superimposed upon this point to point organization is an anterior posterior topography with caudal regions of the cerebellar nuclei projecting upon the rostral olive and vice-versa. As has been previously reported, these connections are overwhelmingly crossed with only a small corresponding ipsilateral projection.

The cerebello-thalamic fibers are also topographically ordered with the caudal and rostral regions of the cerebellar nuclei projecting respectively to the medial and lateral zones of the thalamus. The thalamic nuclei receiving the densest cerebellar efferents are the VLc, the VPLo and the VLo. In several cases nucleus X was labeled but even with massive injections of dentate and interpositus there were surprisingly sparse projections to the VA. There was also intense labeling of CL and the reticular nucleus. While the cerebello-thalamic pathways are mainly crossed there is nevertheless a small corresponding ipsilateral component. In some cases the terminal labeling in the VLc, VPLo and VLo appeared in striking narrow horizontal bands or strips across the ventral thalamic nuclei and in other cases as a discontinuous series of patches.

166 PURKINJE CELL ACTIVITY IN EYE MOVEMENT AND FIXATION IN THE MONKEY VERMIS. Manabu Kase* and Hiroharu Noda Brain Research Institute, Depts. Physiol. Anat., Sch. Med., UCLA, Los Angeles, CA 90024

Single unit recordings were made from Purkinje cells (P-cells) in the vermis (Lobus VI and VII) of the monkey during saccadic eye movements and steady fixation. Most P-cells exhibited a considerably high level of simple spike discharges (55 - 100 Hz) which were interspersed by characteristic complex spike discharges (0.5 - 1.5 Hz). There were two classes of P-cells.

One class of P-cells showed changes in activity only with eye movements. These cells increased discharges, typically starting 10 - 20 msec before the initiation of a saccade and showing peak activity at about the middle of the course of the saccade. In a small number of P-cells, the firing decreased during a saccade with a time course similar to the transient increase. However, complete cessation of firing extending the entire duration of eye movement was seldom observed. Many P-cells in this class also showed preferred direction and the increase in activity was observed only when the saccade was in the preferred direction of the concerned cell. Although there was a clear relation between the duration of bursts and the size of associated eye movements, no relation was found between instantaneous firing rate within the burst and amplitude of accompanying eye movement.

The other class of P-cells also showed changes in activity during saccades. Discharges in these cells were completely suppressed during a saccade. Furthermore, the level of tonic discharges of the cells varied considerably (for example, 0 - 120 Hz in a cell) from one point of fixation to another, showing a higher level of activity when the gaze shifted to the preferred direction of the cell. The discharge rate was clearly a linear function of eye position in some cells, indicating that these cells convey information relevant to eye position in the orbit. (Supported by NIH Grant EY01051).

167 DISTRIBUTION OF VESTIBULAR NERVE FIBERS TO THE CEREBELLUM IN THE CAT. Gary E. Korte* and Enrico Mugnaini. Dept. of Biobehavioral Sciences, Univ. of Conn., Storrs, Conn. 06268

The cerebellar distribution of the vestibular nerve in the cat has been re-examined with silver degeneration techniques and in 1-2 um thick sections of plastic embedded material. The vestibular ganglion was manually destroyed via the bulla by twisting a dental burr into the internal meatus. After survival times of 3-6 days, the animals were processed for examination by the Fink-Heimer and Nauta-Laidlaw techniques or prepared for electron microscopy. The extent of the lesion was analyzed under the dissecting microscope and by light microscopic examination of 1-2 um thick sections of the plastic embedded remaining nerve stump.

The Fink-Heimer and Nauta-Laidlaw techniques revealed a conspicuous fiber bundle entering the cerebellar white matter and terminating in the granular layer of all folia of the nodulus and the ventral folia of the uvula on the ipsilateral side. Relatively fewer degenerating fibers were traced to the cortex of the ipsilateral flocculus. No projection to the paraflocculus, lingula, lateral cerebellar nucleus or any contralateral cerebellar region could be ascertained (some degenerating fibers were present in the fastigial nucleus, but we are still uncertain as to whether they pass by or give rise to a terminal arborization).

These observations were confirmed by light microscopic observation of 1-2 um thick plastic sections from specimens processed for electron microscopy. Electron microscopic controls are in progress.

In conclusion, a re-examination of the cerebellar terminal field of the primary vestibular fibers in the cat has shown that it is mainly represented by the cortex of the ipsilateral nodulus and uvula, and to a lesser extent by the cortex of the ipsilateral flocculus.

168 $[K^+]_o$ RISE PRECEDES $[Ca^{++}]_o$ FALL DURING SPREADING DEPRESSION. R. P. Kraig, C. Nicholson and J. M. Phillips*. Dept. Physiol. & Biophys., N.Y.Univ.Med.Ctr., 550 First Ave., New York, NY 10016.

Recent experiments from this laboratory have used spreading depression (SD) to explore the capacity of the brain to reversibly undergo fluctuations in the extracellular ionic milieu. During SD in the cerebellar molecular layer of the catfish, Corydoras aneus, the $[Na^+]_o$ typically falls from 149 mM to 57 mM, and the $[Cl^-]_o$ falls from 137 mM to 47 mM while the $[K^+]_o$ rises from 2 mM to 35 mM (1,2). It has recently been established that Ca^{++} and K^+ fluxes are related in certain membranes (3,4) and also that correlated $[K^+]_o$ rises and $[Ca^{++}]_o$ falls occur in the brain during aminopyridine application (5), convulsive activity (6), repetitive stimulation, spreading depression and anoxia (7). We have utilized the slowly developing SD of the catfish cerebellum to investigate the temporal relationship between $[K^+]_o$ and $[Ca^{++}]_o$ changes. Pairs of ion-selective micropipettes were fabricated from theta-tube capillaries and sensitized with Ca^{++}-selective liquid ion exchanger (8) or Corning 477317 K^+ exchanger. SD was initiated in the exposed catfish cerebellum by a microinjection of 1M KCl.

Baseline $[K^+]_o$ was about 2 mM and baseline $[Ca^{++}]_o$ about 1.6 mM. Thus the two ISM were approximately equal in sensitivity to ion changes. During SD the $[K^+]_o$ always began to rise several seconds before the $[Ca^{++}]_o$ began to decrease. At the peak of SD the $[Ca^{++}]_o$ decreased to about 25% of its baseline value. The resolution of Ca^{++} and K^+ ISMs was such that $\pm$ 0.1 mM could be detected. In no instance did $[Ca^{++}]_o$ begin to fall before the $[K^+]_o$ began to rise.

We conclude that a prolonged neuronal Ca^{++} influx, as manifested by a decrease in the $[Ca^{++}]_o$, does not precede the well established rise in $[K^+]_o$ during SD. Rather the marked delay in the $[Ca^{++}]_o$ decrease suggests at least two partially separable events occurring during SD: a rise in the $[K^+]_o$ and a subsequent fall in the $[Ca^{++}]_o$.

169 STRUCTURE OF THE PURKINJE CELL DENDRITIC MEMBRANE DURING SYNAPTOGENESIS. D. M. D. Landis and T. S. Reese. Mass. General Hosp., Boston, MA 02114; LNNS, NINCDS, NIH, Bethesda, MD 20014.

Freeze-fractured Purkinje dendritic spines in mature mice have aggregates of intramembrane particles arrayed on their external membrane leaflet at synaptic junctions with parallel fibers. We investigated the formation of this postsynaptic specialization and attempted to relate it to parallel fiber synaptogenesis by freeze-fracturing cerebellar cortex during postnatal development. Criteria for recognizing Purkinje dendrites, especially in younger mice, were established by tracing their continuity with cell bodies. Dendritic segments distal to the region of apparently mature spines were examined in detail because this is where spine formation and synaptogenesis occur. However, the membrane structure of distal segments was generally like that of the rest of the Purkinje dendrites and cell bodies, except that coated vesicle openings were more frequent; these proved to be a reliable marker to identify comparable regions of Purkinje dendrites in thin sections and replicas. Infrequently, aggregates of particles which resembled but were smaller than postsynaptic specializations on mature Purkinje spines were found on the external leaflets of dendritic shafts, usually distal to the zone of well-formed spines. The membrane at these aggregates was sometimes indented by varicose processes, but the course of these unidentified processes was usually different from the adjacent parallel fibers. Thin sections of distal dendritic segments revealed numerous junctions between parallel fibers and dendritic shafts which, like mature synapses, were characterized by bands of submembrane fuzz in the Purkinje dendrites. Parallel fibers often contained a few synaptic vesicles near these junctions. Since parallel fibers do not contact Purkinje dendritic shafts in adult animals, the junctions with the dendritic shafts observed during development either must become or be replaced by spine synapses. The clear disparity between the large number of these junctions in thin sections and the small number of particle aggregates seen on distal dendrites with the freeze-fracture technique suggests that the vast majority of these junctions do not have the membrane structure of a mature spine synapse. Thus, the postsynaptic particle aggregates which characterize Purkinje spines are probably acquired after the formation of spines begins. If the junctions on Purkinje shafts are developing synapses, then early forms of these synapses lack intramembrane particles; an alternative interpretation of our data is that synapse formation begins later than spine formation. In this case, the junctions on the Purkinje shafts could not be regarded as precursors of synaptic junctions.

170 CALCIUM DENDRITIC SPIKES IN THE MAMMALIAN PURKINJE CELLS. R. Llinás, M. Sugimori* and K. Walton. Dept. Physiol. & Biophys., New York Univ. Med. Ctr., 550 First Ave., New York, NY 10016.

Electrical excitability of Purkinje cell dendrites in the molecular layer of the cerebellar cortex in rats was studied after blockage of potential-dependent Na^+ conductance with tetrodotoxin (TTX, 10^{-5}) and potential-dependent K^+ conductance with 3-aminopyridine (3-AmP, 5 x 10^{-3} M). The drugs were applied by superfusion utilizing a push-pull cannula kept in place by an agar dome which also served to stabilize the cerebellum. Following the application of the above drugs, no sign of field potentials generated by either local or white matter stimulation could be evoked. Thus, the parallel fiber field potential and the antidromic and orthodromic activation of the surface of the cerebellar cortex was absent.

As previously reported in pigeons (Llinás, R. and Hess, R.: *Proc. Natl. Acad. Sci. 73*, 2520-2523, 1976), intra- and extracellular recordings after TTX and 3-AmP indicate that the dendrites of Purkinje cells are capable of generating action potentials following either extracellular or direct electrical stimulation. In addition, activation could be obtained by extracellular iontophoretic injection of sodium glutamate from an electrode containing a 1M solution. Their overall properties were enhanced by increasing the Ca^{++} concentration in the superfusate to 2.5 mM. Finally, superfusion with $MnCl_2$ (10mM), which itself does not block either parallel fiber activity or the antidromic invasion of Purkinje cells, was shown to block the TTX— 3-AmP resistant dendritic electroresponsiveness. It is concluded that Purkinje cells in mammals can generate Ca^{++} spikes. Their possible role in functional modifiability will be discussed. (Supported by USPHS grant NS-13742 from NINCDS)

171 A DETAILED STUDY OF CLIMBING FIBER PROJECTIONS TO THE ANTERIOR FOLIA OF THE PARAMEDIAN LOBULE OF THE CEREBELLUM IN THE CAT. J.P. Lund, T.S. Miles* and J. Courville. Fac. Méd. Dent. and Centre Rech. Sci. Neurol., Univ. de Montréal, Canada.

Previous experiments have compared the somatotopy of cortical and peripheral inputs to the cerebellar cortex via climbing fibers (CF). The majority of single CFs in the anterior lobe respond to both inputs (Allen et al., Exp. Brain Res. 20: 255, 1974; Miles and Wiesendanger, J. Physiol. 245: 425, 1975), but a number appears to receive only a peripheral projection. In view of the fine somatotopic distribution of cerebro-cerebellar projections, this might be explained by an improperly located cortical stimulus. Alternatively, 2 or more populations of CFs to a given region might exist, some responding to the periphery alone, others to convergent inputs. In the present study, the analysis of the fine topography of cortical and peripheral CF inputs to a restricted region, the anterior folia of the paramedian lobule, was carried out in paralysed, nembutal-anesthetized cats. Penetrations were made at 200 μ intervals across folia a and b and the peripheral receptive fields of CFs were mapped. Responses to stimulation of the infra-orbital (I.O.) superficial radial (S.R.N.) and sciatic nerves of both sides were recorded as were those to stimulation of each of an array of 8 electrodes inserted into the pericruciate somatomotor cortex. CF responses to stimulation of one or more cortical sites were elicited in 96% of all Purkinje cells tested: 65% of those also received an input from the periphery, but 31% did not. Only 4% could not be excited from the cortex, probably because no electrode was placed in the region projecting to them. The majority of neurones had small tactile receptive fields on the ipsilateral forelimb. The hindlimb was also represented. CFs responded to stimulation of peripheral nerves at a characteristic latency. The majority fired at short latency (16-34 msec), others fired at short and long latency (120-250 msec) and a few, only at long latency. Those firing at long latency rarely had a peripheral receptive field. A clear correlation was observed between the cortical and peripheral sites projecting through a CF. 78% of all CFs had a cortical best point which received an input from the same region of the periphery from which the CF was also excited. It would appear that all CFs to this region of the cerebellum receive an input from the somatomotor cortex. When present, the sensory receptive field of these CFs is on that part of the body which would move in response to a motor command from the same region of cortex.

172 THE NUCLEUS OF THE PONTOBULBAR BODY. A SEPARATE PRECEREBELLAR NUCLEUS? George F. Martin and J.M. Walker, Depts. of Anat. and Psychol., The Ohio State Univ., Columbus, Ohio, 43210.

The nucleus of the pontobulbar body (PBu) is situated along the migration route of neurons from the rhombic lip of the fourth ventricle to the basilar pons. Partly because the basilar pons is formed from that migration, the PBu is often included as part of the pontine grey.

It appears from material in our laboratory, however, that the opossum PBu is not simply a remnant of the pontobulbar migration, but that it has afferent connections which are highly organized and different from those of the basilar pons proper. Although the PBu has an input from the face motor-sensory cortex, like the pontine nuclei, it also receives projections from the red nucleus and spinal cord, regions which generally are not considered as sources for afferent projections to the pons. The PBu also receives a small input from the cerebellum. There is overlap of these projections within the PBu, although they each tend to have their own sphere of influence. A parallel finding is that PBu neurons contain reaction product after horseradish peroxidase injections into many areas of the cerebellar cortex. Although there is some topography to the PBu-cerebellar projection, it is not sharply defined.

Taken together such evidence suggests that, in the opossum at least, the PBu is as different from the basilar pons as either the reticulotegmental or lateral reticular nuclei and that it deserves to be set off from the basilar pons as a precerebellar cell station in its own right. Certainly its position along the pontobulbar migration should not be used as evidence against such a designation.

173 OPERANTLY CONDITIONED SACCADIC EYE MOVEMENTS AND CEREBELLAR UNIT ACTIVITY IN THE CAT. J.G. McElligott and L.E. Mays. Dept. of Pharm., Temple Univ. Medical School, Phila., Pa. 19140.

Cerebellar neuronal activity from the posterior vermis (lobes VI and VII) was recorded in 2 cats that were trained to make precise saccadic eye movements. These animals were fitted with an ocular magnetic search coil in order to record horizontal and vertical eye movements, and absolute eye position. With it's head restrained, each cat was placed 70 cm in front of a square matrix array (10 x 10) of green light emitting diodes mounted on an opaque black board. Each trial was initiated by the sound of a buzzer. A center light came on and the animals were trained to fixate on it for 0.75 sec. Subsequently, a second light appeared randomly in any of the four directions (up, down, right or left). The animals were required to make a saccadic eye movement to this second light and fixate on it for 0.75 sec in order to obtain a milk reward. Thus, the task allowed us to dictate absolute start position, amplitude, and direction of the saccade. Cats were trained to generate from 200 to 300 correct responses per daily session. They would produce saccades with an average latency of 180 msec and an accuracy of about 1°. Forty-two cells were comprehensively analyzed with respect to sensory (auditory and visual) and oculomotor aspects of this task. Twenty-six percent of these neurons produced increases or decreases (latency=40 msec) in background activity that were related to sensory stimulation. The vast majority of these sensory related neurons (82%, n=9) produced increases in firing rates (duration=50 msec) after auditory stimulation (buzzer sound). Saccadic related neurons (24%, n=10) were intermingled with these sensory related neurons. These produced increases and/or decreases in background activity that were either related to one or more than one direction of movement. Furthermore, these short phasic changes could occur either before, during or after the initiation of a saccade. This is in agreement with our previously reported results for spontaneous saccadic eye movements (Soc. Neurosci. 6 #174, 1976). In addition, half of these eye movement related neurons manifested changes in tonic firing rates (increases or decreases) that were related to eye position during fixation. Finally, a small percentage of these neurons (5%, n=2) are related to both sensory and motor aspects of the task.

174 THE INFERIOR OLIVARY COMPLEX IN THE RAT: GROSS NUCLEAR ORGANIZATION AND TOPOGRAPHY OF OLIVOCEREBELLAR PROJECTIONS. M. K. McGrane*, D. J. Woodward, M. A. Eriksson, R. A. Burne, and J. A. Saint-Cyr. Dept. Cell Bio., Univ. Tx. Health Sci. Ctr., Dallas, Tx. 75235.

This study was carried out to evaluate the topographic organization in the rat of cerebellar afferent information relayed via the inferior olivary complex to the cerebellum. Examination of a detailed series of coronal sections stained with routine cytological methods, the use of retrograde transport of horseradish peroxidase (HRP) and antrograde transport of tritiated amino acids are being employed in this investigation.

Initial studies were undertaken to determine the anatomical interrelationships of the cell groups constituting the inferior olivary nucleus (IO) of the rat. Serial coronal sections of IO stained with cresyl echt violet were examined by light and dark field microscopy and sections drawn by means of camera lucida. Three major discrete olivary subnuclei were noted including: 1) the principle olivary nucleus (PO) with a dorsal and a ventral lamella (DL and VL); 2) the medial accessory olivary nucleus (MAO), and 3) the dorsal accessory olivary nucleus (DAO). Five minor subnuclei were noted including the β nucleus (β), the dorsomedial cell column (DMCC) of the MAO, the ventrolateral outgrowth of Kooy (VLO), the dorsal cap of Kooy (DC), and a dorsal cell column (DCC) dorsally and medially to the medial accessory olive. Two unusual observations were: 1) just caudal to the dorsal and ventral lamellae the ventrolateral aspects of the DAO and MAO were found to fuse near the ventral surface of the medulla; and 2) the DAO at its most caudal extent folds over on itself dorsally and medially at its lateral edge to form what we designate as the "dorsal fold". The bulk of the olivary complex can be conceived of as a continuous sheet consisting at various levels of five distinct layers. The MAO is continuous medially with the VL; the VL laterally with the DL; the DL dorsomedially with the DAO, and the DAO laterally with the dorsal fold of the DAO at its caudal extent.

An evaluation of the localization of olivocerebellar projections by HRP injections into various cerebellar lobules indicated the following: 1) the lateral lobules of the cerebellum receive fibers from the rostral half of the PO, MAO, and DAO; 2) the anterior cerebellar vermis receives projections from the caudolateral regions of the MAO and the dorsal fold of the DAO; while 3) posterior vermis receives from the caudomedial MAO and β nucleus. The gross organization is that rostral and caudal olive project to lateral and midline cerebellum, respectively, but with specific olivary zones highly related to discrete areas in the cerebellum.

175 IN VITRO STUDIES OF INTERACTIONS AND SURVIVAL OF CEREBELLAR CELLS FROM STAGGERER VS. WILD-TYPE MICE. Anne Messer and Mary E. Hatten,* Dept. Neuropathology, Harvard Medical School, Boston, Ma. 02115

A distinction must be made between genetic factors intrinsic and extrinsic to a specific degenerating cell type if neurological mutants that show such effects are to be used to assess cause-and-effect correlations of neural development. When the growth of granule cells from cerebella of staggerer (sg/sg) mutant mice is investigated in monolayer cell cultures using modified Hams F12 medium plus fetal calf serum, cells from the mutant are found to clump less and survive longer than their wild-type counterparts. Thus, the degeneration of granule cells observed in these mutants in vivo cannot be a function of irreversibly programmed cell death before postnatal day 7, the age at which cells are dissociated (Messer & Smith, Brain Res., in press).

The possibility that the increased survival is a function of cell-cell interactions is examined in two systems. In one, normal cells grown on glass, plastic, or polylysine-coated glass are compared to each other, and then the behavior of sg/sg vs. control cells are compared under the same conditions. Although the polylysine coating both reduces the amount of initial clumping and increases the survival of normal cells, it does not completely eliminate the difference between mutant and control. Mutant and control cultures exhibit the same behavior only when culture conditions are changed to include supplementation with horse serum instead of fetal calf serum in addition to the substrate coating.

A second, more direct test of cell surface differences, uses the agglutinins Concanavalin A, ricinus communus and wheat germ agglutinin (WGA). It shows that while WGA causes dissociated postnatal day 7 sg/sg cells to agglutinate, there is no such effect on control cells using any of these lectins, or on mutant cells with the first two. Thus, there must be some specific cell surface differences between sg/sg cerebellar cells and their controls.

176 THE BASILAR PONTINE GRAY IN THE RAT: AN INITIAL LOOK AT ITS CYTOLOGY AND SYNAPTIC ORGANIZATION. Gregory A. Mihailoff. Dept. Cell Biology, Univ. of Texas Hlth. Sci. Ctr. at Dallas, Dallas, Texas 75235.

Cytoarchitectonic analysis of Nissl-stained, transverse sections of the basilar pontine nuclei in the adult rat reveals the presence of five major divisions named with respect to the longitudinally directed fiber bundles comprising the cerebral peduncle. These include medial, ventral, lateral, dorsal, and peduncular nuclei. An apparent increase in cell-packing density as compared to the opossum (Mihailoff and King, J. Comp. Neur. 159: 521-552, 1975) and cat (Brodal and Jansen, J. Comp. Neur. 84: 31-118, 1946) may account for the difficulty in defining certain other smaller subnuclei such as the median and dorsolateral groups reported in the aforementioned studies in the opossum and cat.

Observations on the form of individual neurons in the pontine gray of the adult rat as demonstrated in Golgi-Kopsch prepared material suggest the presence of two general classes of cells; a projection neuron whose axon presumably terminates in the cerebellar cortex as a mossy fiber and an intrinsic cell whose processes ramify exclusively within the pontine gray. These results are in agreement with the previously cited study in the opossum as well as those in the mouse (Cajal, Histologie du Systeme Nerveux, p. 962, 1906). One interesting difference, however, is that in the rat, characteristics such as numbers of dendritic spines, the frequency of dendritic branching and the length of individual dendrites are quite variable within the general category of projection cells and seem to justify the designation of at least two sub-populations of such neurons.

Electron microscopic examination of rat pontine gray neuropil in aldehyde perfused control brains suggests the presence of at least two types of neuronal somata, one variety exhibiting a smooth contoured nucleus, the other, a highly involuted nucleus. Three general categories of presynaptic profiles can be distinquished and include those containing either round, flattened or pleomorphic synaptic vesicles. The relationship of such vesicle-containing profiles to known basilar pontine afferents and intrinsic elements will be discussed in the context of their role in pontine gray synaptic organization.

177 RUBROBULBAR PROJECTIONS IN THE TREE SHREW (TUPAIA). Heather M. Murray. Dept. Anat., Univ. of New Mexico Sch. Med., Albuquerque, NM 87131.

Radio-frequency lesions were stereotaxically placed in the red nucleus of 16 adult tree shrews. After 4-7 days, the animals were perfused with 10% formalin and brain tissue was stained for light microscopy by the Fink-Heimer method. Cresyl violet acetate was used to stain alternating serial sections for morphological analysis. Degenerating axons from lesions in the caudal two-thirds of the red nucleus were traced across the midline to the ventrolateral border of the contralateral brain stem. Fibers of passage and preterminal degeneration were distributed to the chief sensory nucleus of the trigeminal nerve, medial portions of the spinal nucleus of the trigeminal nerve, lateral areas of the facial nucleus and of the lateral reticular nucleus, and also to a small group of cells presumed to be group f of the inferior vestibular nucleus. Degeneration at the level of the lateral cuneate nucleus extended into areas presumed to be Groups X and Z, and ventrolateral areas of the cuneate and gracile nuclei. Ipsilateral to these lesions a few fibers of passage and a slight amount of preterminal debris was found in the facial nucleus. Lesions that involved the reticular formation surrounding the red nucleus produced relatively large amounts of degeneration in the pontine and medullary reticular formation and also within dorsomedial areas of the facial nucleus contralateral to the lesion. Ipsilaterally, these lesions produced only slight to moderate amounts of degeneration. Lesions that involved only the rostral one-quarter or rostral pole of the red nucleus gave rise to no degeneration in the areas receiving projections from the caudal two-thirds of the red nucleus. (Supported by GRS grant 5 S07 RR 05583-12).

178 NEURONAL AND GLIAL ELEMENTS OF CEREBELLUM VISUALIZED WITH NEW INTRACELLULAR STAIN. C. Nicholson, S. B. Kater, and W. Stewart*. Dept. Physiol. & Biophys., N.Y. Univ. Med. Ctr., New York, NY 10016; Dept. Zool., Univ. Iowa, Iowa City, IA 52242; and NIH, Bethesda, MD 20014

Intracellular staining, using stain ejected from a micropipette directly into a cell, has become a powerful tool for revealing cellular geometry. The most successful stains have been the reactive fluorescent dye, Procion yellow, the metal salt, cobaltous chloride and the protein, horseradish peroxidase. We report the use of a new fluorescent dye, Lucifer yellow, to stain elements of the rat cerebellum.

Rats were anesthetized with urethane and the cerebellum exposed. Micropipettes contained a 3% aqueous solution of Lucifer yellow CHL (resistance of 50-100 MΩ). When a cellular element was penetrated and showed a stable resting potential stain was injected with a negative current of 10-50 nA for 0.5-10 minutes. Some cells gave injury discharges on penetration, indicating that they were neurons, others had high negative (-70 to -80 mV) resting potentials and no discharge, suggestive of glia. At the end of the experiments, (duration about 4 hours), animals were perfused with a 4% solution of formaldehyde and frozen sections cut at 50-100 μm. Sections were dehydrated, mounted in Entellan and viewed under a fluorescent microscope (excitation filter, Schott BG 12, barrier filter 470 nm cutoff).

Purkinje cell dendrites and somata appeared to stain completely, including spines; axons were occasionally seen. Golgi and Basket cells were stained, including both dendrites and axonal plexi. The profiles of these three neurons resembled the classical Golgi stain except that Lucifer yellow gave a more delicate appearance. Numerous glial elements were visualized. Glia stained incompletely and seemed to be composed of many fine filamentous structures, differing from typical Golgi representations. Thus Lucifer yellow migrates more extensively in neurons as compared to glia.

We believe that Lucifer yellow is superior to Procion in its ability to more completely impregnate cellular elements; this may be due to its greatly increased visibility. Like Procion, however, Lucifer yellow will fade on prolonged exposure to a high intensity light source. Unlike cobalt, horseradish peroxidase or the classical Golgi stain, Lucifer yellow does not involve the formation of an intracellular precipitate and thus may yield a more accurate representation of fine structure. 179 PROCESSING OF EYE MOVEMENT SIGNALS IN MONKEY FLOCCULUS. Hiroharu Noda (SPON: S. Hagiwara). Brain Research Institute, Depts. Physiol. Anat., Sch. Med., UCLA, Los Angeles, CA 90024.

In the flocculus of the monkey, discharges of Purkinje cells (P-cells), interneurons, and afferent fibers were compared during saccadic and tracking eye movements, and during steady fixation. As previously reported, the typical behavior of P-cells during a saccade was complete cessation of firing, starting 10-15 msec prior to the saccade (1). During a period of silence in P-cells, interneurons showed a burst of spikes and mossy fiber units showed two types of behaviors. One class of fiber units started a burst 10-20 msec before a saccade, showing peak activity at the beginning of the saccade. The other class of fiber units showed a gradually increasing activity starting 100-200 msec before the saccade, and this long lasting burst reached peak activity at the beginning of the saccade.

During steady eye position, the discharge rate of some P-cells was clearly a linear function of eye position (1). This type of linear relationship was also found in some interneurons and mossy fibers. However, in most units this linearity was limited to only a part of the range of eye positions, and the firing either completely disappeared or reached a maximal rate when the eyes shifted outside this part of the total range. These differences in activity between P-cells and their input cells indicate the manner by which eye movement signals are processed within the flocculus. (Supported by NIH Grant EY01051)

180 ANALYSIS OF ANURAN VESTIBULO-CEREBELLAR CONTROL BY COMPUTER MODELING. A. Pellionisz and R. Llinas. Dept. Physiol. & Biophys., N. Y. Univ. Med. Ctr., 550 First Ave., New York, NY 10016.

A software computer model was developed as a self-consistent framework to study global functional properties of the vestibulocerebellar system of frog. The model was based on existing morphological and physiological data from the vestibular system and the cerebellum. For the latter the neuronal circuitry, as well as the particular functional properties of cells, was implemented. The actual detailed activity of given cells was simulated by means of a multicompartmental model using Hodgkin-Huxley parameters for each compartment. A previous study (Pellionisz, Llinas & Perkel: *Neuroscience 2:* 19-35, 1977) modeled the anuran cerebellar cortex and gave us a first order description of the spatial distribution of neuronal activity produced by inputs through particular sets of mossy fibers

In the present study the physiological activation of the peripheral vestibular system was simulated. This input was projected onto a model vestibular nucleus and cerebellar cortex. At the cortex the spatial organization of the Purkinje cells activated by different kinds of rotation (pitch, roll and yaw) was displayed. The overall distribution of the activity in these modeled neurons suggests that much of the functional specificity found in this cortex does not require specific connectivity. Rather, it seems to be related to the location of the mossy fiber input with respect to the granular layer and in particular with its location in the cerebellar peduncle. These properties, such as spatial distribution of Purkinje cell thresholds and dynamic responsiveness of these cells to tonic and phasic inputs, were displayed and analyzed by the model. The study suggests that such patterns of activity may in fact represent emergent properties inherent in the morphological organization of the circuit. The output of the cortex was utilized as a closed loop control system in the modulation of limb movement. This type of modeling must be considered, therefore, as an heuristic tool which can provide an independent test for many of the neuronal circuit hypotheses which are constantly being postulated in neurobiology. (Supported by USPHS grant NS-13742 from NINCDS)

181 ACTIVITY RELATED TO THE ELECTRIC ORGAN DISCHARGE IN THE CEREBELLUM OF A MORMYRID FISH. C. J. Russell and C. C. Bell, Neurological Sciences Institute, Good Samaritan Hospital, Portland, Oregon 97210.

Extracellular recording throughout the valvula cerebelli of Gnathonemus petersii reveals occasional afferents which fire in relation to the electric organ discharge command signal. But in most regions, units in the valvular ridge (Purkinje cell area) only rarely exhibit strong relationships to this signal. In one area, however, the discharge of afferents in relation to the command is very prominent, indicating strong and synchronous activation. Furthermore, unitary and other activity in these valvular ridges is strongly related both to the command and to electrical stimulation of the electroreceptor surface. This area appears to be quite restricted, and possibly comprises only one or two ridges in the ventral portion of the valvula.

The afferent volley following the command occurs about 15-20 msec after the command signal recorded from the tail in curarized preparations. The volley is accompanied by a field potential which is negative with respect to the dorsal surface of the valvula. This potential reverses polarity as the recording electrode is moved from the granule cell area into the ridge. Units in the ridge have been observed to be excited at the time of the afferent volley, inhibited at the time of the volley, inhibited for a period following the volley, or excited for a period following the volley. A type of activity which is highly variable in waveform, with predominantly low frequency components, occurs from 40-80 msec following the command signal. This activity is reminiscent of dendritic spikes or of climbing fiber activity.

Units respond to electrical stimulation of the skin with thresholds similar to those of Mormyromast receptors. When such stimuli are given during the time when electroreceptors would normally be activated by the electric organ discharge the responses interact with the command-related activity. This interaction has been observed to take the form of inhibition, excitation, or change in the time course of the response. The time course of the responses to both command and to external stimuli, the response thresholds to external stimuli, and the nature of the interactions all suggest that this area of the valvula is related to the processing of electrosensory information arriving via Mormyromast afferents and is thus related to electrolocation. The fact that the area in which these responses are found is so restricted indicates that the valvula is also functionally quite diverse. (Supported by NIH (NINCDS-06728) and NSF (BMS73-06867))

182 MICROGEOMETRY OF CEREBELLAR CORTICONUCLEAR PROJECTION IN THE PIGEON. Dietrich W.F. Schwarz and Stuart Wood*. Depts. Otolaryngology and Anatomy, Univ. of Toronto Toronto, Ontario, Canada.

Previous evidence indicates that Purkinje cells (PC) within longitudinal sagitally oriented stripes of cerebellar cortex project onto distinct cerebellar nuclear regions. If this pattern were to hold for the geometrical arrangement of PC projection onto single nuclear cells it would be difficult to conceive how the information mediated by parallel fibers through transversally oriented rows of PC could be utilized at postcerebellar levels. We studied the geometrical layout of the PC projection to small nuclear zones. Small horseradish peroxidase injections into the cerebellar nuclei of pigeons were achieved by means of an electrophoretic deposition technique via recording microelectrodes. As a result relatively small numbers (50-450) of PC were found labelled in serial sagittal frozen sections of the cerebellum. The location of these PC was precisely charted on maps which represent the cerebellum as one flat sheet of tissue with the folia imagined unfolded. A strong tendency for labelled PC to be arrayed transversally, i.e. in the direction of parallel fibers, is evident on these maps as shown on our poster. It is concluded that the known longitudinal arrangement of the cortico-nuclear projection merely represents a gross anatomical structurization, whereas the finer convergence pattern is organized transversally.

183 FRACTURED SOMATOTOPY OF MINIATURIZED PATCH-LIKE MOSAICS IN GRANULE CELL TACTILE AREAS OF RAT POSTERIOR CEREBELLUM AS REVEALED BY MICROMAPPING. Georgia M. Shambes, Jon W. Joseph*, John M. Gibson, and Wally Welker. Department of Neurophysiology, Univ. of Wisconsin, Madison, WI 53706.

We have discovered somatic sensory receiving areas in the caudal cerebellum previously unknown in any mammal. Patterns of tactile projections to granule cell (GC) layer in cortex of posterior cerebellum (hemispheres and vermis) in 40 anesthetized albino rats were defined using tungsten micromapping techniques. We found four distinct relatively short latency GC tactile areas. Multiple unit responses were evoked by threshold natural stimulation of cutaneous tissues. Data were obtained from 1430 recording locations. Peripheral projections terminate within columnar assemblies of granule cells. These columnar inputs appear as individuated patches or tiles of different sizes and shapes with major axes ranging from less than 500 μm up to 1500 μm. The overall array of adjacent columnar patches in each area collectively make up a mosaic. Somatotopic organization within each single patch is highly specific, whereas somatotopy is fractured or disjunctive from patch to patch within the mosaic. Electrode densities as high as 75/mm^2 were required to delineate the fine grained features of the projections within patches. Each patch of the mosaic receives input from a definable type of cutaneous structure or region. The fact that adjacent patches receive inputs from body structures that often are used together in discriminative or instinctive behaviors suggests that particular patterns of contiguity of the patches within a mosaic may constitute a neural substrate for such act sequences. Our data support Snider's early contention that tactile projections, rather than proprioceptive inputs alone, play an important role in cerebellar sensori-motor functions. These findings necessitate re-examination of several current views regarding afferent, efferent and intra-cerebellar circuits and their functions. (Supported by NSF grant BMS 75-08124 and by USPHS grants NS06225 and NS07026.)

184 VISUAL MESSAGE UNITS OF THE RABBIT CEREBELLAR FLOCCULUS. John I. Simpson and Rainer Hess, Dept. of Physiol. & Biophys., NYU Med. Sch., N.Y., N.Y. 10016 and Neurobiol. Sec., Max-Planck-Inst. for Biophys. Chem., Goettingen, W. Germany.

Previous investigation of the visual messages of the cerebellar flocculus has focused on the climbing fiber (CF) input evoked from the ipsilateral eye. We now report on some of the visual responses of other types of neuronal elements in the flocculus. Experiments were performed in anesthetized, immobilized rabbits. Extracellular unit recordings were made primarily from that portion of the flocculus which receives both mossy fiber and CF visual inputs. Visual stimuli consisted of a large field Julesz pattern moving with various velocity step profiles. Purkinje cell CF activity modulated by stimuli presented to the contralateral eye showed direction and speed selectivity. Optimal speed was about 1°/sec., as found previously for CF's driven from the ipsilateral eye. Contralaterally driven CF's were most strongly activated by movement in a direction ± 30° from vertically downward. This preferred direction differs from those found for ipsilaterally driven CF's. In cases where both CF and simple spike (SS) responses of a Purkinje cell were modulated by stimuli presented to one eye, the changes in their respective activity were oppositely directed, but with different time courses. In response to a velocity step of a few degrees/sec. the change in CF activity consisted of an initial transient overshoot (peak latency about 0.5 sec.) followed by a return to a plateau level. In contrast, the SS activity gradually changed over 1-2 sec. to reach a plateau level. Modulation of the Purkinje cell SS response in opposite direction to that of the CF response could be found in floccular areas in which only CF field potentials were evoked by flash stimuli. This observation is consistent with the disfacilitatory effect on Purkinje cells of the CF collateral projection to Golgi cells. The reduction in SS activity associated with an increase in CF activity was not manifested as a specific silent period following each CF response. Integration and differentiation of the velocity profile of the visual stimuli are reflected in the response profile of some floccular units. An example of a (saturated) integration is present in response profiles showing that the rate of change of firing frequency but not the final plateau level is related to the stimulus speed. An example of a (double) differentiation is present in response profiles showing that the 'edge' of a velocity step is enhanced by an activity pattern similar in form to a Mach band. A question of interest is to what extent are these integral and differential operations dependent upon cerebellar cortical circuitry? (Supported by USPHS grant NS-13742 from NINCDS).

185 TOPOGRAPHICAL ORGANIZATION OF DENTATE AND INTERPOSITUS PROJECTIONS TO THE THALAMUS IN DOG AND CAT. G. B. Stanton.* (Sponsor: Duke Tanaka, Jr.), Department of Anatomy, College of Medicine, Howard University, Washington, D. C. (20059).

Studies of cerebellofugal fibers in the monkey have indicated a topographical organization of projections to the thalamus from the dentate and interpositus anterior nuclei with a distinct difference in the mediolateral distribution of terminals from each nucleus (Stanton, '77). The results of the present study suggest that the dentatothalamic and interpositothalamic projections in the dog and cat display a similar organization. Discrete lesions and/or localized isotope injections were placed in the dentate and interpositus nuclei of the dog and cat. In some cases these were combined with horseradish peroxidase injections in the ipsilateral motor cortex. Degenerating axons and axon terminals were stained with a modified Wiitanen technique. Lesions of the dentate nucleus in the dog produce 3-5 patches of preterminal degeneration paralleling the internal medullary lamina in the medial part of VL. Ventral parts of the dentate project heavily to the dorsal arch of the VA-VL complex and the dorsal parts project mainly to centrolmedial regions of VL. These results suggest an inverted projection from the dors oventral axis of the dentate to the thalamus as is the case in the monkey. Projections from the interpositus anterior to the thalamus in the dog are less abundant than those from the dentate and more restricted in the anterior-posterior plane. Interpositus anterior projections terminated ventral and lateral to the projections from the dentate in the middle third of VL. The patchy distribution of interpositus terminals in the middle third of VL was similar in the cat as seen with autoradiographic techniques. These results will be related to a possible somatotopic organization of the dentate and interposed nuclei. This investigation was supported by the General Research Support Grant No. 5 S01 RR 05361 from the General Research Support Branch, Division of Research Resources, National Institutes of Health.

186 STAGGERER MUTANT MICE AND NORMAL LITTERMATES EXPRESS DIFFERENT CARBOHYDRATES ON POSTNATAL CEREBELLAR CELLS. E. Trenkner*, K. Herrup, M. E. Hatten*, and S. Sarkar. Dept. Neuropath., Harvard Med. Sch., Boston, Ma. 02115, Div. Med. Genetics, Dept. Med. M-013, Sch. Med. UCSD, La Jolla, Ca. 92093. Several anti-carbohydrate antibodies have been shown to inhibit reversibly nervefiber outgrowth by early postnatal and embryonic cerebellar cells in microwell cultures (1, 2), demonstrating that embryonic and postnatal tissue expresses different carbohydrate moieties. In the current study an anti 1 6 mannan antibody (against yeast) and an anti sialic acid antibody (against Neisseria meningitidis type B) (2) were used to probe cell surface carbohydrates of cerebellar cells from C57B/6 staggerer (sg) mutant mice as compared with their normal littermates. Anti 1-- 6 mannan antibody inhibited in vitro fiber outgrowth between reaggregated clusters of cells from normal 7 day old (P7) cerebellum, but not by cells from P7 sg cerebellum. In cryostat sections, FITC-conjugated anti 1-- 6 mannan antibody stained granule cells of both external and internal granule layers and Purkinje cell bodies of normal P7 cerebellum, but no staining was observed in sections of P7 sg cerbellum. Anti 1-- 6 mannan antibody, therefore, recognizes a mannoside-containing component of normal but not sg cerebellum. Anti sialic acid antibody gave a different reaction. No inhibition of in vitro fiber outgrowth in microwell cultures was observed with P7 cerebellar cells treated with this antiserum (2). However, fiber outgrowth was inhibited in microwell cultures of both embryonic day 13 normal cerebellar cells and P7 sg cells. In addition, whereas postnatal days 13 to 15 cryostat section of normal cerebellum were not labeled with FITC-conjugated anti sialic acid antibody, cryostat sections from postnatal day 13-15 sg cerebellum were heavily labelled. Both the inhibition of fiber outgrowth in vitro and the fluorescent labelling in cryostat sections was blocked specifically by N. meningitidis type B polysaccharide (a sialic acid polymer). The anti sialic antibody, therefore, appears to probe a sialic acid-containing moiety present on normal embryonic and postnatal sg cerebellar cells, but not on normal postnatal cells. These results are in agreement with similar studies performed with plant lectins (3) and suggest that postnatal staggerer cerebellar cells differ from normal cells of the same age with respect to at least two cell surface characteristics.

CEREBRAL CORTEX

187 LONG RANGE ORDER IN CEREBRAL MACROMOLECULES SUGGESTED BY ELF, VHF and UHF FIELD EFFECTS ON CALCIUM BINDING. W. Ross Adey and Suzanne M. Bawin*. Brain Res. Inst., Sch. Med., UCLA, Los Angeles, CA 90024.

Chemical interactions at specific amplitudes and frequencies of weak imposed electromagnetic fields may arise in cooperative processes involving long range order between charge sites on transductive macromolecules at membrane surfaces. In a search for long range order in anionic binding sites on cell surface macromolecules, we have used ELF fields in the range 1 to 100 Hz, VHF fields at 147 MHz amplitude modulated at frequencies from 1 to 30 Hz, and 450 MHz UHF fields also amplitude modulated at frequencies from 1 to 30 Hz. We have found a series of amplitude and frequency "windows" that strongly suggest resonant interactions based on long range order. ELF fields between 6 and 20 Hz reduced $^{45}Ca^{2+}$ efflux from chick and cat forebrain tissue by about 15%, with a maximum effect for fields in air at 10 and 56 V/m. Effects were insignificant at 5 and 100 V/m. Isolated chick cerebral tissue was also exposed to a 147 MHz field, 0.8 mw/cm^2 and amplitude modulated at frequencies from 0.5 to 35 Hz. There was a frequency "window" for increased efflux (15%) at modulating frequencies from 9 to 20 Hz. We have varied the intensity of a 450 MHz field, amplitude modulated at 16 Hz, from 0.1 to 5 mw/cm^2. There was an amplitude "window" for increased calcium efflux between 0.375 and 1.0 mw/cm^2. We hypothesize that membrane surface charge sites behave "coherently" over a considerable area, and that a coherent patch may be triggered to change state by a very weak trigger at one point. This trigger event may involve proton tunneling at the boundary of such a patch.

Supported by Contract N00014-69-A-0200-4037 ONR, Contract NIEHS N00014-76-C-0421, and Contract BRH 2 R01 FD 678-02.

188 OBSERVATIONS ON PYRAMIDAL CELLS OF REGIONS CA3 AND CA4 IN THE HIPPOCAMPUS OF REELER MICE. T.V.P. Bliss*, M.L. Errington* and R. Victoria Stirling*. (SPON: J. Dostrovsky). Nat. Inst. Med. Res., London, NW7 1AA.

The morphology, ultrastructure and pattern of afferent and efferent connections of pyramidal cells in regions homologous to CA3 and CA4 of the normal mouse have been examined in reeler littermates.

Morphology. Observations on Golgi impregnated material show that CA3 cells in reeler have a roughly normal pattern of dendritic arborization despite abnormalities in cell position. CA4 cells in reeler are widely scattered among the granule cells which occupy the hilar region, as shown in Golgi material and by retrograde transport of HRP injected into the contralateral hippocampus. Dendrites of CA4 cells which in the normal animal are confined to the hilus of the dentate gyrus, in reeler assume a stellate configuration with dendrites extending into the granular layer, and in some cases penetrating through the molecular layer to the pial surface. The dendritic excrescences receiving mossy fibre terminations in both CA3 and CA4 pyramids are limited in both reeler and normal animals to the proximal third of the dendritic tree.

Ultrastructure. In the hilar region of both reelers and normal littermates characteristic mossy fibre synaptic profiles are seen in the EM. In reeler, mossy fibre terminals have also been found in the supragranular part of the molecular layer.

Distribution of afferent and efferent fibres. The terminal field of the mossy fibre input to CA3 and CA4 cells was visualised using the Timm's staining method. In reeler, the densely staining mossy fibre band is expanded to accomodate the spread of CA3 cells. In Golgi material, mossy fibres in reeler mice are sometimes seen meandering in the supragranular region before exiting from the hilus. These axons and their terminals are visible in Timm's sections as dense supragranular clumps. Commissural projections were studied using the HRP technique. Injections of HRP into subfields CA3 or CA4 of both normal and reeler mice resulted in retrograde transport to pyramidal cells in contralateral CA3 and CA4 respectively.

These observations demonstrate that pyramidal cells in reeler mice, despite their abnormal locations, are interconnected via the commissural system in a normal manner. The results also emphasize that the position of target cells is a determining factor in the location of mossy fibre terminals.

189 MORPHOMETRIC AND FUNCTIONAL STUDIES ON EFFECTS OF 200 RADS CO-60 PRENATAL RADIATION ON THE BRAIN AND BEHAVIOR OF SQUIRREL MONKEY OFFSPRING. Kenneth R. Brizzee, Neurobiology Department, Delta Primate Center, Covington, Louisiana 70433.

Abnormalities of the brain represent frequently cited radiation effects after prenatal exposure. Species differences in biological dose-response effects indicate that differential radiation effects on various regions of the brain are most likely verifiable in diurnal primates since they are of the same taxonomic order as man and encephalization of brain functions is comparable. The aims of these morphological and functional studies were to compare offspring prenatally exposed to 200 rads Cobalt-60 radiation with 6 matched controls on days 1 and 2 after birth on: 1) brain weight, cortical depth, neuron-glia populations and dendritic spines; 2) neuromuscular reflexes and behavior; 3) homeostatic regulation of temperature, respiration and heart rate.

Prenatal exposure to 200 rads Cobalt-60 resulted in a significant reduction in body weight, crown-rump length and head circumference in the 2-day old offspring. There was also a significant reduction in brain weight and cortical depth in the motor cortex. Examination of cortical areas indicated a significant change in neuron and glia cell populations. Examination of dendritic patterns in cortical regions indicated significant reductions in dendritic spine counts. Regarding neurological and behavioral tests, significant prenatal radiation effects were observed in righting, head-up orientation and tail hanging reflexes, and on climbing performance on an inclined plane. Prenatal radiation exposure resulted in a significant increase in the basal and activation range in homeostatic regulation of temperature, respiration and heart rate. From the morphometric and functional studies it was concluded that extrapolations concerning prenatal radiation effects on regional variations in brain vulnerability and behavioral impairments suspected in man are most likely verifiable in higher diurnal primates.

190 EFFECTS OF IMPLANTATION WITH VARIOUS TYPES OF SUBDURAL ELECTRODE ARRAYS. L.A.Bullara*, D.Jacques, R.H.Pudenz*, T.G.H.Yuen* and W.F.Agnew. Huntington Institute of Applied Medical Research, Pasadena, California.

The generally accepted procedure to fabricate electrode arrays for surface cortical stimulation is to imbed the electrodes in a silastic backing. This technique invariably leads to depression of the brain beneath the electrodes and the herniation of the brain around the periphery of the silastic disc. Extensive observations done at this and other laboratories consistently show this depression and herniation. Attempts to modify the silastic imbedding by using a thicker silastic backing to prevent buckling or thinner backing to allow conformation to the cortical surface have been unsuccessful. However, if the silastic material is eliminated altogether by supporting the electrodes on 9-0 nylon spokes significant reduction of the cortical depression and herniation have been observed. Supported by NINCDS contract No. NOS-NS-0-2275.

191 THE "CALLOSAL ZONE" IN THE FIRST AND SECOND SOMATOSENSORY AREAS OF THE CAT. Roberto Caminiti*, Giorgio M. Innocenti and Tullio Manzoni*. Institut d'Anatomie, Université de Lausanne, 1011 Lausanne, Switzerland, and Istituto di Fisiologia Umana, Università d'Ancona, Italy.

The regions of origin of callosal fibres (callosal zones cf. ref. 1) in the body representations in SI and SII of the cat were studied by retrograde transport of horseradish peroxidase (HRP). Two types of experiments were performed: a) Small, localized injections of HRP into SII, preceded by electrophysiological identification of the cutaneous district represented at the injection site. b) Multiple injections of HRP into areas SI and SII; in the same animals, in contralateral SI and SII, the position of HRP filled neurones (callosal neurones) relative to the somatotopic map was determined by electrophysiological recording of single units and electrode track reconstruction. For histological methods and data analysis see (2). It was found that the callosal zone in SI is discontinuous. A small, rather densely packed group of callosal neurones exists in the most anterior part of SI at the frontal end of the coronal sulcus (area 3a). Moving posteriorly along the coronal gyrus and up along the posterior sigmoid gyrus no callosal neurones are found until the middle portion of the latter gyrus. In SII callosal neurones are more widespread than in SI although their packing density is non homogeneous. In the anterior part of SI and in SII, callosal neurones are found in regions which contain a detailed representation of the distal part of contralateral forelimb. These neurones project to a part of SII where the distal part of the forelimb is represented. In both SI and SII most callosal neurones are in layer III, some in layers V and VI. In coronal sections, callosal neurones in SII appear arranged in clusters of irregular shape and distribution. Most callosal neurones are pyramidal; some are fusiform cells (layer VI) whose main dendrite can sometimes be traced to layer I; very few others are stellate cells. In layer III the average size of callosal neurones is significantly larger than that of neighbouring non callosal neurones. The extent and location of the callosal zones in SI and SII suggest that a transformation of the cortical somatosensory map takes place in the callosal message originating in these areas. The cortical regions of distal forelimb representation are not mute to the contralateral hemisphere.

192 BEHAVIORAL CORRELATES OF NEURONS IN RAT SENSORIMOTOR CORTEX. John K. Chapin and Donald J. Woodward. Univ. Tx. Health Sci. Cntr., Dallas, Texas 75235.

It is known in the rat that there is a considerable overlap between motor cortex (defined as the regions with lowest threshold for movement elicited by electrical stimulation) and somatosensory cortex (the regions which give unit or evoked responses at the lowest threshold of peripheral stimulation). This study considered the question of whether neurons of the sensorimotor cortex (SmC) fire exclusively in relation to sensation, to movement, or to combinations of both in the context of ongoing behavior. Single unit recordings were obtained with microelectrodes driven into the SmC's of unrestrained, behaving rats chronically implanted with a movable microdrive apparatus. Each unit was observed for a period of one to six hours while the animal was (1) at rest; (2) oriented or vigilant to the approach of the investigator's hand; (3) mechanically stimulated in somatosensory receptive fields; (4) undergoing manipulation of its limbs by the investigator; and (5) exhibiting spontaneous exploratory movements or forced treadmill running. Preliminary studies of over seventy cells suggest three general categories of units. Most numerous (60%) were the small (200-400uV) units of all layers which possessed large, variable, and vaguely defined somatosensory receptive fields, were responsive to the approach of a hand during vigilance, but fired in marked correlation with general behavior states such as running, exploration and rest. Responsiveness of such cells to somatic stimulation typically attenuated during movement. The second most commonly found (25%) category included the large (400-1000uV) units of the middle and deep layers which possessed a low resting discharge but fired strongly under appropriate conditions. Some of these cells responded specifically to somatic touch, a few of which were driven only when the limb was held at a particular position. In the rostral part of the SmC most large cells fired in response to passive manipulation of limbs and also to active movement of those limbs. In states of whole body motion the firing relation to movement of specific parts of the body became less apparent. The least commonly found category included the medium size (300-500uV) units of the middle layers of the more caudal SmC which exhibited very regular, constant, and clearly delimited somatosensory receptive fields. These characteristics were preserved during movement. This data suggests the concept that somatosensory information is available to almost all SmC cells but is utilized differentially depending on neuron type and on the behavioral state of the animal.

193 USE OF CORTICAL CIRCUITS DURING SEIZURES: AN AUTORADIOGRAPHIC STUDY WITH ^{14}C-DEOXYGLUCOSE. Robert C. Collins. Dept. Neurol., St. Louis, Mo. 63110

The injection of 25 units of penicillin into anterior motor cortex of rats in 0.1µl of CSF resulted in repetitive spike discharge for 90 minutes. ^{14}C-deoxyglucose autoradiography performed on animals with repetitive contralateral focal convulsions revealed a 2-3 x increase in glucose utilization in a distinct histological pattern in the cortex.

Immediately surrounding the injection there was metabolic activation of all cortical layers, with strict vertical borders on medial and lateral sides. The posterior third of the focus showed full activation of layers V & VI, with on-off columns extending into layer I. The focus ended in a single trailing column. Activation beyond the focus occurred ipsilaterally in 1-3 columns posterior and lateral to the focus in sensory cortex, and specific activation of Sm II above the rhinal fissure. The contralateral anterior motor cortex showed increased glucose utilization in deep layers (probably Vb & VI) with columnar patches in I-III. Throughout the cortex ipsilateral to the focus there was inhibition of normal activity in layer IV, and a more generalized depression of activity below control in all layers of cortex not specifically activated by the seizure.

Focal penicillin seizures result in an increase in glucose utilization in specific cortical circuits arranged in a columnar and laminar pattern, and in widespread decrease in glucose utilization in ipsilateral cortical areas around and beyond these circuits.

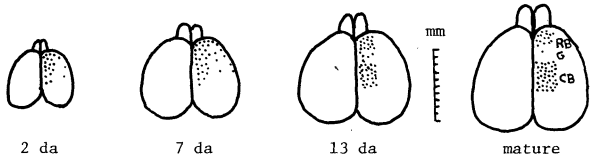
194 NORMAL AND POST-TRAUMATIC DEVELOPMENT OF CORTICOSPINAL NEURONS IN RAT STUDIED WITH HORSERADISH PEROXIDASE. Constance J. D'Amato and Samuel P. Hicks. Dept. Pathology, Univ. of Michigan Medical Center, Ann Arbor, MI 48109.

Corticospinal (CS) neurons in the mature rat labeled with HRP from their cut axons at cervical and lumbar cord levels are distributed in the dorsal cortex in a major caudal band, CB, and a minor rostral band, RB, separated by a gap, G, in which none or few neurons appear (see figures). CB overlaps Krieg's (1946) areas 3, 4, 6 and Hall's and Lindholm's (1974) forelimb to hindlimb motor areas. CS neurons labeled from cervical and lumbar levels are intermixed non-somatotopically in CB. RB, lying in area 10, can only be labeled from cervical cord (Hicks, D'Amato, 1977).

Labeling from cervical levels in rats 2, 4, 5, 7, 10, 13, 17, 21 days or later shows that CB and RB are continuous, the G regions containing many CS neurons, until about 13 days (see figures). After that they can no longer be labeled. Some CS neurons in the rostral medial cingular cortex as well as in cortex lateral to CB and RB can be labeled in the first week. The presence of neurons in G, medial, and lateral regions whose axons extend to the cervical cord only in infancy cannot be accounted for by the normal uneven growth of the cortex.

When the presumptive domain of CB is bilaterally ablated in early infancy, many CS neurons in the G region can be labeled from the cervical cord when the animal matures.

In the diagrams below, the distributions of CS neurons are represented by dots in outlines of fixed brains of normal rats of different ages. (USPHS NS 10531)



195 INFANTILE STIMULATION INDUCES BRAIN LATERALIZATION IN RATS. Victor H. Denenberg, James Garbanati*, Gordon Sherman*, David Yutzey* and Richard Kaplan*. Univ. of Connecticut, Storrs, Conn. 06268

During the first 20 days of life some rat litters were handled daily for 3 min while control litters were not disturbed. When weaned at 21 days half the litters within each group were placed by pairs into standard laboratory cages until Day 70 when all were isolated. The other litters were put into Hebb-type enriched environments until Day 50, then were housed by pairs in laboratory cages until Day 70, and were singly housed thereafter. When approximately 135 days old, rats within each of the 4 experimental treatment groups had (1) a left hemisphere neocortical ablation, (2) a right hemisphere neocortical ablation, (3) a sham operation, or (4) were not distrubed. When 165 days old, all animals were tested for 3 min in the open field for 4 successive days, and their activity recorded.

The activity scores of shams and controls did not differ and their data were pooled. The Handling and the Enriched Environment variables interacted significantly with the Brain Lesion variable. For animals not handled in infancy, regardless of postweaning experience, a cortical ablation in either hemisphere resulted in an increase in activity. In handled animals, ablating the left brain did not affect activity. However, the right brain lesion had complex effects: handled rats reared in laboratory cages after weaning with their right brains ablated were the most active group of all, while handled rats who had had enriched environmental experience after weaning and then had their right brains removed were the least active group.

These findings suggest that, in the rat, handling in infancy results in hemispheric asymmetry of brain organization in adulthood.

196 ORGANIZATION OF THE THALAMIC PROJECTIONS TO THE AUDITORY CORTEX IN GALAGO SENEGALENSIS. D. Fitzpatrick*, D. Raczkowski*, R. J. Ravizza and I. T. Diamond. Dept. Psychol., Duke University, Durham, NC 27706, and Dept. Psychol., Pennsylvania State University, University Park, PA 16802.

In our continuing investigation of the sensory pathways in the prosimian primate, Galago senegalensis, we have examined the connections of the auditory cortex utilizing the retrograde transport of horseradish peroxidase (HRP). Iontophoretic injections of HRP were made in various portions of the auditory cortex and, following a survival time of 24 hrs, the tissue was processed for HRP histochemistry.

Primary auditory cortex (AI), as defined on the basis of cyto- and myelo-architecture, is located on the rostral pole of the temporal lobe, midway between proisocortex and the dorsal extremity of the sylvian fissure. HRP injections in AI resulted in labeled cells in the ventral division of the medial geniculate body (GM_V) which were always arranged in a characteristic laminar pattern. Injections in the dorsal portion of AI resulted in bands of labeled cells along the medial border of GM_V; if HRP was injected more ventrally in AI, the band in GM_V was more laterally located.

Injections of HRP in the different cortical regions surrounding AI led to distinctly different patterns of labeled cells in the thalamus. Injections ventral to AI and dorsal to proisocortex resulted in labeled cells in the caudal extremity of the medial geniculate body. Injections in the lateral bank of the sylvian fissure, medial to AI, produced a prominent focus of labeled cells in the magnocellular division. Injections placed near the dorsal tip of the sylvian fissure led to labeled cells in the suprageniculate nucleus (Sg). Following injections in the cortex intercalated between AI and the target of Sg, labeled cells were observed in the dorsal division of the medial geniculate body and in other portions of the posterior group. Finally, injections in the medial wall of the sylvian fissure produced label primarily in the anterior portion of the posterior group, adjacent to the ventrobasal complex.

197 INTERHEMISPHERIC CONNECTIONS BETWEEN THE NEOCORTICAL FOREPAW REPRESENTATIONS IN THE VIRGINIA OPOSSUM. Robert E. Foster and Ford F. Ebner. Neuroscience Section, Div. of Bio. and Med., Brown Univ., Providence, RI 02912.

The anatomical distribution of commissurally projecting cells in one hemisphere and their axonal terminations in the other were correlated with the limits of the area showing evoked potentials to electrical stimulation of the forepaw. Within the somatic sensory cortex of the opossum (D. virginiana) the density of commissural cells and their axon terminals varies, but all regions give rise to and receive at least some commissural connections. To chart the distribution of commissurally projecting cells, horseradish peroxidase (HRP) was placed in the transected neocortical commissure. Two days later the forepaw representation on one side was mapped with microelectrodes and small electrolytic lesions were placed along its borders. The animals were perfused and the brains processed to demonstrate the HRP reaction product. The results show that within the central region of the forepaw area only a small number of cells in layers II-III give rise to commissural axons, while along the boundaries of this area such retrogradely filled perikarya are much more numerous and located in all cell layers, with the majority still in layers II-III. The distribution of commissural axon degeneration following large lesions of somatic sensory cortex on one side shows two main patterns. First, within the central region of the forepaw area, dense terminal degeneration is present only in layers I-II and VI, with only sparse degeneration in the other layers. In contrast, the zones adjacent to the central region show dense terminals in layers I through VI. Electron microscopic examination of commissural axons 6-9 days after unilateral decortication showed that their terminals contain round synaptic vesicles and form asymmetrical membrane differentiations in all layers of both regions. Dendritic spines were the most commonly identified postsynaptic element. Thus, even though all parts of opossum somatic sensory cortex give rise to and receive interhemispheric connections, the present results suggest that there are subareas that can be distinguished by the organization of their commissural connections.

198 THE HUMAN AUDITORY CORTEX: A NEW CYTOARCHITECTONIC MAP. Albert M. Galaburda* and Friedrich Sanides*. (SPON: Gary Van Hoesen) Harvard Medical School, Boston, Ma. 02115.

As a part of a larger study on the microscopic right-left asymmetries in the human brain the primary and association auditory cortices were parcellated in six separate hemispheres using serially sectioned, whole-brain human material stained with the Nissl method. By employing cytoarachitectonic criteria adapted from the Vogt school (F. Sanides, in The Structure and Function of Nervous Tissue, G.H. Bourne, Ed., Academic Press, New York, 1972) the following findings were made: The primary receptive area KA (D.N. Pandya&F.Sanides, Z. Anat. Entwickl.-Gesch. 139:127, 1973) was found mostly on the anterior gyrus of Heschl, and seemed to show varying degrees of focal differentiation, especially in the size of IIIc pyramids; as in the rhesus monkey, belts of association cortex, parakoniocortex, were found surrounding the koniocortex KA. Several divisions of parakoniocortex were noted: a rostral, parvocellular division; an internal division characterized by large IIIc pyramids; a lateral division notable by the presence of rows in layer III; a caudo-dorsal division which is similar to the internal division except for the presence of only foci of large IIIc pyramids and a darker layer V; and finally a temporoparietal division, Tpt, with features of parietal cortex, felt to be a form of integration cortex on architectonic grounds. An area in the parinsular region, proA, making up part of the medial border of KA, was felt to represent a more primitive auditory cortex, A-II.

The morphology of each division, in addition to its location, correspond largely to the auditory areas of v. Economo and Koskinas (Die Cytoarchitektonik der Hirnrinde des erwachsenen Menschen, Springer-Verlag, Berlin, 1925) with one major exception. The caudo-dorsal parakoniocortex was found to extend to the caudal end of the Sylvian fossa and around the back onto the medial aspect of the parietal operculum, there extending rostrally for about one centimeter. To our knowledge this is the first time a cytoarchitectonic map of the auditory cortex has clearly shown the presence of this type of cortex well into the parietal operculum. This data provides for the first time a cytoarchitectonic substrate for the neurophysiologic findings of auditory evoked potentials in the parietal operculum (T.J. Imig et al., J. Comp. Neurol. 171:111, 1977).

199 EFFECTS OF DIPHENYLHYDANTOIN ON EVOKED POTENTIALS AND SINGLE NEURON ACTIVITY IN THE ANTERIOR CEREBRAL CORTEX OF DOMESTIC CATS. F.A. Harris and A.L. Towe. Dept. Physiol. & Biophys. (SJ-40), Univ. of Wash. Sch. Med., Seattle, WA 98195.

Surface-recorded gross potentials and extracellularly recorded single neuron activity evoked by skin stimulation were studied in pericruciate and precoronal cortex of chloralose-anesthetized, immobilized cats before and after topical application of diphenylhydantoin to each recording site. A minute amount applied in crystalline form produced an immediate and profound reduction in evoked potential amplitude, followed by recovery along a time course suggestive of spreading cortical depression. Occasionally, after an extremely small amount of the drug was applied, the gross potential evoked by contralateral forepaw (CF) stimulation increased, "diphenylhydantoin spikes"—gross potentials analogous to strychnine and bicuculline "spikes"—appeared after off-focus (IF, CH and IH) stimulation, and the evoked discharge of single neurons increased to CF stimulation (sa neurons) or to all inputs (m neurons). In precoronal cortex, the effects of the drug applied in saline solution at 1 mg/ml, buffered to pH 7.4, included a brief initial reduction in gross potential amplitude, followed by recovery (about 2 min) and then an increase lasting from 15 min to 1.5 hr. In pericruciate cortex, the same effects occurred in response to CF stimulation. In addition, "diphenylhydantoin spikes" appeared, appended to the normal gross potentials evoked by off-focus (IF, CH and IH) stimulation. The evoked discharge of single neurons increased, generally in parallel with the enhancement seen in the gross potential evoked by CF stimulation. There were a few paradoxical instances in which neuron response increased while the simultaneously recorded gross potential decreased. One precruciate neuron changed from an sc type (response only to CF and CH) before drug application to an m type (response to all paws) after drug application. It remains to be explained why an agent which is used chronically as an anticonvulsant drug, should produce "convulsant" activity, like that produced by strychnine and bicuculline, when applied acutely to the surface of the cortex. The increased excitability of single neurons after topical application of the drug may bear a relation to the increased tendency to seizures associated with abrupt withdrawal of the drug in persons under chronic therapeutic treatment (i.e., there may be a critical local concentration at which this drug has an excitant effect). (Supported by NS00396 and NS05136)

200 MEASUREMENT OF CELLULAR AND EXTRACELLULAR PARAMETERS OF CEREBRAL CORTEX BY ANALYSIS OF CORTICAL ELECTRICAL IMPEDANCE. James W. Havstad* (SPON: Robert P. Scobey). Department of Pharmacology, School of Medicine, University of California, Davis, CA 95616.

Electrical impedance of cerebral cortex has often been considered to be determined by extracellular current flow, thereby providing little information about cellular elements. Ranck (Exp. Neurol. 9:1-16, 1964) has obtained a different conclusion using an analysis based on randomly oriented, branching cellular elements. This problem has been reexamined by measurement of magnitude and phase angle of impedance of superficial cortex in the rabbit. From anatomical and passive electrical characteristics of the superficial cortex, a mathematical model of cortical impedance was developed, which resembles that of Ranck in assuming random dendritic structures. Comparison of experimental data with prediction from the model supports the conclusion that impedance is a measure of both cellular and extracellular parameters.

Impedance magnitude and phase angle are measured substantially continuously and simultaneously at one-half decade frequency intervals from 5Hz to 15.8kHz, using a four-pole electrode array and subthreshold currents. The electrodes rest on the exposed pial surface, and measure impedance to a depth of about 0.25 mm. Impedance magnitudes are about five times the resistivity of isotonic saline and decrease with increasing frequency. Phase angles are negative and show peaks of about 2.4 degrees around 50Hz and 3 degrees at 15.8 kHz. Good agreement with the model is found when a finely lamellar structure for glia is assumed. The low frequency phase angle is due to current flow in dendrites oriented substantially parallel to the measuring field, and is a measure of dendritic membrane time constant. The high frequency phase angle peak is due to similarly oriented glia, but is independent of glial membrane resistance.

Analysis of impedance changes during spreading depression shows the expected changes in dendritic membrane permeability and extracellular volume, and allow monitoring of their individual time courses. An additional unexplained change in dendritic membrane is required during recovery from spreading depression to account for prominent features in the experimental data.
(Supported by NIH grant MH17471).

201 LIGHT AND ELECTRONMICROSCOPIC ANALYSIS OF INTRINSIC NEURONS IN CATS SUPRASYLVIAN GYRUS; DEGENERATION PATTERNS AFTER CORONAL LESION. V. Hayes*, B. Weissman*, I. Kaiserman-Abramof, J. Ferguson. Division of Neurology and Department of Anatomy, Case Western Reserve University School of Medicine, and Veterans Administration Hospital, Cleveland, Ohio.

To determine the origin, extent, and termination of neurons intrinsic to cat suprasylvian gyrus (SS), light and electronmicroscopic (EM) sections of degeneration patterns were studied after a transverse (coronal) subpial cortical lesion was made by a fine wire leukotome. Fink-Heimer sections at 3 days showed maximal terminal degeneration in layers I and II up to 8 mm anterior and posterior from the lesion. Fiber degeneration, maximum at 7 days, extended 10 mm anterior and posterior from the lesion, was mostly horizontal and mainly restricted to layers III-VI.

For the EM study, counts of layer II neuron soma and neuropil terminal degeneration in a 29/39μ area around each cell were made 1 and 2 mm from the lesion.

Survival time (days)	Areas analyzed	Terminal/ area	% Degeneration	Cells analyzed	Terminals/ Soma section	% Degeneration
Control	11	88	0	13	7	0
2	8	84	1	10	8	2
4	10	81	1	10	4	0
21	8	98	2	8	4	2

The degeneration shown in the table above represents dark degeneration and was 2% or less in all areas for cell soma and neuropil. A significant decrease in axon terminals/cell soma/area (ATCA) occurred between the second and fourth day and was still present at 21 days. This abrupt and lasting decrease in ATCA numbers could represent terminal degeneration with removal over the period studied. In addition to the decrease in ATCA, the observation that glial processes occupied increased surface areas of neuron somata may indicate glial removal of degenerating terminals and occupation of the vacated terminal sites.

These EM data for layer II SS in the cat argue that the major effect of a single coronal lesion is the removal of terminals from neuron cell bodies. The Fink-Heimer study suggests that the soma terminal loss could extend for over 16 mm in SS.

202 ROLE OF VISUAL CORTEX IN ANTICIPATORY ORIENTATION TOWARD MOVING TARGETS BY THE GERBIL. David Ingle, Brandeis University, Waltham, MA 02154

Throughout the vertebrate phylogeny, the optic tectum appears to mediate rapid orientation of eyes or head toward objects of interest to the animal. We have developed a procedure for cine analysis of visually-elicited orientation by the Mongolian Gerbil (Meriones unguiculatus) by which subtleties of visuomotor behavior can be discovered and analyzed quantitatively. Repeated analysis of six normal gerbils, trained to wait for the sudden appearance of discs baited with seeds, reveals that the initial head turn typically undershoots a stationary target. However, when stimuli emerge from behind frontal barriers and move toward the periphery, the gerbil's first head turn is typically an overshoot of the target position seen at the initiation of the turn. That is to say, the gerbil's turn leads a moving target and sets him on a collision course.

Two gerbils with large lesions of visual cortex made normal initial head turns toward stationary objects throughout their visual fields. However, both animals consistently failed to show the "anticipatory" overshoot of head movement (and subsequent pursuit) associated with temporalwards moving objects. Further studies are in progress, using unilateral lesions more nearly limited to striate cortex. These data confirm the qualitative observation of Schneider (Science, 163:895-902, 1969) that hamsters can orient accurately following large lesions of visual cortex. They add the new information that "tracking" of a rapidly moving target depends upon integrity of cortex as well as of the optic tectum. Our observations are in agreement with those of Humphrey (Perception, 3:241, 1974), who noted that a long-term destriate monkey was capable of accurate eye saccades but showed no smooth pursuit abilities. It seems likely that a cortically triggered mechanism can "override" the simpler orienting behavior mediated by the optic tectum during pursuit of moving targets.

203 RECIPROCAL CONNECTIONS OF THE THALAMUS AND THE INFERIOR PARIETAL LOBULE. David L. Kasdon* and Stanley Jacobson. Departments of Neurosurgery and Anatomy, Tufts Univ. Sch. Med., Boston, Mass., 02111.

The inferior parietal lobule (IPL) of the rhesus monkey represents association cortex with multimodal sensory input subserving language, visual and related higher cortical function. We have studied the IPL with eight cortical injections of HRP demonstrating diverse thalamic input to this region (Anat. Record 187:769). A major projection to the superior portion of the IPL was from the anterior nuclei and Paracentralis of the intralaminar group. Ventralis Lateralis and oral Pulvinar projected primarily to the anterior-inferior portion of the IPL, whereas Lateral Posterior projected most strongly to the anterior and superior portion of the IPL and to area 19. The projections of the inferior Pulvinar were heaviest to area 19, but there was some overlap in the mid-superior portion of the IPL with the medial and lateral Pulvinar. The major projection from the posterior thalamic complex was to the mid-IPL. In addition to this retrograde HRP study, tritiated amino acids were also injected in the same eight parts of the IPL and the brains processed for autoradiography so that the reciprocal anterograde connections of the IPL to the thalamus could be compared to the HRP material. The heaviest projections from the thalamus to the IPL were reciprocated by strong projections from the IPL to the thalamus.

204 VERBAL CROSS-CLUEING FOLLOWING CEREBRAL COMMISSUROTOMY. Santosh Kumar, Glenda M. Bogen* and Joseph E. Bogen. Ross-Loos Medical Center, Los Angeles, CA 90026.

Following complete cerebral commissurotomy for medically intractable epilepsy (Bogen & Vogel, 1962), behavior seems normal in ordinary social situations and in routine neurological examination (Bogen & Vogel, 1975). But specific deficits can be demonstrated using special tests (Sperry, Gazzaniga & Bogen, 1969); these include an inability to retrieve correctly with one hand a test object originally presented to the opposite hand. The disability for cross-retrieval in spite of excellent same-hand retrieval demonstrates both the capacity of each cerebral hemisphere to function independently, and a lack of interhemispheric transfer of discriminative information. Cross-retrieval from right hand to left is improved if naming out loud is permitted during palpation with the right hand; this has been attributed to the right hemisphere's ability to hear and comprehend spoken words. A recent, quantitative, systematic study affords comparisons between subjects for this verbal cross-clueing strategy and confirms its presence for a decade or more after operation.

205 EFFECT OF DIMETHYL SULFOXIDE ON CEREBRAL INFARCTION IN THE MONGOLIAN GERBIL. Jerry W. Lawson and Charles P. McGraw, Dept. Neu. Bowman Gray Sch. Med. Wake Forest Univ., Winston-Salem, NC 27103

Dimethyl sulfoxide (DMSO) has several characteristics that should enable it to improve morbidity and mortality in acute cerebral ischemia: 1) as a strong diuretic it should reduce blood volume, intracranial pressure, and tissue edema, and 2) as a vasodilator it should improve cortical blood flow. DMSO has been reported to be beneficial in the treatment of central nervous system trauma, possibly due to its reported anti-inflammatory, antiedemic, anticoagulate, diuretic, hypothermic, vasodilatory, and respiratory stimulatory effects as well as to its ability to correct membrane instability and penetrate the blood-brain barrier. de la Torre and Surgeon reported that in rhesus monkeys subjected to experimental cerebral infarction, DMSO-treated animals had less brain damage and greater protection from the severe neurological deficits seen in control animals.

Two hundred and thirty-four young adult Mongolian gerbils of both sexes weighing 40 to 60 grams were divided into three groups: Group 1 (180 animals operated on, one-half DMSO-treated and one-half saline-treated); Group 2 (42 animals sham-operated on, one-half DMSO-treated and one-half saline treated); and Group 3 (12 animals not operated on, DMSO-treated). The animals operated on were anesthetized with either ether or ketamine. A ventral midline cervical incision was made from the mental protuberance of the mandible to the manubrium. The left common carotid artery was located by blunt dissection, care being taken not to injure the jugular vein or the adjacent nerves. In Group I animals, the artery was doubly ligated with 5-0 monofilament nylon suture and transected between the ligatures. Then, in all animals, the incision was closed with 9-mm stainless steel autoclips. Each animal was then given a 1-ml intraperitoneal injection of 1% trypan blue solution. In one-half of the animals in the two operated groups and in all 12 control animals, 0.5 ml of DMSO solution was injected intraperitoneally one hour post-ligation. Then, every eight hours for 72 hours, either 5 or 2.5 gm/kg of DMSO solution was injected intraperitoneally by a double-blind protocol. The other half of the animals in the operated groups received saline injections on the same treatment schedule. Clinical signs of infarction were recorded. The accumulative probability of dying was calculated.

DMSO had no significant effect on the number of infarctions, mortality, or the extent of clinical morbidity. However, it did significantly decrease ($p < 0.05$) the amount of trypan blue staining in animals with infarction. A 10 percent incidence of drug toxicity in animals receiving the higher dose was observed.

206 PREFRONTAL CORTICOFUGAL PROJECTIONS IN MACAQUE MONKEYS. George R. Leichnetz, Juan Astruc and John T. Povlishock*. Department of Anatomy, Medical College of Virginia, Health Sciences Division, Virginia Commonwealth University, Richmond, Virginia 23298.

Anterograde degeneration studies using the Nauta and Fink-Heimer silver techniques following unilateral partial ablations of the medial prefrontal cortex (Area 9) in rhesus and cynomolgus monkeys have led us to the conclusion that this region has corticocortical projections to Area 6, superior temporal cortex (Area 22), superior and inferior parietal cortices (Areas 5 and 7), prestriate area (Area 19), entorhinal area (Area 28a) and, via the cingulum bundle primarily, to the hippocampus (primarily caudal CA_3). This region gives rise to subcortical projections to the corpus striatum, including the head of the caudate nucleus (but also the vertical portion of the tail), although the putamen is notably lacking in degeneration. The dorsal globus pallidus is traversed by large numbers of degenerating fibers of passage, some of which is suggestive of preterminal and terminal debris. The basal and lateral amygdaloid nuclei likewise receive medial prefrontal input. In the thalamus some preterminal degeneration was present in the anterior nuclear complex, caudal MDpc, LD, LP and to a much lesser extent in the pulvinar. The central lateral and parafascicular nuclei contained moderate to heavy amounts of degeneration. Brain stem projections were observed to the pretectum and tectum, and the paramedian mesencephalic reticular formation (midbrain limbic area). Recent electron-microscopic studies have provided evidence thus far confirming direct prefronto-hippocampal and prefronto-amygdaloid projections. EM verification of other prefrontal target areas is under way. Likewise, current autoradiographic investigations have substantiated in large measure the findings of the silver studies. Supportive EM and autoradiographic evidence will be presented. In addition, comparisons will be drawn to ongoing investigations of the efferent connections of the dorsal and ventral convexity, and the possible diversity of roles of the various prefrontal subregions will be discussed. This study has been supported in part by USPHS NB 08418 and A. D. Williams Research Grants.

207 CLAUSTRUM TO FRONTAL CORTEX CONNECTIONS IN THE CAT, STUDIED BY RETROGRADE TRANSPORT OF HORSERADISH PEROXIDASE (HRP). Alfonso Llamas*, Carlos Avendano* and Fernando Reinoso-Suarez* (SPON: D.A. Pasquier). Departamento de Morfologia, Facultad de Medicina, Universidad Autonoma de Madrid, Spain.

The distribution of HRP labeled neurons in the claustrum has been investigated as part of a broader study of the afferent connections of the frontal cortex in the cat.

Nineteen adult cats were selected for this study. In 11 of these animals 0.3 to 2.0 microliters of 30% aqueous solution of HRP (Sigma VI) were injected in various parts of the prefrontal, premotor and motor areas; the remaining eight cats received injections in other regions of the cerebral cortex in order to get a general view of the claustrum-cortical connections. After the survival time of 36 to 50 hr. animals were perfused and processed according to the method of Llamas and Martinez-Moreno (An. Anat. 23: 431, 1974)

The results can be summarized as follows: 1) all the injections gave rise to labeled neurons in the dorsal (insular) claustrum; 2) the ventral, or prepiriform claustrum, was always free of labeled cells; 3) the more rostral and dorsal injections in the frontal cortex (dorsal part of gyrus proreus and rostral part of gyrus sigmoideus anterior) labeled neurons in the dorsal and rostralmost part of the claustrum; 4) the more ventral and rostral injections in the medial surface of the hemisphere gave rise to labeled neurons in the rostroventral extreme of the claustrum; 5) more caudal injections in the motor cortex (including both banks of the sulcus cruciatus) labeled cells in progressively more caudal sections of the claustrum, always in its dorsal one half or one third.

As a rule, more caudal injections in the cortex produce labeling in more caudal locations in the claustrum; and dorsal injections, both in the convexity and the medial surface, produce labeling of the dorsal part of the claustrum. A ventral-to-ventral topometry was also found in the convexity and in the medial surface of the hemisphere.

208 TOPOGRAPHICAL ORGANIZATION OF THE THALAMIC PROJECTION FROM THE MOTOR CORTEX OF THE RAT. L. C. Massopust, P. A. Young, and C. J. Seliga*. Dept. Anat., St. Louis Univ. Sch. Med., St. Louis, MO 63104.

Considerable attention has been given to the convergence of pallidal, cerebellar, and cortical projections in the ventral tier thalamic nuclei of gyrencephalic animals. Similar studies in lissencephalic animals such as the albino rat are meager. Utilizing selective silver impregnation and autoradiographic techniques, electrolytic lesions or injections of tritiated amino acids were made at 4 predetermined sites in the motor cortex as localized in the physiological maps of Hall and Lindholm (1967). From the anterior two sites, degenerating or labelled fibers entered the white matter, coursed through the caudate-putamen complex and internal capsule, and then penetrated the dorsolateral aspect of the anterior part of the thalamus. Terminal areas were seen in the reticular, ventral anterior, and intralaminar (IL) nuclei. More posteriorly, terminal areas were concentrated in the IL, in the dorsomedial part of the ventral dorsal nucleus (VD), in the dorsolateral part of the ventral medial nucleus (VM), and along the extreme lateral border of the medial dorsal nucleus (MD). From the posterior intermediate site, corticothalamic terminal areas were observed in the reticular, IL, and along the lateral border of the ventral lateral nucleus (VL). Further posteriorly, terminations formed a sharply localized "comma-shaped" area near the ventromedial border of the VL. Lesions or injections in the most posterior part of the motor cortex exhibited projections and terminations similar to the posterior intermediate except that the comma-shaped terminal area was located more laterally and dorsally in the VL. Because of these connections with the VL it is postulated that the posteromedial part of the cortical area described by Hall and Lindholm is the primary motor area (area 4). Since the anterior part of this cortical area projects largely to the IL, VD, and VM, it may correspond to the premotor cortex (area 6). Other investigations in our laboratory show that somatosensory cortical, pallidal, and cerebellar projections terminate topographically in the ventral tier nuclei and intralaminar areas, thus showing an organization similar to that in higher mammals.

209 STUDIES ON CAUDATE NUCLEUS INHIBITION OF SEIZURE ACTIVITY IN THE LIMBIC SYSTEM AND CEREBRAL CORTEX. R. J. Morgan, G. T. Schneider* and C. C. Turbes. Colorado State University, Ft. Collins, CO 80521 and Creighton School of Medicine, Omaha, NE 68178 U.S.A.

Multiunit and slow wave activity were recorded from extracellular microelectrodes in the dorsal hippocampus and amygdala in twenty-eight cats. The electroencephalogram was recorded from the right and left frontal, parietal temporal and occipital cerebral cortex. Three channels were recorded on an F.M. tape recorder for further data analysis. The data was processed with a Varian V-72 minicomputer. Channels were sampled alternately at 2.5 ms and 120 data segments for each channel of 2.56 seconds duration each. These data were transformed using a Fast Fourier Transform algorithm to give a power spectral estimate. Stimulating electrodes were located in the left septal nucleus, stimulation produced after discharge at cerebral cortex and the limbic system. Generalized seizures were induced with pentylenetetrazol. Focal application of penicillin to the cerebral cortex was used to produce a focal seizure. Stimulation of the caudate resulted in inhibition of septal afterdischarge and generalized seizure activity in the cerebral cortex and the limbic system. Caudate stimulation caused desynchronization of synchronized seizure activity induced by local application of penicillin to the cerebral cortex.

210 VARIATIONS IN THE FISSURAL PATTERN OF THE CEREBRAL NEOCORTEX OF THE SPIDER MONKEY (ATELES). Benjamin H. Pubols Jr. and Lillian M. Pubols. Dept. of Anatomy, College of Medicine, Pennsylvania State University, Hershey, PA, and Dept. of Anatomy, Medical College of Pennsylvania, Philadelphia, PA.

The existence of variations in the fissural pattern of the neocortex of primate brain specimens has been recognized for well over 100 years (Gratiolet, 1854; Huxley, 1861). Since then, a number of observers have described the external features of the neocortex of Ateles, but little attention has been paid specifically to the question of interhemispheric variability, either between or within specimens of the same genus.

The present report is an attempt to characterize and categorize 40 hemispheres of 22 specimens of Ateles acquired during the course of a series of previously published investigations of the somatic sensory system of this species. The fissural patterns of the dorsolateral neocortical surface have been classified according to certain salient features illustrated below.

Fig. 1 illustrates a synthetic "typical" hemisphere (left dorsolateral view), in which (1) the caudal spur of the inferior precentral sulcus (pci) comes to within 5 mm of, but is discontinuous with the base of the central sulcus (c) (68% of cases), (2) the superior (pcs) and middle (pcm) precentral sulci are discontinuous (83% of cases), (3) the transparietal (tps) and superior postcentral (pts) sulci are discontinuous (65% of cases), and (4) there is no true superior frontal sulcus (fs) (40% of cases). Fig. 2, also synthetic, illustrates a few of the variations on this pattern: (1) pci and c are continuous, (2) pcs and pcm are united to form a single sulcus, (3) a transversely oriented fs is present, and (4) tps extends anteriorly across the postcentral gyrus to separate regions of representation of arm and leg, as defined by electrophysiological studies (Pubols and Pubols, 1971). Three other hemispheres also showed such somatotopically related transverse fissures, in either precentral motor, or postcentral sensory cortex. In still other hemispheres, tps and pts joined to form a triradiate sulcus. Interhemispheric variability was as pronounced within as between specimens.

211 SOME OBSERVATIONS ON LAMINAR ORIGINS AND TERMINATIONS OF OCCIPITO TEMPORAL CORTICAL CONNECTIONS IN RHESUS MONKEY. K.S. Rockland* and D.N. Pandya. Dept. Anat., Boston Univ. Sch. Med., Boston, Ma. Neurological Unit, Beth Israel Hosp.; Bedford V.A. Hosp.

Laminar origins and terminations of cortico-cortical connections were studied using anterograde (tritiated amino acids) and retrograde (horseradish peroxidase) transport methods. In general four differential patterns of laminar connectivity could be identified. 1) In sequential forward connections, axon terminals were observed mainly around layer IV. The cells of origin of these sequential projections were localized primarily in the supragranular layers, with some degree of variability in different architectonic areas. Thus, pyramidal cells of L. IIIa,b of area 17 (a few in L. IIIc) projected around L. IV of area 18; neurons of L. IIIc,b of area 18 (a few in L. IIIa and infragranular layers) projected around L. IV of area 19; and, conforming to the supragranular trend, cells in L. IIIb,c of area 19 (some in L. IIIa and infragranular) sent terminals rostrally to L. IV of inferotemporal cortex (area 21). 2) Each of these areas (i.e. areas 18, 19, 21) also projected caudally to the immediately adjoining region. Terminations in this instance, however, were confined primarily to the plexiform layer. Unlike the supragranular preference of rostrally directed projections, the cells of origin of these caudally directed projections were generally found in both supra- and infragranular layers, with some interregional variability. Thus, L. I of area 19 received projections from both areas 21 and 20 (area TF of Bonin and Bailey). The cells of origin of the first-layer projection from area 21 were found in both supra- and infragranular layers (in Ls.IIIa,b and Vb,VI), while neurons in area TF occurred almost exclusively in infragranular layers. The L. I projection from area 19 to area 18 originated from pyramidal cells in both supra- and infragranular layers (Ls.IIIb,a and V,VI). 3) Laminar origins and terminations of intra-regional projections varied widely. In the anterograde direction, local area 17 projections ended in Ls. I and V, with some terminals in L. IIIc, while in areas 18 and 19, these were limited to L. I. Distant intra-19 projections (from preoccipital gyrus to lunate, superior temporal, intraparietal, occipito-temporal sulci) predominantly terminated in Ls. I to IV. 4) Neurons giving rise to callosal connections occurred in L.III: large pyramids in L. IIIc of juxtastriate cortex, and medium to large neurons in L. IIIc,b of area 21. Thus, sublaminar specialization within layer III may be occurring, since layer III neurons are also involved in both rostrally (L. IIIc,b) and caudally (L. IIIa,b) directed cortico-cortical connections.

212 MEDIAL PREFRONTAL CORTEX AND BEHAVIOR OF DOGS. Carl E. Rosenkilde and Waclawa Lawicka*. Dept. of Neurophysiology, Nencki Institute of Experimental Biology, Warsaw, Poland.

A group of mongrel dogs was trained on a go-left/go-right time discrimination task involving 10 and 30 sec of bodily restraint. Another group learned a spatial delayed alternation task in which the animals were restrained during the delays. The effects of two selective prefrontal ablations were evaluated in retention of these tasks. A dorsal lesion comprised the proreal gyrus, while a medial lesion involved the precruciate area but spared the anteromedial field.

Normal dogs showed systematic bodily orientation during the periods of restraint in both situations. No behavioral changes resulted from dorsal prefrontal lesions, but medial damage disturbed positional mediation and instrumental choice in time discrimination as well as in delayed alternation. These deficits are unrelated to the delayed response impairment which previously has been reported after dorsal but not medial lesions. Interference with spatial responding based on kinesthetic cues may account for the present effects of medial prefrontal damage.

213 DESCENDING PROJECTIONS TO THE REGION OF THE GIGANTOCELLULAR TEGMENTAL FIELD OF THE MEDULLA OBLONGATA. Jerome Siegel, Patricia M. Saxton* and Timothy Hageman*. Inst. for Neuroscience and Behavior, Univ. of Delaware, Newark, DE 19711.

The gigantocellular tegmental field (FTG) of the medulla exerts inhibitory influences in both ascending and descending directions (Brodal, Neurological Anatomy, 1969; Mancia et al., Brain Res. 25, 1971, 638). There is evidence that inhibition produced by stimulation to some forebrain structures is mediated by this bulbar inhibitory area (Sauerland et al., Brain Res. 6, 1967, 164). This study was undertaken to identify those regions in the rostral parts of the brain which have direct projections to the bulbar reticular formation. In rats and cats HRP was injected into the bulbar brain stem in the area of the FTG. In all animals it was found that cortical cells which project to the bulbar brain stem are limited to the frontal region. In the cat these areas are precruciate-anterior sigmoid, coronal and proreus gyri (areas 6 and 8). In the rat labeled cells were found in the frontal lateral dorsal cortex (area 2). In both species the HRP positive cells were located bilaterally in clusters of 3 - 15 cells and were always limited to the deep layers of the cortex. It is striking that the only cells in the cerebral cortex in the cat which project to the bulbar area are totally included within cortical areas that have been demonstrated to exert inhibitory influences upon behavior (Wilcott and Sabol, Neuropsychol. 15, 1977, 155).

Cells in the central nucleus of the ipsilateral amygdala were labeled in animals in which the HRP injection site included the central-lateral bulbar brain stem. This confirms the report by Hopkins (Neurosci. Lett. 1, 1975, 263). The amygdaloid projection was much more evident in rats than in cats. Only one cat (with the largest HRP injection: 1 µl) showed some labeled cells in the amygdala and the ventral part of the mesodiencephalic junction, while all rats had the amygdaloid label and also exhibited two discrete clusters of labeled cells in the hypothalamus. One was a periventricular dorsal group with a medial-lateral distribution of cells. More caudally there was a ventral tier of cells above the mammillary complex.

At the level of the midbrain all animals showed a prominent label in the deep layers of the contralateral superior colliculus. In addition, cells in the oculomotor complex and surrounding central gray and the reticular formation at all brain stem levels were clearly labeled. The most caudal cells, which were labeled by axoplasmic transport rather than by direct filling, were located in the contralateral vestibular complex.

214 VASCULAR RESPONSE AND LEVEL OF OXIDATION OF CYTOCHROME a,a_3 IN ASTROCYTOMAS IN SITU. A. Sylvia, M. Rosenthal, D. Bigner* and G. Somjen, Dept. of Physiology and Pharmacology and Microbiology, Duke University Medical Center. Durham, N.C. 27710

Tumors were induced by inoculating either cerebral cortex or subcutaneous tissue of rats with a suspension of the cultured pure astrocytoma cell line RG 2 developed by Dr. W. Wechsler. Four to six days later, the rats were anesthetized with pentobarbital, and the tumor exposed by opening the skull but not the dura. Dual wavelength reflectance spectrophotometry was used to record changes in the redox ratio of cytochrome a,a_3 (605-590 nm), the oxygenation level of hemoglobin (577-585 nm) and the relative volume of blood in an area approximately 3 mm in diameter and 1 mm in depth in intact cortical tissue in situ. The rats were immobilized with tubocurare and, in the control state, ventilated with 30% O_2 and 70% N_2. Addition of CO_2 to the inspired gas mixture caused vasodilatation in the glioma in the brain, but not when the glioma was located in subcutaneous tissue. This indicates that vessels invading the tumor retain the regulatory responses typical of the body region, and do not acquire those typical of the tissue of origin of the neoplastic cells. In addition, rhythmic vasomotion was a regular finding in the gliomas in skin but not in brain. The redox ratio of cytochrome a,a_3 in the unstimulated, unperturbed control state was compared to that during breathing 100% O_2 and 100% N_2. Unlike normal cerebral tissue in which cytochrome a,a_3 is at least 30% reduced in the unstimulated state, in astrocytoma tissue reduction levels varied from 0 to 15% regardless of whether the glioma was located in skin or brain. The 30% or greater reduction levels were found not only in the cortex of normal control rats, but also in the untreated hemisphere of inoculated rats, and also in normal cortex adjacent to the tumor on the inoculated side. In having nearly fully oxidized cytochrome a,a_3, the mitochondria of astrocytoma cells resemble isolated mitochondria, and differ from those of cells in non-neoplastic brain tissue in situ. It may be that the neoplastic cells lack a regulatory or control function typical of normal brain cells. Alternatively, the values measured in normal brain may be intermediate between neuron and glial population, and the astrocytoma cells may reflect the normal state of glia.

215 PULVINAR AND OTHER CAUDAL THALAMIC AFFERENTS TO SUPERIOR TEMPORAL GYRUS IN THE RHESUS MONKEY. John Q. Trojanowski, Dept. of Anatomy, Tufts University School of Medicine, Boston, Ma. 02111

In five juvenile rhesus monkeys, using the horseradish peroxidase (HRP) technique, pulvinar and other caudal thalamic afferents to the superior temporal gyrus (STG) were examined. As in a similar series of experiments in the squirrel monkey (Brain Res., 85:346-353) the HRP was combined with tritiated amino acids for later study of the efferents of STG. In the five animals, unilateral injections of the tracers were made such that the injection sites in total involved the entire length of STG. The material was processed in the usual manner to reveal HRP labeled neurons and the location of these neurons was charted with an x-y pantograph. The HRP results in the Rhesus monkey accord well with those previously described in the squirrel monkey (Brain Res., 85:347-353). As far as the pulvinar is concerned, the anterior third of STG primarily receives projections from the caudal part of the ventromedial portions of medial pulvinar nucleus while the posterior third of STG receives projections both from the medial and lateral pulvinar nuclei. The middle third of STG, into which secondary auditory cortex extends, receives the bulk of its input from the medial geniculate nucleus rather than from the pulvinar. As noted in the squirrel monkey study, several other caudal thalamic nuclei were found to project to STG as well, i.e., the medial dorsal and suprageniculate nuclei and nucleus limitans. Thus in the Rhesus monkey as in the squirrel monkey, it is the pulvinar nucleus in caudal thalamus which is the primary source of input to STG exclusive of the primary and secondary auditory areas. The relationship of pulvinar to STG is topographical and paralleled by less well organized projections from other caudal thalamic nuclei.

216 ORGANIZATION OF THE PRIMATE AND HUMAN CEREBRAL CORTEX STUDIED WITH THE DIRECT CORTICAL RESPONSE. John Turner*, Christer Lindquist*, and Robert G. Grossman. Depts. Neurosurg., Inst. of Neurol. Sci., Glasgow, and Univ. Texas Medical Branch, Galveston, TX. 77550.

The organization of cortical cytoarchitectonic areas was studied with the direct cortical response (DCR) in 27 baboons and subsequently in 30 adult patients who underwent electrocortical mapping to localize functional areas of the cortex as a guide to neurosurgical procedures. The DCR of the primate and human cortex is considerably more complex than that of lower mammals. The fully developed DCR is a mosaic consisting of a series of potentials that have different thresholds, latencies and spatial distributions. The amplitudes and latencies of the potentials are a function of the gyrus studied, stimulus-recording distance, and stimulus intensity. When studied at S-R distances of 6-9 mm, the fully developed DCR consists of a positive wave (P_1) occupying the initial 4 msec after the stimulus, a biphasic negative wave (N_{1a}, N_{1b}) with peaks at 8 and 16 msec in the baboon and 12 and 25 msec in the human, a large positive potential (P_2) with a peak at 40-60 msec, and a late slow negative wave with a peak at 125-150 msec. Differences in the organization of eulaminate, agranular and koniocortices are revealed by the DCR. The morphology of the response is simplest in the frontal eulaminate cortex, where P_1 is small or absent, N_1 is prominent, the distinction between N_{1a} and b is not marked, and P_2 is not prominent. The agranular motor cortex can be identified by a series of 1.5 msec duration notched waves riding on P_1 (a,b,c). The somatosensory koniocortex can be identified by a more complex series of wavelets inscribed on the P_1 wave. The visual cortex also has a complex P_1 morphology that is not present in the surrounding parietal cortex. On the basis of differential sensitivity to ischemia ($N_1 > P_2 > P_1$) and strength-duration, conditioning-testing, and field potential analysis we tentatively assign the origin of N_1 a and b to EPSPs in elements in the upper cortex; P_2 to IPSPs in elements in the upper cortex, and P_1 to EPSPs in deeper elements. The early portion of P_2 contributes to the total amplitude of the early P_1 positivity. P_1, a,b,c, may be presynaptic fiber responses. The DCR can be used clinically for identifying cortical gyri, and DCR morphology and interaction with spontaneous potentials provides a tool for studying cortical organization.

217 SELECTIVE INHIBITION OF SOME WIDE-FIELD SENSORIMOTOR CORTEX NEURONS BY HIGH-INTENSITY SKIN STIMULI. C.F. Tyner and M.G. Miller*. Dept. Neurosciences, Walter Reed Army Inst. Res., Wash. DC 20012.

We studied single neurons extracellularly in forepaw postcruciate (4*) cortex in chloralose-anesthetized cats and held arterial blood gas levels normal. We found cells by serially shocking the four limbs' central footpads (needle electrodes, 30 milliamp (ma)(13.5 v), 0.1 msec, 1/sec) during microelectrode advance. Prior study of this tissue (Towe, et.al., Exp. Neurol., 50, 734, 1976) has emphasized two neuron populations: sa cells (superficial, contralateral forelimb (CF) receptive fields, mostly touch sensitive, few pyramidal tract (PT) axons); and m cells (deeper, whole-body receptive fields, mostly hair sensitive, providing most PT axons).

We placed most neurons from our sample (n=170 to date) into the sa/m classification, but found about 13% of cells in this tissue unresponsive to 30 ma CF shock although responsive to other stimuli. Most of these i neurons, about 10% of the total sample, responded to stimulation of ipsilateral and hindlimb footpads, contralateral forelimb shoulder, and both splanchnic nerves: they thus closely resemble m neurons. Further study showed nearly all wide-field i cells responsive to low-intensity CF shock with thresholds similar to those of m cells (1.0-4.5 ma); but unlike m cells they ceased responding to CF shock at intensities above 8-15 ma.

Single-blind shock stimulation of the experimenters' skin (intradermal needles, 0.1 msec, 1/sec) showed sensory thresholds of about 0.9 ma (0.4 v) with a transition from moderately irritating to clearly painful sensations in the 6-14 ma (2.7-6.3 v) range; from comparing these results with those of Collins, et.al. (Arch. Neurol., 3, 381, 1960), we infer that A-delta but not C fibers are probably recruited over the 6-14 ma span.

Most m neurons in this tissue show unexpected behavior following CF stimulation, perhaps due to modulation by nearby sa cells (Towe, et.al., 1976). We envision the wide-field i cells as a significant subset of the m population -- perhaps as large as 20% -- which receives potent inhibition following intense stimulation of the topographic skin focus, and believe their behavior may represent the modulation of corticofugal activity by painful stimuli.

218 BRAINSTEM PROJECTIONS TO CEREBRAL CORTEX IN WATER SNAKES. Philip S. Ulinski. Dept. Anat., Univ. Chicago, Chicago, IL 60637.

It is now well established that several brainstem structures project to the cerebral cortex in mammals. However, comparable projections in reptiles have received less attention. The possible existence of brainstem projections in banded water snakes (Natrix sipedon) was investigated following unilateral transections of the midbrain designed to interrupt all ascending fiber systems. Animals survived for seven to 28 days and their brains were then prepared by the Fink-Heimer procedure. The experiments demonstrate a large contingent of axons which reach the forebrain via the medial forebrain bundle. A minority of the fibers decussate over the anterior commissure. They run along the medial surface of the septum on both sides of the brain and gain access to the cortex through the alveus. They pass through medial cortex (Ulinski, 1974, J. Comp. Neur., 158: 243) and begin to slant upwards as they approach the medial edge of dorsomedial cortex (DM). They pass through layer 2 of DM and turn to run in the inner two thirds of layer 1 of DM. They, therefore, occupy the same region of cortex as commissural afferents from the contralateral DM and are positioned to intersect both layer 1 cells and the ascending dendrites of layer 2 cells. Some of the axons proceed through DM and reach layers 2 and 3 in the medial part of dorsal cortex. The projection reaches the full rostrocaudal extent of DM. Brainstem afferents are thick, smooth axons which do not resemble in their morphology the catecholaminergic fibers described in the cortex of turtles (Parent and Poitras, 1974, Brain Res., 78: 345) and lizards (Baumgarten and Braak, 1968, Z. Zellforsch., 86: 574). The precise origin of these cortical afferents is, unfortunately, not yet known. (Supported by PHS Grant NS 12518).

219 LIGHT SENSITIVE NEURONS IN THE INFERIOR PARIETAL CORTEX OF THE RHESUS MONKEY. Tom C.T. Yin and Vernon B. Mountcastle. Dept. Physiology, Johns Hopkins University, Baltimore, MD. 21205

Studies of single neurons in the parietal cortex of alert monkeys suggest that there exists within area 7 a neural mechanism for the direction of visual attention. Classes of visuomotor cells related to fixation, visually-evoked saccades, and smooth pursuit eye movements were identified. These cells are neither sensory nor motor in the usual sense. We have now studied a new class of neurons in area 7 which is sensitive to visual stimuli. They have large, contralateral receptive fields which sometimes extend past the midline but never include the fovea. Two subclasses have some functional properties that differ. Those of the larger subclass discharge at shorter latencies (79 $\pm$ 6 msec), subtend larger receptive fields with maximal activity evoked by stimuli at their peripheral rims, and discharge tonically during maintained visual stimulation; their discharge is not enhanced when the animal saccades to the stimulating light. Those of the smaller subclass respond at longer and more variable latencies (116 $\pm$ 26 msec), may subtend smaller receptive fields, and respond to the onset of a maintained visual stimulus with a phasic discharge which may be enhanced if the animal saccades to the test light. Cells of either subclass are sensitive to moving stimuli and may be directionally sensitive as well.

Light sensitive parietal cells differ from the saccade visuomotor cells: (1) the saccade cells do not respond to our test light (a light-emitting diode, λ = 660 nm); (2) many saccade cells discharge differently when saccades of the same amplitude and direction are made in different positions in the field. Visual fixation cells are not sensitive to the light stimuli, per se, for over 90% of them have restricted gaze fields; i.e. they are activated only when the animal fixates the light in a restricted zone of the visual field.

Saccade cells discharge, on average, 126 $\pm$ 39 msec after light onset and 73 $\pm$ 39 msec before eye movement. Thus, the light sensitive cells discharge well-before the saccade cells, which suggests that the former may provide the afferent input signals to the visuomotor neurons of area 7. Moreover, they are maximally sensitive to the appearance of novel objects in the far peripheral edges of the visual fields. Their properties suggest that the light sensitive cells are driven by signals reaching them via the retino-collicular branch of the visual system.

CHEMICAL SENSES: SMELL AND TASTE

220 THE FLAVOR CHEMISTRY OF CAT FUNGIFORM PAPILLAE TASTE SYSTEMS. James C. Boudreau and Joseph Oravec*. Sensory Sciences Center, University of Texas at Houston, 77030.

The properties of fungiform papillae taste systems were investigated by recording single unit pulse potentials from single neurons in the geniculate ganglion. These neurons were found to be responsive to a wide variety of water soluble compounds naturally present in vertebrate tissues, such as inorganic ions and a wide variety of nitrogen and nitrogen-sulfur compounds, including nucleotides. Among the salts, phosphate compounds and $CaCl_2$ are particularly stimulatory. Certain amino acids (L-cysteine, L-proline, L-lysine, L-histidine) and peptides (e.g., carnosine), are highly stimulatory as are the di- and tri- phosphate nucleotides. Nitrogen heterocyclic rings with pKa values greater than 5.0 are often associated with prominent stimuli. Unresponsiveness or inhibition is associated with anionic groups, aromaticity hydrophobicity, amine groups with low pKa values and most non-acidic oxygen compounds. The chemoresponsive neurons of the geniculate ganglion are divisible into three distinct functional groups with differing fiber diameters. These groups are selectively responsive to different chemical aspects of food solutions, with two of the unit groups being highly responsive to selected nitrogen compounds. Both unit groups I and II maximally respond to 5 and 6 member ring N heterocycles, but their response could be differentiated in terms of the Pka of the active group and the effect of ring substituents. Group III unit stimuli are less well defined but large responses may be obtained to nucleotides at concentration levels at or below those commonly found in animal tissues. This work supported in part by NSF Research Grants.

221 LIGHT AND ELECTRON MICROSCOPIC LOCALIZATION OF ACETYLCHOLINESTERASE IN THE MAIN AND ACCESSORY OLFACTORY BULBS OF THE MOUSE. Gail D. Burd*, Keith A. Carson and Jacob S. Hanker (Spon: A. Rustioni) The Dental Research Center and Neurobiology Program, University of North Carolina, Chapel Hill, N.C. 27514.

Light microscopic enzyme histochemical and electron microscopic morphological studies have previously demonstrated both the discrete laminar organization of the acetylcholinesterase (AChE)-positive fibers and the ultrastructural features of the layers of the main olfactory bulb (MOB). Our studies utilized catalytic osmiophilic polymer generation to demonstrate the fine structural localization of AChE in both olfactory bulbs.

In light microscopic studies of the MOB, dense areas of stained fibers and terminals were observed adjacent to the mitral cell layer (MCL) and in the periglomerular region (PGR). Sparse fiber staining was present in the granule cell layer (GCL). A band of stained fibers ran in the plane of section (coronal) subjacent and concentric to the MCL. Groups of stained fibers were also observed near the apical pole of the cells of the MCL. In the PGR densely stained fibers outlined individual glomeruli. Throughout the MOB, cell body staining was negligible. Ultrastructurally, stained fibers in all locations had similar morphology. They were small, about 0.5μ, and unmyelinated. The stain was located on the axolemma and in the adjacent extracellular space. Frequently larger processes, presumably dendrites, apposed to the stained fibers also had stained plasma membranes. In the GCL, stained fibers appeared among groups of unstained fibers as well as near granule cell perikarya. Groups of stained fibers in the external plexiform layer(EPL) were observed near proximal dendrites. Profiles of stained fibers circumscribed individual glomeruli and, often, stained fibers were closely associated with nerve cells in the PGR. Stained fibers did not appear to be localized near one specific nerve cell type, but instead they were in close proximity to all three types.

The accessory olfactory bulb (AOB) had a different staining pattern. In contrast to the MOB, the glomerular layer of the AOB contained few, if any, AChE-positive fibers. The EPL had a small number of stained fibers, while many more were found subjacent to the MCL and in the GCL. Ultrastructurally, the stained fibers were very similar to those of the MOB.

The absence of AChE-positive neurons in the MOB and AOB indicates that the stained processes are extrinsic afferents. AChE positive perikarya have been found in the horizontal limb of the nucleus of the diagonal band, far lateral preoptic area, rostral lateral hypothalamus and the corticomedial complex of the amygdala. These areas have been suggested to contribute some of the centrifugal fibers to the olfactory bulbs. Supported by NIH grants DE 02668, DE 00288, MH 14277, HL 15888 and RR 05333.

222 ENHANCEMENT OF TASTE RECEPTOR BINDING BY EXPOSURE TO HIGH STIMULUS CONCENTRATION. Robert H. Cagan, Veterans Administration Hosp., and Monell Chemical Senses Center, U. of Pa., Philadelphia, PA 19104

A sedimentable fraction (P2) containing plasma membranes from the taste epithelium of catfish (*Ictalurus punctatus*) barbels was shown to bind L-[^{3}H]alanine [Krueger and Cagan, J. Biol. Chem. 251: 88-97 (1976)]. L-Alanine is among the amino acids shown electrophysiologically to be stimulatory to the catfish taste system [Caprio, Comp. Bioch. Physiol. 52A: 247-251 (1975)]. Our previous procedure, which employed the taste epithelium from only the barbels, has been extended in the present work to include the taste epithelium from the rostral, dorsal and dorsolateral surfaces of the fish. Previously this was difficult because of excessive mucus secreted on the body surface. It is now made possible either by intramuscular injection of atropine or by rapid sacrifice of the fish, which helps avoid the mucus contamination. Alanine-binding activity is enriched about 10-fold in Fraction P2 compared with the whole homogenate. Recovery of the binding activity in this fraction is essentially quantitative. By using the additional taste tissue noted as well as that of barbels, the yield (mg protein) of Fraction P2 is increased by around 10-fold.

The present results show an increase in the amount of L-[^{3}H] alanine bound to Fraction P2 after its prior exposure *in vitro* to a high concentration of L-alanine. Previously we noted (Krueger and Cagan, *op. cit.*) the loss of binding activity of Fraction P2 upon storage at -65°C. It is now demonstrated that similar storage of Fraction P2 in a high concentration of ligand (10 mM L-alanine, unlabeled) results in a substantial increase of binding (5 to 7-fold). Binding is measured after removal of the storage L-alanine by centrifugation and washing Fraction P2 twice with buffer. The enhancement is not contingent upon freezing the preparation; it occurs, for example, by exposure to 10 mM L-alanine for 30 min on ice. Prior exposure to D-alanine causes enhancement but to a lesser extent; it is also a less effective electrophysiological stimulus (Caprio, *op. cit.*).

The results could indicate the presence of "hidden" receptor sites, possibly as a consequence of the isolation procedure or possibly existing *in vivo*. It is postulated that some of the receptor macromolecules are readily accessible to ligand and others are localized within the cell membrane such that they become accessible upon perturbation of the membrane structure due to a high ligand concentration. (Supported in part by NIH Research Grant NS-08775 from NINCDS.)

223 RESPONSES OF HAMSTER RECEPTOR NEURONS TO CONTROLLED ODOR STIMULATION. Richard M. Costanzo and Robert J. O'Connell*. The Rockefeller University, New York, N. Y. 10021.

Selection of appropriate test odorants and precise control over their purity, concentration, and waveform are critical components to an adequate study of quality coding in the olfactory system. Although it is usually assumed that most mammals respond to a range of different odor qualities, the selection of a particular test odorant is often arbitrary and unrelated to those compounds normally discriminated by the experimental animal. Recent work in this laboratory has led to the isolation and identification of several biological odorants from estrous hamster vaginal discharge. This material contains compounds which normally elicit strong behavioral responses in the male (pheromones). Since the olfactory input for these behaviors must be initially processed by the receptors, it is conceivable that at least some receptor neurons might be more selective in their response to behaviorally active compounds. Seven compounds (chemical purity $>$ 99%) were selected for study. Three of these, n-amyl acetate, ethyl acetate, and ethyl isobutyrate, are traditional odors not found in vaginal discharge. The remaining compounds, dimethyl disulfide, n-butanol, n-hexanol, and ethyl n-butyrate, are found in vaginal discharge; and one, dimethyl disulfide, is a powerful behavioral attractant for the male. An improved flow dilution olfactometer was constructed which included high efficiency odor saturators (teflon packed glass columns), a teflon mixing chamber, and a rotary sample valve for on-line injection of odor stimuli. Quantitative calibrations of both the stimulus concentrations and waveforms produced by the olfactometer were made using a flame ionization detector.

Odor stimuli were delivered to the exposed olfactory mucosa and extracellular responses recorded with metal microelectrodes. Most of the units studied to date are responsive to all odorants; however, the relative sensitivity to these compounds varies from neuron to neuron. The concentration-response functions for a typical odorant usually encompass 1-2 log units of concentration while individual thresholds for different compounds range from 3.16×10^{-7} to 1.0×10^{-4} molar. We have yet to observe a neuron exclusively sensitive to one odor. (Supported by NIH Grant NS 08902.)

224 EFFERENTS AND CENTRIFUGAL AFFERENTS OF THE HAMSTER OLFACTORY BULB. B.Davis, F.Macrides, W.Youngs* and S.Schneider*. The Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

The efferents and centrifugal afferents of the main olfactory bulb (MOB) were studied in the hamster using orthograde and retrograde tracing techniques. Following injections of tritiated amino acids which were restricted to the MOB, autoradiographic grains were observed ipsilaterally in layer IA of the entire anterior olfactory nucleus (AON), the so-called anterior continuation of the hippocampal rudiment, the entire rostrocaudal extent of the prepyriform cortex and olfactory tubercle, the anterior and posterolateral cortical amygdaloid nuclei and the lateral entorhinal cortex. No subcortical or contralateral projections were observed. Following injections of HRP which were restricted to the MOB, contralateral HRP-positive cells were identified only in pars externa, dorsalis, lateralis, ventralis and posterior of the AON. More heavy labelling and a wider distribution of labelled cells were observed ipsilateral to the injected MOB. HRP-positive cells were found throughout the AON, in the anterior continuation of the hippocampal rudiment and in the anterior portion of the prepyriform cortex. No labelled cells were found in the olfactory tubercle, cortical amygdaloid nuclei or entorhinal cortex. HRP-positive cells were also observed ipsilaterally in subcortical structures of the basal forebrain and bilaterally in the midbrain. Labelling was observed in the fusiform cells of the diagonal band near the medial base of the forebrain at the level of caudal olfactory tubercle. Heavy labelling was seen in a distinct group of large, predominantly multipolar cells ("nucleus of the horizontal limb of the diagonal band" or "magnocellular preoptic area") that continued from the level of caudal olfactory tubercle to the level of the nucleus of the lateral olfactory tract. This band of HRP-positive cells could be followed more caudally to a position dorsal and medial to the nucleus of the lateral olfactory tract at the lateral margin of the lateral anterior hypothalamic area. Well-defined, isolated cells were found in the dorsal and median raphe nuclei, and on rare occasions in the locus coeruleus. The finding that the anterior continuation of the hippocampal rudiment is reciprocally connected with the ipsilateral MOB suggests that it may be grouped with the AON and anterior prepyriform cortex as structures which exert cortico-cortical influences on MOB function. The observed projections from the subcortical forebrain and midbrain may mediate limbic-hypothalamic influences on MOB function. (Supported by NINCDS grant NS12344 and NSF grant BNS75-07652)

225 CONDITIONED TASTE AVERSION IN GENETIC OBESITY. Melvin Enns*, Geoffrey Nowlis*, Joel Grinker* (Spon: Victoria Luine). Rockefeller University, New York, New York 10021.

Sucrose consumption of 24 genetically obese and 24 lean female Zucker rats (age 3-4 mo., wt. $\bar{x}$ = 432g and $\bar{x}$ = 220g) was examined using a conditioned taste aversion paradigm. Rats received either .1M sucrose (experimental) or water (control) paired with apomorphine hydrochloride (30mg/kg ip) and then the intake of .01M, .0316M, .1M and .316M sucrose was measured. The degree of the conditioned aversion was similar for obese and lean rats and was a function of test solution concentration; experimental subjects drank significantly less .1M and .316M sucrose than controls. Following a second conditioning trial, the intake of .75M glucose, .1M sucrose, .001M saccharin and .025M sodium cyclamate was measured. Again, the degree of the conditioned aversion was similar for obese and lean rats and was related to type of sweetener; experimental subjects drank significantly less .75M glucose and .1M sucrose than controls. Next, .1M sodium chloride was paired with the apomorphine hydrochloride and the intake of .1M sodium chloride was measured. The degree of the conditioned aversion and the rate of extinction were similar for obese and lean rats; experimental subjects drank significantly less .1M sodium chloride than controls on the first test day but not on days 2,3 and 4.

In another experiment, the same absolute dose of apomorphine hydrochloride for all subjects (equivalent to 30mg/kg for lean rats) produced similar conditioned taste aversions between 16 obese and 16 lean female Zucker rats (age 4-6 mo.; wt. $\bar{x}$ = 445g and 224g) to .1M sucrose or .1M sodium chloride. However, during four weeks of weekly conditioning and daily testing, experimental and control obese rats decreased their sucrose intakes while experimental and control lean rats increased their sucrose intakes. These long-term changes did not occur with sodium chloride. The data confirm previous findings of normal or subnormal sucrose intakes by obese Zucker rats (Grinker and Roswell, EPA, 1974; Grinker, Obesity in Perspective, 2, 1975) and suggest that experiential rather than sensory factors contribute to the decreased intake. (This work is supported by NSF Grant BNS 76-09957).

226 TRANSMISSION WITHIN OLFACTORY RECEPTORS. R. C. Gesteland, J. A. Weier*, G. D. Adamek* and R. A. Yancey*. Northwestern Univ. Dept. of Biol. Sci., Evanston, IL 60201.

Current pulses injected intracellularly in mud puppy olfactory receptor neurons evoke action potentials when they depolarize the soma membrane as little as 1 mv. These neurons, like olfactory receptors in other vertebrates, fire spontaneously and irregularly in the absence of stimulation. Low intensity odorous stimulation commonly acts by adding additional impulses without changing the slow burst patterns of the spontaneous activity. Thus these cells apparently achieve high sensitivity by being poised close to a noisy threshold. It would be expected that more intense stimulation would evoke large depolarizations and a regular-interval, rapid action potential rate. However, intracellular records from the soma region, the only portion of the cell large enough to sustain penetration, do not support this. The maximum depolarization recorded with highest achievable stimulus concentrations is a few mv. Most stimuli presented at intensities sufficient to increase spike rate evoke soma depolarizations too small to be distinguished from noise. Further, while penetration-evoked soma depolarization results in action potentials of 60 mv, naturally-occurring ones never have amplitudes greater than 10 mv. Thus action potentials do not invade the soma actively, stopping 2 or more length constants away. Since the soma lies between a long dendrite at the end of which the stimulus acts and the axon, the receptor region is separated from the site of spike origin by 4 or more length constants. The intervening soma effectively decouples the dendritic receptor potential from the axonal generator potential and both from the recording electrode. The longitudinal current flow in the cell transmits the stimulus information and this current cannot be measured directly. We would expect considerable loss of current through the unsheathed soma and axon membranes and, as a result, poor sensitivity of the receptors. Extracellular measurements suggest that an unusual transmission process which avoids this loss may be involved. Monopolarly-recorded action potentials of single cells in the soma region commonly have 6 or 7 clearly distinguishable phases. These could result from an abrupt change in propogation velocity of the action potential in the vicinity of the recording electrode or from summation of more than one active event. The former is not likely here since the action potentials do not invade the soma. It may be that the stimulus evokes dendritic action potentials and that current from these modulates the rate of occurrence of action potentials of axonal origin. Supported by NSF Grant No. BNS 75-02339 and Northwestern University.

227 CHOLINE ACETYLTRANSFERASE AND ACETYLCHOLINESTERASE IN THE OLFACTORY SYSTEM OF THE RAT. D.A. Godfrey*, C.D. Ross* and A.D. Williams* (SPON: N.R. West). Depts. of Pharmacol. and Anat. and Neurobiol., Washington Univ. Med. Sch., St. Louis, Mo. 63110.

Quantitative histochemical mapping procedures have been applied to measure choline acetyltransferase (ChAc) and acetylcholinesterase (AChE) activities in the olfactory system of male Sprague-Dawley rats. Data for many regions in one rat, which have been supported by measurements on certain of these regions in three other rats, are summarized below, enzyme activities in amount/kg dry wt/min, mean ± SEM (no. of samples):

Region	ChAc(μmoles)	AChE(mmoles)
OLF. BULB, olf. nerve layer	9±3(3)	2±1(6)
glomerular layer	472±40(6)	42±3(11)
ext. plexiform layer, superf.	557(2)	48(2)
ext. plexiform layer, deep	353±20(6)	30±1(8)
mitral cell body layer	408±30(3)	37±1(3)
int. plexiform layer	439±24(3)	42±2(6)
granular layer	224±14(11)	25±2(10)
ANT. OLF. NUCLEUS, layer I	328±21(14)	33±1(15)
layer II	349±11(17)	39±1(27)
ant. commissure	52±22(3)	10±1(4)
PIRIFORM CORTEX,ROSTRAL, layer I	271±35(4)	29±2(8)
layer II	558±34(3)	50±3(4)
layer III	447±57(4)	54±5(7)
PIRIFORM CORTEX,CAUDAL, layer I	510±67(5)	60±9(4)
layer II	1115(2)	119(2)
layer III	1264±235(3)	165±28(5)
OLF. TUBERCLE, layer I	1230±80(3)	307±26(4)
layer II	1450(2)	480±39(3)
layer III	1362±79(10)	437±33(9)
NUCLEUS OF LOT, layer I	964±34(3)	116±16(9)
layer II	2563±139(3)	258±12(8)
layer III	1428±242(4)	151±34(3)
HORIZ. LIMB OF DIAGONAL BAND	982±55(10)	149±4(6)
LATERAL OLF. TRACT (LOT)	70±13(12)	8±1(11)

These data suggest that the olfactory nerve fibers and the mitral cells (whose axons comprise the bulk of the lateral olfactory tract) are not cholinergic, but that cholinergic neurons are nevertheless prominent in the olfactory system. Attempts to identify these cholinergic neurons have been started in collaboration with Dr. J. L. Price, through measurements of enzyme activities following surgical lesions at various locations. (Supported by NIH Grant NS08000 to F. M. Matschinsky).

228 IDENTIFICATION OF GENICULATE GANGLION SOMATA THAT PROJECT VIA THE RAT CHORDA TYMPANI USING HORSERADISH PEROXIDASE. Maximo M. Gomez. Dept. Anat., Bowman Gray Sch. Med., Winston-Salem, N.C. 27103

The chorda tympani nerve contains chemosensitive and mechanosensitive fibers whose cell bodies are located within the geniculate ganglion (GG). This study was designed to determine the topographic organization of these somata within the GG and to distinguish them from the neurons whose peripheral processes run in the greater superficial petrosal (GSP) and posterior auricular (PA) nerves. The CT was cut in the infratemporal fossa, several dry flakes of horseradish peroxidase were applied to the central end three times during an 8 hr. period and allowed to disolve in the surrounding tissue fluid. After intracardiac perfusion and fixation, both the experimental and contralateral control GG were removed and reacted en bloc with diaminobenzidine and H_2O_2, dehydrated, embedded in paraffin and serial sectioned at 15u. In the experimental GG, 3% of the total GG cells contained HRP positive granules. These cells are all in the lower size range of GG somata, being 15u to 25u in maximal cross-sectional diameter. The labeled cells are primarily located in the ventral region of the GG where they are spread close to the main trunk of the VIIth nerve (posterior in the ganglion). The labeled cells that are found more dorsally within the GG nearly always occur along the medial margin of the ganglion. Although these preliminary results are not quantitative for the afferents in the CT, similar HRP experiments are in progress to determine the subpopulations of somata within the GG that project via the GSP and PA nerves. This will allow the study of the architectonics of these neuronal subpopulations and a correlation between some aspect of perikarial morphology or location and the peripheral sensory field to which they project.

(Supported in part by NIH Grant NS 10389)

229 TOPOGRAPHIC ORGANIZATION OF THE ASSOCIATION FIBER SYSTEMS IN THE OLFACTORY CORTEX OF THE RAT. L.B. Haberly*, M.B. Luskin*, and J.L. Price (Spon: M.B. Bunge). Dept. Anat. and Neurobiol., Washington Univ. Sch. of Med., St. Louis, MO 63110.

Studies of the association fiber systems in the olfactory cortex of the rat, using HRP as a retrograde and anterograde axonal tracer and the autoradiographic method, have revealed the presence of a broad and overlapping, but systematic topographic organization. This organization is present in the projections to the cortical areas at the level of the lateral olfactory tract (anterior olfactory nucleus, anterior piriform cortex, olfactory tubercle, and ventral agranular insular cortex) and encompasses the projections from the anterior olfactory nucleus, piriform cortex, and a newly discovered projection from the entorhinal cortex. These fiber systems are organized such that fibers from progressively more caudal areas terminate in broad strips, oriented parallel to the lateral olfactory tract, which are progressively further removed from the tract on both the lateral and medial sides. Thus the anterior olfactory nucleus (the most rostral olfactory cortical area) projects most heavily to the cortex deep to the tract; the anterior piriform cortex projects to the cortex deep and adjacent to the tract both medially and laterally; the posterior piriform cortex projects to strips further removed from the tract with little projection to the cortex deep to the tract; the entorhinal cortex projects only to the cortical areas furthest removed from the tract (most medial portions of the olfactory tubercle and the anterior olfactory nucleus).

There is also an organization in the tangential dimension in other portions of the association fiber system, but no other clear examples of topographically ordered (systematic point to point) projections have been found. Thus while many of the olfactory cortical areas or cytoarchitectonically distinct subdivisions of these areas have characteristic projection patterns to restricted regions, neighboring areas often project to non-adjacent regions.

Commissural fiber projections from three cortical areas have been demonstrated (from the anterior olfactory nucleus to the opposite anterior piriform cortex; from the anterior piriform cortex to the opposite posterior piriform cortex and adjacent cortical areas; from the nucleus of the lateral olfactory tract to the medial portion of the opposite anterior piriform cortex and adjacent portion of the olfactory tubercle). In all cases the commissural projection is matched by a very similar ipsilateral projection from the same area, but no evidence for any further degree of organization of a topographic nature has been found within any of these systems. Supported by NIH Grants NS09518 and NS05162.

230 BEHAVIORAL AND BIOCHEMICAL SUPPORT OF OLFACTORY NEURON REPLACEMENT. Joseph W. Harding[1], Kate Donlan[2*], Nancy Chen[1*], John Wright[2*]. Dept. Veterinary Pathology, Dept. Pyschology[2], Washington State Univ., Pullman, WA 99164.

Behavioral and biochemical evidence is presented which strongly suggests that the primary olfactory chemoreceptor neurons in the adult mouse are capable of being replaced, presumably from a population of undifferentiated stem cells. This data further corraborates previously published biochemical and morphological studies which supported the unusual notion of neuron replacement in adult mice (Harding et al, Brain Res, in press). Mice were trained to find buried food pellets of various sizes within a time period of three minutes. After training, mice were bilaterally olfactory nerve sectioned. Starting two days after nerve section and continuing until 30 days postop, the olfactory capabilities of the animals were determined using the food finding test. At day 3 a few operated animals began to find the buried food pellets. The number of animals finding the buried pellets steadily increased and by day 19 all the operated animals were finding the pellets. Although all the operated animals were finding the pellets, the latency for finding was longer than for unoperated mice. Animals were taken for biochemical analysis at various points during the time course of loss and return of olfactory mediated behavior. At days 3,9,12,21, and 45, mice were intranasally irrigated with ^{14}C-β-alanine, the precursor of the specific olfactory neuron marker, carnosine. Carnosine is known to be synthesized in the olfactory epithelium and transported to the bulb. Both ^{14}C-β-alanine and ^{14}C-carnosine content were measured in the olfactory epithelium and olfactory bulb. Three days following nerve section the amount of ^{14}C-carnosine transported to the bulb was less than 10% of control values. The amount transported increased during the time course of the experiment and by day 45 had reached approximately 55% of control values. This return in the ability of the primary olfactory system to synthesize and transport the neuron specific marker, carnosine, is consistent with the return of olfactory mediated behavior, the concept of neuron replacement, and the formation of new functioning synapses with the bulb.

231 PREPARATION AND CHARACTERIZATION OF CELLS FROM RAT OLFACTORY MUCOSA. James D. Hirsch* and Frank L. Margolis. Dept. Physiol. Chem. & Pharmacology. Roche Inst. of Molec. Biol., Nutley, NJ

Our lack of understanding of olfaction may be blamed in part on the inability to assess the functions of the individual cell types in the olfactory mucosa. Interaction of odorant molecules with the chemosensory neurons is known to occur but this process is poorly understood. The role of the sustentacular cells is unclear. The basal cells are progenitor cells for the neurons, but the factors controlling their division and differentation are unknown. Thus, studies of isolated olfactory cells should be helpful to elucidate the individual cellular functions in olfaction.

The turbinates and nasal septum containing the olfactory and respiratory epithelia were subjected to enzymatic digestion with collagenase and hyaluronidase and mechanical disruption yielding a suspension of viable cells which synthesize RNA and protein from radiolabeled precursors. The olfactory neurons, sustentacular cells and respiratory epithelial cells could be identified by phase contrast microscopy, but the basal cells could not be identified. The cell suspensions were fractionated in discontinuous gradients of bovine serum albumin at unit gravity. Separation of the olfactory neurons from the various non-neuronal olfactory cells was achieved. Cells containing the olfactory neuron-specific marker protein (OMP) and the neuronal enzyme carnosine synthetase were in the upper fractions of the gradients. Nonneuronal cells containing carnosinase were in the lower fractions. These gradients were also analysed by immunocytochemical and histochemical techniques. The OMP and S-100 proteins were localized in cells from the gradient by staining with the PAP technique. S-100-containing nonneuronal cells were partially separated from OMP containing neurons by our fractionation technique. This is the first report of the presence of the S-100 protein (a presumptive glial marker) in this tissue and raises questions as to which olfactory cell type contains this protein and whether they are glial-like. Staining for secretory cells of Bowman's glands with Alcian Blue 8GS (pH 1.0), showed their presence in the suspension and their separation from the neurons. The Bowman's gland cells sedimented rapidly in the gradient.

Clearly, care must be taken to characterize separated cells by a variety of morphological and biochemical criteria before conclusions are drawn about the purity of the cell fractions. We have obtained cell suspensions enriched in olfactory neurons or nonneuronal cells. Work is in progress to purify these fractions further. The cell fractions will be used to probe the role of the individual olfactory cells in olfaction and study the interaction of odorant molecules with the chemosensory neurons in vitro.

232 SINGLE UNIT ACTIVITY IN THE OLFACTORY PATHWAY IN THE PIGEON. Larry V. Hutchison, Lyle J. Rausch and Bernice M. Wenzel. Dept. Physiol., UCLA Sch. of Med., Los Angeles, CA 90024.

Previous evoked potential and neuroanatomical studies in our laboratory identified 3 structures in the pigeon forebrain as primary ipsilateral projection areas of the olfactory bulb (OB), viz., cortex prepiriformis (CPP), lobus parolfactorius (LPO), and hyperstriatum ventrale (HV). Also identified were several secondary projection areas, viz., hyperstriatum accessorium (HA), hyperstriatum dorsale (HD), paleostriatum augmentatum (PA), paleostriatum primitivum (PP), nucleus septalis laberalis (SL), and neostriatum caudale (NC). We now report results of electrically stimulating the pigeon's olfactory nerve (ON) and recording extracellular single unit responses in the OB and ipsilateral projection areas confirming previous evoked potential records. Mean spike discharge rates in forebrain projection areas varied over a wide range for different cells (0.28->30 spikes/sec). Stimulation of ON with 8-12 V pulses (single or train), 0.5-1.0 ms duration, at 0.1-1.0 Hz resulted in modification of spontaneous activity (+25% change in rate). Response patterns of the majority of affected cells involved enhancement while a smaller number of cells showed depression. PST histograms for some cells showed peak spike discharge rates or periods of inhibition at a constant latency, consistent with latencies of phases of the evoked potential characteristically recorded from that site or through the same electrode. There appeared to be some degree of anatomical localization of effects; LPO and PP show a larger proportion of cells inhibited by ON stimulation, whereas the cell populations of the projection areas of the hyperstriatal complex generally show excitation. Records to date indicate that low rates of spontaneous activity may be characteristic of the mitral cell layer of the OB and in some cases a burst of spikes may be elicited at a latency comparable to the bulbar response (20-40 ms).

Tetanic stimulation of ON (20 Hz-20 sec) produced either potentiation-recovery or depression-rebound-recovery in forebrain projection sites. The time course of post-tetanic changes varied markedly for individual units from a few seconds to several minutes. Active units in other forebrain areas not known to receive olfactory input were not effectively modified by ON stimulation. (Supported by USPHS grant NS 10353 to B.M. Wenzel and a postdoctoral fellowship to L.V. Hutchison under grant MH 06415 to the UCLA Brain Research Institute.)

233 RESPONSE OF THE HAMSTER CHORDA TYMPANI NERVE TO TWO-COMPONENT MIXTURES. Angela M. Hyman* and Marion Frank* (SPON: C. Pfaffmann). Rockefeller Univ., New York, N. Y. 10021.

Most mammals are stimulated by taste mixtures in natural feeding situations. Yet, neurophysiological investigations have principally considered single-component stimuli. For instance, although the hamster chorda tympani nerve has been well characterized in its responses to individual substances, its responses to mixtures have not previously been studied.

Summated electrophysiological responses of the whole nerve were recorded to .01M NaCl, .05M NH_4Cl, .01M $CaCl_2$, .003M HCl, .1M sucrose, and .07M D-phenylalanine applied to the tongue individually and in two-component mixtures. The actual response to each mixture was less than the value calculated as the arithmetic sum of the responses to the components presented alone.

The response to a mixture will equal the value calculated as the arithmetic sum of the responses to the individual components if the components stimulate two independent sets of receptors. Alternatively, if the components stimulate the same set of receptors, the response to a mixture can be predicted from the response functions of either component presented alone. The response to a mixture will lie between these extremes if the sets of receptors stimulated by the components partially overlap. In order to determine which of these alternatives best describe the mixture data, summated responses were also recorded to the individual substances in ascending concentration series. Power functions were fitted to the response values for each substance at its concentration in the mixtures and plus and minus ½ log-step. The response to each mixture could then be scaled between the theoretical value predicted from the response functions and that calculated as the arithmetic sum of the component responses. Values on this scale express the degree of overlap of receptor stimulation by the different substances. The scaled values for the different mixtures indicate, for example, that $CaCl_2$ and HCl predominantly stimulate the same set of receptors whereas NaCl and D-phe do not. The individual stimuli can be divided into two groups: sucrose and D-phe, and the electrolytes. Although the extent of the overlap between sets of stimulated receptors varies, in general, it is greater between substances in the same group than between substances in the different groups. However, the electrolytes overlap somewhat more with sucrose than with D-phe.

Inhibition was observed when certain electrolytes (e.g., $CaCl_2$ and NH_4Cl) were mixed at these concentrations.

234 OBSERVATIONS ON MORPHOLOGICAL CHANGES IN THE VOMERONASAL ORGAN OF GARTER SNAKES FOLLOWING VOMERONASAL NERVE SECTION. John L. Kubie*, Ruu Tong Wang* and Mimi Halpern (Spon: K. Koizumi). Dept. of Anatomy and Cell Biology and Program in Biological Psychology Downstate Medical Center, Brooklyn, N.Y. 11203.

Following vomeronasal (VN) nerve section the VN mucosa of garter snakes undergoes a dramatic retrograde necrosis which when viewed in Bodian stained sections is marked by a loss of the cell bodies occupying the bipolar nuclear layer, a loss of the dendrites of bipolar neurons and an apparent thinning of the superficial epithelial layer. The layer of undifferentiated cells does not undergo major morphological changes.

Partial VN nerve section results in degeneration of bipolar cells in those columns from which the severed axons emerged. Results of several partial vomeronasal nerve lesions reveal that the projection from the VN organ to the accessory olfactory bulb via the VN nerve is topographically organized: dorsally situated VN nerve fibers originate from bipolar neurons in the anterior, dorsal portion of the organ; ventrally situated fibers originate from caudal, ventral regions of the organ.

Electron microscopic observations of the VN organ two weeks after transection reveal that although the columnar cells themselves do not undergo degeneration, the organization of the epithelial cell layer changes from a simple columnar type with cell nuclei restricted to its basal portion to an epithelium with many nuclei lying adjacent to the luminal surface. Thinning of the epithelial layer is partially due to shortening of columnar cell cytoplasmic processes which line the lumen of the organ. In addition, following nerve cuts, columnar cells contain an increased number of lysosomal and secretory granules particularly at their luminal pole.

In the bipolar cell layer a marked loss of cell bodies is observed. Cells undergoing degeneration become polymorphic, contain many large lysosomes, multivescicular bodies and lamellar vescicles. Cytoplasmic organelles become disorganized. The nuclei are reduced in size, irregular in shape and contain randomly dispersed chromatin. Intermingled with the debris of degenerated neurons were a few neurons whose morphological characteristics were identical to normal bipolar neurons. In addition, at the base of the bipolar nuclear layer 2 or 3 compact rows of neuron-like cells were observed. We presume that the remaining neurons are either cells which differentiated following the nerve cuts or cells whose growing axons had not yet reached the level of the nerve cut at the time of surgery.

The layer containing undifferentiated cells was free of signs of degeneration. Degenerating columns were marked by cell proliferation and an increased frequency of mitotic figures when compared with healthy columns in the same animal. Supported by NIH grant NS 12152

235 ORBITOFRONTAL NEOCORTEX OF RATS AND ODOR DISCRIMINATION. L. Leach*, S. Kiefer*. Ariz. St. Univ., Dept. of Psych., Tempe, AZ 85281. (SPON: E. Davis, Dept. of Anatomy, Univ of Calif. at Irvine, Medical School, Irvine, CA 92717).

Leonard (Brain, Behav, Evol. 6: 524, 1972) has shown that the rat's orbitofrontal neocortex receives input from the primary olfactory cortex (piriform area) via the dorsomedial thalamic nuclei. The present study compared the ability of unoperated rats (Group U, n=20) and rats with bilateral orbitofrontal ablations (Group OF, n=10) to acquire a discriminative learned odor aversion. Three stimulus conditions were used. In condition PO drinking water in the presence of an odor was followed by toxicosis induced by injections of apomorphine hydrochloride. In condition UO drinking water in the presence of an odor different from that used in condition PO was never paired with toxicosis. In condition NO all rats drank water in the absence of an odor without the induction of toxicosis. It was found that bilateral orbitofrontal ablations impaired the ability of rats to associate odors with toxicosis and/or to discriminate between the paired and unpaired odors. After 6 presentations of each condition, rats in Group U exhibited the ability to discriminate between paired and unpaired odors. The Group U rats exhibited a significant aversion to drinking water during condition PO relative to either conditions UO or NO, but did not exhibit a significant aversion to drinking water during condition UO relative to condition NO. After 6 presentations of each condition, rats in Group OF drank less water during both conditions PO and UO relative condition NO but the differences were not significant. It is concluded that in the rat the region of the orbitofrontal neocortex shown by Leonard (1972) to receive input lower olfactory areas via the dorsomedial thalamic nuclei plays a role in acquiring a disciminatively specific avoidance to odors.

236 A THEORETICAL MODEL OF CHEMOSENSORY TRANSDUCTION IN CATFISH. Joseph F. Metcalf. Center for Sensory Studies. University of Florida, Gainesville.

The olfactory and gustatory chemoreceptors of catfish are extremely sensitive to low stimulus concentrations, and show a high degree of specificity for amino acids. The stimulus-response relationship does not obey Beidler's fundamental taste equation, however, and is best described as a power function with exponents between 0.08 and 0.14 (Suzuki and Tucker, Comp. Biochem. and Physiol, 1971; Caprio, O. and T. V, 1975).

A simple modification of a previous model (Metcalf, Neuroscience Abstracts, 1976) is proposed to account for the rapidly adapting catfish chemoreceptor responses and predict the power function relationship between response and stimulus concentrations. The amino acid, A, is assumed to bind a specific receptor protein, P, which has a single binding site for the amino acid on the external surface of the receptor cell, and multiple (i) binding sites for substance X on the inner or cytoplasmic side of the membrane. X is assumed to be a precursor of substance Y. Binding of the amino acid to the active receptor protein P(X)i, produces an activated complex, A-P(X)i, which generates substance Y and the inactive receptor, A-P. Y is assumed to function as in internal transmitter, and the amplitude of the receptor response is assumed to be determined by the rate at which Y is generated. The active form of the receptor protein, P(X)i, is regenerated by subsequent steps of the reaction sequence.

The Continuous System Modeling Program (C.S.M.P.) was used with the IBM 370 computer to simulate the time-course of receptor response and generate response amplitudes as a function of stimulus concentration. The simulated responses show a rapid rise to a peak followed by a rapid decline to a low value. The response amplitudes are described by a power function of stimulus concentration extending over a wide range. The exponent of the power function, n, is equal to the reciprocal of i, the number of internal binding sites for substance X on the receptor molecule.

The proposed model is consistent with the time-course of receptor response, and accounts for the quantitative stimulus-response relationship, extended dynamic range, and extreme sensitivity of the olfactory and gustatory chemoreceptors in catfish.

237 TASTE RESPONSES TO SOLUTIONS OF DEUTERIUM OXIDE. Inglis J. Miller, Jr. and Gregory Mooser*, Dept. of Anatomy, Bowman Gray School of Medicine of Wake Forest Univ., Winston-Salem, NC 27103 and Dept. of Biochemistry, University of Southern California, Los Angeles, CA 90007.

Deuterium oxide (D_2O), the "heavy hydrogen" analog of water (H_2O), has been used in studies of excitable tissues because its chemical properties are similar to ordinary water but its physical properties differ because of greater atomic mass. Recently, Richter (P.S. E.B.M. 152, 677, 1976) demonstrated that rats discriminate between D_2O and H_2O in favor of water when offered a choice, but concluded that rats were unable to taste a difference among the two compounds. In the current study, summated electrophysiological responses were recorded from whole chorda tympani nerves in the rat in response to stimulation of the tongue with solutions of D_2O. Solutions consisted of sodium chloride, sodium benzoate, potassium chloride, potassium benzoate, quinine hydrochloride, and sucrose in concentrations from .01 to 1.0 molar for the salts. Sucrose concentrations included .02 to 2.0M and quinine HCl solutions of .003 to .03 M were used. Distilled H_2O was used to prepare control solutions of the same molar concentrations for comparison with solutions of D_2O. Application of D_2O to the tongue, which was previously rinsed with H_2O, resulted in an immediate response that was maintained until the D_2O was rinsed with H_2O. The magnitude of this response was intermediate to those elicited from H_2O solutions of NaCl between .03 and 1.0 M. NaCl and KCl responses from D_2O solutions were comparable in magnitude to H_2O solutions for concentrations above 0.1 M when this concentration was used as a standard; however responses to D_2O solutions of NaClat .01 and .03 M concentrations were greater in magnitude than for corresponding H_2O solutions. D_2O solutions of sucrose elicited responses which were smaller than equivalent concentrations of H_2O solutions; on the other hand, responses to quinine solutions of D_2O were greater than comparable H_2O solutions. Responses elicited when potassium benzoate was rinsed from the tongue with pure solvent, which have been called "water responses" by some investigators, could be elicited by D_2O. These preliminary observations are being continued to determine the effects of solvent-solute interactions on taste responses. (Supported in part by NIH Grant NS 10389).

238 INTERACTIONS BETWEEN NERVES AND EPITHELIA DURING TASTE BUD AND PAPILLA DEVELOPMENT IN FETAL SHEEP. Charlotte M. Mistretta and Robert M. Bradley. Dept. Oral Biol., Sch. Dent., U. Mich., Ann Arbor, MI 48109.

To study nerve-epithelium interactions during taste bud and papilla development, autogenous cross-grafts of anterior dorsal tongue mucosa and external cheek skin were made in 12 fetal sheep aged 52-107 days of gestation (term=147 days). Grafts, including epidermis and dermis, were made in fetuses during sterile surgical procedures; fetuses were then replaced in utero. At 134-144 days fetuses were delivered and fixed by perfusion. Graft and control tissues were dissected and prepared for light microscopy. In the youngest fetal age at the time of grafting (52 days, weight ~ 20 g) epithelium contains immature fungiform papillae and presumptive taste buds; cheek epidermis contains follicle plugs, the first stage in wool follicle development.

All grafts continued to differentiate at transplant sites and became innervated. Cheek skin transplanted to the dorsal tongue acquired the cornified cell layers, mature wool follicles, and wool fibers characteristic of normal mature cheek. Although grafts remained at the tongue site for 37 to 82 days, no fungiform papillae or taste buds formed. Tongue epithelium transplanted to the external cheek acquired additional cell layers and mature filiform papillae. However, only in tongue grafts that had been made in fetuses aged 52-67 days of gestation were there any structures resembling fungiform papillae or taste buds; in older fetuses the taste buds and papillae that were already present degenerated and did not re-form. About 1-5 fungiform papillae were present in each tongue graft made in the younger fetuses. These papillae had a typical fungiform shape and broad connective core, but were atypical in that they usually had a filiform-type, keratinized point on one edge. Two-three of these papillae on each graft contained a structure resembling an immature taste bud. The buds were composed of a cluster of disoriented cells with no taste pore.

From these initial results we conclude that: 1. Tongue nerve fibers will not induce taste bud and papilla development in nongustatory, cheek epidermis, even when the epidermis is grafted at a very immature stage of development. 2. Not only taste bud development, but also, fungiform papilla differentiation and maturation is under the influence of tongue nerves. 3. A few structures resembling taste buds and fungiform papillae can be induced to form in tongue epithelium under the influence of the nongustatory, trigeminal innervation to the cheek if the tongue is transplanted early enough in development. Therefore, it is suggested that nerves and epithelia interact differently at different stages of development in the process of taste bud and papilla differentiation. (N.I.H. Grant DE-04491)

239 DEOXYGLUCOSE AND ELECTROPHYSIOLOGICAL MAPPING OF CHORDA TYMPANI ACTIVITY IN RAT NUCLEUS SOLITARIUS. M.A. Orlandi*, R.P. Erickson, A.E. Johnson* and L.C. Skeen, Departments of Psychology, Physiology and Anatomy, Duke University, Durham, N.C. 27706

In order to better elucidate the taste pathways within the mammalian central nervous system, we have initiated a series of studies in rats which combine electrophysiological analyses with an autoradiographic method that allows anatomical localization of stimulus-induced cerebral deoxyglucose consumption (Science, 187: 850, '75). In the present studies, rats were given IV pulse injections of ^{14}[C]-2-deoxy-D-glucose (150-250μCi/kg) and exposed either to a) natural taste stimuli on the tongue (e.g., 0.1M NaCl), or b) electrical stimulation of chorda tympani nerve (3-15v/0.2ms., 20/sec) combined with recording electrode placements in nucleus tractus solitarius (NTS) guided by natural taste stimuli. The animals' brains, and those of control rats, were subsequently processed for x-ray film autoradiography (DuPont, LoDose). Under the latter conditions, maximal ipsilateral NTS activity proved stable over the 1 hr. stimulation period.

Autoradiographs of cryostat-cut 30μm coronal sections from the same brains reveal highly localized patterns of increased activity-related deoxyglucose consumption (i.e., increased optical density) within a portion of the ipsilateral, but not the contralateral, NTS. Similar increases in autoradiographed NTS optical density are less circumscribed, and predictably less intense, in animals exposed to natural taste stimuli, and they are not found in the control animals. High optical densities in other neural structures (e.g., components of the vestibular and auditory systems) are similar among all animals. These results show that neuroanatomical components of the taste pathways can be directly visualized and partitioned with deoxyglucose autoradiography in correspondence with simultaneously determined electrophysiological response properties of their cells. Further studies will be aimed at more refined electrophysiological and anatomical analyses of the individual neuroanatomical subdivisions associated with each deoxyglucose circumscribed taste pathway.

Supported by Grants from NSF (BMS 75-04230 and BNS 75-22692), NINDS (NS-09623), and the U.S. Army (14195-L).

240 TASTE DISCRIMINATION, GENERALIZATION, AND THE GUSTATORY NEOCORTEX. J A. Phillips* and J.J. Braun* (SPON: A S. Schwartz). Arizona State University, Tempe, AZ 85281.

The learned discrimination and generalization capacities of rats lacking gustatory neocortex (N=12) were compared to normal rats (N=12) using similar salts as stimuli. All rats were trained to avoid LiCl (.12 M). After training, normal rats (Group NT) were found to generalize to NaCl solutions (.04 M, .12 M, & .36 M) in proportion to how closely they resembled the LiCl training concentration. Group GN generalized along an absolute continuum of stimulus intensity. In addition, at near-threshold concentrations of NaCl (.004 M, .012 M, & .036 M) Group GN did not generalize, whereas Group NT did. Both groups were able to discriminate .12 M LiCl and .12 M NaCl, but Group GN continued to drink more LiCl than Group NT throughout training, suggesting that they may use post-ingestional effects to make such discriminations instead of taste differences.

In Experiment II, 23 rats were trained to avoid LiCl (.12 M). Subsequent aversion generalization tests with NaCl solutions (.12 M, .18 M, & .24 M) supported the results of Experiment I. When the concentration of LiCl was lowered to .06 M, Group NT learned to avoid the solution but Group GN did not. Taken together, these results support the hypothesis that rats lacking gustatory neocortex display elevated association thresholds for detectable taste stimuli.

241 THE ROLE OF NUCLEUS BASALIS IN OLFACTORY BULB RESPONSES TO ODORS IN RABBITS. Harry Potter* (SPON: S.L. Chorover). Dept. of Psych., MIT, Cambridge, Mass. 02139.

The nucleus basalis (NB) includes a group of large, multipolar cells in the basal forebrain which project to the olfactory bulb (OB) and anterior olfactory nucleus (AON). We have examined the activity and responses of these cells while simultaneously recording from units in the OB of awake, partially restrained rabbits. The motivational and arousal state of each rabbit was manipulated by food-deprivation (hunger), sleep, visual and auditory stimulation (arousal), and immobilization (animal hypnosis), as well as by administration of insulin following eating (induced hunger). Records of unit activity from OB and NB were compared with cortical EEG, and nasal air flow recordings obtained simultaneously. While NB units were more sensitive to behavioral state, both NB and OB units responded to odors. Both NB and OB responses to food odors were selectively enhanced during food deprivation and induced hunger, while hypnosis reduced responsiveness to all odors. Insulin induced hunger was also often accompanied by changes in valence of OB or NB unit responses to odor. None of the observed state-dependent odor responses could be accounted for by changes in sniffing patterns. Effects of state manipulation and reversible inactivation of NB (via Lidocaine infusion) upon OB unit responses to odor are examined.

Supported by NIGMS Grant NIH-5-T01-GM01064-15 and NIH Grant MH 28244-01, and NIMH Grant MH 07923-13.

242 TASTE RESPONSES OF GLOSSOPHARYNGEAL NEURONS OF THE MUD PUPPY (NECTURUS MACULOSUS). David W. Samanen*and Rudy A. Bernard (SPON: P.P.C. Graziadei). Dept. Physiol., Michigan State University, East Lansing, MI 48823.

The electrophysiological responses to four taste stimuli (HCl, NaCl, quinine hydrochloride, and sucrose) were recorded from glossopharyngeal single-fiber preparations of an aquatic amphibian, the mud puppy, Necturus maculosus. The effects of stimulus concentration upon the response magnitude, the response latency, and the form of the response were observed over a 3.5 Log_{10} range. The response was observed to take one of three forms: increasing activity on stimulation, decreasing activity on stimulation, or increasing activity to the distilled water rinse. All response parameters (magnitude, latency, and form) were found in 9 specific combinations (e.g., 1. responses of increasing magnitude and decreasing latency as stimulus concentration increased, or 2. responses of constant magnitude and latency over the range of concentrations.

Following the standard extracellular, macroelectrode recording, the isolation of each neuron was evaluated by computer analysis of the diphasic action potential amplitude. An enumerator computer program, employing the neuron's diphasic amplitude window, counted impulses over the 20 sec test period and pre- and post-stimulus distilled water rinses. To determine the response latency, a fluid switch circuit was used to determine the stimulus delivery time after each experiment.

Most neurons were found to be multiply sensitive (to two or more of the stimuli). However, the neurons also exhibited a degree of chemospecificity, often giving one of the 9 types of responses to one of the 4 stimuli. The type of taste response with constant magnitude and latency over the range of concentrations was stimulus-specific. In contrast, 12 of 24 fibers responded with increasing magnitude and decreasing latency to more than one of the stimuli.

243 CONTRIBUTION OF THE ANION TO THE SALTY TASTE. Susan S. Schiffman* Dept. Psychiatry, Duke Univ., Durham, N.C. 27710.

A group of sodium salts listed on the federal GRAS lists (sodium acetate; sodium ascorbate; sodium bicarbonate; sodium carbonate; sodium chloride; sodium citrate; monosodium glutamate; sodium phosphate, dibasic; sodium phosphate, monobasic; sodium tartrate; sodium succinate; sodium bromide; sodium sulfate) were compared at .2M Na^+ to determine the similarity of their tastes. There were a total of 19 different solutions, with 6 of the salts prepared twice: 1) at the pH normally found at .2M Na^+ and 2) at pH 7.0 adjusted by adding the corresponding acid or CO_2. ALSCAL, a multidimensional scaling procedure developed by Takane, Young, and DeLeeuw (Psychometrika, in press), was applied to the similarity measures to arrange the salts in a multidimensional space with salts tasting similar clustered near one another. The anion had an important contribution, inhibiting the salty taste in some cases and adding additional tastes of its own. Differences between PTC tasters and nontasters were found.

244 LAMINAR DISTRIBUTIONS OF SHORT AXON CELLS IN THE HAMSTER OLFACTORY BULB. S.Schneider*, F.Macrides, B.Davis and W.Youngs*. The Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

The laminar distributions of short axon (SA) interneurons in the main olfactory bulb (MOB) of adult hamsters were studied with rapid Golgi techniques. Six clearly identifiable classes of SA cells were observed and characterized according to somal location, dendritic arborization and axonal ramification. Two of these classes, the Golgi and Blanes cells, had their somata restricted to the interior regions of the MOB and were not observed more superficially than the mitral body layer (MBL). The Blanes cells could be found throughout the granule cell layer (GRL), whereas Golgi cells tended to lie in the superficial GRL and internal plexiform layer (IPL). The dendrites of these two classes extended in all directions from the somata and were not oriented with respect to the layers of the MOB. Their dendrites and axons tended to be restricted to the GRL but occasionally could be traced as far peripherally as the deeper portion of the external plexiform layer (EPL). Two other classes had somata which were restricted to the IPL and MBL, and dendrites which exhibited clear orientations with respect to these layers. One class (horizontal cells of Cajal) had dendrites which ran tangentially in the IPL and MBL, and extended only short distances into adjacent layers. The other class (vertical cells of Cajal) had radially oriented dendrites which extended peripherally into the superficial region of the EPL and centrally for greater distances into the GRL. Both classes gave rise to axons which projected peripherally as far as the border between the EPL and the glomerular layer (GL), but terminated predominantly in the EPL. Another class of SA cells had somata located predominantly in the superficial EPL and to some extent in the periglomerular regions of the GL. They had dendritic and axonal processes which extended far into the GL and appeared to branch around and between individual glomeruli, as well as in the superficial EPL. The sixth class, periglomerular (PG) cells, had somata located throughout the GL. Most PG cells gave rise to one dendritic trunk that arborized within a single glomerulus. Occasionally a second, less elaborate dendritic process emerged from the main trunk or from the soma and extended into an adjacent glomerulus. The axons of PG cells were only partially stained in our material. Such axons were restricted to the GL, but terminal arborizations were not found. These laminar distributions based on morphological observations correlate with electrophysiological data from our laboratory that reveal laminar distributions of response properties for spike generating interneurons in the MOB. (Supported by NSF grant BNS75-07652 and NINCDS grant NS12344)

245 INTENSITY CODING IN THE PONTINE TASTE AREA. Thomas R. Scott and Richard S. Perrotto*. Dep't. Psychol. and Inst. for Neuroscience and Behavior, Univ. of Delaware, Newark, DE 19711.

Increases in taste stimulus concentration have been shown to be represented by monotonically rising response rates from neural populations in the chorda tympani and solitary nucleus. Individual neurons within these populations nearly always show a similar direct relationship between stimulus intensity and discharge rate. In contrast, thalamic taste cells respond idiosyncratically and unpredictably to concentration changes, and population intensity-response functions show occasional non-monotonicity. Third-order neurons of the pontine taste area mediate between solitary nucleus and thalamic cells, and their responses to changing taste intensities were the subject of this study.

Forty single neurons from the pontine taste areas of acute Nembutalized rats were isolated by tungsten microelectrodes. Four qualities representing the four "basic tastes" were used, each at five concentrations covering a range of at least two log units. Pontine taste neurons responded similarly to, but not quite as vigorously as those of the solitary nucleus. NaCl evoked the most robust activity, followed closely by HCl. Sucrose and QHCl were only 35% as effective in stimulating these units. Responses were nearly always excitatory and of short latency. All stimuli elicited monotonic intensity-response functions from the pontine population sample, and all were adequately fitted to power functions with exponents of .18 to .22. Across-fiber patterns of activity within any quality correlated very well across intensities, indicating a high degree of taste constancy. In all of these characteristics, pontine units mirrored the activity patterns of first- and second-order neurons and were discrepant from those of fourth-order thalamic cells.

246 PRIMARY OLFACTORY NERVE AND UNDERWATER ELECTRO-OLFACTOGRAM (EOG) RESPONSES IN THE FRESHWATER EEL. Wayne L. Silver and Don Tucker. Dept. of Biological Science, Florida State University, Tallahassee, Florida, 32306.

Averaged neural activity recorded from small bundles of primary olfactory nerve with Pt-Ir wire electrodes and the "underwater" EOG recorded with calomel electrodes via Ringer-agar filled capillary pipettes were obtained from the freshwater eel. Both response magnitudes increased exponentially with logarithmic increase in stimulus concentration ranging over the 6 log units tested (10^{-8}M to 10^{-2}M), signifying power functions, $R=kC^n$, or exponential functions in terms of log C, $R=(10)^{n\log C}$. However, the exponent n, determined by the slope of a regression line fitted to the points of a log-log response concentration plot, was twice as large for the EOG (.21±.04, N=11) as it was for the neural response (.10±.02, N=8) with amino acid stimuli. Therefore, with decreasing concentrations, the EOG response declines at a rate twice as great as the neural response, suggesting that at lower stimulus concentrations the EOG response may appear to be absent. This may account for the EOG threshold ($10^{-8.2\pm1.1}$M, N=11) being higher than the neural response threshold ($10^{-9.9\pm2.4}$M, N=8). A given electrophysiological threshold concentration was determined from the extrapolation of the regression line to the control level. The control response has been concluded to be due primarily to chemical contaminants.

The freshwater eel has been reported to possess one of the most sensitive olfactory systems of all vertebrates (Teichmann, H., Z. Vergl. Physiol., 42:206, 1959). With behavioral conditioning techniques, threshold concentrations as low as 10^{-18}M were observed for such substances as phenethyl alcohol. Preliminary results in the present study show thresholds for phenethyl alcohol of $10^{-7.5}$M for the EOG and $10^{-9.9}$M for the neural response. Exponents were .15 for the EOG and .09 for the neural response. Although not as low as those obtained with behavioral conditioning methods, the electrophysiological threshold concentrations reported here for the freshwater eel are equal to or lower than those determined in a similar manner for other fish. (Supported by NIH grants, NS-08814 and NS-05258).

247 EFFECTS OF DEAFFERENTATION OF ACCESSORY AND/OR MAIN OLFACTORY SYSTEMS ON INFANT AND ADULT FEEDING BEHAVIOR IN RATS. Pauline J. Singh, Scott Manaker*, and Myron A. Hofer. Dept. Psychiatry, Albert Einstein Col. of Med., Montefiore Hosp., Bronx, N.Y. 10467.

It has been reported that 18 to 19-day-old pups which have undergone intranasal perfusion with 5% $ZnSO_4$ solution have exhibited deficiencies in suckling but not in solid food ingestion (Alberts, 1976). This indicates that the accessory system (which is not deafferented by $ZnSO_4$ treatment) is involved in solid food ingestion but relatively unimportant in normal nursing behavior. In this experiment the role of the accessory system as well as that of the main system in infant and adult feeding were more extensively investigated. Seven litters were observed, each litter having been culled to 7 pups. At 18 to 19 days of age, pups within each litter underwent vomeronasal nerve section (VN), which results in deafferentation of the accessory system; intranasal perfusion with 5% $ZnSO_4$ solution (Zn); bilateral olfactory bulbectomy (BOB), which results in deafferentation of main and accessory systems; or surgical control procedure (SC). Some pups were left intact as normal controls (N). After 24 hrs with their lactating mother, Zn and BOB pups lost weight, whereas VN, SC, and N pups gained weight (differences at $p<.01$). Pups were observed for latency to approach and ingest food pellets after 24 hrs of deprivation from their mother and solid food. Although their level of general activity was not different from that of other groups, BOB pups had a significantly longer latency ($p<.05$) to food pellet ingestion than VN, SC, or N pups; whereas the latency of the Zn pups fell between those of the VN, SC, or N pups on one hand and that of the BOB pups on the other and was not significantly different from any. Results of VN pups indicate that an intact accessory system is not necessary for suckling or solid food feeding. Deafferentation of the main system (Zn pups) is followed by a definite suckling deficiency; and BOB, which includes deafferentation of both systems, results in marked deficiencies in both types of feeding.

248 RAT CHORDA TYMPANI RESPONSE TO NaCl: ADAPTATION OR TRANSFORMATION? David V. Smith and Susan Plock*. Dept. Psychol., Univ. Wyoming, Laramie, WY 82071.

Both the transient portion of the integrated chorda tympani response and the initial burst of impulses in single peripheral neurons are extremely sensitive to the rate of stimulus change (Smith & Bealer, 1975). In addition to this rate-sensitive transient, the rat chorda tympani response to NaCl shows a slow exponential decay during the "steady-state" phase of the response (Smith, Steadman, & Rhodine, 1975). Following adaptation to NaCl, a period of postexcitatory depression occurs in which there is suppression of both the transient and "steady-state" components of the response to a test stimulus. The magnitude of this postexcitatory depression is dependent upon the concentration (Smith & Bealer, 1976) and duration (Smith, Bealer, & VanBuskirk, 1977) of the adapting stimulus; the time course of the recovery of excitability during a subsequent distilled water rinse mimics the time course of the slow decline in the response to the adapting stimulus. Responses of taste receptor cells do not show a transient component (Balnave, 1976; Sato, 1976), which suggests that the response is proportional to the number of occupied receptor sites rather than to their rate of binding (see Heck & Erickson, 1973). However, the rise time of the receptor potential has been shown to be sensitive to the rate of stimulus flow (Sato, 1976) and the slow adaptive process reflected in the decline in the chorda tympani response to NaCl is also seen to occur in the taste receptor cell (Ozeki, 1971). These data suggest a model of the probable sequence of events leading to the first-order neural response to NaCl. The taste receptor potential is proposed to be proportional to the number of occupied receptor sites minus the magnitude of a slowly increasing adaptive process. Time course analysis of the response of the rat chorda tympani nerve to HCl shows that the slow decline seen in the response to NaCl does not occur to all compounds, suggesting that this adaptation is the property of a specific receptor mechanism. This adaptive process to NaCl dissipates only slowly during the rinse period, producing the prolonged period of postexcitatory depression. The response of the chorda tympani nerve is proposed to be sensitive to the amplitude of the receptor potential and to its rate of change, i.e., the first-order nerve adds a differential to the taste receptor input. The decline from the initial transient reflects the transfer function between receptor cell and first-order nerve, while the slow decline represents an adaptive mechanism. Thus, the rate sensitivity of the chorda tympani nerve can be accounted for under an occupation model (Beidler, 1954) of taste receptor stimulation.

249 NEONATAL 6-HYDROXYDOPAMINE ALTERS SPECIFIC OLFACTORY PREFERENCES AND BRAIN CATECHOLAMINE CONTENT IN RATS. S.K. Sobrian, E.M. Marasco* and C. Cornwell-Jones*. Dept. Psych., Princeton Univ., Princeton, NJ 08540.

Preferences of Sprague-Dawley rat pups for conspecific odors and catecholamine(CA) content of olfactory brain regions were altered by neonatal 6-hydroxydopamine(6-OHDA) treatment. Responses to arbitrary (non-ethological) odors, whether familiar or novel, were not altered. Littermates reared in cedar shavings were injected subcutaneously on Days 0-3 with 50 ug/g of 6-OHDA or 0.9% saline. Pups were tested in a 2-choice situation requiring a locomotor response. On Days 8-14, saline-injected pups spent significantly more than 50% of test time over cedar nest shavings in favor of natural cedar, while 6-OHDA pups were indifferent to either odor. Group differences were significant on Days 10-14. This 6-OHDA induced change was specific to social odor. It did not reflect a deficit in locomotor ability: pine-reared 6-OHDA and saline pups 5-14 days of age avoided cedar odor, spending significantly less than 50% of test time over natural cedar in preference to natural pine. Therefore, drug treatment did not impair ability to orient to odors. Moreover, a general deficit in olfactory learning can not account for these results. Both 6-OHDA and saline pups reared in cedar acquired a preference for this normally aversive odor. Drug-induced behavioral deficits coincided with reductions in CA content of several olfactory innervated brain regions. Norepinephrine in olfactory bulb and prepiriform cortex was significantly lower than control levels at Day 14 (66.8% and 63.4%, respectively). Dopamine in olfactory tubercle was unaltered; amine changes in amygdala did not parallel behavioral changes.

Drug treatment also altered the preference of pine-reared pups for conspecific but not arbitrary odors. Pups injected Days 4-7 were less attracted to pine nest shavings than saline controls; aversion to lemon odor was unaltered. Injections beginning after postnatal week one (Days 8-11) had no effect on the development of odor-guided behavior.

Therefore, 6-OHDA produces a selective deficit in the development of conspecific but not arbitrary odor preference. This deficit is independent of rearing conditions, does not reflect motoric or general olfactory learning impairment, but coincides with CA alterations in brain regions receiving olfactory innervation.

250 2-DEOXYGLUCOSE UPTAKE PATTERNS IN RAT OLFACTORY BULB UNDER DIFFERENT ODOR CONDITIONS. William B. Stewart*, John S. Kauer and Gordon M. Shepherd. Dept. of Physiology and Section of Neurosurgery, Yale Univ. Sch. of Med., New Haven, Conn. 06510.

Previous work with the 2-deoxyglucose (2DG) method has revealed localized regions of glucose uptake in the rat olfactory bulb (Sharp, Kauer & Shepherd, Brain Res. 98:596-600, 1975). The glomerular layer, where the olfactory axons terminate, is especially active in this regard. Preliminary experiments suggest that spatial variations in the density of this layer are associated with specific odor stimulation, both in rats (Sharp, Kauer & Shepherd, 1975; Sharp, Kauer & Shepherd, J. Neurophysiol. (in press) and in tree shrews (Skeen, Brain Res. 124:147-153, 1977). We have made a systematic study of these patterns under a variety of carefully controlled stimulus conditions. In olfactory bulbs of rats exposed to purified air, localized 2DG uptake was absent or minimal. Animals breathing room air had small distinct foci, as previously reported (Sharp, Kauer & Shepherd, 1975). These were predominately located in the midlateral and posteromedial portions of the bulb. Animals exposed to the odor of one of the following substances: dimethyl disulfide (a putative pheromone; Singer et al, Science 191: 948-950, 1976), amyl acetate and camphor, showed patterns which were relatively distinct from each other. The effects of different odor concentrations on the patterns have also been studied. The significance of the patterns for sensory processing will be discussed. Certain behavioral conditions that may contribute to the variability in the patterns will be identified.

251 AMNIOTIC FLUID CONTROL OVER THE FIRST SUCKLING RESPONSE OF NEWBORN ALBINO RATS. Martin H. Teicher* and Elliott M. Blass. Dept. Psychology, Johns Hopkins University, Baltimore Md. 21218.

Olfactory control over neonatal rats first suckling experience was studied within 2 hr. postpartum. Pups were hand-held and slowly brought into contact with a teat of their anesthetized dam. 180 pups were partitioned into the following groups: control; washed nipple (3:2 solution of methylene chloride and 95% ethanol) and washed nipple coated with one of the following: amniotic fluid, parturient mother saliva, virgin female saliva, parturient mother urine, amyl acetate, vanilla extract, or isotonic saline. A rat was tested in only one condition. Pups readily attached to the unwashed (control) mother. Nipple wash essentially eliminated attachment. This strongly suggests that a substance either secreted or placed by the mother on her mammary area is necessary to elicit suckling in her newborn. The only substances which returned suckling to control levels were amniotic fluid and parturient mother saliva. None of the other fluids raised attachment above wash levels. This suggests chemical specificity. These data also suggest that neonatal rats possess and utilize olfactory sensitivity at birth.

252 GUSTATORY-RESPONSIVE NEURONS IN THE HAMSTER PARABRACHIAL PONS. Richard L. Van Buskirk and David V. Smith. Dept. Psychol., Univ. Wyoming, Laramie, WY 82071.

The parabrachial pontine region contains a significant relay for gustatory responses in both the rat (Norgren & Leonard, 1971; Norgren & Pfaffmann, 1975; Perrotto & Scott, 1976) and the cat (Bernard & Nord, 1971), suggesting the potential generality of such a relay for mammals. The present study shows that taste responses are also found in the pontine parabrachial region of the hamster. In the cat, gustatory responsiveness is confined to the area ventral to the brachium conjunctivum (Bernard & Nord, 1971), but in the hamster gustatory responses are found both dorsal and ventral to the brachium conjunctivum, as is the case in the rat (Norgren & Pfaffmann, 1975). However, all stimulation in the hamster has so far been confined to the anterior portion of the tongue. Anesthesia, general surgical procedures, and stimulus control were comparable to earlier work on the hamster NTS (Travers & Smith, 1976). With the head tilted forward at 27^{o} off the horizontal plane, the parabrachial area is accessible below the suture of the occipital and interparietal plates, and involvement with the transverse sinus is thereby avoided. In this stereotaxic orientation, gustatory responses were found between 3.9 and 4.5 mm rostral to obex, between 3.6 and 4.2 mm below the cerebellar surface, and centered along a line 1.35 mm from the midline. Gustatory stimulation included the four classical stimuli (0.03 M NaCl, 0.003 M HCl, 0.1 M sucrose, and 0.001 M QHCl) plus an array of 14 other compounds. Most of these pontine taste neurons could be characterized as "multiple-stimulus" neurons rather than "best-stimulus" neurons, even under the most stringent criteria (Pfaffmann et al., 1976), and were found to respond to a wide variety of stimuli. In fact, statistically significant responses to at least three of the four classical gustatory stimuli have been found in most of the neurons examined to date. Neither spontaneous rate nor the range of firing rates to gustatory stimuli appears different from that in hamster NTS (Travers & Smith, 1976). In several cases, when the animal was breathing on its own, neurons firing in synchrony with either inhalation or exhalation were found at the same medial-lateral, dorsal-ventral location as gustatory-responsive neurons located just rostral and caudal to these respiratory units. When the animal was mechanically respired there were no respiratory-synchronous units found in this area, but neurons with highly regular spontaneous firing rates were quite commonly found interpolated among small groups of taste-responsive neurons.

253 OBSERVATIONS ON THE NORMAL STRUCTURE OF THE VOMERONASAL APPARATUS OF GARTER SNAKES. Ruu Tong Wang*, John L. Kubie* and Mimi Halpern. Dept. of Anatomy and Cell Biology and Program in Biological Psychology, Downstate Medical Center, Brooklyn, New York, 11203.

The organization of the vomeronasal mucosa of garter snakes contrasts sharply with the organization of the olfactory mucosa. The vomeronasal apparatus consists of a superficially positioned epithelium, a very thick intermediately located bipolar(Bp) cell layer and a deeply situated layer of undifferentiated(Ud) cells. The epithelium is separated from the Bp cell layer by a basement membrane, connective tissue and blood vessels.

The epithelium contains a single layer of columnar cells with apical microvilli and oval nuclei situated basally. The dendrites of Bp cells lace their way between adjacent columnar cells as they pass toward the luminal surface.

The Bp cell layer is 20 to 30 cell bodies deep and organized into hexagonal columns oriented perpendicular to the luminal surface. Pigmented connective tissue septi containing blood vessels separate adjacent columns. Within each column dendrites and axons aggregate into bundles which form parallel arrays also oriented perpendicular to the luminal surface.

The layer of Ud cells is 6 to 10 cells deep and is organized into the same hexagonal columns as the Bp cell layer. Within each column several mitotic figures can be seen among the Ud cells.

Electron microscopic examination of the epithelium reveals that membrane specializations exist between adjacent columnar cells and between the apices of columnar cells and Bp cell dendrites at the luminal surface. Bipolar cell dendrites traveling through the epithelium contain large numbers of neurofilaments and elongated mitochondria while columnar cells contain polyribosomes, secretory or lysosomal granules and a few large mitochondria, but no neurofilaments. The round nuclei of Bp cells are surrounded by substantial perikarya containing large amounts of concentrically oriented, tightly packed smooth endoplasmic reticulum (ER) and rough ER in the polar regions of the cell body. Those Bp perikarya closer to the epithelium contain more smooth ER, a greater number of lysosomes and larger lysosomes than Bp perikarya close to the layer of undifferentiated cells.

Undifferentiated cells are larger than Bp cells, have very large oval to irregularly shaped nuclei and scanty perikaryal cytoplasm. The predominant cytoplasmic organelles of Ud cells are polyribosomes. Very small quantities of rough ER and few mitochondria are observed in them.

The axons of Bp neurons traverse the layer of Ud cells and collect between that layer and the bony capsule to form the bundles of the vomeronasal nerve. Satellite cells ensheath the axons forming bundles of hundreds of axons each.

Supported by NIH grant NS 12152.

254 SOME RESPONSE PROPERTIES OF SINGLE UNITS IN THE OUTER LAYERS OF THE HAMSTER OLFACTORY BULB. W.Youngs*, F.Macrides, S.Schneider* and B.Davis (SPON: R.Hall). The Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

Extracellular recordings from single units in the mitral body (MBL), external plexiform (EPL) and glomerular (GL) layers of the hamster olfactory bulb (OB) reveal three major categories of neurons which can be distinguished according to their pattern of responding to electrical stimulation of the ipsilateral olfactory mucosa (OM) and lateral olfactory tract (LOT). Neurons belonging to the first category responded with a single, fixed latency spike to single shocks of the LOT and were classified as output neurons. Approximately half of them were excited by stimulation to the OM, although a higher percentage of the output neurons with long versus short LOT latencies were excited by OM stimulation. This differential sensitivity to electrical stimulation of the OM may reflect a functional dichotomy of output neurons: smaller cells more sensitive to changes in overall level of OM activation, larger cells more sensitive to specific spatiotemporal patterns of activation. Interneurons composing a second category were recorded in the GL and were localized at the boundaries of glomeruli by iontophoresis of dye at the recording sites. These interneurons often displayed a high frequency, "bursty" firing pattern and showed either no clear response or suppression of spontaneous firing following single and multiple shocks to the LOT. Many of the GL interneurons were excited by OM stimulation. As a group they had significantly shorter OM latencies than output neurons, suggesting that they receive direct excitatory inputs from the OM. Interneurons located predominantly in the EPL compose a third category of neuron. They had low spontaneous firing rates and tended to be excited by OM stimulation with longer latencies than output neurons and GL interneurons. They also tended to be excited by LOT stimulation, showing variable latency bursts related to stimulus strength. Their OM and LOT latencies were consistent with an intrabulbar excitatory pathway to them through output neuron collaterals. Most of the EPL interneurons were suppressed by electrical stimulation of the contralateral OB. Since such stimulation is known to be excitatory to granule cells it is likely that EPL interneurons are short axon (SA) cells. The possibility that interneurons recorded in the GL are granule cells also may be ruled out since granule cell processes do not extend into the GL and do not receive OM inputs. We postulate that they are periglomerular (PG) cells, which are thought to be inhibitory to output neurons. The possibility that SA cells of the EPL are inhibitory to PG cells, and thus provide a disinhibitory pathway for output neurons, will be discussed. COMPARATIVE NEUROBIOLOGY

255 TELENCEPHALIC VISUAL RESPONSES IN THE PAINTED TURTLE, CHRYSEMYS PICTA. A. H. Bass, M. L. Andry* and R. G. Northcutt. Div. Biol. Sci's., University of Michigan, Ann Arbor, MI 48109.

Recent anatomical investigations demonstrate a widespread distribution of primary retinal targets in the mesencephalon and diencephalon of turtles (Bass and Northcutt, 1975; Bass, 1976). Electrophysiological methods were used to investigate the possibility that such a multiplicity of retinal targets reflects a plurality of visual regions in the telencephalon.

Eleven painted turtles, Chrysemys picta, were analyzed for multiple unit activity responsive to photic stimulation. Animals were anesthetized with Nembutal (25 mg/kg, i.p.); multiple unit activity was recorded with platinum-irridium electrodes (75 u). Superficial units were associated with surface negative evoked responses; deeper units were associated with response component polarity inversions. On and/or off cluster activity occurred only to contralateral stimulation.

Surface recorded evoked responses were comparable to those reported by Belekhova et al. (1964) and by Karamian et al. (1966). Histological examination of electrode tracks revealed sites of multiple unit activity in the following regions: pars dorsomedialis and dorsolateralis of dorsal cortex; dorsomedial segment of posterior dorsal ventricular ridge; and a dorsolateral segment of anterior dorsal ventricular ridge which appears to correspond to the rotundal target of Hall and Ebner (1970) in Pseudemys.

This research was supported by NIH Fellowship 1 F22 NS 02622 and NIH Grant 2 R01 NS 11006.

256 ANATOMICAL STUDIES ON AFFERENT AND EFFERENT CONNECTIONS OF THE MORMYRID ACOUSTICOLATERAL AREA. C.C.Bell and C.J.Russell, Neurological Sciences Institute, Good Samaritan Hospital and Medical Center, Portland, Oregon 97210.

There are three types of electroceptors in mormyrids; ampullary,mormyromast, and Knollenorgan. Electrophysiological and anatomical work has been done on afferent projections from these receptors to the CNS. The present study extends these findings.

Electroreceptor afferents from dorsal posterior skin run in the dorsal branch of the posterior lateral line nerve. Those from ventral posterior skin run in the ventral branch. The latter branch also contains ordinary (mechanoreceptor) lateral line afferents and efferents. We labelled axons of each branch to determine termination sites. Under anesthesia, a branch was exposed and cut near the sensory ganglion. HRP in a weak solution of DMSO (dimethyl sulfoxide) was put on the cut end. After closing the wound, animals survived 5-7 days. Sections were prepared in the usual way. DMSO enhances diffuse, agranular filling with HRP (Keefer et al, Neuroscience Letters, 3 (1976) 233-237). Filled axons could be seen in nerve and CNS.

There are two structural discontinuities on each side of the cortex of the mormyrid posterior lateral line lobe (PLLL). These run longitudinally,defining three zones; medial, dorsolateral, and ventrolateral. Following dorsal branch labelling filled terminals are seen in three separate patches, medially within the medial zone and ventrally in each lateral zone. With ventral branch labelling terminals are lateral in the medial zone and dorsal within the lateral zones. The results indicate three distinct mappings of electroreceptor afferents onto PLLL cortex. Electrophysiological studies have shown that the ventrolateral zone receives ampullary while the other two zones receive mormyromast input.The somatopy seen here confirms that seen physiologically in the ampullary and medial mormyromast zones. Afferents also end in the nucleus of PLLL. These are probably from Knollenorgan receptors. Finally, terminals are found in the anterior nucleus just deep to the crista cerebellaris following ventral but not dorsal branch filling, indicating that mechanoreceptors end here, as has been suggested by others.

Injection of HRP (in distilled water) into ganglion lateralis of the mesencephalon shows heavy projections from all three zones of the contralateral PLLL. Both ganglion and beard cells project. Neurons of the nucleus of PLLL do not go to g. lateralis but to g. exterolateralis.

The results indicate that mormyromasts are more similar to ampullary than to Knollenorgan receptors in their central connections. (Supported by NIH (NINCDS-06728) and NSF (BMS73 - 06867))

257 TELENCEPHALIC AFFERENTS AND SDH DISTRIBUTION IN POLYPTERUS. M. R. Braford, Jr. and R. G. Northcutt. Div. Biol. Sci's., University of Michigan, Ann Arbor, Michigan 48109.

The distribution of succinate dehydrogenase (SDH) in the telencephalon of the bony fish Polypterus palmas was studied with the method of Pearse. High concentrations of SDH were found in the glomerular layer of the olfactory bulb and in the superficial neuropil of all pallial areas. The pallial distribution occurs in a band of varying thickness which occupies the superficial one-third of the neuropil of Pl, extends almost to the ependymal surface in a restricted rostral part of P2, and is narrower in the remainder of P2 and in P3. Following lesions of the olfactory bulb, terminal degeneration was seen in the superficial one-third of Pl. Large diencephalic lesions produced terminal degeneration in P2 and P3. The combined distribution of the olfactory and ascending projections coincides in precise detail with the high SDH concentrations in the pallium. Areas of moderate or low SDH concentrations in the subpallium also correspond closely to the areas which receive olfactory or ascending inputs. Similar correlations have been reported for sensory areas in the telencephalon of reptiles and mammals. Although the nature of the ascending projections in Polypterus remains to be determined, these data suggest that SDH distributions are reliable markers for sensory projection areas and may be useful as predictors in the absence of experimentally determined connections. (Supported by NSF Grant GB-40134 and NIH Grant 2 R01 NS 11006.)

258 RETINOTHALAMIC PROJECTIONS IN LIZARDS AS REVEALED BY ANTEROGRADE AUTORADIOGRAPHY. Ann B. Butler and R. Glenn Northcutt. Dept. Anat., Georgetown U., Wash., D.C. 20007 and Div. Biol., U. Mich., Ann Arbor, Mi. 48104.

While the retina has been found to project to multiple sites in the dorsal thalamus of birds, most previous studies in reptiles have identified only one dorsal thalamic retinal target, nucleus geniculatus lateralis pars dorsalis (PD). A reexamination of the retinal projections in two lizards, Iguana iguana and Gekko gecko, was therefore undertaken. Five animals received intraocular injections of (^{3}H)proline, 9.4 μC/μl. The brains were fixed by perfusion 1-6 days postoperatively. Mounted paraffin sections were coated with NTB3 emulsion and developed after 20 days exposure.

In the contralateral thalamus a number of retinal targets could be identified in both species. The pars ventralis (PV) and pars dorsalis (PD) of the geniculate and nucleus ventrolateralis pars ventralis (VLv) were found to receive retinal projections as previously described (Butler and Northcutt, '71, Brain Res., 26: 1-13; Northcutt and Butler, '74, JCN, 157: 453-466). Additionally, the retina projects to (1) a nucleus lying dorsal to PD, the dorsal optic nucleus (DON), (2) a nucleus which caps the dorsal surface of nucleus rotundus, nucleus dorsocentralis (DC), (3) a nucleus lying between PD and nucleus dorsolateralis anterior, nucleus intercalatus thalami (IC), and (4) part of nucleus ventrolateralis pars dorsalis (VLd). Part of DON was previously included as the dorsal portion of PD in Iguana and degeneration was also previously charted in this region in Gekko. Ipsilateral retinal projections were traced to the more laterally lying of these nuclei: PV, PD and DON. If more than one of these thalamic visual nuclei is found to project to the telencephalon, the relationship of the PD of reptiles to the dorsal lateral geniculate nucleus of mammals will have to be re-evaluated. (Supported by NIH Grant No. NS11006 and NSF Grant No. GB-40134 to RGN and NIH Grant No. NS12966 to ABB.)

259 THE ACCESSORY OPTIC SYSTEM IN TELEOST FISHES. T.E. Finger and H.J. Karten, Dept. Anat. & Neurobiol., Sch. Med., Washington Univ., St. Louis, Mo. 63110 and Dept. Psychiatry, State Univ. N.Y. at Stony Brook, Stony Brook, N.Y. 11794.

Karten, et al (PNAS 1977) have demonstrated that the accessory optic nuclei (AON) in pigeon are cell groups which both receive a direct retinal input and project directly to end as mossy fibers in caudal cerebellum. A homologous AON system in other vertebrates should be expected to have similar connections. In order to determine if piscine forms possess a cell group which might meet these criteria, HRP was injected into the corpus cerebelli of catfish and goldfish in order to identify cells projecting to cerebellum. In other specimens, the eye was injected with tritiated proline and the brain processed for autoradiography in order to demonstrate retinal projections.

In both species, we were able to identify two distinct nuclei which both received retinal input and projected to cerebellum. These cell groups lie along the medial and ventral aspect of the rostral tectum. The more ventral group in goldfish forms a spherical nucleus roughly 200 μ in diameter and lies ventrolateral of Schnitzlein's n. Rotundus and immediately dorsal to the optic tract as it courses into the ventral tectum. The dorsal AON in goldfish lies along the junction of tegmentum and tectum at the level of the posterior commissure. Cells in this dorsal nucleus lie within the boundaries of what has been termed area pretectalis by Schnitzlein. In catfish, these AON are connected by a band of cells, whereas in goldfish, the two groups are separated.

Karten et al found that the avian AON receive input from only the displaced ganglion cells. The possibility that specific retinal targets may receive input from only a specific class of ganglion cells in teleosts must also be considered.

260 COMPARATIVE ASPECTS OF NICOTINIC AND MUSCARINIC ACETYLCHOLINE RECEPTORS IN BRAIN, by Renee Foders and P.M. Salvaterra, Div. of Neurosciences, City of Hope National Med Ctr., Duarte, CA. 91010.

Nicotinic and muscarinic acetylcholine receptors were studied in crude brain membrane fractions by ^{125}I-αbungarotoxin (^{125}I-αBTX, McQuarrie et al., J. Biol Chem 251, 6327, 1976) and ^{3}H-quinuclidinyl benzilate (^{3}H-QNB, Yamamura & Snyder, Proc. Natl. Acad. Sci., 71, 1725, 1974) binding. All species studied (rat, rabbit, mouse, goldfish, frog & Torpedo) showed similar receptor levels in whole brain and exhibited pronounced regional differences. In the fish and frog ^{125}I-αBTX and ^{3}H-QNB binding is highest in optic tectum lower in forebrain and lowest in cerebellum. In Torpedo ^{125}I-αBTX binding shows cerebellum > optic tectum > olfactory lobe > electromotor nucleus while ^{3}H-QNB shows olfactory lobe > electromotor nucleus > cerebellum > optic tectum. For mammals ^{3}H-QNB binding is caudate > hippocampus > cerebrum > cerebellum while ^{125}I-αBTX is variable with cerebellum usually the lowest. While all regions have higher ^{3}H-QNB binding the ratio of ^{3}H-QNB to ^{125}I-αBTX binding varies 15-400 fold indicating the relative importance of muscarinic vs. nicotinic receptors. This point is illustrated by data from hippocampus and caudate of two mouse strains:

Strain	Hippocampus		Caudate	
	^{125}I-αBTX[a]	^{3}H-QNB[a]	^{125}I-αBTX	^{3}H-QNB
Swiss	.038	1.12	.016	1.55
C58/J	.026	0.62	.003	1.32

[a] pmoles/mg

The Swiss mouse is higher in both markers than the C58/J, however, the ratio of ^{3}H-QNB to ^{125}I-αBTX is about the same in hippocampus but is 4-5 times higher in caudate of the C58/J. Choline acetyltransferase (CAT) levels were determined (Fonnum, Brochem J. 115, 465, 1969) and found in general to parallel ^{3}H-QNB binding, but it is interesting to note a higher CAT acitivity in the hippocampus and caudate of the C58/J relative to the Swiss mouse.

261 GENETIC APPROACHES TO BEHAVIORAL DISORDERS IN MAN. Benson E. Ginsburg. Behav. Genet. Lab., Dept. Biobehavioral Sci., Univ. of Conn., Storrs, CT 06268.

Genetically based behavioral disorders in man include those in which there is strict determinism associated with anomalies definable at the chromosomal, genic, and/or mechanism level; those in which there is a correlation with polymorphic markers, suggesting a genetic susceptibility associated with particular chromosomes or chromosomal regions; and those for which multiple predisposing genetic bases exist, suggested by genealogical studies and twin studies compatible with a genetic diathesis but not with one particular mode of inheritance in association with a given syndrome. The latter are of particular interest because where multiple genetic etiologies are involved, the analysis of causal mechanisms will depend upon a suitable genetic taxonomy deriving from genealogical and marker studies in which the multiple genetic bases within a syndrome can be separately followed. Twin studies and work with genetically uniform strains of mice point to the possibility that individuals with identical encoded genotypes may not have identical effective genotypes; i.e., that different genes may be activated. Findings in our laboratory illustrate the efficacy of this approach using familial dyslexia, hyperkinesis, tendencies to aggression, convulsive seizures, and developmental differences in reaction to alcohol. Each of these have diverse genotypes within the syndrome, and the mechanisms associated with the behaviors are genotype rather than phenotype dependent. (Supported by NIH AA 00297, NIMH MH 28021, and by a grant from The Grant Foundation, Inc.).

262 INFRARED AND VISUAL ORGANIZATION OF THE TECTUM OF BOID SNAKES. Eric Haseltine*, Len Kass and Peter Hartline.(SPON: Delores Schroeder). Dept. of Psych. Indiana Univ., Bloomington,Ind.47401 and Dept. of Physiology and Biophysics, Univ. of Ill., Urbana,Ill.

Single and multiunit recordings were made in the tecta of two species of boid snake, Python reticulatus and Corrallus endyris. These snakes possess at least 16 infrared sensitive labial pits.

The topographic organization of visual input to tectum was similar to that of the infrared projection, but maps of the two modalities were not in precise register. Rostral electrode placements were associated with nasal infrared and visual fields,and lateral penetrations produced receptive fields in both modalities situated inferiorly.

Seventy percent of neurons for which labial pit input could be determined were driven by one pit only, and 30% were driven by two or more pits.

Single unit infrared receptive fields were found to be consistently larger than visual fields. Visual fields in P. reticulatus averaged 24° in width,whereas infrared fields averaged51°. Mean visual receptive field width in C. endyris was 14°, while infrared fields were 50° wide one the average.

Bimodal neurons(those responding either to visual or infrared stimuli) were commonly encountered in the tectum of C.endyris. Both visual(average field 34° wide) and infrared(average field 60° wide) receptive fields of these units were larger than those of simple visual and infrared units respectively. Response dynamics of bimodal neurons differed according to the modality of stimulation. Strictly visual stimulation produced a phasic "on" response,followed by and "off" response.Purely infrared stimuli elicited a phasic"on" response with no "off" response. Pronounced post-excitatory depression typically followed response to an infrared stimulus. Temporal characteristics of visual and infrared componants of bimodal neuronal responses, were similar to those of purely visual and infrared units respectively.

263 ACTIVITY-INDUCED HYPERPOLARIZATION IN A MAMMALIAN SENSORY NEURON. Richard A. Jaffe and Sanford R. Sampson. Biol. Dept., Battelle-Northwest, Richland, WA. 99352 and Dept. Physiol., UCSF, San Francisco, CA. 94143.

A prolonged hyperpolarization of the membrane potential following repetitive activity has been demonstrated in several vertebrate and invertebrate neurons. It has been suggested that this hyperpolarization may affect nerve function either by altering the threshold for excitation or by causing conduction block. In a small population of neurons in both cat and rabbit nodose ganglia, repetitive action potentials generated in the cell body caused a persistent hyperpolarization. Measurements were made on nodose ganglia and vagus nerves removed from anesthetized cats or rabbits, maintained in vitro and superfused at 37°C with solutions approximating the ionic composition of extracellular fluid. Intracellular recordings were obtained with glass micropipets filled with 3 M KCl or 5 M KAc. In contrast to post-tetanic hyperpolarization, activity-induced hyperpolarization in nodose ganglion neurons began with the first action potential and persisted no longer than 5 sec after stimulation was stopped. The magnitude of this hyperpolarization was often as high as 10-15 mV and appeared to be dependent on the frequency of discharge, some hyperpolarization being observed at frequencies as low as 1-2 spikes per second. This persistent hyperpolarization occurred only if action potentials were generated in the cell body, and sometimes caused failure of somatic spike generation. The mechanism by which repetitive activity induces hyperpolarization in nodose ganglion neurons is not known. The possibility that it is simply a summation of afterhyperpolarizations seems unlikely, because the duration of the afterhyperpolarization rarely exceeded 30 msec, while activity hyperpolarization was seen with somatic spikes occurring as infrequently as 1-2 per second. It is suggested that the hyperpolarization following repetitive activity in nodose ganglion neurons could, in large part, be accounted for by specific changes in membrane conductance. Further studies will be necessary to confirm this hypothesis and to determine which species of ion are involved.

264 ANATOMICAL BASIS FOR VISUAL AND NONVISUAL INTEGRATION IN PIT VIPER TECTUM. Leonard Kass, Michael S. Loop and Peter H. Hartline. Dept. Physiol., Univ. of Illinois, Urbana, Il. 61801

The optic tectum of the rattlesnake is used as a model for integration of visual and nonvisual sensory modalities (Hartline, Loop,Kass; these abstracts). In this study we examine the anatomical layering of visual, infrared, and bimodal tectal neurons and their spatiotopic organization.

Visual and infrared cell layers were identified in the tectum of the pit vipers Crotalus viridis and Sistruris melitus. 48 lesions were made after recording visual or infrared activity at varying electrode locations in the tectum. Histological reconstructions of these lesions (Prussian Blue staining technique, Akert and Welker, '61) were correlated with the micrometer depth readings of 271 visual, infrared, and bimodal single unit recordings. We used a thermoneutral black wand against a light background as the visual stimulus and a warm soldering iron in the dark as the infrared stimulus. The visual cell layer extends across the entire tectum from approximately the level of the posterior habenula to the anterior border of the posterior corporo quadrigemina. The visual cell region extends across the midline and comprises zones 7-13, i.e., the superficial 600-700 microns of the optic tectum (stratum fibrosum et griseum superficiale and stratum griseum centrale). The infrared cell group is found everywhere in the tectum below the visual laminae (layers 1-7). Eighty percent of the infrared neurons are found between 500-1200 microns from the surface of the optic tectum. In layer 7 (stratum griseum centrale) the visual and infrared cell groups are mixed; bimodal neurons which respond to a combination of visual and infrared input are located predominately in this layer.

Spatiotopic tectal maps for both modalities were constructed from receptive field centers for superficial (visual) and deep (infrared) recordings with multi-unit electrodes. In both modalities , rostral loci yielded anterior (nasal) fields; medial loci yielded superior fields. Thus, the axes of the spatiotopic maps for both modalities are aligned similiarly across the tectal surface. But the maps differ in detail. Corresponding meridian lines do not have the same shape; the magnification factor (mm tectal locus separation / degree field center displacement) is about 1.5 times greater in the infrared map than is found in the visual map. This requires that the same tectal sublayer receives information (visual and infrared) from two disparate regions of space as do the bimodal neurons.

The approximate similarity of spatial organization of the visual and infrared systems in the optic tectum probably allows orientation behavior to be mediated by either modality.

265 DIFFERENTIAL RESPONSES TO TEA AND BARBITURATES IN FOUR IDENTIFIED LEECH NEURONS: ROLE OF CA. Anna L. Kleinhaus and James W. Prichard. Dept. Neurol., Yale Med. Sch., New Haven, CT. 06510

Previous work from this laboratory showed that tetraethylammonium chloride (TEA) and barbiturates interfered with action potential repolarization in leech Retzius cells. However, the drugs acted by different mechanisms. TEA apparently blocked a K current which normally repolarizes the cell and allowed the effect of a late divalent cation conductance mechanism to dominate membrane behavior during excitation (Kleinhaus and Prichard, J. Physiol. 1975). Barbiturates, on the other hand, interfered with the repolarization mechanism in some other way, possibly by blocking a Ca-activated K conductance in the Retzius cell (Kleinhaus and Prichard, J. Pharm. exp. Ther., (in press).

TEA applied both extracellularly in the bath and intracellularly by iontophoresis prolonged the action potentials of leech sensory neurons. The average value for the increase above control of action potential durations after extracellular application was 500% for N cells, 240% for P cells, and 162% for T cells. With intracellular application the respective increases were 422%, 185%, and 141%. Both amplitude and duration of the TEA-prolonged action potentials were directly related to the Ca concentration. The ability of these neurons to sustain active membrane responses to depolarization when Ca was the only cation available to carry current was found to segregate the cells in the same order. This correspondance suggested that the differential responses to TEA could be explained by variations among the cells in the numbers of Ca conductance channels available to affect membrane behavior when outward K currents were largely blocked.

Pentobarbital and methohexital, 0.1-1.0 mM, also prolonged the action potentials of leech neurons, and in the same order that TEA did. Resting membrane potential and maximum rate of rise of action potentials were also affected, but not in the same order. The effect of Ca on the barbiturate-prolonged action potentials was the opposite of its effect on the TEA-prolonged ones. In all four cells the barbiturate prolongation was reversed by Ca and favored by a reduction in its concentration.

The barbiturates thus interfered with repolarization in all the cells, but the effect was greater in those which appeared to have larger Ca conductances. These observations and our earlier findings on the Retzius cell are compatible with the theory that barbiturates block a Ca-activated K conductance which participates in repolarization to a different degree in each cell type.

266 SOME CONNECTIONS OF THE OCTAVOLATERALIS AREA IN THE BOWFIN, AMIA CALVA. C. A. McCormick* (SPON: T. J. Neary). Div. Biol. Sci's., University of Michigan, Ann Arbor, Michigan 48109.

In adult specimens of the bowfin, Amia calva, either the anterior or posterior lateral line nerve was sectioned proximal to its ganglion. Following survival times of 8 to 17 days, the brains were processed by the Fink-Heimer method. After entering the brain, both nerves form ascending and descending bundles which terminate in the portion of the octavolateralis area designated by Pearson as nucleus medialis. Nucleus medialis consists of four cell types. Purkinje-like cells are situated immediately ventral to the cerebellar crest, and their dendrites have either a vertical or horizontal orientation. Interspersed among the Purkinje-like cells and ventral to them are small granule-like cells. Small fusiform cells and large polygonal cells are also found ventral to the Purkinje-like cells. Both lateralis nerves terminate ipsilaterally throughout nucleus medialis. Terminal degeneration is also found in the ipsilateral eminentia granularis of the cerebellum. No primary fibers ascend to the midbrain. Lesions of the glossopharyngeal nerve reveal no terminals in the octavolateralis area. Injections of HRP into the torus semicircularis indicate that the major projection from the octavolateralis area is from the Purkinje-like cells. Approximately 350 of these cells were labelled; 90% were located contralaterally. A few cells in nucleus medialis ventral to the Purkinje-like cells were also labelled bilaterally. This research was supported in part by NIH Grant 2 R01 NS 11006.

267 ORGANIZATION OF THE DORSAL COCHLEAR NUCLEUS IN MAN. J.K. Moore* (SPON: W. Wiederholt). Dept. Neurosci. and Neurobiol. Unit, Scripps Inst. Oceanog., UCSD, La Jolla, CA 92093.

The dorsal cochlear nucleus (DCN), generally described as vestigial in man, is in fact a well developed part of the human cochlear complex, being relatively larger in man than in the cat (Moore and Osen, in prep.). It differs significantly, however, in its internal cytological organization from that of the cat and other lower mammals. In the cat and prosimian primates, as in most mammalian species, the DCN exhibits a pattern of synaptic organization with features common to laminar cortical structures, a pattern oriented around a layer of radially oriented efferent neurons, the pyramidal or fusiform cells, which receive spatially segregated synaptic input from extrinsic fiber systems and intrinsic cortical neurons, including a prominent layer of granule cells. This laminar pattern of organization is completely lacking in the human DCN.

The alteration in cytoarchitecture in the human DCN is the outcome of a progressive loss of lamination observed in a phylogenetic series of primates. This loss is incipient in prosimians in which there is an apparently incomplete migration of the DCN granule cells, with retention into adult life of an extensive embryonic or external granular layer in addition to the normal internal granular layer. In both ceboid and cercopithecoid monkeys, granule cells are entirely subependymal: in cercopithecoids, this external granular layer is considerably reduced in volume. Associated with failure of migration and reduction of the granule cell population is a shift in the position of the pyramidal neurons to the central region of the nucleus. In the ape (gibbon) and in man, only vestiges of the molecular and granular layers remain. Thus in hominoids, the entire dorsal nucleus is equivalent to the central region of other mammals, with a large population of pyramidal cells oriented longitudinally, parallel to cochlear fibers, rather than radially across them. It remains a matter of speculation as to how changes in cytoarchitecture and loss of internal circuitry affect the function of the DCN in man.

268 FACILITATION OF TONIC IMMOBILITY BY STIMULATION OF THE VAGINAL CERVIX IN THE RAT. A. N. Naggar* and B. R. Komisaruk (SPON: Benjamin Natelson). Institute of Animal Behavior, Rutgers University, Newark, NJ 07102.

Stimulation of the vaginal cervix with a plastic rod induced tonic immobility ("animal hypnosis") in response to inversion combined with brief manual restraint, in otherwise insusceptible female rats. Mean duration of the response was 14.8±1.9 (s.e.m.) seconds. In a second experiment, estradiol benzoate administration potentiated this effect somewhat. Short latencies to immobilization (≤5 seconds) were observed in at least two of the five trials in 6 of 6 EB treated animals, while only 2 of 6 oil treated controls met this criterion. Duration of tonic immobility was not significantly affected by EB treatment. This study supports the hypothesis that tonic immobility may utilize a neural system which is common to lordosis, the immobile mating posture of the female rat which is also facilitated by cervical stimulation and by estrogen.

269 STRUCTURE AND FUNCTIONAL RELATIONS: A MORPHOLOGICAL AND QUANTITATIVE ANALYSIS OF THE DEVELOPING MESENCEPHALIC NUCLEUS OF V IN BIRDS. C. H. Narayanan and Y. Narayanan*. Dept. of Anat., Sch. Med., New Orleans, LA 70119.

In order to understand structure-function relations during ontogeny between the neurons of the mesencephalic nucleus of V and jaw muscles, changes in cell morphology at the EM level and quantitative estimates based on cell number and cell size of the developing mesencephalic nucleus were investigated in white peking duck embryos. Frequency of oral activity (beak-clapping) from onset to hatching were recorded in embryos of the duck, chick and quail at one day intervals. Jaw movements showed a five-fold increase in the chick and quail, and a twelve-fold increase in duck embryos close to hatching. Estimates of cell number were determined from serial sections of brains stained with hematoxylin, eosin and orange-G. Cell loss amounting to more than 65% in normal development was observed between 6 and 16 days of incubation in the quail; 9 and 20 days in the chick, and 10 and 26 days in the duck.

Electron microscopic examination of the cells of the mesencephalic nucleus of the duck embryo which we have studied in detail, revealed significant developmental changes in their morphology and have been classified for the sake of convenience into three periods extending from the early appearance of the cells to hatching: An early phase, from 6 to 12 days, a mid-incubation period, 13 to 18 days; a last phase, from day 19 to hatching. The cells are recognizable as early as 6 days and are irregularly round or oval with very few cytoplasmic processes and an eccentrically placed nucleus which is more electron dense than in the adult. Growth of the cell continues through this phase and at the end of day 12 there is a reordering of cytoplasmic organelles with increasing basophilia of the peripheral cytoplasm. In the mid-incubation period, axons with neurofilaments and neurotubules are observed. Nissl granules appear in the periphery. The last phase is marked by an increase in the number of nerves associated with the cell soma. Coated vesicles appear to be budded off from the hypertrophic golgi. There is a greater accumulation of Nissl and a tremendous upsurge of neurofilaments and neurotubules, and myelination of the nerves. However, synapses associated with the neurons or its processes are absent at any stage until hatching, and suggested: a) the survival of neurons depends on the establishment of peripheral connections only; b) that mechanisms involved in the regulation of both quantitative and qualitative aspects of jaw movements are effective only after hatching. Supported by U.S.P.H.S. Grant DE04258-02.

270 EFFECT OF PREOPTIC LESIONS ON BEHAVIORAL THERMOREGULATION IN TWO TELEOSTS. D.O. Nelson* (SPON: J.E. Heath). Dept. Physiology and Biophysics, Univ. of Illinois, Urbana, IL 61801.

Fish can regulate their internal body temperature using physiological and behavioral responses. Behavioral thermoregulation consists of coordinated whole animal activity to create an environment of optimal temperature. Presence of central receptors involved in thermoregulation in fish has been demonstrated but not well localized previously.

Sunfish (Lepomis cyanellus) and goldfish (Carrassius auratus) were acclimated to 5, 15, or 25°C and then placed in a horizontal temperature gradient ranging from 2 to 30°C and position at various temperatures recorded over time. Fish avoided high and low extremes while spending large proportions of time in water near their acclimation temperature. Internal body temperature recorded with an implanted thermocouple remained relatively constant. After lesions were placed in medial and lateral preoptic regions in the forebrain, fish distributed themselves in the gradient spending nearly equal amounts of time at all temperatures available. Body temperature fluctuated significantly.

It is suggested that central temperature reception and integration is confined to discrete areas in the fish similar to that of higher vertebrates. Electrophysiological investigation of cells in this region is in progress.

271 HISTOFLUORESCENCE STUDY OF THE MONOAMINE-CONTAINING NEURONS IN THE BRAIN OF THE SUNFISH, Lepomis gibbosus. A. Parent, L. Dubé*, M.R. Braford Jr. and R.G. Northcutt. Lab. Neurobiol., Fac. Med., Laval Univ., Quebec, Canada and Div. Biol. Sci's, Univ. of Michigan, Ann Arbor, MI 48109.

A study of the morphological organization of the monoamine (MA)-containing neurons in the brain of the sunfish was undertaken by means of the Falck-Hillarp paraformaldehyde histofluorescence method (Falck et al., '62). Numerous MA perikarya are present in this teleostean brain. By far the largest number of MA cell bodies occur in the hypothalamus especially along and within the ependymal wall of the lateral and posterior recesses of the third ventricle. They consist of small bipolar cells displaying a strong yellow-green fluorescence. One of their processes protrudes into the lumen of the ventricle whereas the other contributes numerous closely packed MA terminals that form "islands" of highly fluorescent material distributed in various areas of the medial hypothalamus. In the brain stem a small group of large sized catecholamine (CA) neurons occurs in the dorsal portion of the isthmal tegmentum, partly within the periventricular gray. These closely packed neurons often emit one short and thick process that bifurcates close to the cell body. More caudally a few medium sized and elongated CA type neurons are scattered within the central portion of the lower medulla oblongata. These neurons are embedded in a mesh of fine varicose CA processes. In addition serotonin (5-HT) type cell bodies are found in the raphe region from caudal midbrain to upper medullar levels. Numerous MA axon terminals are also concentrated in various areas of the sunfish brain such as: the dorsolateral quadrant of the lower medulla, the lateral edge of the isthmal tegmentum, the valvula cerebelli, the optic tectum and the torus semicircularis. At diencephalic levels CA terminals are present in nucleus glomerulosus and more abundantly in the whole preoptico-hypothalamic complex, especially the inferior lobe. The entire telencephalon also receives a strikingly massive and complex MA innervation. MA fibers (mainly CA) ascend within the basal forebrain bundles and ramify more abundantly in the dorsomedial and the ventral part of the dorsolateral telencephalic territories. The profuse telencephalic CA innervation in the sunfish could arise from the CA neurons of the isthmus which appear strikingly similar to the locus coeruleus of reptiles and mammals.

272 THE DISTRIBUTION OF GANGLION CELLS IN THE RETINA OF THE CALIFORNIA HORNED SHARK(Heterodontus francisci). Ellengene H. Peterson and Michael H. Rowe. Dept. Anat., Univ. Chicago and Dept. Anat., Univ. Ill. Med. Center, Chicago, Ill. 60680.

The distribution of retinal ganglion cells was examined in cresyl violet stained whole mounted preparations of the retina of the California horned shark. A consistent observation was the presence of two distinct ganglion cell layers. In addition to the conventional ganglion cell layer located just external to the fiber layer, there was a second ganglion cell layer located between the conventional ganglion cell layer and the inner nuclear layer. The ganglion cells closest to the fiber layer have been called the inner ganglion cell layer (IGCL), and those farther from the fiber layer the external ganglion cell layer (EGCL). The degree of separation between the two layers was not constant, being greater in regions of high ganglion cell density. Ganglion cell density in the IGCL ranges from approximately 0-700 cells/mm^2, and in the EGCL from about 0-160 cells/mm^2. Isodensity maps of the IGCL show an elongated region of high ganglion cell density (visual streak) extending from nasal retina to temporal retina, and oriented so that its long axis follows approximately the horizontal axis of the eye. The ganglion cell distribution in the EGCL is qualitatively similar to that in the IGCL, but the overall densities are lower, and the density gradients are much weaker. Ganglion cells in the visual streak of the IGCL range in soma diameter from 9-28 µm with a mean of 14.4 µm. Ganglion cells in corresponding regions of the EGCL range from 10-27 µm with a mean of 17.4 µm. Both distributions are unimodal. In non-streak regions of the retina the size differences between cells of the two layers seem less pronounced. In addition to the ganglion cells in the IGCL and the EGCL, many 'displaced' ganglion cells were observed with somas located in the inner nuclear layer. These cells ranged in size from 10-35 µm and appeared to have a relatively uniform retinal distribution.

273 NEURAL CONTROL OF THE PROBING PHASE OF BURROWING IN BIVALVE MOLLUSCS. David J. Prior, Sch. Biol. Sci., Univ. of Kentucky, Lexington, Kentucky 40506.

The behavioral responsiveness of an animal to a particular stimulus often varies drastically. As a portion of a study of variation in responsiveness, the control of the probing phase of burrowing behavior in bivalve molluscs has been examined. The mechanics of burrowing in several bivalves have been previously described (Trueman, 1967). Cyclical burrowing in bivalves includes probing the substrate with the tip of the foot, expansion of some portion of the foot to establish an anchorage and finally pedal retraction, which due to the anchorage, draws the animal down into the substrate. The probing phase of this sequence consists of alternating extensions and retractions of the distal portion of the foot. The frequency of probing varies considerably between species and between individuals within a species but usually is in the range of 1 probe/1-5 sec. Simultaneous recordings of foot movement and pedal nerve activity were made from preparations consisting of the foot, pedal ganglion and cerebral ganglia. Stimulation of the cerebral-pedal connectives resulted in prolonged series of cyclical probing movements and corresponding cyclical bursts of efferent activity in the pedal nerves. The mean probing frequency recorded from this sort of preparation is 1 probe/1.8 sec. which is well within the range observed in intact animals. The major bursts of pedal nerve activity corresponds with the retraction phase of probing. During probing neither tactile stimuli applied to the surface of the foot nore electrical stimulation of the pedal nerves will disrupt the cyclical efferent output. The probing bursts can be ellicited from isolated pedal ganglia and do not differ in frequency from those observed in the narrowly intact preparations. Hence, the motor program for probing is entirely within the pedal ganglion. Intracellular recordings have been made from both retraction motor cells (RMC) and extension motor cells (EMC) in the pedal ganglion. During foot probing the RMCs generate bursts of spikes as a result of cyclical excitatory synaptic input. The antiphasic bursts generated by the EMCs occur due to rebound activation following cyclical inhibitory synaptic input. The EMCs show a greater tendency for rebound activation than do the RMCs. Supported by NSF Grant BMS74-15217-A01.

274 VISUAL DISCRIMINATIVE PERFORMANCE IN THE TURTLE FOLLOWING LESIONS OF FOREBRAIN VISUAL STRUCTURES. Tony Reiner* (Spon. H.Karten). Dept. Anat., S.U.N.Y. at Stony Brook, Stony Brook, N.Y. 11794.

An ascending tectofugal visual pathway has been described in mammals, birds and reptiles. In mammals and birds, this pathway has been shown to play a major role in visual functions (Snyder and Diamond, BBE, 1968 and Hodos and Karten, Exp. Br. Res., 1966 and JCN, 1970). In reptiles, however, information about the functional role of the tectofugal pathway is meager. The present work was carried out with turtles (Chrysemys picta picta). In turtles the tectofugal visual pathway consists of the following serially connected structures: the tectum, nucleus rotundus thalami, and the dorsal ventricular ridge of the telencephalon (DVR) (Hall and Ebner, BBE, 1970 and JCN, 1970). The role of the tectofugal pathway was examined in turtles by studying the effects of lesions placed in nucleus rotundus or the DVR upon visual discriminative performance.

One group of turtles was preoperatively trained to criterion on a simultaneous intensity discrimination (0.4 log unit difference), while a second group was trained to criterion on a simultaneous pattern discrimination (horizontal vs. vertical stripes). Half the animals in each group received bilateral lesions of nucleus rotundus, while the other half received lesions of the DVR. Turtles were retrained to criterion on the same discriminative problem that they had been trained on preoperatively. Once a turtle had either reattained criterion, or demonstrated an inability to do so, training was terminated. Turtles were then anesthetized, perfused and the extent and locus of the lesions reconstructed from cresyl violet stained frozen sections.

The results were: 1) Turtles with extensive destruction of nucleus rotundus were unable to relearn their discriminative task, whether intensity or pattern. 2) Turtles with extensive DVR damage were also impaired in their postoperative discriminative performance. However, these turtles did relearn. 3) Turtles with only slight damage to either the DVR or nucleus rotundus showed good retention of their discriminative tasks.

The results indicate that the forebrain components of the tectofugal visual pathway play a major role in visual functions in the turtle. However, further research is necessary in order to determine the basis for the greater deficit following nucleus rotundus lesions than DVR lesions.

275 THE AVIAN TECTOFUGAL VISUAL PATHWAY: PROJECTIONS OF ITS TELENCEPHALIC TARGET, THE ECTOSTRIATAL COMPLEX. Teresa C. Ritchie and David H. Cohen. Dept. Physiol., Sch. Med., Univ. of Virginia, Charlottesville, VA 22901.

The avian visual system includes two major ascending pathways, a thalamofugal pathway homologous to the mammalian geniculo-striate system and a tectofugal pathway corresponding to the tecto-thalamo-extrastriate system. The tectofugal pathway involves a topographic retinal projection upon the optic tectum with efferents from various levels of stratum griseum centrale projecting upon subdivisions of the thalamic nucleus rotundus. Rotundal subdivisions project to subdivisions of ectostriatum, a prominent telencephalic nucleus, which then sends fibers to nearby neurons forming a peri-ectostriatal belt (E_p). This report describes further projections of this system in the pigeon.

First, a series of electrolytic lesions were made in the ectostriatal complex including E_p, and resulting degeneration was studied with selective silver methods. The complex projected upon a longitudinally oriented cell column in lateral neostriatum intermedium (NIL), degenerating axons streaming dorsolaterally and caudally from the lesion to terminate throughout this column. The terminal field extended rostrocaudally from caudal ectostriatal to caudal archistriatal levels. Degenerating fibers were also followed from the lesion, through the lamina medullaris dorsalis, to a cell group in archistriatum intermedium dorsalis (AID).

Second, to identify the cells of origin of these two projections, horseradish peroxidase was injected into the terminal fields and the material processed after 1-3 days by conventional procedures. Injection of the NIL field labelled cells in the dorsal E_p, extending as dorsally as lamina hyperstriatica. Labelled cells following injection of the AID field were located ventrocaudally to ectostriatum, a region where E_p forms a caudal cap around ectostriatum.

Third, electrophysiological experiments were conducted on urethane-anesthetized birds with stimulating electrodes on the optic papilla. Field potentials evoked by papillary stimulation were recorded with 4M NaCl micropipettes and computer averaged. Localized negative fields with peak latencies of 18 and 13 msec were found in regions corresponding to the NIL and AID terminal fields respectively.

These findings confirm that ectostriatum projects upon E_p. E_p has at least dorsal, lateral and ventrocaudal subdivisions, the dorsal division projecting upon a region of NIL and the ventrocaudal division projecting upon a subnucleus of AID. Electrophysiological results confirm that both these terminal fields receive visual input.

276 THE SYNAPTIC ORGANIZATION OF OPTIC AFFERENTS TO THE NORMAL GOLDFISH TECTUM. John T. Schmidt. Develop. Biol. Div. Nat'l Inst. for Med. Res., Mill Hill, London,NW7 1AA England

Potentials in the tectum of large (12-20cm) goldfish, evoked by stimulation of the optic nerve, were recorded extracellularly with double barrelled electrodes (DC,saline,3MOhms; AC, Woods Metal-Pt., 0.1MOhm). Four fiber groups (m_1,m_2,m_3,m_4) were recorded at latencies of approximately 3,4,6 and 8 msec after stimulation (Conduction velocities of approximately 5,4, 2.5 and 2 m/sec). The same four groups were recorded from the optic nerve when the tectum was stimulated. The fastest of these (m_1) was not followed by a postsynaptic wave. Fiber groups m_2,m_3 and m_4 gave rise to postsynaptic potentials, which following computation of their second spatial derivatives with depth, were found to have current sinks at depths of approximately 90-110 µm, 110-200 µm and 200-300 um respectively. Thus the fastest conducting optic fibers make their synapses most superficially, the opposite of the arrangement in the frog tectum(Chung,Keating and Bliss,Proc.Roy.Soc.B187(1974)421). These postsynaptic waves fatigued at repetitive stimulus rates of 20-40 per second, and in twin pulses at interstimulus intervals of 10-15 msec; and were reversibly blocked by topical application of Nembutal. The fiber potentials, however, were virtually undecremented under these conditions.

To compare these electrophysiological findings with the actual anatomy, the cobalt procedure (Tyrer and Bell,Brain Res. 73(1974)151) was used to visualize the profiles of the optic fibers in the various tectal laminae. In contrast to previous reports using radioautography, four discrete layers were found. The thick, dense superficial band and its thin superficial satellite band (90-200 µm) were noted as in radioautographs. In addition, there were two deeper bands of sparse optic fiber innervation at approximately 240 µm (Central Grey) and approximately 350 µm (Deep White). These two deep bands appear to correspond to the m_4 fiber group. The dense superficial band apparently contains both the m_2 and m_3 fiber groups, the m_2 just superficial to the m_3. The fastest fiber group (m_1), which had no presynaptic wave associated with it, was of maximum amplitude in the superficial 100 µm and probably represents efferent cell bodies with fibers projecting back through the optic nerve to the retina. Filled cell profiles could often be seen in the superficial laminae with the cobalt technique.

277 THE HISTOGENESIS OF THE GOLDFISH RETINA. S. C. Sharma and F. Ungar*. Dept. Ophthal., N.Y. Med. College, New York,N.Y.10029

The order of production of retinal cells was studied in the embryos of the teleost, Carassius auratus, using ^{3}H-thymidine autoradiography. Cells become post-mitotic first in the fundus of the neuroepithelium and continue longest at the margin. In the fundus the cells whose nuclei will reside in the inner region of the retina, near the vitreous, stop dividing before the cells whose nuclei will reside near the outer region of the retina. The sequence of cells becoming post-mitotic in the fundus zone is such that cells destined to become ganglion cells are produced first, followed by amacrine cells, bipolars and Muller's cells. The last cells to stop dividing in the fundus differentiate as horizontal cells followed by receptors.

In the later stages of development, no labelled nuclei were found in the fundus zone; however, cells near the margin of the retina were labelled. The label incorporation in the marginal areas suggests that the retina increases in area by addition of new cells at the retinal margin.

278 GROUP SIZE DEPENDENT DISPLAY OF SEXUAL BEHAVIOR IN THE SQUIRREL MONKEY. C. J. Sherry+ and F. A. Rowe. (Illinois Institute of Technology, Chicago, Ill. (+Current address Texas A & M Univ. College Station, Tx. 77843)

Observations of social behavior of infrahuman animals is usually obtained from paired encounters of animals or in larger social groupings. Primate social behavior in general and sexual behavior in particular are usually obtained under one of three conditions: 1) natural habitats with large naturally occurring social groupings (Thorington, R.W. in Rosenblum, L.A., The Squirrel Monkey, Academic, 1968); 2) seminatural habitats in a laboratory (DuMond, F.V. ibid); or 3) paired encounters in a laboratory (Mason, W. A. Primate Behav. 1971, 2, 107). Little data has been obtained about the effect of group size, when the group is smaller than the naturally occurring social group on the display of social and/or sexual behavior. The squirrel monkeys used in this experiment were housed individually in a room with temperature and humidity controlled and food and water available ad librium. The light dark cycle was adjusted to 12 hours on, 12 off. The monkeys were observed for 15 minutes a day on four consecutive days by two observers in each social condition. They were scored for the display and duration of various social behaviors. When observing the male squirrel monkeys individually (A), in pairs (P), groups of three (T), or four (Q), we found that sexual behaviors such as mounting occurred more often in larger groups of animals (P X=0), (T X=0.98, S.D.=2.18) (Q X=0.88, S.D.=1.71). Other sexually related social behavior also tended to occur more often in larger groups. For example, penis display, a socially aggressive signal, tended to occur more often in groups of three or four than in pairs (P X=1.69 S.D.=4.03), (T X=3.79 S.D.=4.32), (Q X=3.13 S.D.=4.32). Masturbation, an individually oriented sexual behavior, also tended to occur more often in larger groupings (A X=0), (P X=0.57 S.D.=1.28), (T X=0.83 S.D.=1.26), (Q X=1.38 S.D.=3.10). Autofellatio, another individual sexual behavior also occurs more often in larger groups (A, P, T X=0), (Q X=0.58 S.D.=1.08). Grooming did not occur in groups of three or four, but it did occur in pairs (X=0.57 S.D.=1.36). Marking (i.e. rubbing urine on the hand or foot and then rubbing it on the perch) did not occur in animals observed alone, in pairs, or groups of four, but it did occur in groups of three (X=0.58 S.D.=0.82).

It will be important to determine why group size effects sexual behavior, in general, and individually directed sexual behaviors, in particular.

279 HYPERPOLARIZING POTENTIALS INDUCED BY Ca-MEDIATED K-CONDUCTANCE INCREASE IN HAMSTER PARASYMPATHETIC NEURONS. T. Suzuki* and K. Kusano. Dept. Biol., IIT, Chicago, IL. 60616.

Three types of hyperpolarizing potentials in the hamster submandibular ganglion cells were analysed by modifying ionic constituents of the perfusion saline or by applying several drugs: (1) the spike induced hyperpolarizing after-potential (S-HAP), (2) the hyperpolarizing (H-) phase of postsynaptic potential and (3) the spontaneous transient hyperpolarizing potential (HP). Experiments were carried out in vitro. All these potentials reversed polarity at membrane potential (E_m) between -75 and -85 mV, which was close to the K-equilibrium potential. The average resting potential of the ganglion cells was -53 mV (range: -40 - -75 mV). In most neurons action potentials were suppressed by 10^{-7}M tetrodotoxin (TTX) but were resistant in others even to 10^{-6}M TTX. Action potential overshoot increased slightly in raised $[Ca^{2+}]_o$ and decreased in low $[Ca^{2+}]_o$. The S-HAP was due to the K-activation but it could be separated into two components: an initial component due to delayed rectification and a late component. The late component was Ca^{2+}-sensitive and it was easily suppressed by lowering $[Ca^{2+}]_o$, or by Mn^{2+}. This component was enhanced by increasing $[Ca^{2+}]_o$, TEA, caffeine and dibutyryl cyclic AMP. Perfusion of Cl^--free saline, substituted with acetate, reduced membrane potential slightly but it did not modify the S-HAP. Application of depolarizing pulses to TTX-sensitive neurons also induced hyperpolarizing after-potentials, similar to the S-HAP. The postsynaptic potential (PSP) was a monophasic depolarizing (D-) potential in some neurons, but in others the D-phase was followed by a small H-phase in control saline. The reversal potential of the D-phase was +1.4 ± 4.9 mV SD (n=5). Perfusion with: K^+-free, 2 mM caffeine- or 2 mM dibutyryl cyclic AMP-containing salines increased the H-phase of the PSP. An increase of membrane conductance was sometimes observed during the H-phase. Spontaneous transient HP occurred in some neurons at irregular intervals (e.g., 16 mV in amplitude, 3 sec in duration, ca. 0.3 Hz at -52 mV E_m). HP was insensitive to TTX but was suppressed by Mn^{2+}. Caffeine induced rhythmic HP's in many neurons; often followed by repetitive spiking. Membrane resistance decreased during HP, then increased slightly before returning to the basal level. In a few neurons which had a low E_m, caffeine induced a long-lasting hyperpolarization. These membrane potential-dependent phenomena appeared to be induced by the Ca-activated K-conductance increase. (Supported by the US PHS Grant NS-12275).

280 EFFECTS OF SEPTAL LESIONS ON THE AGGRESSIVE BEHAVIOR OF THE WESTERN FENCE LIZARD, SCELOPORUS OCCIDENTALIS. Robert S. Tarr*, (SPON: Michael Patterson). Dept. of Physiol., Chicago Coll. of Osteopathic Med., Chicago, Ill. 60615.

The effects of septal lesions on interspecies and intraspecies aggressive behavior was examined in a two part study. Part I was the effects of septal lesions on reactivity and "emotionality". 16 animals were lesioned:8 septal, 3 outside septum and 5 sham. Each animal was then individually rated (blind) by two observers on a rating scale for light touch, handling and mildly noxious stimulation (pinch). Animals were classified by total average score into 3 classes (low, middle, high) of reactivity and emotionality. Comparison of lesion site with behavioral rank was made. Septal lesioned animals were widely distributed in all 3 classes of reactivity and emotionality, did not average higher scores than the non-septal and sham lesioned animals and showed no signs of a "septal syndrome".

Part II was a study of intraspecies aggressive behavior. Groups of animals were observed in a large (100 sq. ft) seminatural environment. Aggressive behaviors (dominance, subordinance, challenge and assertion display, submissive posture, location preference in the territory and response to display) were recorded for each animal. Animals were removed, lesioned and returned for comparison with prelesion behavior. 12 animals received septal lesions, 5 were given non-septal lesions and 9 were sham lesioned. 20 control animals, (reported earlier Physiology and Behavior, Vol.18(6),1977) were also removed and only anesthetized then returned. The 20 control animals, the 9 sham lesioned animals and 4 of the non-septal animals showed no change in aggressive behavior upon reintroduction. 9 septal animals showed no change. 3 of the septal lesioned animals showed a partial loss of display, flight and submissive behavior. This is in contrast to amygdaloid lesions in these animals which consistently produce a near total loss of intraspecific aggressive behavior (referenced above).

281 EFFERENT PROJECTIONS OF THE SEPTAL AREA IN THE TEGU LIZARD. T. J. Voneida and C. M. Sligar*. Dept. Neurobiol., Northeast. Oh. Univ. Coll. Med., Kent, OH 44240 and Dept. Anat., Sch. Med., CWRU, Clev., OH 44106.

A mixture of {^{3}H} proline-leucine concentrated to 25 µCi/µl was pressure injected into the septal area of 10 adult lizards. Injection rates varied from 0.055-0.35 µl/hour. Following survival times ranging from 3 days to 2 weeks, labeled pathways were traced dorsally into the ipsilateral medial cortex and caudally via ipsilateral stria medullaris thalami and medial forebrain bundle. Labeled fibers in stria medullaris enter the medial habenular and dorsomedial thalamic nuclei; those in the medial forebrain bundle appear to terminate within the hypothalamus as follows: medial preoptic, dorsal and lateral hypothalamic areas; anterior, posterior and paraventricular nuclei; medial mammillary nuclei. Mesencephalic projections (pre-rubral field, central grey and substantia nigra) appear not to result from septal injections, but were consistently noted when injection sites included nucleus accumbens. (Supported by Grants MH-07051 and EY-04090 from the National Institutes of Health).

282 SOMATOSENSORY PROJECTIONS TO THE THALAMUS IN RANID FROGS. Walter Wilczynski, Timothy J. Neary, and Michael L. Andry*. Neurosci. Prog. and Div. Biol. Sci., Univ. of Mich., Ann Arbor, MI, 48109.

Electrophysiological studies (Vesselkin, et al., BB&E 4:295, 1971) indicate that there is an extensive somatosensory representation in the thalamus of anurans. In order to determine more precisely the pattern of termination of ascending somatosensory input, we have engaged in a series of both anterograde autoradiographic and retrograde HRP experiments in ranid frogs. No evidence for a direct spinothalamic projection could be seen following injections of up to 4 uCi of a [^{3}H]-proline-leucine mixture into the spinal cord proper. When injections were placed near the obex region, however, an extensive thalamic projection was observed, primarily contralateral to the injection. Label was present in an intermediate portion of the anterior nucleus and in the medial half of the posterior nucleus. In addition, label was present over the entire rostrocaudal extent of the ventral thalamus, excepting a dorsolateral area rostrally. After large HRP injections into the rostral thalamus, HRP-positive cells were found in the caudal medulla. These labelled cells were present in the reticular formation ventrolateral to the hypoglossal nucleus, and in a perisolitary band of cells lying dorsal and lateral to the solitary tract. Of 112 cells counted in two cases, 26 were found in the reticular area, with 15 of these ipsilateral to the injection sites. Eighty-six cells were found in the perisolitary band, with 73 of these contralateral to the injection sites. No labelled cells were seen in the spinal cord proper.

This work was done in collaboration with R. Glenn Northcutt and was supported by NIH Grant NS 11006 to RGN, NIH Fellowship NS 05923 to TJN, and NIH Fellowship NS 02622 to MLA.

DEVELOPMENT AND AGING

283 INTERRELATIONS OF SENSORIMOTOR CORTICAL AND SUBCORTICAL CIRCUITS SUBSERVING CONTACT PLACING IN THE KITTEN. Vahe E. Amassian, Richard Ross and Birgit Zipser. Dept. of Physiology, SUNY, Downstate Medical Center, Brooklyn, N.Y. 11203.

Contact placing (CP) of the forepaw recovers after either extirpation of contralateral sensorimotor cortex (J.Physiol. (1972) 230: 55-56P) or after a midbrain decerebration prior to the fourth postnatal week. However, forepaw CP is abolished by transecting the spinal cord at C1, the kitten being maintained on artificial respiration. In decerebrate kittens, a radiofrequency lesion of the Vestibular N. ipsilaterally abolishes forepaw CP (J.Physiol. (1977) 266: 97-98P). Participation of the Vestibular complex in CP could account for its facilitation (eg, an increased probability and reduced latency of CP) when the kitten is moved to the placing apparatus instead of P→K. After recovery from a SM cortical lesion, the 'stand alone' capacity of the subcortical circuitry is secondarily lost when the kitten ages, CP probability gradually diminishing at 1-2 months until it resembles the effect of an initial cortical removal at 5 weeks.

Starting with the second week, if corticofugal output is acutely removed by cooling SM cortex, forepaw CP is temporarily lost to lateral but not to dorsal stimulation; cooling during the first week is usually ineffective suggesting that SM cortex does not acquire an important role in a behavior-lateral CP until the second week (J.Physiol. (1976) 263: 144-145P). This influence is probably mediated by PT neurons; thus, cooling the rostral bulbar pyramid of 2-3 week old kittens through a probe implanted via the cerebellum abolished lateral CP first contralaterally, the forelimb adopting an extended posture. When placing failed, the early SI cortical response to contralateral forelimb stimulation was unaltered in amplitude or was reduced suggesting that cooling had spread to the medial lemniscus. Cooling with the probe slightly withdrawn spared lateral placing, but reduced the SI response. The possibility that, early in development, PT neurons might mediate lateral CP tonically rather than by dynamic responses to contact was supported by the finding, at 3-4 weeks, that thalamic cooling adequate to block the early SMI responses to stimulation contralaterally of the forelimb and cerebellum, respectively, did not abolish lateral CP.

Electrophysiological indices of maturation were sought that might relate to the above findings. In a sample of 100 individual, antidromically labelled PT neurons, the shortest conduction time from bulbar pyramid to motor cortex fell from 32 to 10 to 5 msec in the first, second and third weeks respectively. During the second week, the fastest PT neurons conduct at 3 m/sec, ie, they are unmyelinated when they first function in CP. Significantly, resting discharge first becomes prominent in the second week, providing a basis for the tonic PT influence on CP. Aided by NS11219.

284 RELATIONSHIP OF SIZE AND NEURONAL DENSITY OF CAUDATE NUCLEUS TO THE NUMBER OF DOPAMINERGIC NEURONS IN DIFFERENT MOUSE STRAINS. A CENTRAL MODEL OF NEURON-TARGET ORGAN INTERACTION. H.A. Baker*, T.H. Joh, and D.J. Reis. Lab. of Neurobiol., Dept. of Neurol., Cornell University Medical College, New York, NY 10021.

Differences in the activity of brain tyrosine hydroxylase (TH) between 2 inbred mouse strains, Balb/cJ and CBA/J are due to differences in the number of immunocytochemically demonstrable TH-containing dopaminergic (DA) neurons in the midbrain (Ross et al Nature, 264.654, 1976). We sought to determine if the strain-dependent differences in DA cell numbers were associated with any morphological or biochemical variations in a target of DA neurons, the caudate nucleus (CN). As previously found, TH activity in the substantia nigra (SN) and CN of Balb was greater than in CBA mice. TH activity in the SN of Balb (2.13±.08 nmol/Dopa/hr/SN) was 23% higher than in CBA mice (1.66±.04) and 19% greater in the CN of the Balb (734.4±25.11 nmol Dopa/gm CN/hr) than in CBA mice (601.9±18.3) ($P<.01$). The total number of midbrain neurons immunocytochemically stained for TH in Balb was 16% greater than in CBA mice (7,404 vs. 6,250 cells). No strain difference in TH activity or cell number was observed in the locus coeruleus. The CN volume in Balb was 16% larger than in the CBA mice (8.19±0.28 vs. 6.92±.23 mm^3 $P<.05$). Since the neuronal density (87,314± 6,335 in Balb vs. 89,236±6,637 cells/mm^3 in CBA) did not differ, the total number of CN neurons was greater in Balb than in CBA mice. In CN, choline acetyltransferase (CAT) activity was identical for both strains. However, glutamic acid decarboxylase (GAD) activity, was 19% lower ($P<.01$) in the CN of Balb (12.22±.75 nmol CO_2/gm CN/hr) than in CBA mice (15.05±.74). In contrast, in SN, GAD activity was the same in the two strains. CAT activity in Balb was 27% higher than in the CBA mice (71.04±6.0 nmol ACh/SN/hr and 52±4.4 respectively $P<.05$). We conclude that strain-dependent differences in numbers of DA neurons directly correlate with the size and number of neurons in the terminal field. The finding suggests an interaction between cell number and target organ size in the CNS, as in the periphery. Biochemical mechanisms involving cholinergic and gabergic systems important in the interaction between the SN and CN may compensate to provide for neurological normalcy in these strains.

285 SYNAPTIC MODIFIABILITY IN MIDDLE-AGED AND SENESCENT RATS. C. A. Barnes. Dept. of Psych., Dalhousie Univ., Halifax, N. S., Canada, B3H 4J1

The perforant path - granule cell synapse in the hippocampus shows a long-lasting type of increased effectiveness after brief episodes of high-frequency stimulation. Since the synapse is a favored candidate for the site of information storage in the nervous system, it was of interest to determine whether there were any differences in the synaptic physiology of mature and very old organisms. Thirty-two middle-aged (16 months) and 32 old (34 months) hooded rats were tested on a complex spatial discrimination task on which the old rats showed retention deficits. These same rats were then prepared for chronic stimulation and recording of perforant path-granule cell responses. All electrophysiological testing was performed with the animals awake and unrestrained. With the stimulation parameters used in this study, electrical afterdischarge did not occur. After one burst of high-frequency stimulation, the fractional increase in the synaptic response, as well as the time course of decay of this increase over a period of one week, was virtually identical between age groups. When high frequency bursts were delivered at 24-hour intervals, however, a large difference in the retention of the elevated evoked response became apparent between age groups. Fourteen days after the final high frequency stimulation, the young rats continued to show the large increase in synaptic response, whereas the response in the old animals had decayed back to the initial baseline. If this physiological model bears any relation to learning in the natural situation, it predicts that the deficit which comes with age is in retention and not in initial learning.

The fractional increase of synaptic response was affected by the time of day in the young but not in the old rats, suggesting alterations of circadian rhythmicity in CNS functioning of the old rats. At the end of the study the effects of pentobarbital anesthesia on the synaptic response was measured. The size of the extracellularly recorded EPSP in both groups was reduced, however the reduction was significantly greater in the old animals. This suggests that extrapolations of electrophysiological data obtained from preparations using this anesthetic to awake animals is extremely tenuous, particularly when age comparisons are being made.

286 OBSERVATIONS ON THE DEVELOPMENT OF BRAINSTEM-SPINAL SYSTEMS IN THE NORTH AMERICAN OPOSSUM. J. Beals[1], J. Culberson[2], R. Dom[3] and G. Martin[4]. Dept. of Life Sciences, Otterbein College, Westerville, Ohio[1], Depts. of Anatomy, West Virginia Univ., Morgantown, W. Va.[2], Univ. of S. Carolina, Charleston, S.C.[3], and The Ohio State Univ., Columbus, Ohio[4].

The opossum's embryology makes it a potentially good model for studies of developing motor systems. The young are born 12 + days after conception and are carried in the mother's pouch for 90 days or more where they are accessible for experimental manipulation. Of particular interest is the fact that their hindlimbs remain immobile for a week or more after entrance into the pouch. We have begun studies with the opossum which were designed to gain insight into the development of brainstem-spinal connections and their possible correlation with the ontogeny of hindlimb activity.

By using the Fink-Schneider method on pouch young opossums with appropriate lesions (see C.M. Leonard, Brain Res., 53: 412-416) we have been able to demonstrate "immature" suprasegmental fibers in the marginal layer of the lumbar cord prior to the development of hindlimb motility. The electron microscope reveals that marginal axons are small and unmyelinated at such stage. By the time random hindlimb movements begin, "immature" brainstem fibers can be found in the expanding neuropil of the mantle zone. At that stage they can be demonstrated in most of the areas which contain such fibers in the adult and HRP studies show that they take origin from most of the cell groups giving rise to comparable fibers in the mature animal. Once the young are weaned and able to ambulate in an adult fashion, brainstem-spinal axons are mature in appearance (all techniques) and can be demonstrated by the Fink-Heimer method. Correlative electron microscopic studies are underway which are designed to address questions of developing synaptology in these systems.

287 NOCICEPTION: POSTNATAL DEVELOPMENT OF RESPONSIVENESS TO ANTICHOLINERGICS. C. T. Bennett and J. M. King. Neuropsychology Br., Experimental Medicine Div., Biomedical Laboratory, Chemical Systems Laboratory, APG, MD 21010.

Responses of rats (5, 10, 15, 20 and 25 days of age) to nociceptive stimuli were measured using the tail flick and hot plate tests. Following baseline measurements, the neonates received either saline (0.9%) or benactyzine (5.0 or 10 mg/kg) and tested 15 minutes later. In the hot plate test, 5 mg/kg benactyzine had no behavioral effect at any day tested. By 20 days of age, however, 10 mg/kg of benactyzine significantly reduced response latency in this procedure. In contrast to this is the effect of benactyzine on the tail flick behavior of the neonates. Beginning at 5 days of age, the low dose of benactyzine (5 mg/kg) significantly reduced tail flick latency. This effect was antagonized by physostigmine (0.3 mg/kg). The data clearly indicate a differential effect by dose, and by age, on the two tasks differing in motor complexity. These studies suggest that the functional development of the cholinergic system mediating nociception does not develop homogenously.

288 INTRACELLULAR LOCALIZATION OF ALPHA-FETOPROTEIN (αFP) IN THE DEVELOPING RAT BRAIN - AN IMMUNOCYTOCHEMICAL STUDY. Robert H. Benno* and Terence H. Williams. Dept. of Anatomy, University of Iowa, Iowa City, Iowa.

Alpha-fetoprotein (αFP) is a serum protein present temporarily in high concentrations in the serum of developing vertebrates, but absent in the adult. Molecules of αFP with specific estrogen binding properties exist in the developing rat brain and, on the basis of biochemical evidence, it has been hypothesized previously that αFP is present extracellularly in the developing brain. Whereas an appropriately timed action by estrogen on the developing rat brain appears to be both beneficial and necessary, it has been claimed that premature estrogenization may be deleterious, and that αFP serves to block this effect. The objective of this study is to localize αFP in developing brain to gain clues concerning its true role.

Thirteen, 15, 18 day fetal, 2 and 5 day postnatal and adult male and female Sprague-Dawley rats were perfused with Bouin's fixative and embedded in paraffin. Five micron sections were cut and processed for immunocytochemistry by the unlabeled antibody peroxidase-antiperoxidase technique.

Intracellular localization of αFP in the rat brain was noted in all animals aged from 15 days fetal to 5 days postnatal. Many recognizable neuronal cell groups contain αFP. These include some that have been shown to possess high affinity estrogen receptors. An interesting finding was discrete high intensity localization in some, but not all, of the cells lining the ventricles. Also, αFP was associated with meninges, choroid plexus, circumventricular organs and blood vessels. The localization of αFP in cells surrounding blood vessels in the brains of the 18 day fetal animals and the absence of similar staining in the 2 and 5 day postnatal animals suggested to us that maturation of the blood-brain barrier (BBB) prevents access of blood borne αFP into most brain areas. Persistent αFP localization observed in the circumventricular organs and choroid plexus up to postnatal day 5 can be explained by absence of the BBB in these areas. αFP was absent in the adult brain.

Two alternative hypotheses can be constructed to explain the observed immunocytochemical localization of αFP in developing rat brain:

(1) All neural cells may require αFP for some process associated with differentiation and/or migration.

(2) Only a particular population of cells, possibly estrogen sensitive cells, may require αFP.

Supported in part by an NSP predoctoral fellowship to R.H.B. and NIH grant NS11650 to T.H.W.

289 SOURCE OF NORADRENERGIC SPROUTING IN THE CEREBELLUM OF RATS TREATED NEONATALLY WITH 6-HYDROXYDOPAMINE. Ranbir K. Bhatnagar and Richard H. Schmidt*. Dept. of Pharmacol., Univ. of Iowa, Iowa City, IA 52242.

Treatment of neonatal rats with subcutaneous 6-hydroxydopamine (6-OHDA) is known to produce an extensive, permanent degeneration of noradrenergic (NE) fibers in the telencephalon, but results in a marked regenerative sprouting of NE terminals in the cerebellum. It is not known if the locus coeruleus is the source of all or any of these sprouted fibers, as other NE cell groups also appear to contribute to the cerebellar innervation. This study was conducted to determine the regional distribution of locus coeruleus innervation to the cerebellum in normal and 6-OHDA treated rats.

Female rat pups were injected subcutaneously with 100 mg/kg 6-OHDA or vehicle on postnatal days 1 and 2. When 100 days of age unilateral electrolytic lesions (2mA for 10 seconds) or sham implacements were made in the locus coeruleus. Two and three weeks later the cerebellum was removed and dissected into anterior, middle and posterior regions as described in the abstract by Schmidt and Bhatnagar. Each region was assayed for synaptosomal NE uptake, dopamine β-hydroxylase (DβH) and endogeneous NE.

Ipsilateral to the lesion in vehicle control rats NE levels in the parietal cortex were reduced to 15% of sham control, while on the contralateral side NE was reduced by less than 25%. This, as well as histology, indicates that the lesions were complete.

In the cerebella of sham-lesioned vehicle control rats the anterior region of cerebellum contained about 150% as much innervation as the other two regions. Neonatal 6-OHDA treatment caused increases in NE, DβH and NE uptake in all regions. The largest increase (60%) occurred in the posterior region while the smallest increase (20 to 30%) was found in the middle region.

In the vehicle control rats the lesion destroyed, in all cerebellar regions, 50 to 60% of the NE innervation of the ipsilateral side and 20 to 30% on the contralateral side. In rats treated neonatally with 6-OHDA the lesion destroyed 75 to 80% of the NE innervation on the ipsilateral side relative to sham-lesioned drug treated levels. No degeneration was detected on the side contralateral to the lesion. These data demonstrate that the locus coeruleus is the source of all 6-OHDA induced sprouting in the cerebellum and this sprouting is exclusively ipsilateral. The normal contralateral projection thus does not regenerate or sprout following the initial neurotoxic effects of 6-OHDA.

290 DELAYED DISAPPEARANCE OF PLACING AFTER HEMISPHERECTOMY IN THE KITTEN. Joseph E. Bogen, Berry Campbell* and Merton Suzuki*, Ross-Loos Med. Grp., Los Angeles, CA 90026.

After sensorimotor corticectomy, frontal lobectomy or hemispherectomy there is an immediate and enduring loss of paw contact placing in the contralateral limb. A second ablation (of the remaining frontal lobe) results in immediate return of placing (Bogen & Campbell, Science 135:709-710, 1962) suggesting that the previous loss was due to unbalanced, tonic, ipsilateral inhibition. The cortical origin of this inhibition is indicated by subsequent experiments in which hemispherectomy of kittens 10-12 days old is followed by loss of contralateral paw contact placing only after a five week delay. During this delay, chin contact placing and visual placing appear, before subsiding gradually rather than abruptly as in the adult cat. This experiment exposes the ontogenesis of corticofugal influences on a behavior whose essential features appear to be organized subcortically.

291 ELECTROPHYSIOLOGICAL PATTERNS ASSOCIATED WITH NONNUTRITIVE SUCKLING IN 11-13-DAY-OLD RAT PUPS. Stephen C. Brake*, Virginia Wolfson*, and Myron Hofer. Dept. Psychiat., Montefiore Hosp., Bronx, N.Y., 10467.

Previous investigation of suckling patterns in infant rats have employed negative pressure recordings or direct observation of pups. These studies seem to indicate that suckling is a consistent, reflexive response at least over relatively short periods of time. In order to measure more directly activity associated with suckling over time we allowed pups to suckle an anasthetized lactating dam for up to 4 hrs while recording EMG's from the left ventral jaw muscle (digastricus). EMG's were also correlated with simultaneous negative pressure recordings and visual observations. Pups were separated from their mothers either 2-6 hrs or 20-24 hrs prior to testing to assess the effects of differing amounts of maternal deprivation on suckling behavior. At no time was milk available. Muscle activity was scored with respect to overall intensity (amplitude and frequency of EMG) as well as frequency of three different EMG patterns: long rythmic bouts (associated with suction and a clear opening and closing of the mouth), bursting (suction with no visible body movement), and treading (suction and movement of limbs). 20-24 hr pups initially displayed long rythmic bouts which dropped out within 30 min. These bouts were absent in 2-6 hr pups. In both the 20-24 hr and 2-6 hr pups, intensity of muscle tone decreased significantly within an hour. Frequency of bursting and treading remained essentially the same for both groups. Bursting and treading often occurred sequentially, though each occurred independently. 20-24 hr pups, and to a lesser extent 2-6 hr pups, tended to detatch from the nipple after about an hour. These data show specific alteration in patterns of suckling as a function of amount of deprivation and time attached to the nipple. Quantitive analysis of all data will be presented at the meeting.

292 INTERAXONAL CONNECTIONS IN PERIPHERAL NERVES OF NORMAL NEWBORN RATS. G.M. Bray, S. Perkins* and A.J. Aguayo, Division of Neurology, The Montreal General Hospital and McGill University, Montreal, Que.

Vagus nerves , which in newborn rats contain bundles of naked axons, were examined by freeze-fracture and thin-section electron microscopy. On the day of birth, six litters of Sprague-Dawley rats were perfused with 1.5% glutaraldehyde and 0.5% formaldehyde in 0.08 M Sorensen's phosphate buffer. The vagus nerves were removed from each animal and either post-fixed with osmium ferrocyanide and embedded in epoxy resin for thin sectioning or frozen in 20% glycerol, fractured in a Balzers 301 freeze-fracture apparatus, replicated and examined by transmission electron microscopy.

In both longitudinal and cross-sections, many adjacent naked axons were joined by tube-like structures approximately 0.1 μm in diameter and 0.05 μm in length. These structures formed cytoplasmic channels between axons and were surrounded by membranes that were continuous with the adjoining axolemma. These interaxonal communications disappeared as axons became individually ensheathed by Schwann cells.

The presence of large interaxonal connections in newborn rats suggests that axons of mammalian peripheral nerves have a syncytial arrangement during early development. Such connections may be important in metabolic cooperation and other forms of cellular interactions during neurogenesis.

293 QUANTIFICATION OF THE EEG OF THE DEVELOPING RAT[+1]. Bronzino, J.D.[+2], W. B. Forbes, C. A. Tracy*, P. Stisser*, O. Resnick*, and P. J. Morgane. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545

In order to quantify the changing patterns seen in the EEG during development of the rat and determine the impact of protein malnutrition on these EEG patterns, we have applied spectral analysis techniques to obtain a "power spectral atlas" of the electroencephalogram of the developing rat. We have analyzed the EEG recorded from several brain sites (specifically, the parietal cortex, frontal cortex, and the hippocampus) in rats that are 90-120 days old. Studies of the power spectra obtained from three other age groups (i.e., 8-14 days, 21-22 days and 30-35 days, postpartum) together with the results from the adult rat group provides a measure of the changing EEG-pattern during development. In the case of the 90-120 day old age group, 42 animals have been implanted with chronic indwelling electrodes and the EEG recordings have been obtained from the 3 brain areas mentioned above during 4 different vigilance states (i.e. waking (W), slow-wave sleep (SWS1, SWS2) and REM sleep). These 42 animals comprised four different dietary treatment groups: (1) 25% protein casein diet, (2) 8% protein casein diet, (3) those reared initially on a 25% diet and switched to 8% at weaning (25-8%), and (4) those reared initially on an 8% diet and switched to 25% at weaning (8-25%). A continuous two hour segment of EEG taken during the same time of day for each animal was scored for the 4 vigilance states and analyzed. This procedure consisted of randomly selecting 8 epochs (8 seconds duration) from each vigilance state, for each brain site (n=3), for each animal (n=42). Using a PDP-11 computer each 8 second epoch of EEG was converted to a digital format using a sampling interval of 7.813 msec., thereby insuring a Nyquist frequency of 64Hz. Fast Fourier Transform routines were then employed to obtain a power spectral representation for each epoch of EEG. The power spectra obtained were then averaged to provide a mean (± standard deviation) power spectrum for that vigilance state. Using this approach, the results obtained from the different age groups and different dietary groups have been compared in a quantitative manner, thus providing a highly sensitive indicator of the EEG of the normally developing rat, as well as, the EEG of the animal subjected to dietary insult during critical periods of its development. The significance of these results will be described in relation to brain ontogeny and the effect of malnutrition on brain development.

294 BLOOD-BRAIN BARRIER: AGING IN PRIMATES. E. M. Burns and T. Kruckeberg*. Dept. Gen. Nursing, College of Nursing, UIMC, Chicago, IL 60612 and Dept. of Research, Mercy Medical Center, Chicago, IL 60616.

An ultrastructural study of the changes occurring with age in the blood-brain barrier was performed in Macaca nemestrina. Three groups of animals were used in the study: three four-years of age; ten ten-years of age; and seven twenty-years of age, thus representing young, middle-aged and elderly populations. Samples were obtained from the frontal and occipital poles of the cerebrum from all animals for light and electronmicroscopic evaluation of the blood-brain barrier. Samples were also obtained from the posterior pituitary. All samples were fixed by immersion. Full cortical thickness blocks of tissue, not greater than 1mm in width, were postfixed, dehydrated, en bloc stained with uranyl acetate and embedded in epon. Ultrathin sections, perpendicular to the pial surface or perpendicular to the neurohypophyseal surface, were made, further stained on the grid with uranyl acetate and Reynold's lead and photographed either using the Siemens 1A or Phillips 300 electron microscope.

Barrier-type cerebral cortical capillaries were compared with fenestrated neurohypophyseal capillaries in the different age groups. Cerebral cortical and neurohypophyseal capillary profiles were analyzed using the optomax modular television scanning image analysis system (courtesy of μm Micromeasurements Company, Burlington, Mass.). Ultrastructural differences found in the cerebral and neurohypophyseal capillaries of animals from the three age groups will be discussed. (Supported by: #NO1-AG-6-2145 in collaboration with D. M. Bowden, Regional Primate Research Center, Seattle, WA).

295 POSTNATAL MATURATION OF A CHOLINERGIC INFLUENCE ON NEUROLEPTIC CATALEPSY. Dorothy K. Burt, Martha L. Crowner*, Suzanne M. Hungerford*, Katherine L. Melville*, Craig Shanklin* and Luis A. Baez. Dept. Psych. Southern Ill. Univ., Carbondale, Ill.

Catalepsy can be elicited in rats by dopamine receptor blockers and by cholinergic agonists. Neuroleptic-induced catalepsy is antagonized by anticholinergics in adult rats. These and related data suggest that CNS cholinergic and dopaminergic systems interact functionally. This study was designed to investigate the postnatal maturation of this neuropharmacological interaction.

A total of 216 rats were used in the first experiment. Animals of 10, 15 and 20 days of age were injected with saline or one of the following doses of atropine sulfate: 0.156, 0.312, 0.625, 1.25, 5.0 and 20.0 mg/kg. Fifteen minutes later all animals were injected with 1.0 mg/kg spiroperidol, a specific dopamine antagonist. All injections were intraperitoneal. Spiroperidol produced catalepsy at all ages, and this effect was not antagonized by atropine in 10- or 15-day-old animals. At 10 days atropine actually appeared to enhance the cataleptic action of spiroperidol. In 20-day-old rats, on the other hand, catalepsy was reversed by atropine in a powerful and dose-related manner, with 5.0 mg/kg nearly abolishing catalepsy.

A second experiment investigated the cataleptic effects of clozapine. This neuroleptic does not produce catalepsy in adults and has been reported to possess anticholinergic properties in addition to blocking dopamine receptors. Rats of 10, 15 and 20 days of age were injected with saline or clozapine (4.0, 8.0 and 16.0 mg/kg), 12 animals per dose. Clozapine reliably elicited catalepsy in 10- and 15-day-old animals, but failed to do so in the 20-day-old group.

These data suggest that a cholinergic influence on dopaminergic neurons involved in catalepsy becomes functionally mature after fifteen days of age in the rat. Such a hypothesis is consistent with data which indicate that cholinesterase-containing interneurons mature at about this time in the neostriatum (Butcher and Hodge, Brain Res., 1976). However, there appear to be two different cholinergic actions as a function of age. Since there was some indication in the first experiment that atropine might enhance catalepsy in the youngest animals, we tested 10- 15- and 20-day-old animals with one of the following doses of atropine only: 0.156, 0.312, 0.625, 1.25, 5.0, 10.0 and 20.0 mg/kg. Atropine treatment produced slight to moderate catalepsy in 10- and 15-day-olds, but had no cataleptic effect by 20 days of age. Thus, cholinergic blockade has behavioral effects similar to those of dopaminergic blockade up to 15 days of age. After this age, cholinergic blockade antagonizes the effect of dopamine blockade by spiroperidol.

296 REGENERATION OF AN INTERSEGMENTAL INTERNEURON IN THE LEECH. Ronald L. Calabrese. Dept. of Biology, UCSD, La Jolla, CA 92093

The paired heart control neurons of the leech comprise a favorable preparation for studying the regeneration of central synaptic connections, because they are easily identified and penetrated with microelectrodes. The segmental heart motor neurons (HE cells) receive monosynaptic inhibitory input from a set of segmental heart interneurons (HN cells). The HN cell of the third segmental ganglion [cell HN(3)] synaptically contacts ipsilateral HE cells in segmental ganglia 3-18 by an intersegmental axon. Cell HN(3) produces rhythmic impulse bursts at the heartbeat frequency and each ganglionic region of its intersegmental axon can produce these impulse bursts in isolation.

When the intersegmental axon of cell HN(3) is cut and regeneration is prevented, neither the proximal soma + axon nor the distal axonal remnant degenerate even after 18 weeks. Both sections of the severed neuron continue to produce rhythmic impulse bursts and remain connected to appropriate HE cells on their respective sides of the cut. Thus under conditions where regeneration can occur the distal axonal remnant of cell HN(3) presents a possible target for its ingrowing proximal to contact. If such contact were made and through-conduction of impulses restored, then synaptic connection with the HE cells in all segmental ganglia would resume simultaneously. Alternatively, during regeneration the ingrowing cell HN(3) proximal axon could contact the HE cell in each segmental ganglion directly. Resumption of synaptic contact with the various segmental HE cells would thus follow an anterior-posterior temporal sequence and the distal axonal remnant of cell HN(3) would remain to function autonomously.

I have been able to distinguish between these two alternative mechanisms of regeneration by monitoring physiologically the re-establishment of cell HN(3)-HE cell synaptic contacts following severance of the cell HN(3) axon by crushing an interganglionic connective. For 5 weeks following crushes of the cell HN(3) axon no physiological signs of its regeneration were observed in any preparation; both the proximal and distal severed axons remained active and functional but did not conduct impulses across the crush. Regeneration was first observed in some HN(3) cells 6 weeks after crushing their axons; by 9 weeks after the crush the HN(3) cells in all preparations tested had regenerated. The regenerated HN(3) cells always resumed normal synaptic contact with their appropriate HE cells in all segmental ganglia. In such regenerated preparations no signs of a functionally autonomous distal axonal remnant could be detected.

These results indicate that the HN(3) cell regenerates its intersegmental synaptic connections by functionally connecting with its severed distal axonal remnant.

297 RATE OF APPEARANCE OF α-BUNGAROTOXIN BINDING SITES DURING DEVELOPMENT OF CHICK CILIARY GANGLION AND IRIS. V. Chiappinelli* and E. Giacobini. Lab. Neuropsychopharm., Dept. Biobehavioral Sciences, Univ. of Conn., Storrs, CT 06268.

The binding of ^{125}I-α-bungarotoxin (α-BTX) has been examined in the developing chick ciliary ganglion and its end organ, the striated iris muscle. Specific α-BTX binding (Total ^{125}I-α-BTX bound minus ^{125}I-α-BTX bound in the presence of 1000 fold excess unlabelled α-BTX) increases four fold from 7 days of incubation (d.i.) to 11 d.i. (from 4.2 fmole/ganglion to 19 fmole/ganglion), after which the amount of binding remains unchanged up to 4 months after hatching (a.h.), the oldest age tested. Specific binding in the ciliary ganglion is inhibited up to 90% by 10^{-5} M d-tubocurarine, suggesting that, as at the neuromuscular junction, α-BTX binding is associated with the nicotinic cholinergic receptor.

The large increase in binding of α-BTX in the ciliary ganglion occurs after the initiation of ganglionic transmission, similar to the increases seen in choline acetyltransferase (ChAT) and acetylcholinesterase activities (J. Physiol. 257 (1976) 749-766), but while a second period of large increase in ChAT activity begins at 12 d.i., the level of α-BTX binding in the ganglion has already reached its adult value by this time.

In contrast to binding in the ganglion, α-BTX binding in the iris remains very low until 12 d.i., then, soon after functional innervation is established, it increases steadily until 4 months a.h. The total increase from 12 d.i. to 4 months a.h. is almost 40 fold (from 2.8 fmole/iris to 106 fmole/iris).

Supported by PHS Grant NS-11496 and the Univ. of Conn. Research Foundation. ^{125}I-α-BTX was the generous gift of Dr. Douglas Fambrough.

298 EFFECT OF AGE ON ODOR ADAPTATION IN HAMSTERS. Catherine Cornwell-Jones. Dept. Psycho., Princeton Univ., Princeton, N.J. 08540

Hamsters 10-56 days old reared in pine shavings prefer the odor of natural pine to the scent of cedar nest shavings in which conspecifics have been housed. Placing pine-reared hamsters in cedar shavings changes their odor preferences, but the particular changes induced depend upon the age of exposure. Following three days of exposure to cedar, cedar nest odor attracts pups 10-12 days old, and is neutral for both juveniles 29-35 days old and for adult males 49-56 days old. Exposed juveniles also acquire a tolerance for the odor of natural cedar shavings which have not housed hamsters, but the odor remains aversive to exposed adult males. The fact that juveniles but not adults adapt to natural cedar odor implies that odor processing systems in the hamster loose some degree of plasticity between puberty and adulthood. Receptor adaptation cannot account for the changes observed in pups or adults. An exposure-induced decrease in receptor sensitivity would have produced indifference rather than the observed attraction to cedar nest odor in pups. The same process would have produced tolerance of both natural cedar and cedar nest odor in adults rather than the observed aversion to the former and tolerance of the latter. The evidence therefore implies that changes in central rather than peripheral mechanisms mediate odor adaptation in hamsters.

299 EMBRYOLOGIC DEVELOPMENT OF A MOUSE SYMPATHETIC GANGLION. Michael D. Coughlin, Dahna M. Boyer* and Ira B. Black. Dept. of Neurology, Cornell University Medical College, N.Y., N.Y. 10021.

Although the postnatal development of the mammalian superior cervical ganglion (SCG) has been studied extensively, regulation of its embryologic development is essentially unknown. The present investigation analyzes the morphological and biochemical ontogeny of embryologic mammalian sympathetic neurons in vivo and in culture.

To define normal development of the SCG in utero, ganglia from litters of different gestational ages were assayed for tyrosine hydroxylase (T-OH) activity, an index of adrenergic neuron maturation. T-OH activity was readily detectable in ganglia of 13-day embryos, and increased approximately 100-fold between this time and birth. Enzyme activity rose gradually between days 13 and 16, increased rapidly between days 16 and 17, and rose gradually once again, between day 17 and birth at 19 days.

Tissue culture studies of the embryonic SCG were undertaken to determine whether embryologic development in vitro paralleled that in vivo, and whether conditions necessary for ganglion differentiation varied during prenatal growth. SCG explants from 13, 14 and 15-day embryos grown in basal medium without added Nerve Growth Factor (NGF) readily adhered to the culture dish surface and exhibited extensive fiber development by 48 hours of incubation. Neurites were maintained for 3-4 days in culture and thereafter began to degenerate. Explants of 14-day gestation ganglia grown in basal medium without added NGF exhibited a marked increase in T-OH activity during the first three days in culture, resulting in more than an 8-fold total rise. This in vitro increase in T-OH activity paralleled that which occurred in vivo: after 3 days in culture T-OH activity was the same as that of the in vivo 16 to 17-day ganglion. Ganglia from 14-day embryos exhibited similar increases in enzyme activity in vitro in the presence of anti-serum to NGF (Anti-NGF) or NGF + Anti-NGF. In direct contrast, ganglia from 17 and 18-day fetuses failed to grow without added NGF, or in medium containing Anti-NGF or NGF + Anti-NGF: virtually no axon outgrowth occurred and T-OH activity decreased by half. These observations suggest that developmental regulatory mechanisms change radically during embryologic and fetal life of the mammalian SCG. (Supported by the Dysautonomia Foundation Inc. and the National Science Foundation.)

300 LONG-LATENCY EVENT-RELATED POTENTIALS IN INFANTS: PROBABILITY-DEPENDENT WAVES. Eric Courchesne, Leo Ganz, Anthony M. Norcia*, and Rachel Y. Courchesne*. Dept. of Psych., Stanford U., Stanford, CA 94305.

Few reports on the averaged event-related potential (ERP) in infants and children have examined waves with latencies later than 250-300 msec. Courchesne (1977) recorded ERPs to tachistoscopically presented slides in 6 to 8 year-old children. He showed that infrequently presented nontargets (stimuli not having experimenter-determined importance) which deviate from an on-going sequence of background stimuli always elicit long latency negative, Nc waves (ca 450 msec) and positive, Pc waves (ca 960 msec) in children; frequently presented nontargets (i.e., backgrounds) do not elicit these Nc and Pc waves. Our study was designed to determine whether or not infants have similar probability-dependent waves. We recorded ERPs from 22 infants, 22 to 32 weeks of age. Slides were flashed for 100 msec onto a screen in front of the infant, and were only presented when the infant was awake, looking at the screen, and not moving. Two sets of slides were used; one set for ten of the infants and the other set for the other ten infants. Each slide in Set 1 contained either an array of 5 red triangles or an identical array of 5 red circles. Each slide in Set 2 contained the face of one of two women; both faces were full-front, eyes open, and occupied the same area on the screen. Infants saw sequences of slides consisting of random orderings of 88% of one member of a slide set and 12% of the other member of a slide set. ERPs to these slides were recorded from Cz, Fz, above the eyebrow, and on the infraorbital ridge; reference was the mastoid.

All stimuli elicited ERPs consisting of high amplitude, long latency negative waves (ca 50 uV at Fz; ca 700 msec) and positive waves (ca 27 uV at Fz; ca 1300 msec); these waves are similar in shape to Nc and Pc waves in 6 to 8 year-olds but are somewhat higher in amplitude and longer in latency. These waves in infants were maximal in amplitude at the same scalp sites as the Nc and Pc waves. As with children, these waves in infants were higher in amplitude to infrequently presented stimuli than to frequently presented stimuli. Given the similarities in amplitude, latency, waveshape, location of maximum amplitude, and sensitivity to stimulus probabilities, it seems that these late negative and positive waves in infants are early representatives of the probability-dependent Nc and Pc waves found in children.

301 THE SUBCELLULAR DISTRIBUTION OF ENDOGENOUSLY PHOSPHORYLATED PROTEINS FROM CEREBRAL CORTEX OF NEWBORN RATS. Leonard G. Davis* (SPON: Yigal H. Ehrlich). Missouri Institute Psychiatry, Univ. of Missouri-Columbia, Sch. Med., St. Louis, MO 63139.

We have reported recently that specific proteins which serve as endogenous substrates for protein kinase activity in the CNS are unequally distributed among subcellular fractions from the cerebral cortex of mature rats (Ehrlich,Davis,Gilfoil and Brunngraber, Neurochemical Res.,in press). Comparison of the endogenous phosphorylative activity in fractions from cortices of newborn and adult rats may provide information pertaining to the role of cyclic AMP and specific phosphoproteins in the regulation of various neuronal functions. The crude mitochondrial (P2) microsomal (P3) and cytosol (S3) fractions, as well as, preparations enriched in myelin (P2A), synaptosomes (P2B) and mitochondria (P2C) from cerebral cortices of newborn (pups) and adult rats were prepared. Endogenous phosphorylation assays were carried out by incubating aliquots of each fraction with gamma-^{32}P-ATP in the absence and presence of cyclic AMP. The specific proteins which incorporated ^{32}P-phosphate were identified by autoradiography after SDS-slab-gel electrophoresis. The number of phosphorylated bands (16) detected in total homogenates of the pups was the same as in the adult, but the relative distribution of labelled phosphate among the bands differed in the two preparations. The P2 fraction from adult rats demonstrated 12 bands. The phosphorylation of two of these bands (MW=84K,78K) was highly stimulated by cyclic AMP. Corresponding preparations from the pup had low phosphorylative activity toward these two bands and they were not stimulated by cyclic AMP. In addition, bands in the MW range of 15-20K, which in the adult were highly phosphorylated in the absence of cyclic AMP, were minor bands in the pup P2, but they showed cyclic AMP dependent phosphorylation. Two bands (MW= 56K,52K) were more prominent in the pup P2 than in the adult, while another band (47K) was greater in the adult than the pup. The phosphorylation pattern of P3 of pups was similar to that of the adult. The cytosol fractions of adult and pups showed marked differences, particularly, in sensitivity to added cyclic AMP which was higher in the pup. In addition, bands (80K,47K) were major in the pup S3 and minor in the adult S3. The P2A fraction of adult was characterized by high levels of cyclic AMP-independent phosphorylation of bands in the MW range 15-20K which were not detected in the pup. Characteristic bands of osmotically shocked P2B fraction from adult (84K and 78K) were low in the corresponding preparations from pup supporting the suggestion that these bands are involved in synaptic function. Alternatively, a band (47K) of this fraction was more prominent in the pup indicating that this phosphoprotein may have an important function prior to maturation. (Supported by intramural funds from Mo.Inst.Psych.)

302 MATERNAL REGULATION OF SYMPATHETIC NEURON DEVELOPMENT. Mark D. Dibner and Ira B. Black. Dept. of Neurology, Cornell University Medical College, N.Y., N.Y. 10021.

The role of maternal salivary glands in the ontogeny of sympathetic neurons was studied in neonatal rats. Pregnant females underwent bilateral sialectomy on day 11 of gestation, and development of the superior cervical ganglion (SCG) was examined in pups at birth and at various postnatal ages. Salivary gland removal in mothers prevented the normal postnatal development of postsynaptic tyrosine hydroxylase (T-OH) and DOPA decarboxylase activities, and presynaptic choline acetyltransferase activity in the SCG. Total ganglion protein, a measurement of overall SCG growth, also failed to develop normally in progeny of mothers lacking salivary glands. Maternal sialectomy also altered development of other sympathetic ganglia in the offspring: T-OH activity and total protein failed to develop normally in the sixth lumbar sympathetic ganglion. Salivary extirpation in mothers did not affect development of neonatal body weight, suggesting that the effects on sympathetic neuron ontogeny were not caused by nutritional deficits.

Postnatal sialectomy in mothers of 1 and 2 day old, but not 4 or 6 day old animals blocked SCG development to a lesser degree than prenatal maternal sialectomy. These data imply that during fetal and early postnatal life maternal salivary factors regulate sympathetic neuron development.

303 HIPPOCAMPAL AFTERDISCHARGES AND PRENATAL CARBON MONOXIDE. R.S. Dyer, C.M. Eccles*, S. Swartzwelder*, L.D. Fechter, and Z. Annau. Dept. Environmental Health Sciences, Johns Hopkins Univ., Balto., Md. 21205.

Exposure of pregnant rats to levels of carbon monoxide sufficient to produce a maternal COHb saturation of 15% throughout gestation is known to produce a variety of neurochemical and behavioral changes in neonates. To date, no neurophysiological changes have been shown in neonates subjected to similar exposures, nor have any changes yet been shown using any of these techniques with animals tested as adults. Since there is evidence that neurons in the hippocampal formation are sensitive to hypoxia, and since seizure disorders are among the disturbances reported in cases of perinatal hypoxia, the present investigation was designed to determine the influence of prenatal hypoxia upon adult afterdischarge (AD) properties. Pregnant Long-Evans rats were exposed to either 150 ppm CO or 0 ppm CO throughout gestation. At birth, the exposed females and their litters were removed from the CO, and all litters were reduced to eight. Pups were weaned on post-natal day 21 and housed in groups of 3 or 4 by sex until surgery. On day 65±5 the animals had bipolar nichrome wires implanted into the dorsal hippocampus for stimulation and recording, and skull screws implanted for grounding and cortical recording. Following two weeks recovery, thresholds for producing AD's were determined according to the method described by Racine (EEG, 1972). The results indicated that the first AD elicited from the exposed animals was on the average 30% longer than those elicited from control, but that there was no significant difference between AD thresholds determined for the two groups. There were no apparent sex differences in either threshold or duration of AD. Since longer AD's precede the kindling of motor seizures (Racine, EEG, 1972), it is possible that animals prenatally exposed to low levels of CO kindle more rapidly to motor seizures than controls. This research was supported in part by NIH grants HL 054053 and EHS 00454.

304 GROWTH OF THE OCULAR MOTOR SYSTEM. S. S. Easter, Jr., Institut d'anatomie, Université de Lausanne, 1011 Lausanne, Switzerland, and Division of Biological Sciences, University of Michigan, Ann Arbor, Michigan 48109.

The eye of a goldfish enlarges as the animal grows; the eye diameters of 5-6 and 10-12 cm fish are about 4 and 6 mm, respectively. It is known that the retina grows by adding new neurons (Johns, P. R., Neurosci. Abstr. 2: 1188, 1976). I have examined the ocular motor system to learn how it adjusts to the increased mechanical load of the larger eye.

Individual superior oblique muscles and attached trochlear nerves were dissected from thirteen goldfish 5-12 cm long, which range in size corresponds to a range in age from less than one to between two and three years. Both nerve and muscle were sectioned transversely and examined electron microscopically. Photographic mosaics were made at magnifications of 800X-8000X (muscle) and 2400X-3600X (nerve).

Muscle fibers were identified as membrane-bound profiles containing ordered myofilaments. Fiber diameters ranged from less than 2 to more than 30 um, with the smallest fibers at the outer surface of the muscle. White fibers (those with relatively few mitochondria) were generally larger than red fibers, and the two types were segregated into different parts of the muscle, as noted by Kilarski and Bigaj (Zeit. Zellf. 94: 194, 1969). Cross sectional area of the muscle was larger in the larger animals, due partly to an increase in fiber diameter, but principally to an increase in fiber number, from a mean of 373 (5-6 cm animals) to a mean of 810 (10-12 cm animals). Both red and white fibers became more numerous. This growth by addition of new muscle cells strongly suggests that neuromuscular synaptogenesis continues as the animal grows.

Nerve fibers were all myelinated, with diameters ranging from 2 to 15 um in animals of all sizes. Mean fiber number was slightly higher in the older animals; 81 (5-6 cm animals) vs. 97 (10-12 cm animals), but the variance was too great to permit a firm conclusion as to whether the larger muscles were innervated by more nerve fibers. Some of the variance was due to preterminal branching of the fibers while still in the main trunk, which makes the fiber count dependent on the location at which it was made. (Supported by grant 3.776 from the Swiss National Science Foundation to H. Van der Loos, and by a grant from IBRO-Suisse to S. S. E.)

305 VISUAL EVOKED POTENTIALS IN ADULT RATS PRENATALLY EXPOSED TO METHYLMERCURY. C.M. Eccles* and R.S. Dyer (SPON: Z. Annau). Dept. Environmental Health Sciences, Johns Hopkins Univ., Balto., Md. 21205.

The developing nervous system is known to be particularly sensitive to the toxic effects of methylmercury (MeHg). It has been suggested that visual evoked potential (VEP) recording may be a useful method of detecting altered CNS function in the juvenile offspring of pregnant rats given daily doses of MeHg, (Pharm. Biochem. Behav., 1976, 5, 253). The present experiment tests the possibility that exposure of pregnant rats to a single low dose of MeHg may alter VEP's of offspring tested as adults. Five pregnant rats were given 5 mg/kg MeHg as MeHgCL dissolved in corn oil on day seven of gestation by gastric intubation. Six pregnant control rats received corn oil alone. Litters were reduced to eight on day one and weaned at 22 days of age. No apparent signs of toxicity were seen in the mothers or offspring at any time during gestation or postnatal life. At 60 days of age, skull screws for cortical recording and grounding were implanted in thirteen female offspring born to MeHg-treated mothers and in ten females born to control animals. After a two week recovery period, unanesthetized animals were studied with their pupils dilated in a chamber designed to reflect flashes. During a recording session, an animal's VEP's to 100 light flashes at one of four different intensities were recorded and averaged. Each of the light intensities was presented to each animal twice in counter-balanced order during the course of eight sessions. Peak to peak amplitudes and latencies of the VEP's major components were measured.

The most striking difference was seen in the earliest negative component (P_1-N_1) in which the experimental group showed a 40 percent increase over the control in mean amplitude at all light intensities. The second component, N_1-P_2, of the MeHg animals also showed an increase in mean amplitude for all light intensities but this increase was not statistically significant. Mean latencies of N_1 and P_2 were the same for both groups. It appears that a single low level prenatal exposure to MeHg is sufficient to produce long-term alterations in CNS function, and that the VEP technique is capable of detecting these alterations. This research was supported in part by NIH grants HL 054053 and EHS 00454.

306 EMBRYONIC DEVELOPMENT OF SENSORY NERVES IN AN INSECT. John S. Edwards and Su-Wan Chen* Dept. Zool. Univ. Wash. Seattle, WA 98195

The abdominal cerci of the house cricket Acheta domesticus are an elongate pair of posterior sensory appendages. Their numerous mechanosensory sensilla project to the terminal ganglion, and thence principally to giant interneurons of the ventral nerve cord. Aspects of the structure, function and regeneration of this system have been extensively studied. This report concerns the pattern of embryonic development of sensory axons in the abdominal cerci.

Axon-like processes arising from cells with no discernible sensory apparatus, and presumed to be pioneer fibres appear within the lumen of the cercus toward the end of katatrepsis, that is at about 50% of the full development period. They lie on dorsal and ventral midlines, occupying thus the plane of symmetry for subsequent sensory differentiation. Cells which subsequently wrap afferent axon bundles always accompany the earliest axon-like profiles and may prove to precede them. The first appearance of axons in the presumptive neuropile of the terminal ganglion coincides with that of the pioneer fibres. The population of pioneer fibres increases in number prior to elongation of the cercus and deposition of the first (embryonic) cuticle, on which there are no sensilla. With the deposition of the second embryonic (first instar) cuticle, axons from developing sensilla follow the preformed dorsal and ventral pathways through the cercus and thence to the ganglion via the single cercal sensory nerve during the final 15% development.

The neuropile has an open lacunar structure until the arrival of the massive population of sensory axons.

The presence of axons without apparent sensory function in the instar before that in which functional sensilla develop as described above for the cricket embryo parallels the sequence of events in metamorphosing Lepidoptera. In both cases axon-like processes arising from epidermal cells provide the pathway for subsequent functional axons. Contact between periphery and center is thus achieved when they are in closest proximity.

Supported by NIH grant NB 07778.

307 GOLGI AND EM STUDIES OF POSTNATAL DIFFERENTIATION OF DENDRITIC ARBORS OF INTERNEURONS IN LAYERS II AND III OF TRIGEMINAL NUCLEUS CAUDALIS IN NEWBORN KITTENS. William Falls and Stephen Gobel. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20014.

Most of the axons of primary trigeminal neurons entering the gelatinous band of nucleus caudalis do not synapse directly on second order projection neurons in layer I. They synapse on dendrites of interneurons in layers II and III. It is these interneurons which determine to a great extent what features of the stimulus encoded by the primary neuron will be passed on to the second order projection neuron. Developmental studies were designed to examine the postnatal differentiation of the dendrites and axons of these interneurons. These studies show that the two major interneurons of layers II and III (the stalked cell and the islet cell) are present at birth. The most immature forms of both cell types resemble a sea urchin, with short varicose dendrites radiating out in all directions from their cell bodies. During postnatal differentiation many dendrites bead up and are lost while only a few go on to lengthen. The stalked cell lengthens its medial dendrites and retracts most of its other dendrites while the islet cell lengthens its rostral and caudal dendrites. The lengthening of some dendrites and the retraction of others take place utilizing the same basic cellular mechanism. At many sites within dendrites the agranular reticulum gives rise to numerous vesicles called addition vesicles. These vesicles fuse with the dendritic membrane at numerous sites and become part of it. This sequence is responsible for the lengthening of dendritic membranes as dendrites elongate. In retracting dendrites, addition vesicles, instead of adding to the dendritic membrane, fuse with each other to form small cavities within the dendritic shaft. These cavities continue to enlarge, hollowing out the dendrite. The cavities ultimately become continuous with the intercellular space as their membranes fuse with the dendritic membrane. Finally, retracting dendrites, having been almost completely hollowed out by cavities, fragment and disintegrate.

These studies show that the dendritic arbors of the two major interneurons of layers II and III follow similar developmental sequences. They are laid down in preliminary form prenatally and altered postnatally through selective elongation of some dendrites and retraction of others. Dendritic elongation proceeds not from terminal growth cones but from multiple fusions of addition vesicles along the lengths of dendritic shafts. Finally, addition vesicles are involved in mechanisms underlying dendritic retraction as well as dendritic elongation in both of these cell types.

308 DEFICIENCIES IN THE STRUCTURE OF THE LEECH NERVOUS SYSTEM PRODUCED BY LESIONS TO THE EMBRYONIC NERVE CORD. Juan H. Fernandez* and Gunther S. Stent*. Dept. of Mol. Biol., Univ. California, Berkeley 94720. (SPON: John G. Nicholls).

The ventral nerve cord of the leech originates in the embryo from two rows of stem cells lining the medial surface of its germinal bands. These cells proliferate and differentiate into neuroblasts and glioblasts, which form a longitudinal series of ganglionic primordia. Each ganglion arises by the coalescence of two lateral and one medial primordia lying in register (Fernandez, Neurosc Abstr.; Vol. II, 1976). The stem cells are generated by one pair of neuroteloectoblasts present at the caudal end of the germinal bands. The results of the destruction of the ganglionic primordia and of the neuroteloectoblasts of 6-8 day-old embryos of the leeches Hirudo medicinalis and Haemopis marmorata were studied. The lesions were performed with a fine needle and the embryos were allowed to survive from three days to several weeks after the operation. Destruction of the ganglionic primordia resulted in ganglia deficient in nerve cells. The number and location of the missing nerve cells depended on the extent and location of the lesions. Damage to the medial ganglionic primordia also resulted in development of hemiganglia and formation of split connectives. Destruction of the neuroectoblasts, and of a discrete number of stem cells attached to them, in 6-7 day-old embryos resulted in the formation of ventral nerve cords lacking some of the posterior ganglia. However, the same type of lesions performed in 8 day-old embryos was followed by normal development of all ganglia. These results permit the following conclusions: 1) the possibilities for regulation of the embryonic leech nervous system are limited; and 2) the number of stem cells required to form a complete ventral nerve cord is already present by the 8th day of embryonic development. (Supported by NSF grant BMS 74-24637 and National Foundation-March of Dimes grant 1-499).

309 CELL SURFACE PROTEIN DEVELOPMENT IN POST-MITOTIC, PRE-FUSIONAL CHICK EMBRYO MYOBLASTS, IN VITRO. Barry Festoff and Steven Miller*, Neurobiology Research Lab, V. A. Hospital, Kansas City, MO 64128 and University of Kansas Medical Center

It was previously reported (Festoff, J. Cell Biol. 70:190a, 1976) that cytocholasin B (CB) treatment of chick embryo muscle (CEM) produced (2) populations of cells distinguished by the presence or absence of a large (240,000 daltons) membrane glycoprotein. Fibroblastic cells contained high quantities while myoblasts had little, if any, of this protein. Specific antibody to 3T3 cell surface protein (supplied by Dr. K. Yamada, NIH) decorated fibroblasts and elongated myotubes, but not myoblasts in that study.

The present experiments were performed with mechanically-dissociated, highly-enriched myoblast cultures of 12 day old (Stage 38) CEM. Specific avoidance of trypsin was necessary because of the sensitivity of CSP to proteolytic enzymes. Cells were grown on non-collagen coated cover-slips and harvested at 3, 12, 30, 48, 72 and 96 hrs after plating. After washing 3 times in PBS, cells were incubated successively in goat anti-CSP and then FITC-labeled rabbit anti-goat IgG (Miles Labs) with extensive washing between incubations. In parallel cultures mitotic activity was assessed by ^{3}H Thymidine incorporation and the fusion index was calculated by direct observation. Using a Leitz Orthoplan microscope with BG12, KP480, K510 Ploem filters and incident light, CEM fibroblasts were noted to have diffuse punctate immunofluorescence throughout the course. However, myoblastic elements only developed surface fluorescence after cessation of DNA synthesis but prior to the onset of fusion. All binucleates, myotubes and early myofibers contained large quantities of patchy, solid surface fluorescence. These results suggest that CSP in muscle cells is related to the expression of a particular gene activated after mitotic activity ceases but prior to the onset of fusion. Since CSP has been considered to be an "adhesive" protein (Yamada, K. M. et al., Proc. Nat. Acad. Sci. 73:1217, 1976), its role in muscle cell fusion and morphogenesis requires further study.

310 EFFECT OF PROTEIN MALNUTRITION AT VARIOUS STAGES OF DEVELOPMENT ON SLEEP IN THE RAT. William B. Forbes, Carl A. Tracy*, Peter J. Morgane and Oscar Resnick*. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

In order to elucidate the functional effects of protein malnutrition on the developing brain, we studied sleep behavior in adult rats malnourished at various stages of development. Two isocaloric purified diets containing either 25% (HI) or 8% (LO) casein were used. Mothers of experimental animals were fed one of the two purified diets ad lib. for 5 weeks prior to mating and throughout gestation and lactation. Following weaning at 21 days, pups were either fed the same diet as their mother (groups HI-HI and LO-LO) or switched to the other diet (groups HI-LO and LO-HI). At 70-120 days of age, 8-10 pups from each group were prepared with cortical, hippocampal and neck electrodes. 24-hour polygraphic sleep recordings were collected and visually scored in 12-second epochs using a 3-state classification, i.e. waking (W), slow-wave sleep (SWS) and rapid eye-movement sleep (REM). A 12h:12h light/dark schedule was employed both in the colony room and in the recording chambers.

Malnourished groups (HI-LO, LO-HI, and LO-LO) did not differ from group HI-HI in percent of total recording time spent in W, SWS or REM. In comparison with HI-HI, however, all three malnourished groups exhibited relatively more REM during the dark phase and less during the light phase. REM dark/light ratios (s.e.m.) were as follows: HI-HI = .19 (.03); HI-LO = .33 (.05)*; LO-HI = .40 (.08)*; LO-LO = .45 (.09)*; *differs from HI-HI, $p < .05$, randomization test. Institution of an adequate diet following weaning in group LO-HI did not abolish the effect in adulthood. That the REM redistribution effect was greatest in group LO-LO indicates that the effects of pre- and post-weaning malnutrition are additive, the combination producing a somewhat larger effect than either alone. The reported effect was specific to the REM state, there being no consistent compensatory shift in W or SWS distribution among the malnourished groups. The effect on REM was most pronounced in the early portions of the dark and light phases, just following changes in illumination, suggesting that the effect is due to altered modulation of REM occurrance by illumination rather than to a shift in the underlying circadian rhythm of REM.

These data indicate that maternal dietary protein restriction prior to weaning produces altered sleep behavior in adulthood. Since monoaminergic mechanisms have been implicated in sleep cycle control, these findings may shed light on the nature of the functional impact of previously reported (Stern et al., Exp. Neurol., 1975, 49: 314-326) elevations in brain biogenic amine levels in malnourished rats. Supported by NICHHD grant HD 06364.

311 GENETIC DISSECTION OF THE NUCLEAR-CYTOPLASMIC RELATIONSHIP IN MOSAIC SKELETAL MUSCLE FIBRES. P. M. Frair*, and A. C. Peterson. M. R. C. Group in Developmental Neurobiology, Dept. of Neurosciences, McMaster Univ. Med. Ctr., Hamilton, Ontario, Canada, L8S 4J9.

The multinucleated condition develops in the vertebrate skeletal muscle cell by the fusion of mononucleated myoblasts to form myotubes. In the mature myofibres of mammals the nuclei are located peripherally along the entire length of the cell. Although local membrane specializations occur, most notably at the end-plate region, it is not known if each nucleus controls the biochemical functions of a local territory comprised of the immediately adjacent muscle cytoplasm and membrane, or if gene products of every nucleus are uniformly distributed in the cell. We have approached this problem by measuring the distribution of gene products in single skeletal muscle fibres of adult mouse chimaeras, which contain nuclei of both component genotypes. Adult mouse chimaeras were produced by the aggregation of embryos homozygous for different alleles for the subunit of the cytoplasmic enzyme glucose phosphate isomerase (GPI, EC. 5.3.1.9). Changes in the isozyme composition along the length of a cell would indicate that the enzyme remains localized in cytoplasmic territories. Alternatively, a uniform isozyme profile throughout the cell would suggest that the products of individual nuclei are homogeneously distributed.

We have found that the intracellular distribution of GPI isozymes does not change along the length of single mosaic fibres. In addition, the aggregation of subunits is random. These results indicate that individual myonuclei contribute gene products for the maintenance of the muscle cytoplasm throughout the length of the cell. These observations may provide an insight into the mechanisms of proposed neurotrophic functions.

312 ELECTRON MICROSCOPIC EVIDENCE OF DENDRITE PARTIAL DEAFFERENTATION, LOSS AND STRUCTURAL MODIFICATION IN THE SENESCENT RAT BRAIN. Y. Geinisman, W. Bondareff and J.T. Dodge*. Dept. Anat. Sch. Med., Northwestern Univ., Chicago, IL 60611.

An age-related decrease in total numbers of axo-dendritic synapses per square area was found by us earlier in the supragranular zone of the rat dentate gyrus (Neurosci. Abstr., 1976). This phenomenon could be a consequence of a loss of dendrites, or of a partial deafferentation of dendritic trees involving subsequent changes of dendrite morphology in senescence. The study reported here was undertaken to explore these possibilities.

Tissue blocks containing the rostral portion of the right dentate gyrus were dissected from perfused brains of 5 young adult (3 mo.) and 5 senescent (25 mo.) Fischer-344 rats. A 1 µm thick, methylene blue stained section for measuring the width of the molecular layer and a 750 Å thick, uranyl acetate and lead citrate stained section for obtaining electron micrographs were cut coronally from each rostral and caudal block face. These electron micrographs (20 from each section) were taken from the supragranular zone of the molecular layer in a systematic random manner and were used to study: the number of synapses involving dendritic shafts per tissue square area and per dendrite unit length; the number of dendritic profiles per square area; the dendrite volume fraction and surface area by means of stereological point-counting and intersection-counting procedures.

Comparison of mean group values showed a significant decrease in numbers of synapses involving dendritic shafts per tissue square area (by 35%) and per dendrite unit length (by 40%), in the number of dendritic profiles (by 24%), in the volume fraction (by 12%) and surface area (by 27%) of dendrites for senescent rats relative to young adults. The width of the molecular layer was virtually the same in animals from the two age groups.

These findings suggest: (1) a loss of axo-dendritic synapses and dendritic branches occurs in the supragranular zone of the dentate gyrus of senescent rats; (2) the age-related loss of axo-dendritic synapses is independent, at least in part, of the loss of dendrites because the number of these synapses is decreased per unit length of remaining dendrites in senescent animals; (3) the loss of dendrites involves predominantly smaller dendritic branches, since the volume fraction of dendrites in senescence is decreased less than the number of dendritic profiles; (4) structural modifications of dendrites in senescence include a pronounced decrease in the surface area of dendritic membranes available for synaptic contacts. Therefore, a deficiency of synaptic connectivity seems to be characteristic of the dentate gyrus of senescent rats.

313 GROWTH AND COLLATERAL SPROUTING OF MESOLIMBIC DOPAMINE NEURONS IN OLFACTORY TUBERCLE OF RAT BRAIN DURING POSTNATAL DEVELOPMENT. G. Gilad and D.J. Reis. Lab. of Neurobiol., Dept. of Neurol., Cornell University Medical College, New York, NY 10021.

In adult rats the mesolimbic dopaminergic (DA) neurons of the A10 group innervating the olfactory tubercle (OT) will undergo collateral sprouting in response to denervation of a non-DA input to the OT produced by olfactory bulbectomy (Gilad et al Neurosci Abs 2:813, 1976). We sought: (a) to establish whether DA neurons innervating OT in young rats have the adult capacity to form collateral sprouts, and (b) to relate the sprouting to the postnatal development of the OT and its DA innervation, the former established histologically, the latter biochemically by measuring changes in the activity of tyrosine hydroxylase (TH) and the uptake of 3H-DA. Biochemically the uptake of 3H-DA into synaptosomes of OT at 3 d was 7% of, and at 10 d 58% of the adult levels achieved by 21 d. TH activity reached adult levels more slowly: at birth to d 7 it was 12-15%, it then rapidly rose to reach 75% by 21 d and achieved adult levels by 40 d. The adult pattern of cellular organization, not present at birth, was first seen at 3 d, achieving adult lamination by 7 d. In cell bodies of A10, TH was approximately 45% of adult values at birth, rose to 150% by 14 d and declined to adult values by 21 d. Unilateral olfactory bulbectomy performed in 10 d old pups resulted, 30 d later, in a significant increase, ipsilaterally, in OT of TH to 123% of control and 3H-DA uptake to 137% of control. These changes were comparable to the effects of bulbectomy performed in adults. Olfactory bulbectomy performed in 1 d old pups, killed 40 d later did not produce changes in TH or 3H-DA which differed from unoperated littermates. We conclude: (a) in postnatal development there is a rapid increase of the growth of DA terminals into the OT beginning 7 d after birth, (b) during developmental growth TH activity in the cell bodies is first increased, and then recedes back to adult levels in advance of changes in the development of activity in the OT, (c) the hyperinnervation of OT produced as a consequence of collateral sprouting does not occur in response to deafferentation of the OT of 1 d old, but does so in 10 d old pups. The findings suggest that in mesolimbic DA neurons, dynamic changes in TH activity in cell bodies and terminals are similar in developmental growth and collateral sprouting and that collateral hyperinnervation produced by denervation wil not occur in the OT before a critical developmental period, probably relating to the development of adult organization of the tubercle.

314 DEVELOPMENT OF MOTOR CORTEX. J. Glass, G. Fromm, and A. Chattha* U. of Pittsburgh, Pittsburgh, PA 15261

The postnatal development of the sensory evoked response has been studied in detail within primary sensory cortex. Of all the sense modalities, the visually evoked response has received the most scrutiny. Studies of slow-wave activity show the response recorded from kitten visual cortex to resemble by the fortieth day of age the response recorded from the adult. The stimulus specificity of single neurons in visual cortex may be present at birth and is certainly fixed by the end of the sixth-eighth week of life. In contrast to these findings from sensory cortex, little work has addressed itself to the timetable for development of the visually evoked response recorded from nonspecific cortex. We have now studied the development of the visually evoked response, slow wave and single units, recorded from a nonspecific area of cat neocortex, the precruciate gyrus "motor cortex".

Visually evoked activity was recorded from motor cortex of chloralose anesthetized kittens at three, four, and five months of age and in adult cats. The slow-wave response from the adult cat is triphasic, negative-positive-negative. At three months of age the response is only a long duration negative wave. At four months of age a secondary positive-negative complex emerges. By the fifth month of life the response is the triphasic negative-positive-negative response similar to the response recorded from the adult.

In the adult, single neurons in motor cortex respond to the light and discharge in synchrony with the occurrence of the positive component of the slow-wave response. In the four month old kittens, the presence or absence of a unit response is correlated with the presence or absence of the positive component. As the microelectrode penetrates the cortex the surface positive component of the slow-wave response becomes isoelectric at 600 µ, reverses its polarity, and reaches a maximum negativity at 1800 µ below the cortical surface.

The laminar analysis of the positive component of the evoked potential and its association with unitary activity suggest that the positive component represents excitatory synaptic activity generated in the deeper layers of the cortex. Our findings therefore indicate a major change during the third through fifth months of life in the sensory-evoked excitatory drive applied to neurons within motor cortex.

315 LONG TERM EFFECTS OF SPINAL TRANSECTION ON THE DEVELOPMENT OF SYMPATHETIC GANGLIA. Robert W. Hamill, Philippe Y. Cochard* and Ira B. Black. Dept. of Neurology, Cornell Univ. Medical College, New York, N.Y. 10021.

The long term effects of interruption of descending central pathways on neuronal maturation was examined in the sixth lumbar (L-6) sympathetic ganglion of the rat. Previous investigations in this laboratory defined the normal maturation of presynaptic choline acetyltransferase (CAT) activity, post-synaptic tyrosine hydroxylase (T-OH) activity and total protein in the L-6 ganglion. Spinal cord transection was performed at the fifth thoracic (T-5) level in 10-11 day old rats and the effect on the long term maturation of the distal L-6 ganglion determined. Spinal transection prevented the normal ontogeny of CAT activity. Enzyme activity was 39% of sham-operated, littermate controls one week and one year after surgery. Similarly, the normal maturation of T-OH activity was prevented by interruption of central pathways, and was 21% of control both one week and one year post-operatively. These observations suggest that descending suprasegmental pathways regulate the normal maturation of intermediolateral column cholinergic neurons and second-order adrenergic neurons in sympathetic ganglia. Additionally, these effects are long lasting as evidenced by the persistent abnormal development one year after surgery. Furthermore, these investigations demonstrate that segmental mechanisms do not allow significant long term recovery of function.

316 DELETION OF "MISTAKES" IN NERVE-MUSCLE CONNECTIVITY DURING DEVELOPMENT OF RAT EMBRYOES. A.J. Harris* and M.J. Dennis* (SPON: J.H. LaVail). Dept. Physiology, UCSF, San Francisco, CA 94143.

Each internal intercostal muscle in an adult rat is innervated by nerve fibres from the ventral root of the matching thoracic segment. Errors in this segmental arrangement, in which muscle fibres receive innervation from a nerve root of a different spinal segment, are rare. In contrast, intercostal muscles from embryoes up to the 18th day of gestation more frequently (63/167 muscles) contained "mistakes" of this kind. Elimination of "mistaken" connections appears to occur near the time of birth, as they were seen in only 6/120 intercostal muscles from embryoes examined during the period 19 days gestation to 2 days after birth.

Intracellular records from intercostal muscles from 16-18 day embryoes showed that individual muscle fibres were multiply innervated, and that responses to appropriate and inappropriate nerve stimulation could be of equal potency. Multiple innervation from "correct" nerve fibres persisted in 19 and 20 day embryoes, and for some days after birth. Thus deletion of functional connections from inappropriate spinal roots took place earlier than removal of surplus "correct" nerve-muscle connections.

The elimination of inappropriate nerve-muscle synapses during normal development of mammlian embryoes may involve the same mechanisms as the suppression of foreign synapses on adult salamander muscle (Yip and Dennis, 1976).

317 EVIDENCE FOR A DUAL REACTION OF NEURONS IN CHICK EMBRYO SPINAL CORD TO EARLY LIMB BUD REMOVAL. Marieta B. Heaton, Dept. Neuroscience, U. of Fl. Coll. Med., Gainesville, Fl., 32610.

The sequence of nerve fiber outgrowth from chick embryo spinal cord was studied following limb bud (LB) removal at day 2 1/2 - 3 of incubation. Previous studies of nerve fiber growth following LB removal (Hamburger, Amer. J. Anat., 102:365, 1958) had implied that in the absence of the peripheral LB tissue, initial growth patterns were aberrant, with fibers growing out immediately to form a neuroma alongside the spinal cord, as if they were immediately responding to a remote message. Viewing the entire sequence of fiber growth, starting shortly after LB removal and continuing for 4-5 days, it was found that initial outgrowth is not altered by the absence of the periphery. Rather, early sensory and motor neuroblasts send a robust complement of fibers to the peripheral-most portion of the embryo available. This observed growth continued for 3 1/2-4 days following the operation, with fiber diameters similar on operated and control sides. Only at day 6 1/2 of incubation did the aberrant growth pattern leading to formation of the neuroma begin to appear. These results indicate that the absence of the periphery is not signalled immediately, as it had previously appeared, but that a dual reaction occurs, consisting of (1) normal fiber outgrowth, followed by (2) abnormal growth leading to neuroma formation. This observation suggests the possibility that some sort of reaction in the cells which send their fibers to the attenuated periphery on the first few days may trigger the response leading to the marked alteration in the normal developmental program of later emerging fibers. Such a reaction could be conceptualized as a transfer of information from the fibers which reach the depleted peripheral area back to their parent cell populations, or an interaction between the cells that die after failing to make peripheral connections and those which have not yet sent out processes.

Another striking consequence of loss of the periphery, during the stages of robust outgrowth, was a severe alteration in fiber elongation, implying a departure in the normal growth rate on the operated side. This disparity was as great as 1:14 in day 7 embryos (fiber length on operated side to that on control side). It is probably significant that the fibers deprived of LB tissue did not exhibit a tendency to wander or seek termination sites. These observations imply that the normal elongation process may depend on some attractive influence exerted by specific peripheral tissue.

318 AUTORADIOGRAPHIC LOCATION OF [^{125}I]α-BUNGAROTOXIN-BINDING ACTIVITY IN NORMAL AND DEAFFERENTED ANTENNAL LOBES OF MANDUCA SEXTA. John G. Hildebrand and Linda M. Hall. Dept. Neurobiol., Harvard Med. Sch., Boston, MA 02115 and Dept. Biol., MIT, Cambridge, MA 02139.

Neurochemical and developmental evidence strongly indicates that acetylcholine (ACh) is the principal or exclusive neurotransmitter employed by antennal sensory neurons in the moth Manduca sexta (Devel. Biol. 52: 105, 1976). A major synaptic target of these neurons is the antennal lobe (AL) of the brain. Preliminary anatomical observations suggest that olfactory and possibly other chemosensory neurons project to the glomerular neuropil of the AL, while mechanosensory neurons send their axons to a different neuropil region lying caudo-ventral to the glomerular AL (Walker and Hildebrand, unpublished). Electronmicroscopy has shown that synapses in lepidopterous AL are confined to the glomeruli (Z. Zellforsch. 95: 223, 1969). AL contain an [^{125}I]α-bungarotoxin-binding activity that: (1) is extractable with Triton X-100 and displays saturable toxin binding, which can be blocked by cholinergic drugs; (2) is confined to nervous tissue; and (3) appears gradually during the metamorphic development of the adult brain, even in the absence of antennal afferent input to the developing AL (Brain Res. 119: 389, 1977). In the experiments to be described, we have studied the distribution of the toxin-binding activity in normal developing and mature AL, as well as in AL deprived of their normal afferent inputs. Cryostat sections of Manduca brains that had been lightly fixed with paraformaldehyde were treated with [^{125}I]α-bungarotoxin, washed, and subjected to autoradiography to locate toxin-binding activity in the AL. In normal AL, autoradiographic silver grains are predominantly concentrated over glomeruli in the neuropil, even at early stages of adult development. Binding of labeled toxin to cryostat sections is blocked by pretreatment with cholinergic drugs. In deafferented AL, silver grains are similarly distributed. These abnormal AL, although stunted and ectopic, appear to possess rudimentary glomeruli that bind toxin nearly normally. The density of silver grains over neuronal somata and non-glomerular neuropil of the AL appears to be unaffected by deafferentation. Our findings support the hypotheses that toxin-binding activity is associated with, or identical to, synaptic ACh receptors and that these putative receptors develop essentially normally in quantity and histological location in AL deprived of normal afferent inputs throughout adult development. (Supported by NIH grant NS 11010 and NSF grant BNS 75-22581.)

319 TROCHLEAR NERVE: ONSET OF TRANSMISSION AND DEVELOPMENT OF NEUROMUSCULAR RELATIONSHIPS. R. K. Holt, G. S. Sohal and S. D. Stoney*. Department of Anatomy and Physiology, Medical College of Georgia, Augusta, Georgia 30902.

Development of the trochlear nerve in white Peking ducks was studied to correlate electrophysiological findings with the morphological development of the neuromuscular contacts. Electrophysiological measurements showed that the nerve was functional from day 11 of incubation, the earliest age yet tested, onward. Conduction velocity (at 21-23°C) on day 12 when the nerve is composed of small naked fibers was around 0.2 m/sec, and increased to 5.5 m/sec on day 27 (hatching) and a month after hatching when 95% and 99% of the fibers are myelinated. Stimulation of the nerve with single or multiple current pulses evoked contraction of the superior oblique muscle from day 11 of incubation onward. A progressive increase in the strength of muscle contraction was visually noticed with increase in incubation age.

A modification of Koelle and Friedenwald's stain was used to study the motor endplates and the pattern of innervation (Toop, ST 51:1, 1976). Morphological observations indicate that the trochlear nerve first enters the muscle on day 10 or 11. On day 11 the nerve branches into small fascicles with a few fibers ending directly on myoblasts and myotubes. The first appearance of myofibers is on day 17. Muscle differentiation proceeds from the belly outward and the size of myofibers increases gradually until four weeks after hatching, the latest age yet studied. The motor endplates first become identifiable on day 13 and a majority of them are located in the muscle belly. Most of the endplates on day 13 are innervated by multiple fibers. At hatching virtually all endplates are unineuronally innervated. At intervals of one and four weeks after hatching innervation to the superior oblique muscle is essentially unineuronal.

The results of the present study indicate that: i) trochlear nerve becomes functional as soon as it contacts the muscle; ii) stimulation of the nerve can elicit muscle contraction long before the morphological appearance of the motor endplates; iii) developing superior oblique muscle is multineuronally innervated and becomes unineuronally innervated at hatching; iv) loss of the trochlear neurons and their axons observed during normal development could be related to their failure to establish functional connections with the periphery. 320 PRODUCTION OF S100 PROTEIN BY CELLS FROM EARLY EMBRYONIC SENSORY GANGLIA IN VITRO. Beatrice Holton* and James A. Weston. Dept. of Biol., Univ. of Oregon, Eugene, OR 97403.

In vertebrate embryos, neural crest cells migrate from the top of the neural tube and differentiate into a variety of phenotypes including melanocytes and elements of the peripheral nervous system. Cultured spinal ganglia from 4-5 day quail embryos contain neurons and a population of small stellate cells, both of which are derived from the neural crest. Stellate cells from spinal ganglia resemble neural crest cells in vitro and can produce melanin pigment under suitable culture conditions. When the stellate cells associate with neurons in vitro, however, they resemble nerve supportive (glial) cells. Large, homogeneous populations of these stellate cells (up to 10^6 cells/35 mm dish) can be obtained in culture. When such cultures are assayed by complement fixation for the presence of S100, a protein localized almost exclusively in nerve supportive tissue, approximately 0.01% of the TCA-precipitable protein is S100. This result provides evidence that this population, in fact, contains differentiated glial cells. The amount of S100 present, however, is at least an order of magnitude lower than levels produced by glial cells in adult animals. Association of glial cells with mature neurons may be necessary for higher S100 production, since high levels of S100 synthesis in vivo appear at the same time as coordinated nerve firing. This suggests that coculture of neurons with cells producing a low level of S100 may induce the latter to produce S100 at a level comparable to that found in mature nervous tissue. Supported by PHS grants CA-16287 and DE-04316.

321 OUTGROWTH OF CUTANEOUS AND PROPRIOCEPTIVE NEURONS FROM CHICK EMBRYO DORSAL ROOT GANGLIA. Marcia G. Honig* (SPON: C. Stevens). Dept. Biol., Yale Univ., New Haven, Conn. 06520.

In the chick embryo, two populations of cells in the dorsal root ganglion (DRG) have been described (Hamburger and Levi-Montalcini, 1949, J. Exp. Zool. 111:457-501) which differ in the time course of their differentiation. The differences are most apparent in 7-15d embryos in which the ventrolateral (VL) region of the DRG contains large cells which differentiate early and the mediodorsal (MD) region smaller cells which differentiate later. It has been suggested, on the basis of the early onset of tactile reflexes (at about 7d) as compared to the later appearance of proprioceptive reflexes (at about 11d), that the VL population consists of cutaneous afferents and the MD population consists of proprioceptive afferents. To test this directly, cutaneous and proprioceptive cell bodies have been localized in lumbosacral ganglia at St 29-32 and at St 36-38 (Hamburger and Hamilton) by exposing the cut ends of nerves to horseradish peroxidase (HRP) or by injecting HRP under the skin or into selected muscles in the hindlimb and allowing retrograde transport to occur.

At early stages the filled cells were always localized predominantly in the VL half of the DRG, in accord with the early birthdays of these cells. At later stages, MD cells as well as VL cells could be labeled. These two patterns of staining were found when either cells sending axons to the skin or cells sending axons to the muscles were filled. Thus neurons growing to different types of peripheral targets have similar distributions in the DRG.

If one assumes that the outgrowth of sensory cell axons is selective so that backfilling cutaneous nerves labels only cells specified to be cutaneous afferents and injecting muscles labels only neurons specified to be proprioceptive, then the following conclusions can be made: 1) Both cutaneous and proprioceptive neurons have sent axons into the limb by St 29; 2) Cutaneous and proprioceptive cell bodies are distributed in the VL half of the ganglion at early stages and throughout the ganglion at later stages; 3) The two cell populations described by Hamburger and Levi-Montalcini do not seem to represent separate classes of cutaneous and proprioceptive cells.

Alternatively, initial outgrowth of both cutaneous and proprioceptive neurons may be non-selective with subsequent death of those that grow to the wrong target; indeed both types of fills often show some degenerating cells which are labeled. This should result in the observed distributed pattern of cell body localization at early stages, with a separation into two distinct populations following the cell death period. However, at St 37, when cell death is essentially complete, a distributed pattern is still seen. Thus, unless there is extensive late migration of cell bodies, the two morphological cell populations do not represent proprioceptive and cutaneous afferents respectively. Further the somas for both type of afferents have similar distributions in the ganglion at all developmental stages.

322 FINESTRUCTURAL MAPPING OF SYNAPSE FORMATION ON THE SURFACE OF THE MAUTHNER CELL OF THE AXOLOTL (AMBYSTOMA MEXICANUM) J. Jacoby* (SPON: C. Kimmel). Univ. of Oregon, Eugene, Ore. 97403

Electron micrographs were used to map the surface of the Mauthner neuron at 2 stages of the animal's development (40 and 43, which are during the period of rapid dendritic outgrowth). The cell receives a rich supply of morphologically heterogeneous synapses over its surface when mature. The goal of this work is to correlate cell growth and synapse formation.

Maps were prepared which consisted of electron micrographs taken around the surface of the M-cell (identified in sampled thin sections). Plots were made of profiles (synaptic knobs as well as profiles not containing synaptic vesicles) contacting the M-cell surface as well as the associated M-cell inner cell membrane and its adjacent cytoplasm. Two types of measurements were made: 1) the occurrence and distribution over the cell surface of synapses and synaptic knobs; 2) the occurrence and distribution of cytoplasmic cisternae lying on or located near the M-cell inner cell membrane. This was investigated as these structures have been previously suggested as vehicles for the local addition of new membrane during cell growth (Kimmel & Schabtach, J. Comp. Neurol., 156: 49, 1974).

Twelve maps from the stages have been partially analyzed, and a number of patterns have emerged in the distribution of pre- and post-synaptic constituents: 1) Synapses are non-randomly distributed over the cell surface at both stages. 2) The dorsomedial surface of the cell (where the axon emerges from the perikaryon) first receives synapses between these 2 stages, while the dendrites are already innervated at stage 40. 3) On dendrites the number synapses per unit length of membrane increases 50% between 40 and 43. 4) At both stages, cisternae associated with the membrane are slightly more numerous in regions of higher synaptic density. These cisternae also are found more often opposite knobs rather than profiles not containing synaptic vesicles. 5) There is an inverse correlation between the total number of cisternae found locally and the fraction of that total directly on the membrane. This is consistent with the thesis that cisternae are being recruited into the membrane, and that considering also observation 4, the recruitment occurs preferentially near synaptic knobs. This would not necessarily suggest a causal relationship, as there might be some inductive mechanism(s) controlling both events.

323 MORPHOLOGICAL TRANSFORMATIONS OF CELLS AND AXONS IN N. MAGNOCELLULARIS OF DEVELOPING CHICKEN EMBRYOS. Sonal R. Jhaveri* and D. Kent Morest. Department of Anatomy, Harvard Medical School, Boston, MA. 02115, and University of Connecticut, Farmington, CT. 06032.

N. magnocellularis consists predominantly of a homogeneous population of medium-sized cells which receive large, axosomatic endings from the acoustic nerve. The morphological development of these cells and their auditory input was studied using the rapid Golgi and Golgi-Kopsch methods.

At 8-9 days of incubation, cells in n. magnocellularis have round or spindle-shaped perikarya with several long, branched dendrites, which often end in bulbous swellings. Efferent axons have already grown out from the cells, and characteristic terminal plexuses of these axons are seen in n. laminaris bilaterally. By day 10, the dendrites have been replaced by an extravagance of long, somatic processes, giving the cell a very shaggy appearance. This structure is maintained up to day 15, when a remarkable second transformation occurs: the cells lose their processes and present bald, round profiles. Around day 17 or 18, a primitive-looking process, with a tip like a growth cone, emerges from some cell bodies, and somatic spines are evident. By 19-20 days, one or two thin, frail dendritic processes can be seen.

Correlated with this dramatic series of changes in the cells, is a fixed sequence of transformations of the incoming axons. Around day 10, primary sensory axons are seen to end in swellings resembling growth cones. Between days 11 and 13, following the explosive growth of somatic processes, there is a corresponding expansion and ramification of the auditory nerve endings. On day 15, there is a condensation of the terminal axonal branches, which now form a compact, highly branched plexus. In the 16-17 day embryo, the plexus coalesces into a calycine structure now approaching its final form, the end-bulb of Held, which is achieved by days 19-20. The transformation of the plexus to the calycine form occurs around the same time that the cell is denuded of its somatic processes.

A possible causal relationship between the development of the axon and the sequential transformations of the cell is presently under study in embryos with early otocyst removals.

324 EARLY POSTNATAL SYNAPTOGENESIS IN THE RAT VISUAL CORTEX. Janice M. Juraska and Eva Fifkova. Dept. Psych., Univ. Colo., Boulder, CO 80309.

Although synaptic plasticity in response to environmental events has been clearly demonstrated in the visual cortex of the rat, no detailed data concerning the course of early synaptogenesis in this area are available. In this study, synaptogenesis in the visual cortex of hooded rats at 1, 3, 5, 7 and 10 days of age was examined with electron microscopy. The cortex was divided into the molecular layer, the superficial layers (II-IV) and deep layers (V-VI). In the visual cortex at day 1, very few synapses were present in the molecular and deep layers and virtually none in the yet undifferentiated layers II-IV that compose the cortical plate at this age. The synapses that were present were axodendritic and often symmetrical with little subsynaptic web and few vesicles. There were marked increases in axodendritic synaptic density and maturity with increasing age. Axosomatic synapses were seen as early as day 3 but very rarely. What may have been axospinal synapses first appeared at day 7 and were more frequent by day 10. However, this classification is uncertain since no spinal apparatus was detected. Although the rate of synaptogenesis differed somewhat with layers and age, the largest increases were seen between days 3 and 7, paralleling the dramatic increase in dendritic growth seen at this time in the Golgi picture. By day 10 synaptic density had increased by a factor of 6-7 times in the molecular and deep layers when compared to day 1. The increase was even greater for the superficial layers where almost no synapses were found at day 1. Changes in synaptic length are currently under investigation.

Supported by NIH grant EY 1500.

325 PRENATAL RADIATION EFFECTS ON POSTNATAL DEVELOPMENT OF SQUIRREL MONKEY OFFSPRING. Bernice Kaack and Lary C. Walker* Delta Primate Center, Covington, Louisiana 70433.

Increasing interest has been directed toward the use of the squirrel monkey as a primate model for studying the effects of such environmental hazards as radiation on brain mechanisms, physiology and behavior. Due to the increasing encephalization of functions, extrapolations concerning prenatal effects on sensory, cognitive, motor functions are more likely verifiable in diurnal primates since they are of the same taxonomic order as man. The aims of this study were to examine the effects of 10 and 100R whole-body Cobalt-60 irradiation exposure of the mothers during pregnancy on postnatal development of behavior and physiology of the offspring from birth to 30, 365 and 730 days of postnatal life. Specifically, the offspring were examined for: 1) neuromuscular maturation and sensory-learning-motor behavior; 2) homeostatic regulation of temperature, respiration and heart rate under basal and arousal conditions.

Sham-irradiated control, 10 and 100 R prenatally exposed newborn squirrel monkey infants were removed from their mothers at birth, evaluated for physical anomalies, and raised in a nursery under controlled environmental conditions. Prenatal exposure to 100 rads resulted in a significant impairment during the first 30 days of righting, head-up orientation, tail-hanging reflexes and on climbing performance on an inclined plane. From 30 to 365 days of age, prenatal effects included impairments in maturation of visual acuity and depth perception. There was also a retardation of open field exploration and performance in the Wisconsin General Test Apparatus. Prenatal irradiation resulted in a significant increase in the difference scores between basal and arousal conditions in temperature, respiration and heart rate, particularly during the first 30 days of life. The squirrel monkey females included Columbian, Bolivian and Peruvian subspecies phenotypes. Significant interactions occurred between prenatal irradiation effects on behavior, physiology and phenotypic origin of the offspring. Whereas 10 and 100R dose-response effects were apparent on some behavioral and physiological variables, the sex and phenotypic variance among groups precluded establishment of the 10 rad dose as a threshold dose for subtle effects on behavior and physiology. With inclusion of additional offspring, it will be possible to establish dose-response effects on sensory-learning-motor capacity and on maturation of homeostatic regulation of physiology. (Supported in part by NIH Grant HD09942.)

326 PRIMITIVE SENSORY PATHWAYS ORGANIZE SENSORY LONG TRACTS OF HINDBRAIN AND SPINAL CORD IN XENOPUS TADPOLES. Michael J. Katz* and Raymond J. Lasek. Dept. Anat., Case Western Reserve Univ., Cleve. OH 44106.

A third eye primordium was transplanted to Stage 21-22 Xenopus embryos. The tadpoles were allowed to grow to Stages 46-50 (about 3 weeks) and then the transplanted eyes were injected with tritiated proline. After 3 days the animals were fixed and processed for autoradiographic axon tracing.

Three animals in which eyes developed on the tail and four animals in which eyes developed along the side of the head showed optic axons clearly entering the central nervous system. These transplanted optic nerve fibers followed two tracts, the External Sensory Tract and the Internal Sensory Tract, longitudinally (both rostrally and caudally) regardless of the level of their entry into the nervous system. The tracts were both on the same side of the nervous system and never crossed the midline. They ran from the level of the cerebellum through the hindbrain to the end of the spinal cord. The figure below illustrates the positions of these tracts in representative hindbrain and spinal cord cross sections.

These tracts coincide with the Rohon-Beard cell sensory tracts. In the hindbrain the descending tract of nerve V also follows the Rohon-Beard cell tracts, while in the spinal cord the dorsal root fibers which form the tract of Lissauer will eventually follow the Rohon-Beard cell tracts. (Dorsal root fibers do not appear in the Xenopus spinal cord until after Stage 47.) The transplanted optic axons indicate that the Primitive Sensory Pathways of the Rohon-Beard cells are continuous from the cerebellum to the end of the spinal cord. These long sensory pathways provide the organization for at least three different sensory tracts during development. The existence of Primitive Sensory Pathways suggests the existence of other primitive pathways such as Primitive Motor Pathways.

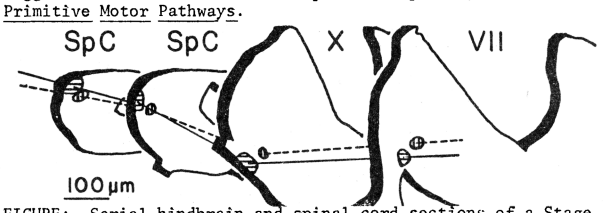

FIGURE: Serial hindbrain and spinal cord sections of a Stage 50 Xenopus tadpole showing two tracts which form the Primitive Sensory Pathways. (VIII=level of entry of nerve VIII, X=level of entry of nerve X, SpC=spinal cord)

327 DEVELOPMENT OF THE SYMPATHETIC INNERVATION TO THE CHICK EYE. Margaret L. Kirby*, Ihsan M. Diab, and Thomas G. Mattio*, Dept. Pharmacological and Physiological Sciences, University of Chicago, Chicago, Illinois, 60637.

Development of parasympathetic innervation of the chick eye occurs over a six-day period including stages 35-40 (8 to 14 days). The nerves include fibers from the ciliary ganglion to the pupillary constrictor, ciliary body and smooth muscle cells in the choroid layer of the eye (Landmesser and Pilar, J. Physiol., 1972). The present study was undertaken to observe the time course of sympathetic innervation of the pupillary dilator using formaldehyde or glyoxylic acid-induced fluorescence for catecholamines. Eyes were removed from chick embryos daily beginning at stage 29 (ca. 6 days) and continuing until 2 weeks posthatching and placed in cold Tyrode's solution. The posterior chamber was opened and the lens, ciliary body and retina were removed. The pigmented layer of the retina and the basal lamina of the choroid coat of the eye were scraped off, leaving the layer of choroid vessels intact. The choroid, including the iris was carefully lifted off of the sclera and cornea, stretched onto a slide, air-dried, and treated to induce fluorescence. At stage 29, the dilatator had a homogenous appearance with a generalized autofluorescent background. During stages 30 and 31, groups of myoepithelial cells and individual capillaries could be seen alternating radially on an autofluorescent background peripheral to the pupillary constrictor. Fluorescent axons could be seen first at stage 39 (13 days) in a circular band just peripheral to the dilatator. Only one or two fibers could be found in the dilatator. By stage 40 (14 days) numerous fluorescent axons with prominent varicosities could be seen in the dilatator proper. At stage 42 (16 days) the innervation of the dilatator was two-thirds complete, but appeared less organized than the innervation of the posthatched iris. In addition to the fluorescent axons in the iris, previously unreported fluorescent ganglion cells could be seen in the choroid proper just peripheral to the iris. These cells first appeared at stage 35 (9 days) as bipolar neurons which then developed into multipolar neurons by stage 39 (13 days). By stage 42 (16 days) the cells contributed to a plexus of fluorescent axons in the choroid. These ganglion cells may contribute sympathetic input to the ciliary body and smooth muscle cells in the choroid, which are known to have parasympathetic innervation. (Supported by PHS 5-PO1 NS-12324-02).

328 LEUCINE INCORPORATION BY IMMATURE AND MATURE AXOTOMIZED FACIAL NEURONS. L. A. Kirschen* and A. LaVelle. Dept. Anat., Coll. Med., Univ. Ill., Chicago, IL 60612.

Differential uptake of (^{3}H) leucine by the facial motor nucleus at selected critical developmental ages and after facial nerve crush at the selected critical ages was examined by liquid scintillation counting. Previous cytomorphological studies have shown that although the hamster facial neurons by 15 days postnatal age have approached the size and morphological configuration of the adult neurons (JEZ 137:285, 1958), their reaction to injury is still not a "mature" one. Chromatolysis occurs without a significant nucleolar change. Only after axotomy at 20 days postnatal age do the facial neurons show the characteristic adult reaction of diffuse chromatolysis accompanied by nucleolar, nuclear and somal swelling. The axon reactions generally peak at 4 days postoperatively.

We used (^{3}H) leucine to examine uptake in hamsters operated on at 15 and 20 days postnatal age and in the adult. The right facial nerves in all animals were crushed, with the opposite sides serving as control. On the 4th day following nerve crush, 2 μCi/gram body weight were injected subcutaneously into each animal. After various post-injection times, the whole facial nuclear groups were removed by dissection, freeze-dried and individually weighed. Unincorporated label was removed, and the tissue was prepared for liquid scintillation counting.

In the 15 day operatives, specific activity was greater on the control sides than on the experimental sides. On the other hand, in the 20 day animals the specific activity was greater on the experimental sides. This latter trend was even further amplified in the adults. These differences between experimental and control sides in all animals were consistent for all post-injection times.

Normal 15 day neuronal groups appear to be operating at maximum synthetic capacity. The additional stress due to injury depresses the already high rate of protein synthesis. The 20 day neurons are more adult-like in that they, as in the adult, are capable of responding to nerve injury by increased protein synthesis. The normal adult neurons seem to be operating well below their protein synthetic capabilities, since injury stimulates the largest increase in protein synthesis. These developmental differences in reaction to injury appear to reflect stage specific levels of metabolism in the hamster facial neurons.

329 DRUG INDUCED TREMOR: EFFECTS OF BRAIN DEVELOPMENT AND ANESTHETICS. W. Douglas Knowles* and M. Ian Phillips (SPON: W.W. Kaelber) Neuroscience Laboratory, Dept. Physiology and Biophysics, University of Iowa, Iowa City, Iowa 52240

Harmaline (10 mg/kg) or tremorine (12 mg/kg) was injected daily into infant rats to determine the age of onset of drug-induced tremor. Tremor to tremorine was recorded in all rats by 8 days of age. Harmaline-induced tremor, however, was not fully established until day 12 in all rats tested. We conclude that these two tremorogenic drugs are acting on different areas of the brain which develop at different ages.

Harmaline has been shown to act on the olivo-cerebellar system (Llinas & Volkind, Exp. Br. Res. 1973) which reaches a mature anatomical structure during the second week after birth (Altman, J. Comp. Neurol. 1972). Electrophysiological recordings were made from the cerebellar cortex of infant rats to determine the age at which the characteristic neural bursting activity appeared in response to harmaline. The development of the bursting activity was found to be coincident with the development of tremor. In all rats by day 12, harmaline induced rhythmic activity of units in the cerebellum. Harmaline provides a useful indicator of cerebellar function and shows that the rat cerebellum is not functionally mature before 12 days of age.

The rate of bursting in the anesthetized infants was approximately one-half the frequency of tremoring in awake infants. The effects of anesthetics on cerebellar function, as measured by harmaline-induced bursting activity, was investigated in unrestrained adult rats using chronic recording techniques. In the awake animal, tremor and bursting occurred at a frequency of 10/sec. Ether (by inhalation) and alcohol (55 ml/kg of 12% ethanol by gastric intubation) blocked bursting activity. Pentobarbital (40 mg/kg, I.P.), chloral hydrate (400 mg/kg, I.P.), and Dial with urethane (0.6 ml/kg, I.P.) slowed the frequency of bursting to 7/sec. and caused bursting to become intermittent. Administration of each anesthetic blocked the tremor.

These experiments demonstrate the use of harmaline and tremorine in the investigation of the functional maturation of the brain and also the functional effects of anesthetics when chronic recordings are made.

330 LAMINAR DISTRIBUTION OF ACETYLCHOLINESTERASE-DEPENDENT STAINING IN CEREBRAL CORTEX: RELATIONSHIP TO SYNAPTOGENESIS IN NEONATAL RAT. Donald A. Kristt and Darrell V. Lewis*. Dept. Neurol. and Path., Sch. Med., Johns Hopkins Univ., Balto., Md. 21205

Our previous work in neonatal rat has shown that early formed synapses are concentrated in "strata" at specific depths in neocortex, (Br. Res. 108:180(1977). Monoaminergic synapses are found in the strata, but account for only 30% of early synapses, (Neuroscience Lett. 1:305(1975). Neurotransmitter(s) utilized in the majority of early synapses remains unknown. Since acetylcholine is a possible neurotransmitter in adult neocortex, this study was undertaken to determine the pattern of acetylcholinesterase (AchE) dependent staining in postnatal neocortex. Although this technique does not identify cholinergic synapses directly, it does indicate the relative likelihood of cholinergic synapse formation in relation to the cell layers of immature neocortex. Mid-dorsolateral cortex (somatosensory) was studied at birth, P-6 (6 days old) and P-16 with the light and electron microscopes. Staining was achieved by use of an acetylthiocholine histochemical reaction. Staining was blocked by AchE inhibitors. At all ages neocortex stains less intensely than deeper cerebral and brainstem regions. At birth, neocortical staining is barely detectable, despite moderate staining of midbrain and basal forebrain somata and neuropil. By P-6, three heavily stained horizontal bands are seen: a) beneath the pia in the marginal zone (MZ); b) at mid-cortical depths (future layers IV and V); and c) bottom of cortex (future layer VIb). Bands a and b are also regions of high synaptic density at P-6. The MZ shows an interlacing plexus of AchE positive fibers. Occasionally, somata are filled with reaction product (RP). The mid-cortical band, b, exhibits somatic and neuropil staining. Somatic staining is usually restricted to the circular perimeter of the cell body, suggesting cholinergic inputs on these cells. The SI barrel fields for mystacial vibrissae are well stained within band b. Band c in layer VI, mainly is due to intense somatic staining of small non-pyramidal neurons. Cortex at P-16 is similar to P-6, but staining is more intense. Preliminary ultrastructural examination demonstrates RP surrounding many axonal profiles in the 3 AchE positive bands. In the MZ, stained axonal profiles frequently contain 40-50μ circular vesicles. Occasionally RP is seen within a synaptic cleft. In the layer VI band, RP is frequently seen within the Granular ER of small neurons. Based on these findings we speculate that (1) cholinergic cell bodies in layer VI may send axons to form synapses in the marginal zone; (2) extrinsic cholinergic inputs -- perhaps from thalamus -- project to the middle AchE positive band, as suggested by staining of the barrel fields.

331 DEVELOPMENTAL CHANGES IN CEREBRAL PROTEIN TURNOVER. A. Lajtha, D.S. Dunlop*, W. VanElden* and J. Toth*. Research Institute for Neurochemistry, Rockland Research Inst. Ward's Island, New York 10035

Studies of incorporation of amino acids in vitro with various preparations from brain (enriched ribosomal systems, brain slices, homogenates, cell fractions, etc.) showed convincingly that the synthesis of proteins proceeds at a much higher rate in preparations from immature brain than in those from adult brain. In rodents at birth the synthesizing rate is 5- to 10-fold higher than in adult in the period from birth to 10 days. This period corresponds to the rapid deposition of most brain proteins, and its end marks the cessation of cell proliferation. Studies of protein metabolism in vitro, while highly suitable to elucidate aspects such as the mechanisms involved, properties of the systems, and factors influencing metabolism, are not suitable for gaining information about metabolic rates in vivo. We found that protein synthesis in adult brain in vivo occurs at several-fold higher rates than in the "best" in vitro system, while protein breakdown in vivo occurs at several-fold lower rates than in in vitro systems. The developmental changes also can not be compared. Our studies and others, indicate that the stability of immature preparations are greater, and while in young in vitro incorporation is 60-80% that of in vivo, in preparations from adult brain incorporation in vitro is only 5-15% of the in vivo rate. Because of difficulties of measuring the question of whether the metabolism of all proteins or only that of a few are altered during development cannot be answered. We have recently adopted methods to measure cerebral protein metabolism in vivo. Our primary purpose was to keep the specific activity of the administered labeled amino acid constant over a long period of time and to maintain the specific activity of this amino acid in the brain free pool close to that in plasma, to avoid difficulties when the precursor undergoes major changes and to avoid misinterpretations due to compartmentation. For shorter time incorporations (up to 6 hours) the labeled precursor amino acid is administered by constant infusion or in a large flooding dose. For longer time experiments (up to 5 days) (^{14}C)Tyrosine was administered either in oil suspension or as a subcutaneously implanted pellet. Studies on adults showed two major metabolic fractions, a rapidly metabolized one (6 per cent of proteins with an average half-life of 15 h) and a slower pool (94 per cent with a half-life of 10 days). In newborn the rate of synthesis is increased above that needed for growth, resulting in increased breakdown during the most active phase. Long-term incorporation studies indicate that such an increase occurs in a relatively small fraction of the total, and that a major fraction of brain proteins has a turnover in young similar to that in the adult.

332 MORPHOLOGICAL DEVELOPMENT OF ROHON-BEARD CELLS: LOSS OF INTRAMITOCHONDRIAL GRANULES PARALLELS LOSS OF CALCIUM COMPONENT OF THE ACTION POTENTIAL. Janet E. Lamborghini, Marsha Smith*, and Nicholas C. Spitzer. Biology Dept., UCSD, La Jolla, CA 92093.

Three steps may be distinguished in the development of the action potential mechanism in Rohon-Beard cells of Xenopus laevis. At early stages the inward current is carried mainly by Ca^{++} (Nieuwkoop & Faber stages 20-25), later by Ca^{++} and Na^{+} (stages 25-40) and finally by Na^{+} alone (stages 40-51)(Spitzer & Baccaglini, Brain Res. 107:610, 1976). Electrophysiological data indicate that the amount of Ca^{++} entering the cells at early stages should raise the internal calcium concentration by several orders of magnitude and that the calcium is rapidly sequestered (Baccaglini & Spitzer, J. Physiol. in press), perhaps by mitochondria. To examine the morphological consequences of the influx of Ca^{++}, we studied the ultrastructure of the perikaryon of Rohon-Beard cells in stage 22, 30, 37/38, and 42 embryos.

Specimens were fixed in phosphate-buffered formalin-glutaraldehyde with 0.05% $CaCl_2$ and postfixed in phosphate-buffered 1% OsO_4. Rohon-Beard cells were identified by their size and characteristic position in thin sections of whole spinal cord viewed at low magnification. High magnification electron micrographs were taken to reveal detailed mitochondrial morphology. Mitochondrial profiles were counted and scored for the presence or absence of dense intramitochondrial granules. In neurons such granules have been shown by energy dispersive X-ray analysis to contain calcium (Parducz & Joo, JCB 69:513, 1976). Mitochondrial profiles were examined in micrographs from one cell from each of three different specimens in all of the four stages sampled (3 cells/stage): approximately 100 mitochondrial profiles/stage were scored.

In stage 22 Rohon-Beard cells 75±5% (SD, n=3) of the mitochondrial profiles scored contained dense granules; in stage 30, 48±9%; in stage 37/38, 3±3%; and in stage 42, 0%. Therefore, dense intramitochondrial granules, an indication of calcium accumulation in mitochondria, decrease in number in parallel with the loss of the Ca^{++} component of the inward current of the action potential in Rohon-Beard neurons.

The percentage of mitochondrial profiles containing dense granules increased from 48±9% to 63±4% (SD, n=4) in stage 30 animals which were stimulated to swim by longitudinal stroking for five minutes with an eyebrow hair. This increase in stimulated animals is consistent with the proposed role of Rohon-Beard cells as primary sensory neurons which mediate swimming behavior, and suggests that the presence of dense intramitochondrial granules reflects the influx of calcium resulting from electrical activity of the cells.

333 BRAIN AGING AND PLASMA STEROID LEVELS: QUANTITATIVE CORRELATIONS. Philip W. Landfield and Gary S. Lynch. Dept. Psychobiol., Univ. Calif., Irvine, CA. 92717.

Our previous studies found that the hippocampus of aged rats exhibits a substantial astrogliosis (Landfield et al, J. Gerontol., 1977). Although gliosis is also seen in some fiber tracts and subcortical regions, it is most prominent in the hippocampus and is not seen in other cortical regions. We have also found that the synaptic neurophysiology of the hippocampus is impaired in aged rats (Landfield and Lynch, J. Gerontol.; 1977, Landfield et al, Neuroscience Abstracts, 1976). The hippocampus is known to be a major target region for corticosterone, and is also, in turn, known to influence ACTH secretion. Therefore, we investigated plasma levels of corticosterone and aldosterone in rats of three ages (4 mo., 13 mo., and 25 mo.) and simultaneously quantified the degree of astrogliosis in the hippocampus of each rat. The number of hypertrophied astrocytes increased dramatically as a function of age, with substantial gliosis beginning in the mid-aged (13 mo.) rats. Resting corticosterone and aldosterone levels increased from the young to mid-aged rats and then decreased again in the aged animals. The adrenal glands show a marked hypertrophy in the aged rats, which appears to have just begun in the mid-aged rats. This pattern suggests an initial hyperfunction of the adrenals in mid-age with a subsequent failure of adrenal function in the aged animals.

The most dramatic finding in these studies, however, seems to lie in a significant quantitative correlation that we found between the degree of hippocampal gliosis in individual mid-aged animals and their plasma levels of corticosterone (r=.76). Based upon the known 2-way interactions of the hippocampus and the adrenal system, this finding suggests that steroid levels may be increased because of reduced hippocampal inhibition of ACTH secretion, or that the corticosterone may directly and causally induce an age-related deterioration of hippocampal neurons. If the latter is the case then, at least in rats, the deterioration may begin to accelerate in mid-age. Studies to test these possibilities are underway.

334 THE DEVELOPMENT OF MOTOR PROJECTION PATTERNS IN THE CHICK HINDLIMB. Lynn T. Landmesser. Dept. Biol., Yale Univ., New Haven Conn. 06520.

A previous electrophysiological study (Landmesser and Morris, J. Physiol. 249:301-326) indicated that the pattern of functional synapse formation by chick lumbosacral motoneurons was highly specific from early developmental stages; at day 5 1/2-6 of incubation, each muscle or portion of the primary muscle mass that gives rise to a certain muscle was activated by the same spinal cord segments as the mature muscle. However, erroneous projections, if they were associated with motoneurons that had failed to form effective synapses, would not have been detected. For this reason and to better localize the motoneuron pools contributing to each muscle during development, the present study utilizing the retrograde transport of horseradish peroxidase was undertaken.

Injection of most of the major hindlimb muscles in late embryos (day 10-12) and young hatchlings showed that the motoneurons which project to each muscle form a compact elongate column of cells with a highly reproducible position in both the rostro-caudal and transverse axes (dorso-ventral and medio-lateral) of the cord.

At stage 28 (5 1/2 days), before the major period of normal motoneuron death and individualization of the muscles, (6 1/2-9 days) similar injections of the four primary muscle masses (dorsal thigh, dorsal shank, ventral thigh and ventral shank) were performed. These injections labeled a population of motoneurons whose position in both axes of the cord was essentially similar to that labeled by the injection of the sum of the muscles originating from that mass. Further partial injections within a given muscle mass revealed that before anatomical individualization of muscles, different regions received projections from distinctly different parts of the cord and that these were appropriate for the muscles derived from that region. Similar regional differences were observed in the formation of synapses as revealed by EMG recording of synaptically activated responses elicited by spinal nerve stimulation. This suggests that prior to any major corrections brought about by cell death, motoneurons growing into the limb ramify and make synapses within boundaries that generally conform to their adult projection. Further, the process of muscle individualization that occurs by cleavage of the primary muscle masses does not itself create the specific projection pattern by physically separating axon terminals that exceed their boundaries from their parent somas, resulting in death. (Supported by NIH grant NS 10666)

335 EFFECTS OF EARLY HYPERTHYROIDISM ON THE DISTRIBUTION OF MOSSY FIBERS IN THE RAT HIPPOCAMPUS. Jean M. Lauder and Enrico Mugnaini. Dept. of Biobehavioral Sciences, Univ. of Conn., Storrs, Conn. 06268

Hyperthyroidism, initiated shortly after birth produces well-defined changes in the development of cerebellar granule cells, including the accelerated growth of their axons, the parallel fibers. The present study demonstrates that this hormonal treatment also affects the development of the hippocampal granule cells, resulting in an altered distribution of the mossy fibers.

On the day of birth pups were distributed into litters of 8 males. Animals were injected with a dose of 5-25 µg l-thyroxine from birth until day 2,5,10,15 or 30. Controls were injected with saline during the same period. At 30 days animals were prepared for either the Timm silver sulfide method for staining of mossy fibers, the rapid Golgi method, or electron microscopy.

An ectopic bundle of mossy fibers was consistently formed infrapyramidally in CA3$_{a-b}$ and CA2 at the mid septo-temporal level of the hippocampus as defined by Haug (1974, Fig. 2C). The size of this aberrant layer was clearly dependent on the dose of thyroxine given and the length of administration. The effect was seen with as little as 2 days of hormone injection. Preliminary Golgi and electron microscopic analyses indicate that at least some of these ectopic fibers derive from collaterals of the suprapyramidal mossy fiber bundle, which terminate on "excrescences" located on the basal dendrites of pyramidal cells. Normally infrapyramidal mossy fibers are absent in this region and the basal dendrites do not have excrescences.

The expanded target area of mossy fibers in the hyperthyroid rat indicates that the normal pattern of axonal growth can be *altered experimentally in the hippocampus at a site* where the segregation of afferents appeared so strict as to be paradigmatic. This provides a promising model for the study of synaptogenesis.

336 EFFECTS OF NEONATAL MEDIAL FOREBRAIN BUNDLE LESIONS ON DEVELOPMENT IN KITTENS. M.S. Levine, C.D. Hull, N.A. Buchwald, L. Erinoff* and A. Heller. MRRC, Sch. of Med., UCLA, Los Angeles, CA 90024. Dept. Pharm. Sch. of Med., Univ. Chic., Chic., Ill 60637.

As part of a series of experiments concerned with the effects of early intervention upon development in the kitten we have been studying the maturation of kittens subjected to bilateral medial forebrain bundle (MFB) lesions at 11-16 days of age. So far, 13 kittens that survived for 46-268 days (mean age at sacrifice 141 days) have had histologically verified lesions of the MFB. Seven of these had large MFB lesions, 6 had smaller lesions. In 9 of these animals the dopamine concentration of the caudate nuclei were analyzed to determine the amount of destruction of the nigrostriatal pathway. Both large and small lesions produced damage to the nigrostriatal pathway evidenced by depletion of dopamine in the caudates (80% and 64% depletion for large [N=3] and small lesions [N=6] respectively). In 6 additional animals the lesions either missed the MFB completely or damaged only a very small portion of it. Dopamine concentrations in the caudates of this group [N=3] approached normal levels although there was some depletion (30%).

Some aspects of behavioral development of the kittens with large and small MFB lesions was compared with that of the kittens that had lesions that missed the MFB and with their intact littermates (N=9). Large MFB lesions produced a transient period of decreased body weight gain (duration 2-10 days). The animals lost weight and had to be hand fed. Kittens with small MFB lesions or lesions in other loci did not display any appreciable period of reduced weight gain. For the first two postnatal months animals with the large MFB lesions typically weighed less than animals in the other three groups. Between 2-3 months of age body-weight of kittens in all groups was approximately the same. *Development of locomotor activity was assessed in an open field.* At about 20-30 days of age the kittens with large MFB lesions displayed more motor activity than kittens in the other groups. This increase in motor activity was sustained and was still apparent at 4-6 months of age. Development of some aspects of learning ability was assessed by determining how well kittens learned a spatial discrimination in order to locate their mother. The results indicated that kittens with large MFB lesions made more initial errors and tended to perseverate in responding incorrectly more often than kittens with small MFB lesions or intact littermates.

Taken together these results indicate that early postnatal damage to the MFB in kittens produces both transient effects (body weight gain) and more persistent behavioral disturbances in motor activity and development of some aspects of learning.

337 EFFECTS OF NEONATAL AND ADULT TREATMENT WITH 6-HYDROXYDOPAMINE (6-HDA) ON RANDOM-INTERVAL BEHAVIOR. T.E.Levine*, L.Erinoff*, A.Heller and L.S.Seiden, Dept. Pharmacol.&Physiol. Sci., Univ. of Chicago, Chicago, IL 60637.

Rats were given intraventricular injections of 6-HDA or saline-ascorbate vehicle as neonates (3-days old) and as adults (49,51-days old) according to the following design:

Treatment Group	Treatment as Neonate	Treatment as Adult
Neonatal	6-HDA (100 µg)	Saline-ascorbate
Adult	Saline-ascorbate	6-HDA (2 x 250 µg)
Vehicle	Saline-ascorbate	Saline-ascorbate

At 73 days of age, the animals were trained on a schedule of reinforcement which reinforced responses on the average of once every 90 sec (random interval 90 sec). The animals treated with 6-HDA as adults stabilized at response rates approximately twice those of vehicle control animals, while animals treated with 6-HDA as neonates had response rates which did not differ from those of vehicle control animals. The rates (resp/30 min ± SE) were as follows: neonatal, 736 ± 122; adult, 1228 ± 175; vehicle, 622 ± 88. The animals treated with 6-HDA as adults were much more sensitive to l-Dopa than animals treated with 6-HDA as neonates or vehicle control animals. 25 mg/kg l-Dopa, following peripheral decarboxylase inhibition (Ro 4-4602), decreased rates of adult 6-HDA treated animals to 6% of control. The rates of vehicle-control and neonatal-6-HDA treatment animals were decreased to 40% and 29% of control responding, respectively, by this dose of l-Dopa. There were no differences in the response-rate-decreasing effects of apomorphine (0.006-0.1 mg/kg) among the three groups. The regional brain catecholamine data for the neonatal and adult 6-HDA treated groups are presented as percent of vehicle control in the following table:

	Catecholamine levels in 6-HDA treated animals			
Treatment Group	Striatum (DA)	Telencephalon (NE)	Diencephalon (NE)	Brainstem (NE)
Neonatal	18%	7%	53%	167%
Adult	54%	16%	43%	78%

Although the animals treated with 6-HDA as neonates had greater catecholamine depletions in the striatum and the remainder of telencephalon, they did not show the high rates on the random-interval 90-sec schedule seen in the adult 6-HDA treated animals. These findings suggest that animals treated as neonates are able to compensate for this behavioral effect of catecholamine depletion. 338 FINE STRUCTURE OF DEVELOPING CHICK SYMPATHETIC NEURONS, WITH REFERENCE TO STORAGE VESICLES AND GRANULES. L. Luckenbill-Edds and C. Van Horn*. Dept. Neuropathology, Harvard Medical School and Dept. Neuroscience, Mental Retardation Research Ctr., Children's Hospital Medical Ctr., Boston, MA 02115.

We have characterized the fine structure of vesicles and granules that appear during the development of sympathetic neurons in the paravertebral sympathetic ganglia of the chick embryo. Ganglia from the lumbar region of embryonic (E), post-hatching and adult white leghorn chickens were fixed according to Karnovsky's method and with Richardson's permanganate fixative which specifically preserves small dense cored vesicles (sdcv). Ganglia exhibiting aldehyde-induced fluorescence (Grillo et al., 1974) were examined electron microscopically to correlate fluorescence with the presence of large dense cored vesicles (ldcv) and chromaffin-like granules (G).

Adult sympathetic neurons fluoresce a bright green color; they contain many sdcv (40-50 nm) and a few ldcv (100 nm) in processes and in the periphery of cell bodies. When chick sympathetic ganglia first develop (E7), clusters of cells and processes that fluoresce yellow-green and contain predominately ldcv are seen near the capsular region of the ganglion. During the middle of development (E11-13), a more intensely yellow-green fluorescence appears in the same region, correlated with cells having a pleiomorphic population of ldcv and G. In these stages, the granule-containing cells are morphologically distinct from cells identified as developing neurons that have not yet elaborated storage vesicles. By late embryonic (E15-18) and post-hatching stages, few cells fluorescing yellow-green and containing granules are present. At these later stages, sdcv begin to appear in developing neurons, first in the Golgi region, then throughout the perikarya and processes. Concomitantly, the cells assume the bright green fluorescence observed in the adult.

Our results raise questions about the function and fate of the yellow-green fluorescing, granule-containing group of cells found in the embryo, a population of cells that is evidently distinct from sympathetic neurons in its requirements for culturing (Jacobowitz et al., 1975).

339 HYPOPLASIA OF DAPHNIA OPTIC CENTERS FOLLOWING THE DELETION OF PHOTORECEPTORS AT VARIOUS DEVELOPMENTAL STAGES BY MEANS OF A UV-MICROBEAM. E. R. Macagno. Dept.Bio.Sci.Columbia U,NYC10027.

During a particular developmental stage, photoreceptors of the Daphnia compound eye grow single fibers into the optic lamina, where they sequentially contact a set of undifferentiated neuroblasts. After this contact, which we found to include the formation of transient gap junctions between fibers and neuroblasts and a characteristic wrapping around of neuroblasts on fibers (PNAS 70:433,1973, 71:1099,1974), the laminar neuroblasts begin to differentiate and elaborate their own processes. In order to further explore the role of this interaction in the formation of specific synaptic contacts between photoreceptor and laminar neurons, we have used a UV microbeam to delete small groups of photoreceptors at the following developmental stages: (1)before optic fibers reach the lamina, (2)after they reach the lamina and make gap junctions but before synapses are formed, (3)after synapses begin to appear, and (4)in the adult. The results for stages (1) and (2) indicate a reduced size or hypoplasia of the optic ganglion which arises from both the loss of cells and a loss of processes and hence a reduced neuropil.

Using computer-reconstruction techniques (Fed. Proceed. 33: 2336,1974), we have analyzed the optic ganglion of experimental animals allowed to survive into adulthood in some detail. We have found (a)that the laminar cells whose receptor inputs were completely deleted before or after early contact have degenerated; (b)that, independent of how many photoreceptors are deleted, the ratio of photoreceptors to laminar cells is fairly constant and about the same as the normal value of 8 to 5; (c)that the size reduction is independent of whether the deleted group is lateral or medial and no "empty" spaces are observed; and (d) that a "cascade" effect is seen in that the medulla, a region which follows the lamina, also shows a hypoplasia due to cell loss and a reduced neuropil. The significance of these results, as well as the results for stages (3) and (4), which are now being analyzed, will be discussed in terms of a possible model for the neurodevelopmental process.

340 POSTNATAL MATURATION OF NEURONS IN THE RABBIT VISUAL CORTEX. Patricia E. Marshall* and Lawrence H. Mathers, Jr. (SPON:M.M. Herman). Department of Structural Biology, School of Medicine, Stanford University, Stanford, California 94305

Using the rapid Golgi and Nissl techniques, the postnatal development of the primary visual cortex has been studied. The overall thickness of the cortex is about 750μ at birth, and increases to 1400-1700μ in the adult. Myelination does not begin until the 5th-10th postnatal day and is observed first in the lower layers and the subcortical white matter. At birth there are indications of the cortical cell plate which characterizes fetal cortical development (Mathers, unpublished observations). This structure appears to persist superficial to the developing infragranular layers, but by the 5th postnatal day it is no longer detectable and the adult pattern of cortical lamination has appeared. Also visible in the Golgi preparations of newborn visual cortex are non-neuronal processes extending from the ventricular lumen to the pial surface. These are not impregnated in tissues from animals 5 days postnatal or older.

At birth, pyramidal cells of the infragranular layers are more well-developed than those of the supragranular layers. The basilar dendritic region appears to develop sooner than the apical dendritic region. Spines are impregnated on both dendritic regions from the 5th postnatal day onward. Pyramidal cells appear to be essentially mature by the 10th-15th postnatal day, though the number of dendritic branches increases beyond this time. Stellate cells mature much more slowly, and there appears to be a period of intense growth between the 10th and 20th day. There is also during this period a great increase in the number of dendritic spines found on stellate cells. This sequence of neuronal development corresponds well with physiological data on maturation of receptive field properties in the visual cortex.

341 NEUROGENESIS IN THE VISUAL SYSTEM OF THE RAT. Lawrence H. Mathers, Jr., Department of Structural Biology, School of Medicine, Stanford University, Stanford, California 94305.

Pregnant Sprague-Dawley rats were injected with ^{3}H-thymidine on the 11th, 14th, 15th, 16th, 17th, 18th, 19th, and 20th day of gestation. The rats were bred in the evening and the next morning was counted as day zero. Each pregnant female was injected with 8uci/gm of body weight. The pups were then delivered and allowed to survive until at least 6 weeks of age. At that time they were anesthetized and perfused with 10% formalin, and paraffin-embedded brains were sectioned at 10u. The sections were coated with Kodak NTB-3 and exposed for 2 months.

In the superior colliculus, labelled neurons were seen in animals who had been injected on the 15th-18th day. In those animals injected on the 15th day, the majority of neurons labelled was in the stratum griseum intermediale (SGI), and in areas deep to this. Very few cells were seen labelled in the superficial gray layers. On the 16th day this pattern persisted, with the exception that some large neurons in the optic layer and the base of the superficial gray were labelled. From the 16th day onward, many neurons in the superficial gray were labelled, and a few in the optic layer and SGI were also labelled.

In the visual cortex, labelled neurons first appeared on the 16th day, in the infragranular layers, and moved progressively upward with each day until at day 19 only neurons at the top of layer 2 and the molecular layer were labelled. In the lateral geniculate, genesis of neurons occurred between days 13 and 15, with a gradient moving from dorsolateral to ventromedial. There did not appear to be a difference in the sizes of neurons labelled at any particular day in the LGN.

342 PROGRESSIVE LOSS OF GANGLION CELLS IN THE DEVELOPMENT OF CHICK EYES EXPLANTED TO THE CHORIOALLANTOIC MEMBRANE. Steven C. McLoon*, W. Franklin Hughes*, (Spon: W.A.Reynolds). Dept. of Anatomy, Univ. of Ill., and Rush Med. Col., Chicago, Ill., 60612

Early removal of the optic tectum in the chick embryo results in the degeneration of retinal ganglion cells which would ordinarily form connections at this site (Hughes and LaVelle, '75). The present experiments show similar loss of ganglion cells from retinas of eyes allowed to develop on the chorioallantoic membrane (CAM) of host eggs. These eyes develop in the absence of a central target with which to form connections. Explanted eyes were selected at several times prior to the regression of the CAM of the host embryo for study by light and electron microscopy. The eyes, with total development times of 9, 13, and 17 days including the pre-explantation period, were micro-ophthalmic but reasonably well-formed and showed development of retinal photoreceptors comparable to normal eyes of the same age.

At 9 days the retinas of explants are identical in appearance to normal retinas of the same age and show a distinct ganglion cell layer. At 13 days depletion of ganglion cells can be seen in the central retina of explants as compared with normal eyes. Electron micrographs show degenerating ganglion cells and axons interspersed with some apparently normal ganglion cells. By 17 days the degeneration of ganglion cells has progressed to loss of a majority of ganglion cells most notably in the central retina.

These results show that the ganglion cell layer in eyes grown on the CAM undergoes normal histogenesis, but the cells cannot be maintained throughout the developmental period without central connections. The progressive loss of ganglion cells which begins at the center suggests that the onset of degeneration is dependent on the age of the cell since the retina matures in a central to peripheral sequence. It is believed that those cells which do not degenerate may arise from the germinal population at a time later than the majority of cells, and do not degenerate within the time limit imposed by experimental conditions. The results support the idea that there is a critical stage in the development of the ganglion cell after which the formation of central connections is required for the maintenance of the cell.

343 EFFECT OF MATERNAL DEPRIVATION ON THE PHYSIOLOGICAL AND BEHAVIORAL RESPONSE TO STRESS IN NONHUMAN PRIMATES. G. P. Moberg and W. Mason. University of California, Davis, CA 95616.

The behavioral and physiological response to novel environment and restraint stress was compared in 16 juvenile Rhesus monkeys which had either been raised with mothers or on cloth surrogates. Following removal from the cage, a blood sample was taken for cortisol determination and a telemetry unit for measuring heart rate was attached. The animals were then tested by being (a) returned to the home cage, (b) placed in isolation in an unfamiliar environment, or (c) restrained in a supine position for 10 min. and then placed in a novel environment. During each test period, behavior was observed and upon completion a second blood sample was taken. All testing conditions were sufficiently stressful to result in an increase in cortisol levels; however, there was no significant difference between rearing groups in the adrenal response. Mother raised animals locomoted more while surrogate raised animals tended to show more crouching and self-clasping. While there was no significant difference in heart rates in the home cage, upon being placed in the novel environment, either directly or following restraint, the surrogate raised animals had signicantly lower heart rates. These data indicate that under the conditions studied maternal deprivation had no effect on adrenal cortical response and only minimal effect upon behavior; however, this early experience appears to have influenced the autonomic nervous system's regulation of heart rate.

344 EFFECTS OF DEAFFERENTATION ON DEVELOPMENT OF THE TRIGEMINAL MOTOR NUCLEUS IN CHICK EMBRYOS. S.A.Moody*and M.B.Heaton. (SPON: D. Walker). Dept. Neurosci., Univ. Fla.,Gainesville, FL., 32610.

The theory of neurobiotaxis (Kappers,1917)was formulated in an attempt to account for several basic processes of neurogenesis, i.e. neuroblasts were hypothesized to send processes and to migrate toward those fiber bundles which provided a source of electrical stimulation. Many early studies failed to support the theory. For example, Rhines and Windle (1944) demonstrated that extirpation of forebrain, midbrain or portions of hindbrain in chick embryos had little effect on development of the remaining motor nuclei.

Evidence favoring neurobiotaxis is rare. Levi-Montalcini(1949) found that after unilateral removal of an otocyst all acoustic and vestibular nuclei migrated appropriately, except for the cells of the vestibular nucleus tangentialis. These apparently did not migrate or differentiate and mature on the side deprived of input from the ganglion fibers. Jacobs (1970) suggested that migration of trigeminal motor neuroblasts might similarly be due to stimulation by the sensory root or descending tract fibers. Therefore, we decided to test this hypothesis by removing the trigeminal ganglion primordia and studying resultant migration patterns.

The trigeminal ectodermal placode was removed unilaterally from chick embryos at stage 11-12, and the metencephalic neural crest destroyed by cauterization. These are the primordial regions of the ganglion cells of V (Hamburger and Narayanan,1969). The embryos were allowed to survive until day 9 of incubation.

In all operated embryos the ganglion was missing unilaterally. The remaining ganglion appeared normal and fibers projected several mm into the brain stem. No such central root fibers could be seen on the operated side. In all cases the motor nucleus of the control side consisted of prominent neurons with very large, clear, eccentric nuclei. The cells were either rounded or had one to three processes. These large cells were absent on the operated side in all cases. The area was filled with smaller cells which resembled the cells of the adjacent regions. In a few cases darkly staining, spindle-shaped cells with very dark nuclei were seen. The region deep to the floor of the ventricle seemed to be more densely packed with small, basophilic cells on the operated side.

Thus, the ingrowth of sensory root fibers seems to be essential for the normal development of the trigeminal motor nucleus in the chick. This evidence, in combination with that of the development of nucleus tangentialis, may indicate that sensory root fiber ingrowth is generally a necessary prerequisite to the development of normal brain stem patterns.

345 LAMINAR ANALYSIS OF ELECTRICALLY EVOKED POTENTIALS IN THE OPTIC TECTUM OF DUCKS DURING DEVELOPMENT. J.B. Munson and M.B. Heaton, Department of Neuroscience, Univ. of Fla. Coll. of Med., Gainesville, Florida

Field potentials were recorded from the optic tectum of duck (Anas platyrhynchos) embryos following electrical stimulation of the contralateral optic nerve head. Recordings were made in embryos on day eleven of incubation through hatching (27th day). Negative potentials were recorded at the dorsal and ventral surfaces of the tectum in all animals. Positive potentials were recorded in the depths of the tectum in all animals. Polarity reversals occurred within 0.5 mm of the respective surfaces. Potentials were reduced or obliterated when stimulus frequencies were increased to 15Hz. In older animals, potentials were more widespread, more complex, larger in amplitude, shorter in latency and of lower threshold than in younger animals. These results are consistent with the generation of postsynaptic activity in the optic tectum of ducks as early as day eleven of incubation. (Supported by EY-01264 and MH-27677)

346 MESSENGER AND NUCLEAR RNA COMPARISONS IN THE NEWBORN AND ADULT MOUSE. Sally Oklund* and William E. Hahn. Dept. Anat. Sch. Med. Univ. Colorado, Denver 80262.

A complex population of messenger RNA is present in the adult mouse brain (Bantle & Hahn, 1976, Cell 8:139; Young et al., 1976, Biochemistry 15:2823). The extent to which alterations occur in nuclear and mRNA populations during postnatal development is not known. We have pursued this problem by hybridizing RNA to labeled unique sequence DNA and cDNA. ^{3}H-cDNA was prepared by transcribing polyadenylated mRNA from total brain of the adult mouse using reverse transcriptase. 90%, or more, of the cDNA was representative of the high abundance class (classes?) of mRNA and the complexity of this DNA was equal to about 1% of the unique sequence fraction of the mouse genome. Hybridization of the cDNA with poly(A) mRNA from adult brain yielded an observed half reaction (=$Cot_{\frac{1}{2}}$) at Cot (concentration x time) 20. A $Cot_{\frac{1}{2}}$ of 60 was observed when mRNA from the newborn was used to drive the reaction. mRNA from the newborn hybridized with the same amount of cDNA as did mRNA from adult brain. These results suggest that essentially all of high abundance class mRNA species present in the adult brain are also present in the newborn. Differences in the observed $Cot_{\frac{1}{2}}$ suggest that the portion of the total mRNA mass comprised by the high abundance class is somewhat lower in the newborn, or that copy frequency of certain species in this class differ markedly between the adult and newborn. The extent to which the cDNA represents "housekeeping" genes which are expressed in all cells, or mRNAs which are "brain specific" is not known. Experiments are in progress to determine whether the complexity of infrequent abundancy classes of mRNA are also similar in the adult and newborn.

Saturation hybridization experiments with unique sequence ^{3}H-DNA show that nuclear RNA from adult, 12-day and newborn are totally overlapping populations of equal complexity. Thus genetic transcription is not grossly altered during postnatal development. Owing to post-transcriptional regulation, this observation does not preclude the possibility of detecting differences in the complexity or composition of the mRNA population which may occur during postnatal development of the brain. (Supported by funds from the NIH and NSF).

347 THE EFFECT OF SPINAL NERVE SECTION ON MOTOR NEURON LOSS DURING DEVELOPMENT IN XENOPUS. Anthony J. Olek*, Charles Edwards. Neurobiology Research Center, Biol. Dept., S.U.N.Y. Albany, Albany, N.Y. 12222

During the development of Xenopus laevis the number of motor neurons in the lumbar ventral horn and the number of axons in the corresponding ventral roots decline. Motor neuron and axon counts are maximal around stage 54, when the limb first shows signs of movement. The counts decrease by approximately 75% during the next few weeks. (Hughes, A. J. Embryol. Exp. Morph. 9:269 1961, Prestige, M.C., Wilson, M.A. J. Embryol. Exp. Morph. 32:819 1974)

The sectioning of one of the spinal nerves innervating the hind limb, before the onset of rapid cell and axon loss, has been found to increase the number of axons in adjacent, untreated nerves, and to increase the number of motor neurons in corresponding spinal cord segments. Either the 10th or 8th spinal nerve was sectioned, the animals were sacrificed two weeks later, and counts were made in the 9th segment of the spinal cord and in ventral root 9. The unoperated, contralateral side was used as a control. The increase in the number of axons in ventral root 9 and of motor neurons in spinal segment 9 ranged from 15-34%. In a few animals sacrificed 4-6 weeks after surgery, the increase in axon numbers appeared to be maintained in ventral root 9 at a time when the number of axons in the treated nerve 8 or 10 approached normal levels. Acute, topical application of solutions of 1.0% colchicine to the spinal nerve produced similar effects to those of nerve section.

This study was aided by a grant from Muscular Dystrophy Association, Inc.

348 AGE DECLINES IN LEARNING, SHORT-TERM MEMORY, AROUSAL AND AGGRESSION IN RELATION TO CELL LOSS FROM THE CORTEX AND HIPPOCAMPUS OF THE RAT. J. M. Ordy and K. R. Brizzee, Delta Primate Center, Covington, Louisiana 70433.

Experiments with human and animal subjects have indicated age declines in learning, short-term memory, arousal and aggression during aging. Cell loss has also been reported from various regions of the cortex and hippocampus during senescence. It has not been established to what extent redundancy of neuronal populations in the cortex and hippocampus is involved in the process of short-term memory consolidation during aging. The aims of this study were to examine life-span changes in behavior with particular emphasis on learning, short-term memory, arousal and pain-elicited aggression in relation to cell loss from the cortex and hippocampus of the Fisher 344 rat. The subjects for this study included 5 young (11 months), 5 adult (17 months) and 5 old (29 months). After behavioral testing, rats were sacrificed for morphometric evaluation of cell populations in the cortex and hippocampus.

The 29 month old group of rats was inferior in passive avoidance learning, 2-6 hour short-term memory retention, arousal and pain-elicited aggression. Although brain weight did not decrease, cortical depth decreased significantly in some regions in old rats. Neuron packing density decreased in visual area 17 but not in auditory area 41. In the hippocampus, cell loss occured in some areas in the old rats. From the results it was concluded that: 1) age declines in short-term memory were related to reduced passive-avoidance learning in the presence of non-significant age declines in other categories of behavior, and 2) age declines in learning and short-term memory of old rats were also correlated with age differences in cell populations not only in the cerebral cortex but in the hippocampus.

(Supported in part by NIH Grant HD/NS 00942 and RR 00164-14).

349 THE FUNCTIONAL DEVELOPMENT OF DOPAMINE RECEPTORS IN THE STRIATUM OF THE RAT. D. L. Ormond* and C. Van Hartesveldt (Spon: R. L. Isaacson). Psychology Dept., Univ. of Fla. 32611

Most evidence indicates that the presynaptic terminals of the nigrostriatal dopamine (DA) system in the rat do not mature until at least the fourth postnatal week. However, a DA-sensitive adenylate cyclase was found to be present at birth (Spano et al., 1976) suggesting that the postsynaptic terminals are responsive to DA much sooner than the presynaptic terminals are mature. In the present study, the rotational model of nigrostriatal function was used to assess the functional maturity of striatal DA receptors in the two-day-old rat.

DA (20µg/.5 µl or 10 µg/.25 µl) was injected unilaterally into the neostriatum, olfactory tubercle, or pyriform cortex of two-day-old rats and their postural asymmetry and rotational behavior recorded. Injection of DA at both doses resulted in postural asymmetry contralateral to the side of the injection, as in the adult, whereas injection of saline did not. Contralateral rotation was observed in animals in all three groups receiving DA injections but was most consistently obtained in animals injected into the pyriform cortex. The contralateral asymmetry observed in animals injected into the pyriform cortex and olfactory tubercle could be the result of diffusion of DA back up the cannula track into the striatum. The fact that rotation was observed more in animals injected into the pyriform cortex suggests that this system may be involved in the locomotor component of the rotational response whereas the striatum may be more concerned with the directional component. The results indicate that the DA receptors in the striatum, and probably in the olfactory tubercle and pyriform cortex, are functional in the two-day-old rat.

350 EMBRYONIC DEAFFERENTATION PRODUCES A DELAYED, SECONDARY MIGRATION OF N. ANGULARIS TO AN ECTOPIC POSITION. T.N.Parks and E.W Rubel. Depts. of Otolaryngology and Physiology, Univ. of Virginia Medical School, Charlottesville, VA 22901.

The avian nucleus angularis (NA) is composed of second-order auditory neurons receiving afferent endings from the cochlear nerve. Extirpation of the otocyst in chick embryos at 50-60 hrs. of incubation prevents entry of VIIIth nerve afferents into the brain and produces hypoplastic and hypotrophic development of certain brain stem auditory and vestibular nuclei (Levi-Montalcini, JCN, 91:209, 1949; Parks & Robertson, Anat.Rec. 184:497, 1976). In the present study, the right otocyst was removed at 2.5 days of incubation and at least three embryos were sacrificed at each of the following ages: embryonic days 9,11,13,15,17 and 19 and posthatching day 28. Nissl- and protargol-stained serial sections of the brain or entire head were examined. There was little observable difference in NA between the experimental and control sides until embryonic day 11. At this time, a large group of neurons, which appear to comprise the medial division of NA, can be seen to move ventrally and medially away from their normal position in the extreme dorsolateral aspect of the brain stem. This abnormal migration continues through embryonic day 15 and appears complete by hatching. At this time and subsequently-at least through one month after hatching--the ectopic NA neurons remain in a position ventrolaterad to n. vestibularis lateralis and mediad to the normal position of n. tangentialis, near or within the dorsal part of n. vestibularis descendens. In some cases, a small fascicle of fibers can be seen connecting the ectopic NA neurons to NA pars lateralis, which retains a dorsolateral position. Three lines of evidence suggest that the abnormally-positioned cells are indeed ectopic NA neurons: 1) Their migration can be followed over time from the normal position; 2) Their morphology resembles that of NA neurons; and 3) They do not resemble any neurons in a similar position on the control side or in normal tissue. The abnormal secondary migration of NA begins several days after completion of the normal migrations of surrounding auditory and vestibular neurons and occurs simultaneously with the experimentally-induced atrophic effects observed in NA and n. magnocellularis. Although it appears unlikely that the cochlear nerve influences the initial migration of NA neurons, the finding of a secondary migration to an ectopic position suggests that afferent innervation may serve to stabilize the position of target cells within the brain.

351 DENDRITIC ATROPHY FOLLOWING COLCHICINE INDUCED NEUROPLASMIC TRANSPORT DISRUPTION: IMPLICATION FOR BRAIN AGING. Ted L. Petit, Dept. Psychol., Univ. Toronto, West Hill, Ont., Canada, M1C 1A4.

A disruption of neuroplasmic transport has been suggested as a possible explanation to account for the dying back of dendritic processes in the aging brain. To test this hypothesis, colchicine, lumicolchicine, or physiological saline was applied in soaked gelfoam pads to the cerebral cortex of the rat. Colchicine is known to disrupt neurotubules and the fast component of neuroplasmic transport. Its isomer, lumicolchicine, which does not bind with neurotubules and has minimal effect on neuroplasmic transport, was used as a control for the non-specific actions of colchicine.

The animals were sacrificed at varying intervals, and their brains subjected to electron microscopic and Golgi analysis. At the electron microscopic level, colchicine application caused a massive disruption of neurotubules. Golgi analysis of colchicine treated cells showed a loss of dendritic spines, followed by dendritic atrophy usually culminating in cell death within 10-15 days. No changes were observed in either lumicolchicine or saline treated brains.

These results clearly indicate that colchicine induced neuroplasmic transport disruption is incompatible with prolonged cell life. Although these dendritic changes bear some resemblance to the condition reported in the human aging brain, colchicine appears to cause a faster and more severe cellular reaction.

352 THE EFFECTS OF VARIOUS PRE AND POSTSYNAPTIC BLOCKING AGENTS ON NATURALLY OCCURRING CELL DEATH IN THE CHICK LUMBAR SPINAL CORD. R. N. Pittman* and R. W. Oppenheim. Neuroembryology Lab., N. C. Dept. of Mental Health, Raleigh, N. C. 27611

Various neuromuscular blocking agents were injected directly into the hindlimb of chick embryos at a time (day 5½-6) when the first neuromuscular contacts are being made. Agents such as α-bungarotoxin, cobrotoxin (Naja naja atra), and α-neurotoxin (Naja naja siamensis) which bind irreversibly to the nicotinic receptors did not affect the time course or extent of naturally occurring cell death. Quantities of d-tubocurarine capable of stopping all motility for the entire 3-day period of cell death produced no apparent effects. Likewise, 4000-6000 LD_{50} (for 20g mouse) of botulinum toxin had no effect on cell death. Therefore, neither an interaction at the receptors nor a release of substances in synaptic vesicles would seem to be essential for motoneuron survival. Work is being continued as to the effects of these agents on endplate formation.

Preliminary work with β-bungarotoxin has shown that this toxin in very small quantities produces a profound increase in the number of motoneurons which die. The possibility that this phenomenon may be due to a mechanism of action other than a phospholipase-A-like activity is currently being investigated.

This system may provide a good in vivo model for studying parameters involved in the initial recognition and early maintenance of neurons.

353 EMERGENCE OF BETWEEN-LIMB SYNCHRONIZATION IN CHICK EMBRYOS. Robert R. Provine, Dept. Psych., Univ. of Md. Balto. Co., Baltimore, MD 21228.

The development of wing and leg movement is described in chick embryos between 7 and 19 days of incubation. (Chicks hatch at 21 days.) The emergence of synchronization between the movements of bilateral limb pairs (the left and right wings and legs) and between an ipsilateral wing and leg was also examined. All active, visually observed limb movements were recorded on an oscillograph which was activated by the experimenter. The records were analyzed in terms of the number of movements occurring during a 10 min. interval and the percentage of total recording time during which motility was present. The amount of between-limb synchronization was interpreted as the duration of concurrent limb motility expressed as a percentage of all limb motility (concurrent and non-concurrent) occurring during a 10 min. interval.

The development of motility in the wings and legs followed a similar course. Motility, expressed either as the number of movements or the percentage of observation time activity was present, increased in all limbs from 7 days up to a peak at about 13 days after which it declined until 19 days. Differences were not detected in the amount of motility of left and right limb pairs. Before 15 days, the wing pairs moved together no more often than a leg pair or an ipsilateral wing and leg. No consistent pattern of between-limb coordination was present. At 15 days and later, there was an increase in within-girdle limb synchronization which appeared concurrently with a decrease in between-girdle synchronization.

In summary, early motility is characterized by considerable independent, jerky limb movement with no obvious patterning existing between the movements of various parts. During development, there is an increase in the proportion of synchronous, in-phase between-wing movements (as in flapping) and 180° out-of-phase leg movements (as in walking). These changes are accompanied by a reduction in concurrent between-girdle movements. These results indicate that there is a dramatic increase in the amount of region-specific spinal cord motor output during the last week of incubation. The present behavioral results do not indicate by themselves whether this transformation is a product of a relative increment in the precision of motor outflow to the limbs or is a shift from unpatterned to patterned motor outflow. (This research supported by NIMH Grant 28476.)

354 CHICK BRAIN CREATINE KINASE ONTOGENY BEFORE THE ADVENT OF CREATINE AND INSULIN. Oscar Ramírez, John Takahashi* and Margarita Hernández*. 831 HSW Cardiovascular Research Institute, University of California Medical Center, San Francisco, CA. 94143 and Departamento de Bioquímica, Centro de Investigación y de Estudios Avanzados del Instituto Politécnico Nacional, México 14, D.F. México.

The ontogeny of brain creatine kinase (CK) was studied during chick embryo development. The cytosolic activity increased 270% in only 10 hours from the 2nd to the 3rd days of incubation; this was followed by a plateau phase throughout development and at the end of incubation another increase of cytosolic (150%) and mitochondrial (374.5%) CK activities occurred from day 17 to day 21 for both sucrose and KCl homogenized tissues. It was observed that 0.1 M-KCl extracted 52% more mitochondrial CK activity than 40 mM-potassium phosphate buffer pH 7.2 when similar samples of mitochondrial fractions were compared at day 21 of incubation. Therefore early embryonic chick brain CK is another "constitutive" enzyme like the early embryonic chick heart CK since creatine has not been enzymatically detected in the embryo until day 4 of incubation. Contrary to previous findings from muscle cultures, insulin does not appear to stimulate the early abrupt increase of brain CK activity since the hormone is not present in the embryo until day 5 of incubation. It is likely that CK increase is associated with neuroblast multiplication at early stages and possibly to neuronal maturation before hatching.

355 ASCENDING, DESCENDING AND TRANSCALLOSAL CONNECTIONS OF THE AUDITORY AND VISUAL FOREBRAIN IN INFANT KITTENS: AN HRP ANALYSIS. Richard Ravizza, Betsy Garlitz* and Paul Cornwell*, Department of Psychology, Pennsylvania State University, University Park, PA 16802.

The thalamocortical, corticotectal, and transcallosal components of the visual and auditory pathways have been studied in three day old kittens using the HRP retrograde transport technique. Over 20 kittens received single (.1 - .3ul) unilateral injections of 40% HRP (Sigma, Type VI) into one of the following structures: inferior colliculus, cortical areas 17-18, 20-21, A1, MSS, or EP. Following a 24 hour survival period each animal was sacrificed, its brain sectioned at 50u, and processed using standard HRP procedures.

Our chief results are threefold. First, numerous conspicuously labeled neurons are invariably seen in dorsal thalamus following each cortical injection. Second, clearly labeled neurons are seen in auditory cortex after injections of the inferior colliculus. Third, labeled neurons are seen in contralateral cortex following cortical injections of HRP.

Taken together these results indicate that these components of the 3 day old kitten sensory pathways are intact shortly after birth. Further, our finding that the thalamocortical and callosal projections are in the vicinity of visual cortex by day 3 stands in contrast to Anker and Cragg's findings based on the Fink-Heimer technique (1). Briefly, they concluded that areas 18 and 19 do not receive thalamic input until days 14 and 21 respectively and do not receive their callosal input until even later. Similar differences in Fink-Heimer and HRP estimates of afferent arrival times at frontal cortex have already been reported by Nauta and Goldman (2). These findings for frontal and visual cortex indicate that for some systems transport techniques may be more sensitive indicators of exactly when axons arrive in the vicinity of their ultimate target.

Anker, R., and Cragg, B. J. Comp. Neuro., 1974, 154, 29-42. Johnson, T., Rosvold, H., Galkin, T., and Goldman, P., J. Comp. Neuro., 1976, 166, 427-444.

356 BEHAVIORAL AND BIOCHEMICAL ANALYSIS OF GAMMA-AMINOBUTYRIC ACID MEDIATED INHIBITION IN THE EARLY CHICK EMBRYO. J. Reitzel*, R. W. Oppenheim and J. L. Maderdrut* (SPON: I-Wu Chu-Wang). Res. Div. of Mental Health Serv., Raleigh, N. C. 27611; Neurobiology Curriculum, U.N.C. Medical School, Chapel Hill, N. C. 27514.

Effects of exogenously administered gamma-aminobutyric acid (GABA), bicuculline and/or picrotoxin upon spontaneous motility of the chick embryo were observed at 4, 6, 7 and 9 days of incubation. GABA, an inhibitory neurotransmitter, was found to decrease motility at each age, whereas the GABA blocking agents bicuculline and picrotoxin produced the expected motility increases at each age studied. Antagonism of the GABA produced motility decrease was observed when GABA and picrotoxin were administered simultaneously.

Spinal cords from chicks 3, 4, 5, 6 and 7 days of incubation were examined for glutamate decarboxylase (GAD) activity using a radiometric cation exchange method. GAD is considered a marker for GABA secreting synaptic terminals in the adult animals. Significant GAD activity was found at all ages studied. GABA transaminase, the most important degradative enzyme of GABA,was found to be present at least as early as 5 days of incubation.

Although synaptogenesis is just beginning in the spinal cord at these stages, these findings suggest that GABA secreting synapses are present and behaviorally functional from 4 days of incubation onward.

357 PERIPHERAL NERVE REGENERATION IN THE STUMP TAIL MONKEY: EFFECTS OF TRIAMCINOLONE ACETONIDE TREATMENT. Irena Rusenas, William P. Graham, III and Stephen H. Miller. Dept. of Surg., M.S. Hershey Med. Cent. of the Penn. State Univ., Hershey, PA 17033

The efficacy of triamcinolone acetonide (Kenalog) in enhancing nerve regeneration was studied in 20 stump tail monkeys (M. arctoides). After a clean surgical transection of the median nerve proximal to the wrist (n=40) and the posterior tibial nerve above the malleolus (n=40), the nerves were immediately repaired using microsurgical technique and epineural suturing. On a double blind basis, either triamcinolone or carrier vehicle without the active steroid was instilled about the site of the nerve repair after wound closure. Myocutaneous nerve conduction velocity and latency determinations were made at monthly intervals for 18 mos. The neurorrhaphies were removed at 12, 14, 18 and 18 months and processed for light and electron microscopic observation.

Percutaneous stimulation of the repaired nerves yielded an evoked electromyographic response from recording needle electrodes in the thenar musculature at three months and at four months from the posterior tibial nerve. Although the amplitudes were markedly reduced from control levels and the latencies prolonged, a distinction could be made between the two groups on the basis of a shorter time course of the fibrillatory response following the initial evoked peak. This indicated to us even in the early regenerative period, a larger number of innervated muscle fibers in one group. Eight months following repair of the median nerve, latencies and conduction velocities were within normal limits in contrast to the placebo group which advanced to this status at 14 months. This data indicate to us a more rapid attainment of appropriate fiber diameter in those nerves treated with triamcinolone.

Examination of osmicated cross sections of nerves distal to the repair supported the electrophysiological results. In the placebo treated nerves, several fascicles contained very few tiny myelinated fibers whereas no areas devoid of large myelinated fibers were seen in the triamcinolone treated preparations. In general, the fibers in the triamcinolone treated nerves were comparable to controls in size and density, while those treated with vehicle were smaller and less numerous. Longitudinal sections through the area of the repair show less connective tissue proliferation, less dispersal of axons into the connective tissue and a marked reduction in the size of the scar tissue at the site of the repair in those nerves treated with steroid.

358 EXCESSIVE POLYNEURONAL INNERVATION OF PARASYMPATHETIC NEURONS UPON REINNERVATION FOLLOWING NERVE CRUSH. P. B. Sargent and M. J. Dennis*. Depts. of Physiology and of Biochemistry and Biophysics, University of California, San Francisco, CA 94143.

The degree of polyneuronal innervation of frog cardiac parasympathetic ganglion cells was measured in normal animals and at various times following vagus nerve crush. The number of inputs impinging on each cell was determined by recording intracellularly from ganglion cells while independently stimulating each of the two cardiac branches of the vagosympathetic nerves. Normally, about equal numbers of ganglion cells receive one and two synaptic inputs, and few cells (8%) receive more than two inputs. When the vagosympathetic nerves are crushed, synaptic transmission fails in 2-4 days and the ganglion cells remain denervated for 3 weeks. During the ensuing 5 weeks synapses are reformed at a rate of 0.4 inputs per cell per week. By the end of this period, when 93% of the cells have been reinnervated, the pattern of multiple innervation is different than normal: two-thirds of the cells are multiply innervated and 31% have at least 3 synaptic inputs. This pattern remains essentially unchanged for another year. In ganglia examined 14 months after nerve crush significantly more cells than normal were multiply innervated (78%) and significantly more cells received at least 3 synaptic inputs (35%). These findings were corroborated by histological results which showed that reinnervated ganglion cells often received synaptic terminals from two or more axons. We conclude that polyneuronal innervation of ganglion cells is more widespread after reinnervation than it is normally. Thus, whatever mechanisms may have acted during development to limit the extent of polyneuronal innervation appear to be absent during adult life. (Supported by USPHS Grants NS00303 and NS10792.)

359 DEVELOPMENT OF NEURONS AND SYNAPSES IN THE ABDOMINAL GANGLION OF APLYSIA CALIFORNICA. S. Schacher* and E. Kandel. Div. Neurobiol. & Behav., Dept. Physiol., Columbia P&S, New York, N.Y. 10032.

It is now possible to grow the gastropod mollusk Aplysia californica in the laboratory from fertilization to adult. In addition, the phenotypic stages of the developing animal and the sequential development of the ganglia comprising its nervous system have been described (Kriegstein, 1977a;b). This provided the groundwork for investigating the developmental mechanisms by which individual identifiable neurons in the abdominal ganglion acquire their characteristic physiological, biochemical and morphological properties.

The present study deals with the early pre-metamorphic development of the abdominal ganglion (16-35 days post-hatching). Initially (16-17 days) each hemiganglion consists of a small group of cells (4-6) surrounding a neuropil containing predominantly incoming fibers from the pleuro-abdominal connectives. During the next 18 days cell number in the hemiganglia increases to 90 neurons and the average cell body volume increases from 25 μm^3 to 65 μm^3. During this time the neuropil also displays an increase in complexity. Differentiating neurons send out primary processes, and in some instances secondary branching, into the neuropil. Even at the earliest stages, morphologically identifiable synaptic contacts are observed. Three classes of postsynaptic elements are found: 1) small spines, 2) larger processes, and 3) cell bodies. Since the axo-somatic contacts are absent in later developmental stages and adults, they may represent initial contacts on individual cells that may later 'move' on to more appropriate contact sites or they may be transient contacts that are later retracted.

An interesting feature of the developing nervous system is that individual ganglia are embedded within a group of 'support' cells containing large secretory granules, 1 to 5 µm in diameter. Following metamorphosis, the granules disappear coincident with an acceleration in growth of the neurons. To examine the possible causal relationship between granule release and neuronal growth, we have released the granules prematurely at early developmental stages by exposing animals briefly to artificial sea water containing high K^+ and low Ca^{++}. Under these conditions, other secretory cells as well as synapses appear to be unaffected. We are currently studying the effects of granule release by comparing the developmental parameters described above in treated animals with those of normal untreated animals. These comparisons may permit us to determine whether the granules have a specific role in the growth and differentiation of neurons in Aplysia.

360 PLASTICITY IN THE SENESCENT RAT: ANALYSIS OF AXON SPROUTING IN THE DENTATE GYRUS. Stephen W. Scheff, Larry S. Benardo* and Carl W. Cotman. Dept. of Psychobiology, Univ. Calif., Irvine, CA 92717.

It is well known that neuronal loss occurs with age in the brain. However, it is not known whether or not cell loss results in axon sprouting and reorganization of existing circuitry. An understanding of the reorganizational capacity of the aged brain might provide insights into the basic mechanism underlying changes in mental capacity. The present study was undertaken to investigate the capacity of senescent brain to support axon sprouting following partial denervation.

The dentate gyrus of the hippocampal formation was used as a model system and the response of afferents following unilateral lesions studied in 3 month old and 24 month old Fischer 344 rats. In young animals removal of unilateral entorhinal input to granule cells elicits reorganization actualized by an outgrowth of the commissural-associational fiber plexus, increased positive staining of AChE, and a repopulation of the dendritic field as seen by ultrastructural analysis. By each measure there is very little variability between animals. Aged animals respond to such a lesion with similar circuitry changes but less dramatically. The outgrowth of the commissural-associational fiber plexus is on the average reduced, AChE positive staining is less pronounced and the dendritic field does not appear to repopulate to the same degree as in younger animals. Although axon sprouting does occur, a response to specific denervation is typified by a wide range. While some animals show robust capabilities of plasticity like the younger animals other show almost none.

Our findings are particularly interesting in that they correlate with other findings from behavior studies which also indicate that old animals are a nonuniform population, showing variable performance. It may be that inherent plasticity properties of senescent nervous system correlate with the decline in mental function. (Supported by research grant AG 00538).

361 THE DEVELOPMENT OF CATECHOLAMINE FIBERS IN THE PRENATAL CEREBRAL CORTEX OF THE RAT. M. Schlumpf, W. J. Shoemaker and F. E. Bloom. Pharmakol. Inst., Univ. Zurich, Switzerland and The Salk Inst., La Jolla, CA 92037.

During the last gestational week, the cerebral cortex of the rat is progressively innervated by catecholamine (CA) fibers in a rostro-caudal gradient. On gestational day 16, the first CA fibers reach the surface of the lateral part of the developing cerebral cortex. The innervation occurs in a characteristic bifurcated pattern, similar to the pattern of synapse formation in the prenatal rat cortex. Comparison of sections prepared for fluorescence histology or Nissl stain suggests that the superficial CA fibers are within the marginal layer, while the second, and deeper, CA fiber band is located below the developing cortical plate near the intermediate zone. The varicose fibers within the marginal layer are horizontally directed and initially consist of a single layered band of fibers which develops into a 2-3 layered band. The deeper CA fibers around the intermediate zone appear as a thicker layer exhibiting diffusely arranged fibers. During prenatal development, both CA fiber bands extend over a progressively larger part of the neocortical rim in a fronto-caudal direction. The zone between superficial and deeper CA fibers is filled by vertically-oriented neuroblastic cells. This zone is crossed by CA fibers very rarely and only in the later developmental stages. After gestational day 17, another strong CA fiber input is observed from the midline into the prospective anterior cingulate cortex areas. The developing CA fiber system is highly organized: these fibers tend to aggregate around ontogenetically and phylogenetically older structures of the cerebral cortex and are generally not associated with neuroblastic cells. Preliminary neurochemical observations on embryonic rat cortex suggest that norepinephrine is the predominant catecholamine present. We conclude that CA fibers in the cerebral cortex of the rat develop early in the third gestational week, a short time after differentiation of the CA synthesizing cell groups of the brain stem. The functional significance of this prenatal innervation remains obscure. That cortical CA terminals make synaptic contacts by postnatal day 3 has been reported, but the permanence of these synapses has not been established.

362 STUDIES ON THE CYCLIC AMP SYSTEM IN HUMAN BRAIN DURING AGING. M. J. Schmidt* and B. Ghetti* (SPON: I. Slater). Lilly Research Labs. and Indiana University Medical Center, Indianapolis, IN 46206.

Cyclic AMP (cAMP) and cyclic GMP (cGMP) concentrations, norepinephrine-stimulated accumulation of cAMP in tissue slices, and cyclic AMP-dependent protein kinase activity were measured in the cerebral cortex and cerebellum of humans 6-12 hours after death. Similar determinations were made on rat cortex 10 min - 16 hrs after death to assess the effects of post-mortem decay on these systems.

Concentrations of cyclic nucleotides in rat brain declined markedly between 10 min and 6 hrs after death, but there was little further decrease during the next 10 hrs. Cyclic GMP was not detected in the cerebral cortex of rats that had been dead longer than 6 hours, and there was a significant loss of cGMP in the cerebellum at this time. Norepinephrine stimulated the accumulation of cAMP in cortical slices from rat brain at all times after death. During the post-mortem period there was a slight decline in the activity of protein kinase assayed in the presence of cAMP and an elevation in activity assayed in the absence of cAMP. Thus, the percentage stimulation of protein kinase by 10^{-6}M cAMP was somewhat greater 16 hrs after death.

These studies demonstrated that valid estimates of cAMP concentrations, protein kinase activity, and hormone-stimulated cAMP accumulation could be made on brain tissues obtained at autopsy. Cyclic GMP appears to decrease rapidly after death and so was not examined in human material.

Cyclic AMP was found in the cerebral cortex and cerebellum of humans although concentrations were lower than those in rat cortex. Levels were comparable in 2-3 day-old infants and 60-80 year-old patients. Norepinephrine stimulated cAMP accumulation only in the cerebral cortex of very young humans. The maximal increase occurred between 5 and 10 min of incubation with 10^{-5}M norepinephrine. No elevation of cAMP was seen in the cerebellum at any age or any concentration of norepinephrine. Protein kinase was found in the cerebral cortex of humans as early as 2 days after birth. The enzyme was maximally activated by 10^{-6}M cAMP. There was no change in activity with increasing age. Kinase activity in human cerebral cortex was comparable to that in samples of rat cerebral cortex.

363 REGIONAL DIFFERENCES IN CRITICAL PERIODS FOR 6-HYDROXYDOPAMINE INDUCED NORADRENERGIC SPROUTING IN NEONATAL RAT BRAIN. Richard H. Schmidt* and Ranbir K. Bhatnagar (SPON: W.J. Steele). Dept. of Pharmacology, Univ. of Iowa, Iowa City, IA 52242.

The ability of 6-hydroxydopamine (6-OHDA) to induce regenerative sprouting of noradrenergic (NE) fibers from the locus coeruleus in the cerebellum and brain stem is unique to fetal and perinatal age rats. This study was initiated to define how the capacity of NE neurons to engage in this process changes with increasing age at time of treatment with 6-OHDA.

Female rat pups from several litters were randomized together at birth and assorted into three groups. These groups received 100 mg/kg 6-OHDA subcutaneously on either days 1 and 2 (Group I), 3 and 4 (Group II), or 6 and 7 (Group III). Controls in each group were injected with vehicle. Several rats from Group III were analyzed on day 8, while all the rest were analyzed when 4 weeks old. Pons-medulla and three cerebellar regions were assayed for endogenous NE and synaptosomal NE uptake. The middle cerebellar region consisted of crus I of the hemisphere, vermian lobules VI through VIII, parafloccolus and flocculus. Tissue anterior and posterior to this was taken as separate regions. Areas included in the middle cerebellar region generally mature at a slower rate than the rest of the cerebellum, as judged from granule cell acquisition data (Altman, J. Comp. Neuro. 136:269).

In general, changes in NE and synaptosomal uptake corresponded closely. In those rats analyzed on day 8 degeneration of NE terminals in the whole cerebellum and parietal cortex exceeded 90%. By 4 weeks of age significant sprouting and regeneration was apparent in the brain stem and cerebellum. In Group I NE levels (µg/gm tissue) in the pons-medulla, anterior, middle and posterior cerebellum were 179%, 162%, 148% and 169% of control respectively. For Group II these values were 132%, 80%, 52% and 81%, while for Group III these values were 123%, 21%, 7% and 24%.

The sprouting response in both brain stem and cerebellum is maximal at the earliest treatment time (Group I) and becomes progressively less with maturation. Between day 2 and 4 the NE projection to the cerebellum loses its capacity to regenerate and sprout in excess of control levels of innervation. Nevertheless the capacity for significant regeneration persists in the anterior and posterior regions until at least 6 days of age. This would be particularly evident if the data were to be expressed as total NE per region. At all ages the regenerative potential is greater in the anterior and posterior regions than in the middle. In conclusion, the critical period for regenerative sprouting is clearly different in different target areas of the locus coeruleus, suggesting that target neurons may influence the regenerative process. (Supported by USPHS grant NS-12121)

364 THE DEVELOPMENT OF FIBER PROJECTIONS IN THE OLFACTORY CORTEX OF RATS. J.E. Schwob* and J.L. Price. Dept. Anat. and Neurobiol., Wash. Univ. Sch. Med., St. Louis, MO 63110.

Although the axonal projection of the olfactory bulb onto the olfactory cortex in the rat is not topographically organized, it varies in a systematic way across the cortex; both the thickness of the layer of termination of the axons (layer IA) and the density of termination within this layer are greatest in areas deep to or near the lateral olfactory tract (LOT) and progressively decrease in areas further removed (medially, laterally, and caudally) from the LOT. In an attempt to establish the relationship between this adult pattern and developmental events, the projection of the olfactory bulb has been studied at several foetal and neonatal ages, using the autoradiographic method. At embryonic day 17 (E17), labeled axons can be traced from the main olfactory bulb through the LOT as far as the rostral pole of the medial amygdaloid nucleus. A few are also found in the developing layer I deep to the LOT, but no label is present lateral, medial or caudal to the LOT. At later ages, the labeled fibers gradually extend away from the LOT, although the fringes of the lateral entorhinal area and the medial part of the olfactory tubercle, which receive the lightest projections in the adult, are not innervated by the olfactory bulb until the end of the 1st postnatal week.

Another feature of the adult olfactory cortex is the lack of overlap between the termination of the olfactory bulb fibers in layer IA and that of the cortical association fibers in layer IB. However, experiments with injections into the bulb or the cortex at E21 and E22 indicate that there is considerable overlap between these fiber systems before birth. Injections into bulb or cortex on the 1st postnatal day (P1) demonstrate that the overlap is nearly eliminated in the lateral and posterior parts of the piriform cortex but not in those areas deep to the LOT. The overlap deep to the LOT largely disappears by P5/P6, and a precise, complementary pattern of lamination is established throughout the olfactory cortex by the beginning of the 2nd postnatal week. However, the commissural projection of the anterior piriform cortex to layer IB of the contralateral cortex is not seen until the end of the 2nd postnatal week. Likewise, the projections of the anterior olfactory nucleus to layer IB of the ipsi- and contralateral piriform cortex and the contralateral anterior olfactory nucleus are not seen until the 2nd postnatal week, although the projections to the ipsi- and contralateral olfactory bulb are present at an earlier age.

Supported by NIH Grants NS09518 and GM07300.

365 RADIOAUTOGRAPHIC AND GOLGI STUDIES OF AN EARLY SPINAL CORD REFLEX PATHWAY. Terry J. Sims* and James E. Vaughn. Div. of Neurosciences, City of Hope Med. Ctr., Duarte, Ca. 91010.

Neurons involved in an early reflex pathway of the mouse (C57BL/6J) cervical spinal cord have been studied by radioautography and Golgi impregnations. The objectives of these studies were to establish the final cell birthdays and the timing of subsequent dendritic development for neurons in an early cutaneous reflex pathway. Final cell birthday data were obtained from 6 week old mice which were pulse-labeled at various embryonic times (E8-E15) with ^{3}H-thymidine. Golgi impregnations were obtained for embryonic days 12 through 20.

Lateral motor neurons (LMN) undergo their final cell birthdays between E9 and E10.5, and more than 80% of the total LMN population is generated between E9.5 and E10. The earliest time at which LMN's are stained by the Golgi method is E12. At this time LMN's are identifiable by their ventral root axons, and these young motor neurons characteristically have only two primary dendrites which are directed in the plane of the intermediate/marginal zone interface. Between E12 and E15, LMN dendrites undergo a rapid increase in growth and complexity so that by E16, relatively extensive dendritic patterns have been formed. A few medium-sized neurons located approximately in the medial region of lamina VI are heavily-labeled with ^{3}H-thymidine at E9. Golgi impregnations of medium-sized neurons in this region of E12 spinal cords indicate that these early-formed cells are commissural neurons. Lateral to these commissural neurons in lamina VI are a number of interneurons whose final cell birthdates occur between E10 and E11. Golgi impregnations at E13 show that many of these interneurons send their axons ipsilaterally into the lateral marginal zone and appear to provide an early synaptic input to dendrites of LMN's. Final cell birthdates of dorsal root ganglia (DRG) neurons occur between E10 and E13. A comparison of final cell birthdates with DRG neuronal size indicates that peak generation occurs at E10.5 for the largest neurons, E11.5 for medium-sized neurons, and E12 for the smallest neurons. There is a considerable degree of overlap in the final cell birthdays of neurons in the spinal cord and DRG. However, with the exception of the very early commissural neurons, the neuronal components of the reflex pathway generally undergo final cell birthdays in a sequence that is opposite to the direction of impulse conduction in the reflex arc. The Golgi study supports the radioautographic data in that the earliest impregnations occur in motor neurons and the early commissural neurons, followed by interneurons and finally DRG neurons. Supported by USPHS grant NS 09573.

366 AGING PRODUCES GREATER BEHAVIORAL EFFECTS OF DOPAMINE AGONISTS IN RODENTS. Robert C. Smith, J. Randolph Strong*, D.E. Leelavathi*, and Carolyn Rolsten*. Tex. Res. Inst. Mental Sciences, Houston, Tex 77030.

Biochemical changes in catecholamines and their enzymes have been reported in the aging brain (McGeer et al, Neurobiol. of Aging). Some motor disorders, such as tardive dyskinesia, which may be related to changes in catecholamine neurons and are exacerbated by the DA agonist, amphetamine (Smith et al, Am. J. Psychiat. July, 1977), have much higher prevalence in older age groups. To begin more systematic investigation of the interaction of age and effects of DA agonists, we examined the behavioral effects of apomorphine (APO), a direct DA receptor agonist, and d-amphetamine (AMP) and methylphenidate (MP), indirectly acting DA agonists, in several age groups of rodents: young (3 & 4 month), mature (11 & 14 month) and old (21 & 27 month) rats (Charles River, males) and mice (C57BL/10J, females) respectively. The old rats and mice showed significantly greater gnawing (GNAW) and/or total stereotyped behavior (SB) after APO (0.25-1.0 mg/kg) than young rats or mice, with mature rats or mice generally falling between these two age groups. Old mice also showed greater GNAW after 4.5 mg/kg AMP or 15 mg/kg MP, and old rats tended to have greater SB 90 min after 3.5 mg/kg AMP. Old rats also tended to show slightly greater locomotor activity 30-45 min after 0.5 mg/kg APO. In rats the greatest age difference in the effects of DA agonists tended to occur later in the time course of behavioral effects (e.g. 45 min post APO), whereas in mice the most pronounced age difference in DA agonist effects occurred earlier in the time course (e.g. 15 or 30 min after APO or MP). Since GNAW and SB in rodents are predominantly mediated by nigra-striatal DA, and have been used as models of dyskinetic disorders in man which are hypothesized to involve DA supersensitivity, our results, which indicate greater effects of DA agonists in old rodents, may a) help explain the greater prevalence of dyskinetic disorders in the aged, and b) provide a better animal model for investigating their neuropharmacology. The neurochemical mechanisms underlying the increased effects of DA agonists in old rodents may involve DA receptor supersensitivity and/or decreased metabolism or re-uptake of the agonist drugs or the biogenic amines released by AMP and MP.

367 EFFECTS OF AGE ON EVENT-RELATED POTENTIALS. E. Snyder and S. Hillyard. Dept. Neurosci., UCSD, La Jolla, Ca. 92093.

A number of studies have reported on sensory evoked potential alterations accompanying the normal aging process in man, but most have only recorded from passive, non-performing subjects. Given the wealth of behavioral data which suggest that a number of cognitive deficits are associated with aging and senescence, we decided to look at specific "event related" potentials (ERPs) which are recorded when subjects are actively performing in decision-making tasks. Of particular interest was the "P3" or P300 component, which occurs in normal, young adults when a decision is made regarding a task relevant stimulus.

The subjects studied to date are 5 young (mean age=28yrs.) and 5 older (mean age=71 yrs.) adults. In an initial, non-task condition, the S passively watched a random sequence of slides of the numbers "2" (90%) and "6" (10%) flashed onto a screen. Next, the Ss were instructed to count the "6"s (targets) and to ignore all other stimuli. For this counting task, the stimuli were 80% "2"s (standards), 10% "6"s (targets) and 10% colorful, non-recognizable figures ("novel" slides). In a final condition, Ss were required to press a button to each target "6" (permitting concurrent recording of ERP and reaction time measures).

ERPs were recorded during all conditions from 3 midline, 2 lateral and 2 ocular channels (Fz, Cz, Pz, C3, C4, upper orbit and lower orbit) all referenced to the right mastoid. For each subject, ERPs were averaged separately (using a MED-80 computer) for the standard, target, and novel stimuli in each task condition.

Striking age-related differences were found in certain late components of the ERP. The amplitude of the P3 component to the target "6"s was greatly attenuated in the older subjects. Further, the latency of the P3 peak was delayed by nearly 80 msec in older subjects (despite there being no substantial differences in RTs for the 2 groups). Similarly, the older Ss had significantly smaller P3 components to the "novel" stimuli. Finally, the young subjects showed greater P3 amplitudes at the right lateral electrode site than at the left to the novel slides, while the older subjects had nearly equal amplitudes over left and right hemispheres.

These data tentatively suggest that the ERP component most closely associated with cognitive activity in younger subjects (the P3 wave) is also the most dramatically altered (in amplitude, latency and lateral distribution) by the normal aging process. Further studies will determine the consistency, nature and significance of these age-related ERP fluctuations.

368 LOSS OF AXONS FROM NORMAL AND PERIPHERALLY DEPRIVED TROCHLEAR NERVE. G. S. Sohal and T. A. Weidman*. Department of Anatomy, Medical College of Georgia, Augusta, Georgia 30902.

A loss of approximately half the number of neurons during normal development and a significantly higher cell loss in the peripherally deprived trochlear nucleus of the duck was observed earlier (EN 51:634, 1976). A study of general developmental features and counts of the number of fibers from electronmicrograph montages from day 11 of incubation through hatching and a month after hatching were made to determine whether or not a similar loss of axons occurs during ontogeny of the trochlear nerve. The first appearance of an identifiable trochlear nerve is on day 10 or 11. It is composed of numerous nerve fascicles of small naked axons with an average diameter of 0.4μm. Schwann cells begin to wrap around fibers on day 15 and on day 18 approximately 39% of the fibers are myelinated with an average diameter of 2.0μm. At hatching the myelinated axons (95%) have an average diameter of 3.0μm and the unmyelinated (5%) 0.7μm. A month after hatching 98% of the axons are myelinated.

Initially, there is an abundant collateral sprouting which roughly coincides with the time of neuromuscular contacts suggesting some sort of interaction between the developing nerve and the periphery. The maximum number of fibers (47,000) in the trochlear nerve is present on day 12 and minimum (1500) on day 27 (hatching). Thus, approximately 97% of the fibers are lost during normal development of the trochlear nerve. Axon loss after removal of the superior oblique muscle is even higher. A majority of the axons are lost on days 13-15. It appears that most of the collaterals are retracted into the parent axon and very few myelinated and unmyelinated fibers actually degenerate. Assuming all trochlear neurons send their axons into the nerve, the ratio between cells and fibers on day 12 is 1:20 and on day 13 and after remains 1:1. Cell death slightly preceeds axon loss which suggests that the direction of degeneration is from cell body to the axon. It appears that at least some cells which die during normal development had sent their axons into the nerve prior to their death. Whether these axons make any meaningful connections with the periphery is uncertain. (Supported by GRS Grant 5-S01-RR-05365-14)

369 PRENATAL DEVELOPMENT OF CATECHOLAMINE NEURONS IN BRAIN BY IMMUNOCYTOCHEMICAL LOCALIZATION OF TYROSINE HYDROXYLASE. L.A. Specht*, V.M. Pickel, T.H. Joh, and D.J. Reis (SPON. D.W. Snyder). Lab. of Neurobiol., Dept. of Neurol., Cornell University Medical College, New York, NY 10021

Using an immunocytochemical technique for the localization of the catecholamine (CA) synthesizing enzyme tyrosine hydroxylase (TH), we sought to determine in the prenatal rat brain: (a) the earliest time of appearance and the distribution of CA neurons labeled for TH, and (b) the ultrastructure of TH containing axons and subcellular localization of the enzyme. Sections of fixed brain from fetuses of embryonic (E) day 10 to E19 were incubated with specific antiserum to TH and immunocytochemically labeled for light and electron microscopy. By light microscopy, neurons containing TH are first detected on E13. These TH containing perikarya are localized exclusively to the mantle zone of the neural tube. During E13-E17, when labeled axons can be traced from the TH containing perikarya into the marginal zone, labeled processes are also present in the proliferating ependymal zone and are frequently associated with dividing cells in areas of the rudimentary cortex and striatum. At E19, labeled axons and terminals in the proliferating ependymal zone are no longer present. At this time the distribution of labeled cell bodies, processes and terminals is beginning to resemble the distribution of CA neurons in the adult. By electron microscopy, TH labeled axons in the prosencephalon at E17 measure 0.1-0.5μm in cross-sectional diameter, and contain numerous varicosities filled with small (70-100 nm) subcellular organelles which are selectively labeled for TH. The axons showed no synaptic specializations. These results indicate that presumptive CA neurons contain the biosynthetic enzyme TH and may be capable of neurotransmitter synthesis as early as E13. The absence of TH labeled perikarya within the ependymal zone at a time (E13) when CA neurons are undergoing final mitosis (Lauder and Bloom, J.Comp Neurol. 155:469, 1974), suggests that only postmitotic neuroblasts which have migrated to the mantle zone contain TH. The early appearance of perikarya and processes containing TH (E13) and the association of the labeled processes with mitotic cells in the ependymal zone (E13-E17) of the rudimentary cortex and striatum are consistent with a view that the CA neurons may serve a regulatory role in the ontogeny of the central nervous system.

370 INCORPORATION OF HORSERADISH PEROXIDASE BY DEVELOPING RETINAL CELLS. Arthur W. Spira* (SPON: S.H. Roth). Division of Morphological Science, University of Calgary, Calgary, Alberta, Canada.

Existing studies of the ability of retinal neurons to incorporate extracellular tracers have been limited to the mature retina of lower vertebrates. No comparable data is available for developing and mature neurons of the mammalian retina. Since our previous observations revealed an early development of synapses in the fetal retina of precocious animals we have considered whether vesicles in developing synapses undergo a recycling process at the neuronal terminal similar to that occurring in the mature animal. To this end horseradish peroxidase (HRP-Type II) was introduced to the retina of guinea pigs from fetal to adult ages. (Retinae were dissected from the posterior eye cup; the neural and pigmented epithelium were separated and incubated in 5% HRP in Ames' medium for one hour. Additional animals were injected intravitreously with 30% HRP in saline). During early stages of retinogenesis HRP was incorporated by growth cones and neuron terminals in large vesicles. Differentiating photoreceptor terminals and synapses of the inner plexiform layer contained the tracer in small (700 A) vesicles and tubules. There was an increased uptake by small vesicles by term fetal stages. Animals born and raised in the dark for up to eight weeks continued to show extensive uptake of HRP in photoreceptor terminals. Results are consistent with the postulate that synaptic vesicles in the developing retina recycle in a manner similar to that found in the mature animal.

Tracer was also incorporated by non-synaptic elements. HRP appeared in small vesicles, large vacuoles, and Golgi saccules of ganglion and photoreceptor cells (inner segments). Unlike glial cells of the CNS, Müller cells took up HRP only in their apices. Cells of the pigmented epithelial layer (PE) demonstrated a surprising capacity to incorporate the tracer. In both fetal and mature animals HRP was taken into small vesicles, large vesiculated bodies, and occasionally in branching cisternae resembling those of the smooth ER. This uptake suggests a potential involvement of PE cells in removal of excess subretinal fluid.

371 ADRENAL EPINEPHRINE AND THE DEVELOPMENT OF TYROSINE HYDROXYLASE ACTIVITY IN SYMPATHETIC GANGLION. Paul Y. Sze and Keith A. Markey* (SPON: S. C. Maxson). Dept. Biobehavioral Sci., University of Conn., Storrs, CT 06268.

In adult mice, bilateral adrenalectomy (Adx) resulted in a 35% reduction of tyrosine hydroxylase (TH) activity in the superior cervical ganglion after 2 weeks. The effect of Adx was shown to be additive to that of decentralization, and was characterized by a decreased V_{max} of the enzyme with no change in the apparent K_m for either tyrosine or 6-MPH_4. The reduction of TH activity following Adx was not prevented by daily replacement with corticosterone (50 umoles/kg, s.c.). However, replacement with epinephrine (22 umoles/kg, s.c., daily) fully maintained TH activity in Adx animals. Daily administration of isoproterenol (22 umoles/kg,s.c.) was equally effective in preventing the decline of TH. Moreover, the effect of Adx could be mimicked by chronic administration of SKF 64139 (420 umoles/kg, s.c.), a drug known to deplete circulating epinephrine by inhibiting adrenal synthesis of the hormone.

The involvement of adrenal epinephrine in the regulation of ganglionic TH was further examined in developing animals. Postnatally, TH activity in the ganglion rises shortly after birth, reaching adult levels at 3 weeks of age. Adx on day 12 was found to arrest the developmental rise of TH activity, while normal development of DOPA decarboxylase was unaltered. Replacement with epinephrine (22 umoles/kg, s.c., daily) and corticosterone (50 umoles/kg, s.c., daily), but not the corticoid alone, permitted the normal developmental rise of TH activity.

These findings indicate that epinephrine not only plays a role in the physiological maintenance of TH activity in adult ganglion, but also serves as an essential factor in the maturation of the enzyme activity in developing ganglion. Thus, in addition to the influence of central innervation, the development of ganglionic TH depends also on hormonal influence of adrenal epinephrine. (Supported by MH 29237).

372 RESERPINE AND/OR α-METHYL-p-TYROSINE INDUCED LESIONS IN BRAINS OF PREGNANT RABBITS AND THEIR FETUSES. Virginia M. Tennyson, Mary Budininkas-Schoenebeck* and John Martin*. Dept. Anat. and Pathology (Neuropathology), Columbia University, College of Physicians and Surgeons, New York, N.Y. 10032.

Pregnant Dutch rabbits were given subcutaneous doses of reserpine (Serpasil, Ciba) and/or α-methyl-p-tyrosine(α-MT, Regis), and their brains and the brains of most of their fetuses were examined by fluorescence and electron microscopy (EM). The adult rabbits weighed 2255-3000 gm. A pregnant rabbit (who aborted her fetuses) received 0.06 mg/day of reserpine from fetal days 14 through 22, and was sacrificed 6 days later. Fluorescence was moderately decreased in the neostriatum. In addition, there was a marked increase in lipofuscin-like granules (autofluorescent bodies in neurons) in her brain, and some areas of focal necrosis containing autofluorescent cells, which were probably lipid-laden macrophages. In another pregnant dam, who was given reserpine (0.038 mg/day) on fetal days 14 through 24, was sacrificed 3 hrs. after the last dose. Fluorescence was absent in the neostriatum of the mother and 8 fetuses. Lipofuscin-like granules were not noticeably enlarged in the mother's brain. EM of the putamen of 2 fetuses showed evidence of damage in neurites. α-MT was given to another dam in multiple doses of 150 mg each three times a day from fetal days 14 through 23, and was sacrificed 1 hr. after the second dose on day 24. This treatment completely depleted fluorescence in the neostriatum of the dam and 6 fetuses, but not in the dam's mesolimbic system. The dam's brain had an increase of lipofuscin-like granules. EM of the putamen of 2 fetuses showed marked damage in some neurites and very large compound granular bodies in neuroblasts. Another pregnant rabbit was given a single dose of 0.125 mg of reserpine in the morning on fetal day 14. That evening and during the next two days, she also received a single dose of 420 mg of α-MT. She died on fetal day 17 and her brain removed soon after death (5 fetuses were present, but were discarded). There was no fluorescence in the neostriatum, mesolimbic system, or substantia nigra. Her brain contained unusually large numbers of greatly enlarged lipofuscin-like granules, particularly in the piriform cortex, dorsal cortex, and neostriatum. This data shows that both reserpine and α-MT given to a pregnant rabbit during a critical period during the development of dopaminergic neuroblasts can produce alterations in the fetal putamen, and in higher doses result in lipofuscin-like granules in the brain of the dam.

373 THE EFFECT OF NERVE GROWTH FACTOR ON REGENERATIVE REPAIR IN THE SEVERED OPTIC NERVE OF THE NEWT (TRITURUS VIRIDESCENS). James E. Turner and Kathleen A. Glaze*. Dept. Anat., Bowman Gray Sch. Med., Wake Forest University, Winston-Salem, N. C. 27103.

Nerve growth factor (NGF) was found to have a strong stimulatory effect on the regenerative capacity of the lesioned newt (Triturus viridescens) optic nerve. A clear dose response relationship was demonstrated to exist between various concentrations of single intraocular NGF injections, administered at the time of lesion, and the number of regenerating axons per nerve cross section at 14 days post lesion. A rapid rise in numbers of regenerating axons was evident in animals treated with NGF concentrations of 2 to 20 B.U. but values plateaued between 20 - 2000 B.U. Light microscopic observations indicated that NGF treated nerves were larger than controls. Quantitative analysis substantiated these initial observations by revealing that a single intraocular injection of 200 B.U. of NGF given at the time of lesion elicited a highly significant increase in both diameters and cross-sectional areas of regenerating nerves 14 days after lesion. Most importantly, NGF treatment elicited approximately a two-fold increase in the total number of regenerating axons per nerve cross-section. In addition, the percentage of nerve cross-sectional area occupied by regenerating axons was significantly increased by NGF treatment. However, the percentage of glial cytoplasm per cross-sectional area remained constant for both control and experimental groups.

374 NERVE-FREE DEVELOPMENT OF MERKEL CELLS IN AMBYSTOMA EMBRYOS. Charles D. Tweedle. Depts. Biomech. and Zool., MSU, East Lansing MI 48824.

At stage 24 (before neural crest migration) aneural Ambystoma maculatum embryos were prepared by surgical removal of all presumptive neural tissue. These experimental animals as well as normal embryos were then allowed to develop in sterile Steinberg's solution. At intervals throughout development sample animals were fixed for electron microscopy and thin sections taken from the digits of the forelimb. Recognizable Merkel cells (mechanoreceptors) were found in all notch stage limbs. At this time, many of the Merkel cells had not acquired a fully differentiated appearance and in normal embryos only 5-10% of the Merkel cells had become innervated. By the four digit stage all of the Merkel cells in normal embryos were innervated. Even after 2-3 months of nervelessness, the aneural Merkel cells showed no obvious ultrastructural signs of breakdown; cell size and the number of dense core granules per cell were not statistically different from normal. In this case, it would thus seem that sensory receptor development and maintenance are not nerve dependent.

375 CHOLINERGIC INHIBITORY MECHANISM MATURES EARLY IN RAT. Carol Van Hartesveldt, F.-C.T. Chang*, and William Guido*. Dept. Psychol., U. Fla., Gainesville, Fla. 32611

The maturation date of a cholinergic system inhibiting behavior has been set at 20 days postnatal, based on evidence that scopolamine injected peripherally increases activity beginning at that age (Campbell et al., 1969). However, in the present experiment, scopolamine injected intracerebrally increased locomotor activity at 2 days postnatal. We injected 10 µg scopolamine in .2 µl saline, 20 µg scopolamine in .2 µl saline, or .2 µl pH-adjusted saline unilaterally or bilaterally into the caudate nucleus of 2-day old rats. We directly observed locomotor behavior for 30 minutes immediately after injection. Rats given scopolamine made significantly more coordinated "walking" movements of all four limbs and tail than did rats receiving saline. We conclude that a forebrain inhibitory mechanism is mature as early as 2 days postnatal in the rat, but cannot be demonstrated behaviorally by peripheral administration of scopolamine until later.

376 DEVELOPMENTAL CHANGES IN SYNAPTOSOMAL UPTAKE OF GAMMA AMINOBUTYRIC ACID IN RAT CEREBRAL CORTEX. A.D. Vanker M.B. Friend* and G.E. Duncan*. Biol. Dept., Georgia State Univ., Atlanta, GA, 30303.

The Na^+-dependent, high-affinity uptake of ^{14}C-gamma-aminobutyric acid (GABA) by suspensions of crude synaptosomal fractions derived from adult female and neonatal (1-3 days old) were measured.The incubation media were modified tris buffers containing either a high concentration (108mM, HNa) or low concentration (18 mM, LNa) of sodium ions. Each experiment was performed at six temperatures ranging from 10^o to 40^o. Cleland's computer program for enzyme kinetics analysis was used to determine the apparent V_{max} and K_m for GABA uptake. In all cases, V_{max} was directly proportional to temperature and was higher in the adult than in the neonate for both HNa and LNa. K_m values for the adult in HNa varied from 3.43 µM at 10^o to 6.91 µM at 40^o; in LNa the range was 5.71 to 8.47 µM. For the neonate, K_m varied from 1.50 to 3.45 µM in HNa and from 3.01 to 3.27 µM in LNa. However the increase in K_m was directly proportional to temperature only for the adult in HNa. Arrhenius plots using the values of V_{max} indicated that the activation energies (E_a) were similar for the adult and the neonate in both media although higher in HNa. van't Hoff plots of K_m indicated that, while the ΔH_m (the energy acquired during the initial interaction of GABA with the transport mechanism) was essentially the same for the adult (4.30 kcal) and the neonate (4.33 kcal) in HNa, ΔH_m were quite different in LNa (adult: 2.60 kcal; neonate: 0.7 kcal). These and other analyses indicate that the Na^+-dependent, high-affinity transport (uptake) of GABA by presynaptic neuronal elements undergoes changes during maturation, and that this transport process is more sensitive to sodium ion concentration in neonatal preparations.

377 THE PENTOSE PHOSPHATE PATHWAY IN REGENERATING SKELETAL MUSCLE. K.R. Wagner*, S.R. Max, F.C. Kauffman and C.L. Koski*. Depts. Neurology, Pediatrics, and Pharmacology and Experimental Therapeutics, Univ. Maryland Sch. Med., Baltimore, MD 21201.

Glucose-6-phosphate dehydrogenase (G6PDH) appears to be rapidly induced in rat skeletal muscle following injection of Marcaine, a myotoxic local anesthetic which causes widespread degeneration followed by regeneration of muscle fibers (Fed. Proc. 36:922, 1977). We have extended these studies on G6PDH and have measured the activities of additional enzymes of the pentose phosphate pathway, viz., the oxidative enzyme, 6-phosphogluconate dehydrogenase (6PGDH), and the non-oxidative enzymes, transketolase, transaldolase, ribose-5-phosphate isomerase and ribulose-5-phosphate-3-epimerase. The specific activities of G6PDH and 6PGDH increased 2 h after a single intramuscular injection of Marcaine, reached 6 times control by 8 h, and 9 times control by 24 h. Actinomycin D and cycloheximide both prevented the increase. Enzyme activities of mixed supernatant fractions from experimental and control muscles were additive. In addition, kinetic analysis revealed a marked increase in Vmax of G6PDH and 6PGDH, but no change in apparent Km. Isoelectric focusing of G6PDH demonstrated a single band with the same isoelectric point in supernatants from experimental and control muscles. The intensity (per mg protein) of the band increased progressively with time following Marcaine injection. These results support the hypothesis that enhanced activities of G6PDH and 6PGDH are attributable to synthesis of enzyme protein. Changes in activity 8 h after Marcaine treatment partly reflect infiltration of muscle by phagocytic cells as indicated by light microscopy and increased β-glucuronidase activity. The specific activities of the non-oxidative enzymes also increased following Marcaine injection, but to a much smaller extent than the oxidative enzymes. We postulate that increased activity of the pentose phosphate pathway is important for anabolic processes in the initial stages of muscle regeneration. (Supported by NIH grant NS 31142 and by the Muscular Dystrophy Assn., Inc.)

378 NEUROCHEMICAL CHANGES FOLLOWING PRENATAL IRRADIATION OF SQUIRREL MONKEYS. Lary C. Walker* and B. Kaack (SPON: A.A. Gerall) Delta Primate Center, Covington, Louisiana 70433.

According to tentative but widely used standards, any human fetus exposed to 10 rads or more during early pregnancy should be therapeutically aborted to avoid the possibility of a physically and mentally retarded child. Thus far, most experimental work on prenatal radiation effects on the brain has been done with rodents. For comparative reasons, increasing interest has been directed toward the squirrel monkey as a diurnal primate model for studying the effects of such environmental hazards as radiation on the development of brain mechanisms and behavior. The objectives of this study were to examine the effects of 10 and 100 R whole-body Co-60 irradiation during pregnancy on neurological maturation, sensory-learning-motor performance in relation to neurochemical and morphological changes in specific cortical and subcortical regions of the offspring brain at 30, 365 and 730 days of postnatal life. More specific aims of this phase of the study were to examine the effects of prenatal radiation on neurotransmitter and hormone interactions regulating specific categories of physiology and behavior.

Infant squirrel monkeys sacrificed at 30 days postnatally showed a slight dosage dependent decline in total protein levels across nine separate brain areas. In addition, the levels of the radiosensitive enzyme glycerolphosphate dehydrogenase were generally higher in the cortices of irradiated animals than in the controls. The magnitude and direction of prenatal irradiation effects on the cholinergic synthesizing enzyme, choline acetyltransferase and the hydrolyzing enzyme, acetylcholinesterase, depended upon the brain area studied and the time of prenatal irradiation. $Na^+ - K^+$ ATPase activity in three brain regions was compared among the control, 10 R and 100 R groups, and similar comparisons were made of the circulating hormones cortisol, T_3 and T_4. These changes in relation to behavior, physiology and morphology are currently contributing to the development of a clinical profile of the primate infant exposed in utero to Cobalt-60 radiation. (Supported in part by NIH Grant 1-R01-HD09942).

379 β-ADRENERGIC RECEPTOR: PRESENCE IN CORTEX AND CEREBELLUM OF NEWBORN RAT. Kenneth G. Walton, Edie Miller*and Ross J. Baldessarini. Mailman Research Center, McLean Hospital, Belmont, MA 02178.

Much evidence now supports the idea that the interaction between a β-adrenergic receptor and adenylate cyclase constitutes a portion of the postsynaptic response mechanism in noradrenergic neurotransmission. This idea is upheld by studies in brain as well as in the periphery. However, one area where the evidence in brain is not yet clear is the time of onset of β-adrenergic receptor-cyclase activity in the young rat. The iontophoretic studies of Woodward et al. (Brain Res. 34:73, 1971) appear to indicate that cerebellar Purkinje cells of the one-day-old rat are capable of responding to norepinephrine (NE) by the same cyclic AMP-mediated mechanism as the Purkinje cells of older rats, even though it is apparent that Purkinje cells of the newborn have not yet received their noradrenergic input from the locus coeruleus. Both this work and the recent studies of Coyle and Molliver (Science 196:444, 1977) showing what seem to be functional noradrenergic synapses in the cerebral cortex of newborn rat suggest that the cerebellum and cortex of the newborn should contain β-adrenergic receptor-cyclase to be consistent with the hypothesized role of this enzyme system in the postsynaptic response to NE. In earlier attempts to answer this question Schmidt et al. (Dev. Psychobiol. 3:53, 1970) found stimulation of cyclic AMP levels by NE in slices of whole brain only after 6 postnatal days, while Perkins and Moore (Mol. Pharmacol. 9:774, 1973) and Harden et al. (Brain Res. 125:99, 1977) found little evidence for stimulation of cyclic AMP synthesis in slices of cerebral cortex before the 5th postnatal day. Using minced preparations in the presence of the potent phosphodiesterase inhibitor 3-isobutyl-1-methylxanthine (IBMX), and measuring cyclic AMP directly by a binding-protein assay, we have found as much as 10-fold stimulation of cyclic AMP levels in cortex and cerebellum from one-day-old rat in response to 1 μM of the β-adrenergic agonist isoproterenol. Stimulation in the absence of IBMX was not always observed, but was sometimes as high as 3-fold. Reasons for the apparent descrepancy with the earlier observations are not clear, but probably are related to the different conditions of incubation and methods of assaying for cyclic AMP. The presence of the β-adrenergic receptor-cyclase system in cerebral cortex of newborn rat appears to support other evidence that noradrenergic synapses are functional at this time and thus is consistent with the possibility that noradrenergic pathways are involved in subsequent stages of cortical development, as suggested by the studies of Kasamatsu and Pettigrew (Science 194:206, 1976). The presence of this enzyme system in cerebellum at one day is consistent with the above-mentioned evidence that the receptor mechanism preceeds noradrenergic synapse formation on cerebellar Purkinje cells, a finding of potential importance to understanding the factors controlling synapse formation generally.

Supported by NIH Grants MH-16674, MH-25515, MH-74370 and a fellowship from the Charles A. King Trust (KGW).

380 UNCROSSED RETINOGENICULATE PROJECTIONS OF ALBINO VS. PIGMENTED A/J-+/c(N7) MICE. Irwin S. Westenberg. V.A. Hosp., Phoenix, AZ 85012.

A developmental abnormality associated with albinism in mammals involves reduced uncrossed retinogeniculate projections (RGP). The effects of mutant genes at the "C", or albino, locus are clearest when coisogenic albino and pigmented animals are compared. To date this approach has been applied only in the case of pigmented inbred strains of mice in which a spontaneous mutation to albinism has occurred. However, any inbred strain may be used; first an inbred albino is crossed with a pigmented animal, or a pigmented inbred animal is crossed with an albino. Then offspring of the cross are backcrossed to the inbred strain. Offspring of the backcross that carry one "+" (wild-type) gene and one mutant "c" (albino) gene at the C locus are selected for the next backcross to the inbred strain. Each subsequent backcross increases the coefficient of inbreeding. This technique is being applied by Wahlsten; he is introducing a "+" gene in the place of a mutant "c" gene at the C locus of inbred albino mice of the A/J strain. An initial cross, A/J x DBA, resulted in pigmented offspring. Each backcross to A/J resulted in albino and pigmented pups; the pigmented pups were always chosen for the next backcross. I have examined the uncrossed RGP of two littermate pairs from Wahlsten's seventh backcross to A/J, designated A/J-+/c(N7); their coefficient of inbreeding is 0.992. Each pair consisted of an albino and a pigmented littermate of the same sex; one pair was male (341 days old), and the other was female (350 days old). The right eye of each mouse was removed, and six days later the mice were perfused. Horizontal frozen brain sections were stained for degenerating optic tract processes and examined on slides coded to conceal each mouse's genotype. In each pair the albino's uncrossed RGP were smaller than those of its pigmented counterpart. The effects were similar to those observed in other, unrelated strains. Given the small number of subjects and the less-than-optimal coefficient of inbreeding, these results are preliminary. The important point is that anomalies associated with albinism can be studied with appropriate genetic controls in many species; one need not wait for spontaneous mutations in inbred strains. Limiting factors include the time required to produce a sufficient number of backcross generations (preferably 10 or more), the risk of reduced vigor with successive backcrosses, and the species for which inbred strains are currently available (rabbit, mouse, rat, guinea pig, hamster, dog, cat, etc.).

Mice were bred, enucleated and perfused in the laboratory of Dr. D. Wahlsten. Histology was performed by C. Kalaha-Brunst.

381 ACTION POTENTIAL MECHANISMS IN PROCESSES OF AMPHIBIAN NEURONS DEVELOPING IN CULTURE. Alan L. Willard* (SPON: S.L. Foote). Biology Dept. UCSD La Jolla, CA. 92093.

In mature neuronal somata the inward current of action potentials (APs) is carried by Na^+, Ca^{++}, or by both ions. In contrast, most neurites have propagated APs in which Na^+ carries the inward current. During development the ionic basis of somatic APs in amphibian neurons changes. The inward current is carried by Ca^{++} at stages when the cells first become excitable, by both Na^+ and Ca^{++} at later stages, and finally by Na^+ alone (1). The same sequence of changes in somatic excitability has been seen in vitro (2). The development of excitability in neurites has not been previously examined. Here I report that APs in neurites of cultured amphibian neurons depend on Na^+ at a time when somatic APs depend on Ca^{++}.

Cells from neural plates of Xenopus laevis were dissociated by exposure to Ca-Mg^{++} free saline and grown in sterile Steinberg salt solution plus 0.1% Bovine serum albumin as previously described(2). Isolated neurons could be recognized by 6 hrs after plating. A single microelectrode was used to record intracellularly from the soma. APs were elicited both by current injection through the recording electrode and by extracellular stimulation of neurites with a glass pipet (2μm tip). Culture dishes were continuously perfused with salines of varying ionic composition.

Intracellular current injection produces 2 kinds of regenerative response in 12-20 hr old cultures. A larger one which appears to be the somatic AP overshoots zero, is as long as 600 ms in duration, and is blocked by 1 mM La^{3+}. Stimuli just at threshold also produce a smaller, briefer response without the larger one. Extracellular stimulation of the neurites leads to regenerative responses of the same amplitude and duration as this smaller response. Unlike the somatic AP, this response is blocked by Na^+ free saline. The latency of this response depends on the length of neurite between the soma and the stimulating pipet and it disappears when the pipet is displaced from the neurite by as little as 10 μm. In some cases neuritic stimulation produces an AP which appears identical to the large somatic AP, presumably due to excitation of the soma by the neuritic AP.

These results indicate that the inward current of APs propagated along neurites of cultured cells depends chiefly on Na^+ at a time when the somatic AP depends on Ca^{++}. Thus the Ca^{++} phase of membrane excitability either occurs at a different time or it does not occur at all. It seems clear that somatic and neuritic membranes are regulated separately during development. It will be of interest to study the control mechanisms by which this regulation is achieved. 382 AGING THEORIES: TESTS BY TWO-DIMENSIONAL PROTEIN MAPPING OF NERVOUS TISSUE. David L. Wilson, Michael E. Hall, and George C. Stone. Dept. of Physiol. and Biophys., Univ. of Miami, Sch. of Med., Miami, Fl. 33152.

An organism and its neurons are about the same age. Therefore, nervous tissue is especially useful for tests of aging theories. Using O'Farrell's (1) two-dimensional gel electrophoresis technique for protein analysis, with some modifications, we have compared the protein patterns for superior cervical sympathetic ganglia (SCSG) for young and old rats. Male Fisher rats with mean longevity of 640 days (2) were used.

Such aging hypotheses as error theories, the cross-linkage theory, the free-radical theory, the mutation theory, and the autoimmune theory predict changes in proteins or protein synthesis with aging. In brief, error and mutation theories predict charge changes (from amino-acid substitutions) in proteins; cross-linkage and free-radical theories predict increases in molecular weight (due to covalent linkages) of proteins; and the autoimmune theory predicts reduction or absence of particular protein species.

SCSG from young (2-4 mo.), adult (9-11 mo.) and old (22-24 mo.) rats were incubated in vitro for one hour in the presence of ^{14}C-leucine prior to protein extraction for two-dimensional mapping. Proteins were separated according to isoelectric point in one dimension and molecular weight in the second dimension. The changes predicted by the above aging theories were detected neither in the staining pattern, showing protein amounts, nor in the labeling patterns on autoradiographs of dried gels, showing newly-synthesized proteins. It is possible that other tissues would show such changes or that the kinds of changes predicted by the theories were too minor to be detected. Nevertheless, the results suggest that, at least for rat, some other mechanisms for aging are present.

Supported by NIH grant NS12393 and by a Biomedical Research Support Grant. MEH is a postdoctoral trainee (NS 7044). We thank M. Rockstein for the Fisher-strain rats.

383 AGING AND ADAPTATION OF DRINKING RHYTHMS IN RATS.
O.L. Wolthuis, D.L. Knook*, V.J. Nickolson* and I.F. de Koning*.
Medical Biol. Lab. TNO and Inst. for Exp. Gerontol. TNO,
P.O. Box 45, Rijswijk ZH, The Netherlands.

In a first study (Wolthuis et al., Neurosci. Letters 2, 243, 1976) acquisition of positively or negatively reinforced suppression of drinking was found to be deficient in old (30 months) rats compared with adult (18 and 12 months) or young (3 months) rats. The test situation was low in interference level, required little motor skill and measurements indicated that the deficits found could not be attributed to age-differences in activity.

The question arose whether age-related disturbances could also be demonstrated in more basic CNS-functions, such as in adaptation of diurnal or circadian rhythms of drinking activity to changes in lighting conditions.

Diurnal and circadian variations in drinking behaviour were investigated in two experiments with female rats of 3, 12 or 30 months old. After 6 days of a standard 12/12 h lighting schedule in both experiments, the rats were either exposed to a reversed light-dark lighting schedule or to continuous lighting for 18 days. Thereafter, they were again exposed to the standard 12/12 h lighting schedule for another 10 days in both experiments. The number of drink responses was sampled each 3 hours throughout the duration of the experiments.

Rats adapted their drinking behaviour rapidly when light-dark conditions were reversed and subsequently changed back to normal. No differences were found between the three age groups. When the normal light-dark conditions were replaced by continuous illumination, drinking activity showed a free-running circadian rhythm. In the young (3 months) and the adult (12 months) rats the period length of this circadian rhythm was 25.0 - 25.5 hours, whereas in old (30 months) rats the period length remained closer to the original 24 hours. In all animals the free-running rhythms persisted for at least 18 days, although the amplitude decreased. When lighting was switched back to the standard 12/12 h schedule, the young and the adult rats returned more quickly to their normal rhythms with a normal amplitude than the old rats.

It is concluded that, when the "Zeitgeber" is absent, old rats keep more closely to a pre-existing rhythm than young and adult rats, which suggests a greater behavioural rigidity in aged rats. In addition, old rats exhibit a greater negligence in drinking behaviour and a changed rest or sleep-wake pattern.

384 EFFECT OF CHRONIC INGESTION OF TRITIATED WATER ON PRENATAL BRAIN DEVELOPMENT.
Stephen Zamenhof and Edith van Marthens*. Mental Retardation Res. Inst., and Brain Res. Inst., Sch. Med., UCLA, Los Angeles, Ca. 90024.

In view of the anticipated increased use of atomic energy in industry, we studied the possible long term effects of chronic radiation exposure. Female rats were given tritiated drinking water [^{3}HOH; 3 μCi/ml (lower dose) or 30 μCi/ml (higher dose)] from adolescence (60 days) and throughout pregnancy resulting in a total exposure to 3.6 or 32.4 mCi over 54 days. No signs of radiation illness were observed. Gestation was prolonged at both dose levels. The ovulatory process (litter size) and pregnancy maintenance rates were normal. However, at both doses, the newborns exhibited highly significant decreases in body and brain weight, and brain cell number and protein, as well as increased vascular fragility (hemorrhages).

^{3}HOH administration at the respective doses was then continued throughout weaning and adolescence. Only during the first ten days of life (in F_1) a high mortality (33%) was found at the higher dose. At 30 days the decreases in protein content of cortex, midbrain and cerebellum were up to 37%, and in the cortical cell population up to 13%, indicating a severe reduction in cell size as well. At 90 days some rehabilitation in cortical weight and its total cell number was observed; yet, the midbrain and cerebellum remained decreased in these two parameters, for both dose levels. Protein synthesis remained severely inhibited in all brain regions.

Administration of ^{3}HOH was then continued at both dose levels throughout pregnancy. At the lower dose, all females had normal pregnancies. At the higher dose, a high incident of failure to maintain pregnancy, a significant decrease in litter size, and high (23%) incidence of still births was encountered. At birth, brain development of surviving offspring (F_2) was again highly significantly decreased at both dose levels. However, there was no more damage in F_2 than in F_1, i.e. there was no cumulative effect of radiation; high mortality and a selection for individuals less susceptible to radiation may be implicated.

All male offspring (F_1 adults) exposed to the higher dose were sterile, but there was no decrease in male fertility at the lower dose. The rate of accumulation of ^{3}HOH in maternal blood and rapidly multiplying tissues (placenta, fetuses) and in the amniotic fluid has been determined. Ova maturation and cell divisions in animals following chronic administration of ^{3}HOH have also been investigated. (Supported by ERDA grant E(04-3)-34.)

385 ACTIVITY IN THE DEVELOPING LATERAL LINE OF THE TADPOLE OF XENOPUS LAEVIS.
David McG. Zimmerman* (SPON: N. C. Spitzer).
Neuroscience Dept., UCSD, La Jolla, CA 92093.

The peripheral portion of the lateral line system in Xenopus consists basically of: 1)hair cells which transduce vibrations in water, 2)axons, whose cell bodies are centrally located, which transmit either afferent or efferent signals, and 3)synapses which carry the signals between hair cells and axons. Two questions about the development of the system are: When is it first active? What are the changes in its physiology over time? The preparation consists of an intact Xenopus tadpole whose post-orbital lateral line nerve has been exposed between the brain and the first sensory organ by means of a small window in the dorsal surface of the animal. The tadpole is immersed in Ringer's solution and viewed through a compound microscope. A suction electrode is used to record activity in the nerve. Stimulation is provided by a gated sinusoidally-vibrating needle applied to the sensory hairs.

The earliest stage at which activity has been previously reported is Nieuwkoop & Faber stage 54 (NF54)(26 days)(Shelton, JEEM 1970). Nieuwkoop & Faber state that the "lateral line system [is] becoming externally visible" at NF43 (Normal Table, 1967). I observe sensory hairs as early as NF41 and record afferent responses at the same time. I see efferent activity, evoked by stimulating another lateral line, as early as NF44. I also record spontaneous activity at these early stages.

Changes are seen in several properties. The duration of the action potential, as measured by the time between zero-crossings of the largest component of the tri-phasic potential recorded from afferent fibers of good signal-to-noise ratio, decreases from 2.3 ± .3msec at NF41 to 1.1 ± .1msec at NF47. The frequency response, measured as the highest frequency at which phase locking is seen, increases from approx. 100Hz at NF41 to >300Hz at NF47. Spontaneous activity increases as a function of stage; at early stages it is rarely seen and of low frequency if present.

The lateral line is thus responsive to stimulation at an early stage, apparently as early as the appearence of the sensory hairs. Since Chung et al. (Proc. R. Soc., 1974) were able to record visually evoked responses from the tectum no earlier than NF43, the lateral line appears to be the first system used to sense the distant environment. Several properties of the system change during development; in particular, the increase seen in frequency response indicates an increased sensitivity. Further investigation may reveal how each of the three elements are involved in producing these changes.

EEG AND EVOKED POTENTIALS

386 EFFECTS OF DISCRETE ELECTROLYTIC LESIONS ON SCALP-RECORDED AUDITORY BRAINSTEM RESPONSES. Joseph Achor* and Arnold Starr. Depts. of Psychobiology and Medicine, UCI, Irvine, CA 92717.

Discrete electrolytic lesions were made in acute experiments on adult cats to provide information about the generation of scalp-recorded auditory brainstem responses. Repeated recordings of monaural "click" evoked responses were obtained from a vertex-neck configuration for one hour prior to and following each lesion to ensure stability of lesion effects. Most of the lesions produced multiple effects in terms of amplitude changes. Few latency changes occurred. Determination of the generators was complicated by the lack of specific knowledge about which auditory structures were affected by the lesions. Most of the lesions interrupted fiber tracts as well destroyed nuclear structures. The most significant findings were the absence of evoked response changes with lesions of certain structures. A lesion in the cochlear nucleus which was confined to the dorsal division had no effect on the Auditory Brainstem Response. In another animal a lesion occupying about 50% of the central nucleus of the inferior colliculus produced no waveform changes during the 9.8 millisecond analysis epoch. A second lesion in that animal which destroyed two-thirds of the opposite central nucleus of the inferior colliculus produced minimal effects. No effect was seen with contralateral stimulation and only a small amplitude decrease in the peak at six milliseconds (Component 5 of Buchwald and Huang, 1975) was observed to ipsilateral stimulation. These results suggest that structures caudal to the inferior colliculus are the generators for the Auditory Brainstem Response. The absence of any effect with a lesion of the dorsal cochlear nucleus suggests that some of the elements of the auditory pathway do not contribute significantly to the scalp recording, even though they are positioned in the beginnings of the pathways.

387 ELECTROPHYSIOLOGICAL CONCOMITANTS OF THE "COROLLARY DISCHARGE" IN THE VISUAL SYSTEM.+ John S. Barlow and Janet Dubinsky. Neurophysiol. Lab, Neurol. Serv., Mass. Gen. Hosp., Boston, MA 02114.

In a multi-faceted study of oculomotor and EEG aspects of the "corollary discharge" in the visual system, postulated to maintain stability of the perceived visual world despite saccadic eye movements, recordings have been carried out under a number of different experimental conditions on a series of human subjects. Eye movement (monitored electro-oculographically and/or by the infrared technique /Biometrics eye-movement monitor/, multi-channel EEGs, and stimuli were recorded on magnetic tape (Ampex PR2200, 1/2-inch tape, 16-channel) or on an improved 24-channel cassette system (Electroenceph. clin. Neurophysiol., 1975, 38:183-186).

Preliminary findings include the following: (1) concordance between perceived direction of afterimage and actual eye position, when eyes open in the dark, as contrasted with discordance when eyes are closed, when gaze is alternated; the perceived excursion of the afterimage remains much the same whereas the excursion of the eyes tends to be larger and less precise when eyes are closed (a difference not ascribable to the EOG technique), suggesting a partial "decoupling" of oculomotor control with eyes closed in contrast to the effect of the "corollary discharge" on the direction of the perceived afterimage; (2) a more limited occipital distribution, and briefer duration, of potentials associated with horizontal alternation of gaze at a stationary pattern of vertical stripes or squares than when the pattern is shifted and gaze remains fixed; (3) results for congruent pattern shift with alternation of gaze (i.e., position of pattern controlled by eye position) resembles those for alternation of gaze alone rather than those for pattern shift alone; (4) a different form and distribution of potentials during reading (e.g., an occipital P300 wave) from that during alternation of gaze; (5) no EEG potentials associated with saccadic eye movements occur during alternation of gaze in total darkness, nor during simulated reading, whether or not an afterimage is present; (6) brief short-latency potentials limited to the occiput appear during the small rapid oscillatory eye movements of voluntary nystagmus, while viewing a patterned visual stimulus.

These findings tentatively suggest, among other conclusions, that (1) the "corollary discharge" in the visual system may already be operative in those parts of the visual cortex sampled by electrodes at the occiput; (2) its electrical manifestation is contingent upon an actual visual input, and (3) its end effect at a perceptual level is independent of whether the eyes are closed or open. 388 THE RELATIONSHIP OF EVOKED POTENTIAL CHARACTERISTICS TO TIME PERCEPTION JUDGEMENTS.[1] Ernest S. Barratt, Perrie M. Adams and James H. White.* Dept. of Psychiatry, University of Texas Medical Branch, Galveston, Texas 77550

Twelve adolescent males were studied in a psychophysiological procedure which involved time perception judgements and visual evoked potentials to different levels of stimulus intensity. The time perception judgements involved 3 modes: Estimation (subject estimates the length of time, 1 to 10 seconds inclusive, a light was presented to him), Reproduction (subject reproduces the interval of time just shown to him by the experimenter) and Production (subject produces the interval of time requested by the experimenter without giving a model of the interval). Each of the 10 time intervals was presented 3 times under each mode. All the trials for a given mode are presented together in a randomized sequence. Between the time judgement modes, visual evoked potentials were recorded at the vertex under different intensity levels. The subjects were then classified as either "augmenters" or "reducers" according to changes in the amplitude of the P100-N140 component across the 3 intensity levels. Comparison of time judgements for the 3 modes was then made on the basis of these evoked potential groups. Reducers (N=6) were found to be more accurate regardless of the judgement mode than were the augmenters (N=6). In addition, reducers would overproduce a given interval and underestimate the interval while the opposite was true for the augmenter. These results suggest that time perception judgement is sensitive to neurophysiological differences observed between individuals and should prove useful in the study of the relationship of cortical potentials to processes involved in attention and memory.

389 SOMATICALLY EVOKED MAGNETIC FIELDS FROM THE HUMAN BRAIN. D. Brenner*, J. Lipton*, L. Kaufman*, and S.J. Williamson*.(SPON: D. Yager). Neuromagnetism Lab., Dept of Physics and Psychology, NYU, N.Y., N.Y. 10003.

A magnetic field produced by electrical currents flowing in the human brain in response to a somatic stimulus has been detected for the first time. Repetitive transcutaneous electrical stimulation of a finger evokes a magnetic field on the contralateral side of the head. This field has been detected with a superconducting detector in an unshielded environment. The field pattern was mapped for stimulation of the little finger and to a first approximation is qualitatively similar to what would be produced by a current dipole source. The dipole would be located near the post central gyrus, oriented parallel to the scalp and perpendicular to the Rolandic fissure. Its location agrees with the location of the projection of the little finger on the somatosensory cortex (the "sensory homunculus"). Stimulation of the thumb produces a 2cm downward shift in the field pattern, again in agreement with the sensory homunculus.

Responses at the fundamental frequency for stimulus repetition rates between 18 and 30 Hz show little intersubject variability and can be characterized by a response latency of 70 ms. Between 3 and 18 Hz, subject responses show large differences. Motor reaction times of a simple pulse had an average value of 172ms. Based on a serial model, this gives a motor response time of 102 ms, a value close to the motor response time of 115 ms calculated for the visual system. (1) The significance of the variation of responses as a function of frequency is discussed in terms of fast and slow neuron types.

390 LONG-TERM CHANGES IN P3 AMPLITUDE AND SCALP DISTRIBUTIONS WITH EVENT REPETITION. Rachel Y. Courchesne*, Eric Courchesne, and Leo Ganz (SPON: J. M. Ford). Dept. of Psych., Stanford U., Stanford, CA 94305.

There are currently several reports on short-term changes in P3 amplitude with event repetition. Courchesne et al (1975) found a decrease in amplitude of frontal P3 waves elicited by repeated nontarget stimuli; Woods et al (1976) found an increase in amplitude of target P3 upon frequent event repetition, while Squires et al (1976) found a decrease in amplitude of P3 waves when target events are repeated with little or no interpositions. There are, however, no reports on long-term changes of P3 amplitudes with event repetitions. This paper studies long-term changes in the amplitude of P3 waves to target and nontarget events with event repetitions.

Subjects counted the number of presentations of target letter Bs (p = .10) which were interposed randomly in a sequence of tachistoscopically flashed background slides (letter As; p = .80). In some sequences, nontarget novels (unrecognizable slides; p = .10) were presented, while in others, nontarget dims (easily recognized, small letters C to Z; p =.10) were presented. The targets elicited high amplitude P3 waves maximal at Pz; neither P3 amplitude nor scalp distribution changed significantly across the first 16 target presentations. However, P3 waves to the dims and novels changed significantly. Dim events always elicited P3 waves, maximal at Cz and Pz. No significant changes in scalp distribution were found. However, P3 amplitude at all electrode sites (Fz, Cz and Pz) decreased at similar rates across the first 16 dim presentations. The P3 waves to the novel events, on the other hand, changed in complex ways. On the initial 3 trials, P3 waves were maximal over the frontal cortex. With each successive novel presentation, the P3 amplitudes decreased frontally and increased parietally; until, after 5 to 8 presentations, they were maximal over the parietal cortex. The data support the notion that there are several distinct types of P3 waves. The differences in the scalp distributions of P3 waves to novel and dim events apparently correspond to different modes of evaluating event content -- a "frontal" mode to process initially unrecognizable events and a "parietal" mode to process initially easily recognized events. With successive presentations of novel events, subjects may be developing "models" of these novel events, and, correspondingly, they may be employing successively different modes to process them. The changing scalp locus of maximum P3 activity may reflect these dynamic changes in the processing of the novel events.

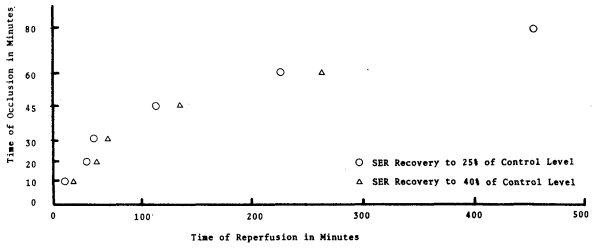
391 RECOVERY OF CORTICAL EVOKED RESPONSES AFTER CEREBRAL ISCHEMIA. Robert J. Gaudet* and K.M.A. Welch (SPON: P. Kellaway). Dept. Neurol., Baylor Coll. Med., Houston, Tx. 77030.

The ability of cortical electrophysiological activity to survive and recover from ischemia was investigated using the Mongolian gerbil. Somatosensory evoked responses (SER) were measured in groups of animals before, during and after various periods of total cerebral ischemia induced by temporary bilateral common carotid artery (CCA) occlusion. The animals were anesthetized with sodium pentobarbital (70 mg/kg), secured in a stereotaxic frame, and platinized-platinum ball electrodes were placed upon the cortical surface. Responses to hind leg electrical stimulation were amplified using Grass P511H pre-amplifiers and processed with a Nicolet averaging computer. A scalar value depending upon first component latency and the differentiated response amplitude was calculated for each averaged response. After control (pre-occlusion) measurements, the carotid arteries were occluded and SER measurements continued for periods of occlusion from 10 to 80 minutes and reperfusion for up to 9 hours. During occlusion SER's were bilaterally depressed with total loss of short latency (<60 msec) components. The effect of duration of ischemia on return of SER's with reperfusion is shown in the accompanying figure. Each point represents the mean of SER return to 25% or 40% of control values in at least 8 hemispheres.



Recovery of SER's and the time course of this recovery seem dependent on duration of ischemia. Data on SER recovery, when related to post-occlusion blood flow and cortical neurotransmitter levels, indicate prolonged alteration in neurotransmission after transient ischemia. (This work was supported by NIH NS 09287-07)

392 DIFFERENTIATION BETWEEN CNS DRUGS IN MACACA MULATTA ON THE BASIS OF STABILITY OF EEG POWER SPECTRA. John E. Gehrmann, James W. Havstad* and Keith F. Killam, Jr.*, Dept. of Pharmacology, School of Medicine, U.C.D., Davis, CA 95616.

We have previously shown that a wide range of drugs acting on the CNS can be differentiated and grouped by analysis of the power spectrum of the EEG (Federation Proc. 35:2258-2263, 1976). These discriminations and groupings were based mainly on the analysis of average relative spectral power in selected frequency bands. This provided an initial basis for classification. However, visual inspection of temporal sequences of spectra indicated that the relative stability of the postdrug state might be of additional utility in further distinguishing the action of CNS agents, especially with regard to the benzodiazepines.

Power spectra of 34 min. segments of spontaneous EEG were calculated for 4 second contiguous epochs with a resolution of 0.25 Hz from 0.25 to 64 Hz. From each of these spectra, the mean power spectral density within each of 5 one-octave bands from 2 to 64 Hz was calculated. The resulting temporal fluctuations in spectral power for 34 min. segments for each of these bands was plotted for visual inspection of relative stability, and the mean and standard deviation also calculated. For further quantitative characterization of relative spectral stability, the power spectrum of each of the spectral band time functions was computed from 0.25 to 250 milliHz.

Meprobamate, glutethimide and amobarbital produced large increases in spectral power and a state which was more stable than predrug (especially at frequencies above 16 Hz). Phenmetrazine produced no noticeable effect for either measure. In contrast, the benzodiazepines: clorazepate, chlordiazepoxide, halazepam, and clonazepam produced moderate increases in total spectral power but showed a marked decrease in the stability of the postdrug state, especially in the 8-15.75 and 16-31.75 Hz bands. Additional distinctions among the benzodiazepines are reflected in the nature of the instabilities of the power spectrum, especially with regard to the periodicities of the fluctuations in time. These are measured by the spectral analysis of the spectral band time functions. These might correlate with the degree of behavioral depressions observed after drug administration.

393 LOCALIZATION OF EXPERIMENTAL BRAIN STEM LESIONS IN CAT WITH MULTIMODALITY EVOKED POTENTIALS: CORRELATION WITH HUMAN HEAD INJURY EVOKED POTENTIAL DATA. Richard P. Greenberg and Donald P. Becker. Div. of Neurosurg., Medical College of Virginia, Richmond, VA 23298.

Multimodality evoked potentials, visual, auditory and somatosensory near field as well as auditory and somatosensory far field evoked potentials, were recorded from 51 comatose, severe head injury patients to locate areas of brain dysfunction not obvious from clinical evaluation (Greenberg, J. Neurosurg. 46, 1977). On the basis of this work in man we hypothesized that in head injury patients who had normal visual evoked potentials but absent or severely abnormal somatosensory and auditory near and far field evoked potentials brainstem dysfunction was marked and that cerebral hemispheric functions were relatively unaffected by the trauma.

To test this hypothesis experimentally the brainstem was completely transected (histologically confirmed) by radiofrequency lesions at the level of (1) the superior colliculi in 5 cats, (2) between the nuclei of the dorsal columns and the entrance of the eighth nerve in 5 cats and (3) the cervico-medullary junction in another 5 cats. Visual, somatosensory, near and far field (median nerve), auditory near and far field evoked potentials were recorded pre- and post-lesion in each animal.

Visual evoked potentials were unchanged from baseline regardless of the area of transection. Somatosensory potentials at approximately 4 msec, 6 msec, and 8 msec persisted after the superior colliculi transection while potentials beyond these latencies were abolished. With transection just caudal to the eighth nerve only potentials at 4 msec and 6 msec persisted. Following cervico-medullary transection all somatosensory potentials were extinguished. Auditory near field potentials were abolished after superior colliculi transection but not after transection caudal to the eighth nerve or at the cervico-medullary junction while auditory far field potentials persisted after all three transections.

These experiments suggest that multimodality evoked potentials are useful electrophysiologic tests with which to diagnose dysfunction of the human brainstem in vivo as they accurately reflect not just brainstem dysfunction but regional stem dysfunction allowing precise localization of injury in this area following head trauma. (Supported in part by N.I.H. grant NS12587 and a Southern Medical Association Training Grant).

394 EFFECTS OF ATTENTION AND STIMULUS SEPARATION ON THE AVERAGED VISUALLY EVOKED RESPONSE IN MAN. STEPHEN R. HARRIS, Psychological Consultant, 202 1/2 W. Washington Avenue, Jonesboro, Ark. 72401.

Averaged evoked cortical potentials (EPs) were investigated as a function of the attentional state and the subjects' (Ss') capacity to differentiate appropriate stimuli. Four adult human Ss viewed a small diffuse light stimuli (1° in diameter) in four positions (1°, 5°, 10° and 20° from the fovea). The stimulus to be attended was presented on one side of the display, and the nonattended stimulus was presented on the other side of the display at the same distance from the fovea. This left the separation between attended and nonattended stimuli either 2°, 10°, 20°, or 40°. The amplitude of the EPs was measured at the first major trough to peak deflection, the surface positive occurred between 150 and 200 msec following stimulation, while the surface negative peak occurred between 200 and 250 msec following stimulation. The data were quantified as percent difference in amplitude between attended and nonattended stimuli at each position. Analysis of variance indicated that the position of the stimuli was significant at the 0.025 level. It was concluded that attention may be studied effectively only when stimuli to be discriminated are presented to separate physiological systems or subsystems.

395 RELATIONS BETWEEN CORTICAL AND THALAMIC SOMATOSENSORY EVOKED POTENTIALS AT DIFFERENT FREQUENCIES OF STIMULATION. J.W. Hutchison* and J.A. Kusske. Neurosurgery Section, VA Hospital Long Beach and Div. of Neurological Surgery, UCI, Irvine, CA 92717

Evoked potentials and associated neuronal activity, induced by repetitive stimulation of the sciatic nerve with brief electrical pulses were recorded simultaneously from the somatosensory cortex, the ventroposterolateral nucleus and centre median nucleus, in cats under gallamine. The early component of the response, extending from the stimulus to 500 msec is of much higher amplitude than the late component, extending beyond the first 500 msec up to 2500 msec after the stimulus. For this reason the early and late components were analyzed separately at different magnifications. Averaging of the gross potential, post stimulus histograms of neuronal activity and autocorrelation studies show that, both in the early as well as in the late part of the response, the amplitude of the gross potentials, their rhythmicities and the probabilities of neuronal discharge with respect to time reach maximum values at specific frequencies of stimulation in the range of 0.25 to 12 pulses/sec. Relations between gross potentials and neuronal discharge within the cortex reach their highest cross correlation levels at specific frequencies of stimulation within the same range. Similarly the relations between gross potentials in the cortex and gross potentials in the thalamus, or between gross potentials in the two thalamic locations show their highest levels of correlation at specific frequencies of stimulation. These results suggest that the development of the somatosensory evoked potential and the associated neuronal response is related to the activity of cortical, thalamic and cortico-thalamic pathways which are most effectively "driven" at specific frequencies of stimulation.

396 CHANGES IN HEART RATE, RESPIRATION, AND EMG ASSOCIATED WITH OPERANT CONDITIONING OF 12-14 HZ SENSORIMOTOR ACTIVITY IN HUMANS. William J. Jackson, June O. Kearns*, Arden V. Nelson*, Dept. of Physiology, Medical College of Georgia, Augusta, Ga. 30902.

The neuroelectric activity of sensorimotor cortex has been controlled by operant conditioning or "feedback" techniques in a number of species, but most often in cats. The cat shows prominent trains of 12-14 Hz activity over the sigmoid (sensorimotor) gyri. Following operant conditioned enhancement of this "sensorimotor rhythm" (SMR), cats adopt a characteristic motionless posture and show decreases in muscle tone, heart rate, and rate of respiration. The clinical relevance of these findings came to notice upon the findings by Sterman and colleagues (Sterman and Friar, Electroencheph. Clin. Neurophysiol. 33:89-95 1972) that operant conditioning of 11-13 Hz sensorimotor activity reduced the frequency and severity of seizures as it had in cats. It is unknown whether there is a normal 12-14 Hz sensorimotor rhythm in humans. In humans, the 9 Hz rhythm "en arceau" or "wicket rhythm" is often presented as analogous to the 12-14 Hz rhythm in cats. However, it is also possible to record prominent trains of 12-14 Hz activity over the sensorimotor area in humans. We compared heart rate, rate of respiration, and submental EMG during alternating 5 minute periods during which the subjects first attempted to generate maximum 12-14 Hz activity and then later during 5 minute control periods. In contrast to the results of experiments using cats as subjects, we found that feedback enhanced 12-14 Hz activity over the sensorimotor strip was associated with increases in heart rate, increased amplitude of submental EMG, but decreased rate of respiration. The optimal site for recording 12-14 Hz activity was approximately 1 cm. posterior to Cz, C3, and C4. Recordings were between Cz-C3 and Cz-C4. It was possible to independently enhance the 12-14 Hz activity in both hemispheres, but somatomotor and visceromotor changes were equivalent regardless of which hemisphere was showing maximum 12-14 Hz rhythms. These results suggest that human 12-14 Hz sensorimotor activity is not associated with the same functions as 12-14 Hz sensorimotor activity in cats.

Supported by NIH-NINCDS contract #NO1-NS62340.

397 SOME EARLY COMPONENTS OF THE HUMAN MEDIAN NERVE EVOKED RESPONSE. M. Kalichman and P. Raudzens*. Dept. Pharmacology, Univ. of Toronto, Toronto, Ont. M5S 1A8 (Canada).

The human median nerve evoked response to electrical stimulation has recently been described in great detail by Goff et al (1977). This response was described as having 20 components between 13 and 513 msec. The latencies of these components may eventually provide a valuable tool for non-invasive quantification of central nervous system (CNS) drug levels; diagnosis of CNS disorders; and monitoring of CNS activity.

In order to exploit the evoked response for these possible advantages, 2 initial steps were required. First, a specific part of the evoked response had to be chosen for optimizing drug sensitivity, reproducibility, and ease of recording. Based on these criteria, it was decided to use the interval 20-45 msec. after the stimulus. Secondly, analysis methods were selected for optimal reduction of non-stationary sources of evoked response variation (e.g. subject movement, electrical artifact, shifts in evoked response latencies). Two methods were chosen to meet this criterion. The first, adaptive filtering (Woody, 1967), will ideally align variable latency signals before averaging. The 2nd method was developed to sort out anomalous evoked responses according to cross-correlation coefficient magnitudes derived from the adaptive filter.

The median nerve response was recorded from 8 different subjects in 18 experimental runs. Recordings were T5-Fp1 (T6-Fp2 for dominant hand stimulation of left-handed subjects). Each experimental run resulted in 20 sets of 100 responses. The 2000 stimuli were 0.5 msec. monophasic pulses (5/sec.) with sufficient intensity to elicit a thumb twitch. Various versions of the 2 analysis methods were used on the sets of data (each stored as 10 averages of 10 responses). With each analysis method, 20 estimates were made of P25-N35 latency or P30-N35 latency. These groups of 20 numbers were each analysed for variability as a characterization of that particular analysis method.

Results:

1. For the above conditions, neither method resulted in improvements over averaging.
2. It has been suggested that not all individuals will present distinct P25 and P30 components (Giblin, 1964). This work suggests that this is not all-or-none between subjects

398 THE EFFECTS OF STIMULUS PATTERNING ON EVOKED POTENTIALS. Zaven S. Khachaturian, Richard R. Bishop*, Kurt L. Reisler*, Dept. Psychiatry, Univ. Pgh. Sch. Med., Pgh., PA 15261, and Dept. Elec. Eng., Penn State Univ., Univ. Park, PA 15802.

In an earlier study we observed that the waveform of evoked potentials (EPs) elicited by habituated stimuli were significantly influenced by the specific patterning of these stimuli. In order to study the influence of "expectancy" as a possible explanation, we investigated this phenomenon further in four chronically implanted cats. During 3-hour daily sessions for five days, the animals were habituated to light and click stimuli alternating at the rate of one/second. Subsequently, one of these stimuli (e.g., light) was presented in six different patterns against a background of continuous presentation of other stimuli (e.g., click) at the rate of one per two seconds. The distinguishing characteristics of the patterns were the number of stimuli (2^0, 2^1, 2^2, 2^3, 2^4, 2^5) presented in a train. During testing each of the six patterns was repeated 25 times in a randomized order at varied intervals. After 150 trials the stimulus modalities were reversed so that the formerly background repetitive stimulus became the "patterned" stimulus and vice versa, and the same procedure was repeated for another 150 trials. The EPs elicited by both the "patterned" stimuli as well as the background "non-patterned" stimuli recorded during the trial were averaged (N=25). The averaging was carried out so that the fidelity of the temporal order of the EPs was maintained, i.e., the 1st, 2nd, 3rd, nth EPs were averaged separately. The results indicated that in most structures the waveform of EPs are markedly influenced by the patterning of a physically constant stimulus. Along the primary sensory pathways these effects were particularly noteable in the EPs elicited by inappropriate modality stimuli e.g. auditory EPs recorded from visual cortex or visual EPs in MGN. These changes were complex, including component morphology, latency and amplitude. Unlike the human EP studies these changes were not limited to the late components (P300) but were present at earlier latencies.

These results indicate that late component changes observed in human scalp EP usually associated with complex psychological processes, have their origins in subcortical structures and may have more parsimonious neurophysiological explanations.

399 THE SPATIAL AND TEMPORAL PATTERN OF ALVEAR TRACT EVOKED POTENTIAL AND CURRENT FIELD IN THE HIPPOCAMPUS OF ANESTHETIZED RATS. L. Stan Leung. Dept. Physiol.-Anat., Univ. Calif., Berkeley, CA 94720

The alvear tract in the dorsal hippocampal CA1 region of anesthetized rats was stimulated electrically and the averaged evoked potential (AEP) field was mapped in the coronal, horizontal and sagittal planes. A clear topographical mapping was shown between dorsal CA1 and the alvear tract. From the depth AEP, the current vector field and current source-sink density maps in different planes, at least three events can be distinguished. The first event was the action potential invading the pyramidal cell bodies. The second event overlapped the first one spatially and temporally, and was marked by the increase of current source density at around the pyramidal cell layer. The third event was long-lasting (up to 200 msec) and was characterized by sources above and sinks below the pyramidal cell layer. Simultaneous post-stimulus time histograms showed pyramidal cells firing at the first and beginning of the second event. Inhibition, if any activity, was observed during much of the third event. These results are discussed in light of our current knowledge of hippocampal functional organization. Supported by MH06686.

400 SPATIO-TEMPORAL INTERACTIONS IN THE VISUALLY EVOKED POTENTIALS OF HUMAN STRABISMIC AND ANISOMETROPIC AMBLYOPES. Dennis M. Levi* and Ronald S. Harwerth* (SPON: S. J. Cool). University of Houston, College of Optometry, Houston, TX 77004.

Steady-state visual evoked potentials to the appearance/disappearance of sinusoidal grating patterns were recorded at temporal frequencies of 4Hz to 32Hz in amblyopic and non-amblyopic subjects. The averaged evoked potentials were evaluated via Fourier analysis. For a given spatial frequency, the responses of the non-amblyopic eyes are characterized by a log-linear relationship between the evoked potential amplitude and the grating contrast, over a range of about 1 log unit above threshold. The contrast responses of the amblyopic eyes show a lower slope and a higher saturation point than the non-amblyopic eyes. Additionally, the data show that the responses of the amblyopic eyes are reduced in amplitude, across the spatial frequency spectrum, with the differences between the two eyes increasing as a function of spatial frequency. Spatial tuning also varies as a function of the temporal frequency of the stimulus. Differences in spatio-temporal properties of the amblyopic and non-amblyopic eyes are considered in relation to neurophysiological studies of amblyopia in cats and monkeys.

401 POWER SPECTRUM ANALYSIS OF EEG AND AUTONOMIC CORRELATES OF TONE-INDUCED AWAKENINGS FROM SLEEP. Arnold Lidsky, E. A. Sersen,* J. Clausen*, D. Anderson*. N.Y. Institute for Basic Research, Staten Island, N.Y. 10314

Following four nights of uninterrupted sleep, during which vertex EEG, EOG, and autonomic functions were monitored, 10 young adult humans were stimulated on two consecutive nights by tones of increasing intensity until a key press response was performed. Twelve awakenings, in addition to pre- and post-sleep thresholds, were obtained on each night, with stimulation commencing early in the appearance of each of five sleep stages (1-4 plus REM). Percentages of sleep stages did not differ significantly between awakening and uninterrupted nights, while heart periods increased significantly on awakening nights, with stages retaining the same rank orders; i.e. longest periods for stage 2, shortest for awake and slow wave stages (3 & 4). Awakening reaction times were shortest for stages 1 and 2, followed by REM, and longest for stages 3 and 4.

The EEG power spectra were obtained by Fourier analyses of the frequency range of 1-32 cycles per second, with results summarized over six clinically relevant bands. Analyses of variance for each frequency band, including EEG data from prestimulation through five seconds postawakening latency in all stages, indicated significant differences between stages, up to 14 cycles per second. Stages 3 and 4 showed their peak power an 1-2 cycle/sec, and greater power than other stages for the delta, theta, and alpha ranges. Stages 1 & 2 had their peak powers in the theta range, while REM power declined monotonically with increasing frequency bands. In addition to sex effects and interactions, EEG power changes as a function of temporal proximity to initial tones and awakening latencies are of particular note. Relative to pre-stimulation segments of each sleep stage, power increased consistently with the onset of auditory stimulation, and generally decreased at least five seconds before awakening. While these events were consistent for the 1-12 cycles per second bands, the magnitudes of the changes increased from the alpha to theta to delta ranges. Furthermore, the latencies of power increments with stimulation (and decrements near awakenings) were inversely related to frequency band category; i.e. largest and earliest rises in the 1-2 cycle per second band. The meaning of EEG Power is discussed in relation to brain functional integrity.

402 EVOKED POTENTIAL CORRELATES OF DELAYED MATCHING IN ADULTS AND CHILDREN. Eileen B. Maisel* and Robert W. Thatcher (SPON: E. R. John). Dept. of Psych., N.Y.U. Sch. Med., New York, N.Y. 10016

Adults and children were tested in a delayed matching-to-sample task using upper and lower case letters of the alphabet. On each trial, a variable number of random dot patterns (control displays) were followed by a letter (standard) and more random dot patterns (inter-information-interval displays, ITIs). A comparison letter was presented last. Comparison letters matched or mismatched the standard. On match trials, the standard and comparison were either physically identical (both upper or lower case letters), or nominally identical (one upper and one lower case letter).

All displays were computer generated and presented in counterbalanced order at a repetition frequency of 1.1/sec. All stimuli were equated for intensity and visual angle and were 20 msec in duration. Participants were instructed to press one lever if the comparison display had the same name as the standard and another lever if it had a different name. Evoked potentials elicited by the displays were recorded from 11 monopolar derivations and a transorbital eye lead. In both adults and children EP waveforms elicited by comparison letters which matched the standard differed from EPs elicited by identical letters which mismatched the standard. In addition, there were differences between nominal identity and physical identity matches and between control and ITI random dot patterns. These effects were observed primarily in the late positive components of the EP.

403 HUMAN EVOKED RESPONSES TO COMPLEX VISUAL STIMULI. H.J. Neville*, E. Snyder, D.L. Woods*, C. Schulman-Galambos and R. Galambos. Dept. Neurosci., UCSD, La Jolla, Calif. 92093 (SPON: R. Galambos.)

This study was designed to see if late components of the human visual evoked response (VEP) to complex visual stimuli show reliable changes with cognitive variables in a no-task situation.

Young adults viewed equal numbers of colorful slides and flashes randomly intermixed. Slides showed pictures of people, places, etc. At the end of the session (128 slides) Ss rated each slide on a scale from 1-7 for "interest" and "surprise", and reported whether they had recognized the person or place in the picture when they first saw it.

VEPs were recorded from 3 midline and 1 ocular site, all referenced to the right mastoid. For each S VEPs were averaged separately for interest and surprise ratings and according to whether the person or place was recognized.

Late VEP components showed large and consistent variations depending on Ss reports of surprise, interest and recognition. The amplitude of P3 (400 msec) was more than twice as large for stimuli rated high than for those rated low on surprise. Slides which rated medium on surprise resulted in P3's of intermediate amplitude. The amplitude of N3 (500msec) also showed a monotonic relation with ratings of surprise: it was more than 10 times larger in VEPs to pictures rated low than high on surprise. While less robust, VEPs for high, medium, and low interest showed similar variations.

Slides "recognized" evoked P3's which were on the average 4 times larger than similar, unrecognized slides; each of 7 subjects tested to date has shown this effect. All VEP variations observed were largest and most consistent at frontal, rather than central or parietal scalp sites.

The fact that late components of the VEP show large and reliable changes with certain cognitive variables in a no-task situation suggests such paradigms may find useful application in clinical populations.

404 VER NONLINEARITIES WITH EQUAL-LUMINANCE CHROMATIC STIMULI. Gregory Phillips*, John Trimble. Depts. of Ophthalmology and Theoretical Biology/Biophysics, Univ. Chicago, Chicago, IL. 60637

Recent psychophysical and electrophysiological studies support the idea of chromatic and achromatic channels within the visual system. Furthermore, it appears as though these channels may have different temporal dynamic characteristics.

Thus far, few attempts have been made to study these channels using the visual evoked response (VER). Regan (Vis. Res.,13,1933, 1973) reported a VER correlate of stimulus wavelength which appeared to be qualitatively different from that of stimulus luminance. Van Hoek (Vis. Res.,16,205,1976) also provides VER data suggesting nonlinear interactions between color and luminance signals.

In an attempt to further clarify the temporal dynamic characteristics of chromatic and achromatic channels, we have applied the technique of white-noise analysis to VERs produced by pure chromatic stimuli.

Light from a red (660 nm) and green (565 nm) light-emitting diode was combined in a two-channel Maxwellian optical system. The subjective luminances of the LEDs were equated using heterochromatic flicker photometry. Keeping the mean luminances of the LEDs constant at these values, their intensities were modulated in counterphase by band-limited Gaussian noise. The first- and second-order Wiener kernels were then calculated for the VER to this stimulus using the fast Fourier transform.

For comparison purposes, kernels were also calculated for the red and green stimuli presented individually with the same mean luminance and dynamic range.

Kernels obtained for pure chromatic stimuli indicate that this channel has a lower bandwidth and significantly less nonlinear interaction than the achromatic channel. This finding is discussed in light of a model describing the temporal dynamics of VER mechanisms.

405 EFFECTS OF MATERNAL PROTEIN DEFICIENCY UPON THE DEVELOPMENT OF AUDITORY BRAINSTEM RESPONSES IN RATS. Robert G. Plantz*, Don L. Jewett, and John S. Williston. Dept. Ortho. Surg., Sch. Med., UCSF, San Francisco, CA 94143 (SPON: R. H. Steinberg)

Two groups of timed-pregnant Sprague-Dawley rats were placed on either 8% or 24% protein diets on their fifteen day of pregnancy and continued on the diet after delivery. Four litters from each group were cross-fostered and the pups tested for their auditory brainstem evoked responses 8 times beginning at 16 days of age and continuing until day 43. Animals were anaesthetized with gaseous halothane and unilaterally presented with 60 db SL clicks. Signals were averaged from needle electrodes inserted into dorsal midline scalp and just below the pinna of the stimulated ear. Mean peak latencies for the first four waves were compared between groups using the Wilcoxson sum of ranks test. On days 16, 18, and 20 all four waves had significantly longer latencies in the undernourished groups than the controls ($P<.002$ for all waves). This difference decreased until day 43 when only wave IV was significantly slower.

An examination of other variables revealed an inverse correlation between body size and wave latency in the deprived group but not the control group. This suggests that development of each of the deprived group was limited by the amount of nourishment each received while the control group received enough nourishment to ensure normal development and also to build up body fat. An inverse correlation between body temperature and wave latencies was significant and suggested that the undernourished pups, which had lower body temperatures under anesthesia during recording than did the controls, may have had slower latencies because of their cooler temperatures. A second study was run with 7 new litters (4-24% and 3-8%) of animals, using the same procedure as before with the exception that body temperatures were held at 36°C for both groups using a water heated pad. These pups were run on their seventeenth day only and showed that while differences between groups were slightly smaller, they still differed significantly for all four waves (<0.05 for wave I and <0.01 for all other waves).

For reasons enumerated in a previous study (Jewett and Romano Br. Res. 36:101, 1972) these data cannot answer the question of whether the locus of the site of the effect occurs at the recep tor, in the central nervous system, or both. They do however indicate that in the rat neonate, undernutrition does effect early sensory pathways in a way that can be detected by far field evoked response averaging.

406 FOCAL RADIATION AND THE BLOOD BRAIN BARRIER. Michael P. Remler. Dept. of Neurology, State Univ. at Stony Brook, NY 11794.

Adult cats with chronic epidural electrodes were given between 250,000 and 1,000,000 U. of parenteral Penicillin G before and in test doses for one week after focal cortical irradiation of 4000 Rads. EEG's recorded during penicillin administration showed focal epileptiform spikes from irradiated area (Conf. Neurol. 35:50, 1973). Histological examination showed no significant changes. This is interpreted as the radiation causes physiologic disruption of the Blood Brain Barrier without fixed anatomical distruction. The penicillin crosses the Blood Brain Barrier only in the irradiated area and causes the epileptic discharge. This supports other evidences that radiation may affect the Blood Brain Barrier at doses below the histologically lethal or visable range.

407 SENSORY FIELD POTENTIALS AS A TOOL TO MONITOR LEVEL OF KETAMINE INDUCED ANESTHESIA. B.M. Rigor* and N. Dafny (SPON: W.A. Weems). Departments of Anesthesia and Neurobiology, The University of Texas Medical School, Houston, Texas 77030.

The effects of 10 incremental doses of ketamine on photic and acoustic evoked responses were determined in five brain sites in freely behaving rats. Permanent semimicroelectrodes (60 in diameter) were implanted stereotaxically under pentobarbital anesthesia within the inferior colliculus (IC) and lateral geniculate body (Lgb), the primary relay sites for acoustic and photic input, respectively. Three additional electrodes were placed in the mesencephalic reticular formation (RF), in the ventromedial hypothalamus (VMH) and within the somatosensory cortex (SC). Following recovery from surgery (6-8 days) the averaged acoustic and photic field potentials following 32 repetitive stimuli were averaged as one set using a 1070 NIC minicomputer. Four sets were recorded at 10 minute intervals before and after each injection. Ten doses of ketamine were studied: 1; 5; 10; 20; 40; 60; 80; 100; 120 and 140mg/kg i.p. Each animal was tested twice with one week interval. In each experiment only 5 randomly selected incremental different doses were used. The dose which induced surgical anesthesia was found to be 80mg/kg i.p. Differences in the number of ketamine-induced changes in sensory field potentials were observed between the photic and acoustic input, where the acoustic evoked responses were more sensitive and exhibited dose-dependent responses, particularly in the SC. The lower subanesthetic doses of ketamine (<80mg/kg) induced depression of the responses while higher doses (100-140mg/kg) induced increases in the response amplitudes, shifted the amplitude to the right (longer latency) and prolonged the duration of the responses. However, the responses from the sensory relay nuclei were affected by the initial dose of 1mg/kg and remained about constant following the remaining doses. The RF and VMH were affected differently by ketamine. In conclusion, the acoustic evoked responses from the SC can be used as an indication of the level of ketamine anesthesia.

408 EVOKED POTENTIAL MEASUREMENTS SUGGESTING LATERALIZED HEMISPHERIC DYSFUNCTION IN CHRONIC SCHIZOPHRENICS. Richard A. Roemer and Charles Shagass*. Eastern Pennsylvania Psychiatric Institute and Temple University Health Sciences Center, Philadelphia PA 19129.

Evoked potentials (EPs) to checkerboard pattern-onset (VEPs), auditory clicks (AEPs), and right and left median nerve (SEP) were obtained from 25 chronic schizophrenic patients and equal groups of nonpsychotic inpatients and nonpatient controls (matched for age and sex). Measurements of EP amplitude and wave-shape variability over time were computed. These were analyzed to determine (a) the extent to which the groups differed with respect to these measures on individual leads for each stimulus type; (b) group differences in measures of hemispheric lateralization, based upon differences between EPs from homologous leads over the two hemispheres for each stimulus type.

EPs were obtained from 14 scalp and one EOG lead. Amplitudes for two epochs (50-150, 151-450 msec for VEP, or 15-100 and 101-450 for AEP and SEP) post-stimulus were computed by Shagass' average deviation method. Variability for these epochs was determined by calculating the correlation between corresponding data points for four consecutive averages; these r's were transformed to Zr for statistical analyses.

Multivariate profile analyses, on the Zr after adjustment for covariance with amplitude and EOG, revealed a number of significant differences. The differences with VEPs and AEPs were due to increased left hemisphere variability in the temporal and occipital areas of chronic schizophrenics. The SEP differences revealed a more stable early response (15-100 msec) and a more variable late response (101-450 msec) at the central leads. None of the differences were related to handedness. The results confirm several earlier reports of greater EP variability in chronic schizophrenics, and demonstrate one kind of relative left hemisphere dysfunction in these patients.

This research is supported (in part) by a grant, MH12507 from the U. S. Public Health Service.

409 ELECTROPHYSIOLOGIC STUDIES OF MULTIPLE SCLEROSIS. V.S. Rossiter, M.L. Tracy*, M.E. Seybold, J.A. Aalbers* and J.J. Stockard. Dept. Neurosciences, UCSD Medical School, La Jolla, CA 92093.

A battery of five electrophysiological tests were performed on 20 neurologic patients with known or suspected multiple sclerosis (MS). Diagnostic classification of possible, probable or definite MS was determined according to McAlpine's criteria (McAlpine et al Multiple Sclerosis: A Reappraisal, 1972). Tests included Brainstem Auditory Evoked Responses (BAER's), Pattern Shift and Diffuse Photic Visual Evoked Responses (PS VER's and DP VER's, respectively), Blink Reflexes and Electrooculograms (EOG's). Sampling was biased to the extent that patient selection was based primarily on history or presence of neuro-ophthalmologic abnormalities, and 19 of 20 patients had clinical evidence of optic neuritis and/or internuclear ophthalmoplegia (INO).

Results are presented in the table below. Eight patients were given a diagnosis of possible MS, 4 patients were probable MS candidates and 8 patients were given a diagnosis of definite MS. Only one patient (possible MS) had normal results on all tests. Patients with a diagnosis of probable or definite MS had abnormalities on two or more tests. PS VER's were superior to DP VER's in assessing lesions of the optic tract, and EOG's were effective in assessing INO's. BAER's were most effective in detecting "silent" lesions in the brainstem auditory pathway. Blink reflexes were abnormal in only two patients and were least effective in confirming the diagnosis of MS. Our findings suggest that a battery of electrophysiologic tests, including BAER's, PS VER's and EOG's can be a useful adjunct in the diagnosis of multiple sclerosis.

		Abnormal Test Results				
		BAER's	VER's		EOG	BLINK
Diagnosis			PS	DP		
Definite MS (n=8)		6	2	3	7	2
Probable MS (n=4)		3	1	0	4	0
Possible MS (n=8)		1	5	2	5	0
TOTAL:	20	10	8	5	16	2

410 AN ELECTROENCEPHALOGRAPHIC RESPONSE SPECIFIC TO DBA/2 MICE. Lawrence J. Ryan* and Seth K. Sharpless. Dept. Psych., Univ. Colo., Boulder, CO 80309.

We have identified bursts of regular, high amplitude spikes in the cortical EEG of adult (60-70 day) DBA/2Ibg mice which are not associated with overt seizures or myoclonic jerks. These episodes are unique enough that DBA mice may be distinguished from mice of the other strains tested by visual examination of their EEGs. The spikes have a frequency of 6.9-7.8 Hz with each episode lasting 0.3-5.0 seconds. Of the 15 DBA mice of this age tested, all displayed at least 9 episodes with a maximum of 52 and an average of 20.3 during a thirty minute recording session. Injection of 30 mg/kg Metrazol, ip, increases the episode's frequency of occurrence. The spike episodes were observed in both restrained and freely-moving mice. Body movements occurred during only 3% of the episodes, but were recorded preceding or following (±5sec.) over 42% of the bursts.

During an episode the spikes are bilaterally symmetrical, occur simultaneously and with the same polarity frontally and posteriorly, and reverse 3mm lateral to the midline. Single spikes occasionally appeared frontally but seldom posteriorly.

To test if these episodes relate to DBA's seizure susceptibility during early life, a preliminary developmental study was begun. Initial results indicate that the episodes are of lower amplitude and are less well organized in 21 and 26 day animals but have a more adult appearance at 32 and 37 days.

Three additional strains were tested to determine the generality of the phenomenon. These spike episodes were not observed in C57BL/6Ibg (N=11) or BALB/c(N=14) mice. Similar episodes which occurred much less often (2.56 episodes/30 minutes), with a lower amplitude and a shorter duration were identified in 6 of 9 C3H mice tested.

DBA mice, then, display a distinct cortical EEG pattern which does not occur in two strains (BALB and C57) and occurs less often and less distinctly in another (C3H). The response's amplitude (5-10X ongoing activity) and frequent occurrence make the spike episodes a conspicuous cortical event warranting further examination.

This research was supported in part by the Council for Tobacco Research Grant 1076.

411 BRAINSTEM EVOKED RESPONSE AUDIOMETRY IN NEWBORN HEARING SCREENING. C. Schulman-Galambos and R. Galambos, Dept. Neurosciences, U.C.S.D., La Jolla, Calif. 92093

Brainstem evoked response audiometry (BERA) has been used as an auditory screening procedure in three groups of newborn infants. Group I consisted of 220 normal term babies tested within 72 hours of birth; no hearing abnormalities were uncovered (386 ears) and their threshold response (for clicks) lay between 10 and 20 dB HL (re adult). Group II consisted of 75 newborns treated in an intensive care unit for 1-14 weeks; 4 were found to have severe sensorineural hearing loss (7 ears) at the time of discharge. Group III consisted of a subgroup (35) of 325 infants one year or older who had previously been discharged from the same intensive care unit; of these an additional 4 showed severe sensorineural hearing loss. All abnormalities identified by BERA were subsequently confirmed by conventional audiometric measures. The estimate of an incidence of severe hearing loss in 1 of 50 babies who required intensive care in the neonatal period calls for careful testing of this population .

412 EFFECTS OF REPEATED ADMINISTRATION OF d-AMPHETAMINE ON THE OCCURANCE OF THE SENSORIMOTOR RHYTHM (12-14 Hz.) IN CORTICAL AND LIMBIC AREAS OF THE CAT. J. Marc Simard*, Calvin C. Turbes, Gerald T. Schneider* (SPON: J. F. Masken). Creighton Univ., Omaha, NE 68178.

The Sensorimotor Rhythm (SMR), recorded from the sigmoid gyrus the septum and the amygdala (all ipsilateral) was studied by spectral analysis, prior to and following repeated administrations of d-amphetamine sulfate (d-A.) (2.5 mg/kg, I.P., each day for 3 days). Ongoing power spectral arrays before administration of d-A., during wakefulness, indicate that power in the 12-14 Hz. band is greatest in the sigmoid gyrus, least in the amygdala and of intermediate value in the septum. Cross-power spectra verify observations of the raw data that spindles of SMR activity often occur simultaneously in the 3 areas studied. Occurance of the rhythm is well correlated with behavioral freezing. During slow-wave sleep, the power relationship between the sigmoid gyrus and the septum reverses, when bursts of the septal rhythm may reach 400 μV. During these epochs, power in the SMR band in the amygdala generally increases.

After an initial injection of d-A., the cortical activity remains desynchronized, while the deep areas take on a slow-wave component correlated with respiration. After 3 days of daily administration of d-A., the slow-wave activity of the sigmoid gyrus is seen to alternate exclusively between a fast, low-voltage rhythm, and the 12-14 Hz. rhythm. The fast rhythm correlates behaviorally with movements or shifts in gaze, while the SMR rhythm occurs when a frozen or staring posture is assumed. Continuous trains of SMR activity of 60 sec or more are often observed seperated from each other by only 1-5 sec of desynchronized activity. Such high percentages of time spent in SMR activity are not observed before administration of d-A., or immediately preceeding the 3rd injection of d-A. The last observation would indicate that abstinence from food, due to d-A., is not the exclusive cause of the observed increase in SMR activity. Preliminary observations have also indicated that the onset and buildup of SMR trains occurs shortly after the animal is seen to freeze behaviorally.

413 SOMATOSENSORY EVOKED RESPONSE AND SENSORY THRESHOLD: DETECTION OF A PERIPHERAL EVENT. Hilton Stowell. Sensory Neurophysiol. Lab., CSH, Georgia 31062.

Event related brain potentials (ERBP), recorded on human scalp or superficial cortex, show ambiguous correlations with sensory thresholds. One subdural study of somatosensory evoked responses (SER) during thalamic nuclear and peripheral skin stimulation (Libet et al., ICS 253: 157-168, 1971) indicates that the primary positive of the SER, though necessary, is insufficient for an introspective, conscious recollection of sensation, and that backward masking of conscious sensation by direct cortical stimuli is effective up to 200 ms after the peripheral stimulus. I am now studying the scalp-recorded SER to subthreshold and threshold electrical pulse stimulation of digits, using a self-stimulation paradigm designed to optimize stability of attention, expectancy, and those task-related variables which are known to affect both sensory thresholds and the waveform of the 60-200 ms time-segment of ERBPs (Hillyard, PROC. NIMH-ERBP CONF. IV: 1-54, 1977). Subjects count the number of self-administered trials (32 per block) and report either the number or percentage of stimuli detected, together with open-ended descriptions of the spatiotemporal and qualitative aspects of sensation. In a control paradigm various percentages of supra-threshold stimuli are randomly injected by experimenter into a block of 32 no-stimulus trials. Under these conditions, the "vertex" positive wave (150-250 ms) is the only valid and reliable correlate of stimulus detection. However, the temporal relationship of averaged, transient (200-500 ms), 9-13 Hz periodicity to both SER primary positive and "vertex" positivity seems to covary with both stimulus parameters and subjective report of sensory quality and detectability.

It is important to note that these data refer to reports of recollected, conscious sensation and not to reaction times or forced-choices in a signal-detection paradigm.

414 EVOKED POTENTIAL CORRELATES OF LOGIC: NEGATION AND EQUIVALENCE.
Robert W. Thatcher and Eileen B. Maisel*. Dept. of Psychiatry and Brain Res. Labs., N.Y.U. Sch. Med., New York, N.Y. 10016

Seven adults were tested in a logic task. A given trial involved the presentation of a variable series of random dot stimuli then a letter (A,B,C, or D) followed by an operator sign (equals, =; not equal, ≠; or no operation, ⌐┘), followed by a second letter. The subjects were instructed to differentially move a two position lever depending on whether the statement formed by the operator and letters was "true" (e.g., A = A, A ≠ B), "false" (e.g., A ≠ A, A = B), or "no operation" (e.g., A ⌐┘ A, A ⌐┘ B). All combinations of letters and operators were presented and all conditions were counterbalanced across a session. The stimuli were computer generated, 20 msec in duration and presented at a repetition frequency of .66/sec. All of the displays were equated for intensity and visual angle (1.5°).

Evoked potentials (EPs) elicited by the displays were recorded from 11 scalp derivations and a transorbital eye lead. EPs elicited by letters in the "truth" condition were different than EPs elicited by identical second letters in the "false" condition. Likewise, EPs elicited by second letters in the "no operation" condition were different than EPs elicited by second letters in the "truth" and "false" conditions. Varimax factor analysis revealed a differential scalp topography for EPs elicited by controls, first letters, operators, and second letters. These analyses indicate extensive frontal lobe involvement.

415 USE OF A DISSOCIATIVE ANESTHETIC (CI 744) FOR UNCOUPLING COMPONENTS IN THE STUDY OF CAT BRAIN ELECTRICAL RHYTHMS.
C. Timo-Iaria, M. Kadekaro and F.A. Kutyna. Dept. Physiology and Pharmacology, Inst. Biomedical Sciences, Univ. of Sao Paulo, Cx. Postal 4365, Sao Paulo, S.P., Brazil and Uniformed Services University of the Health Sciences, Bethesda, MD.

The dissociative anesthetic CI 744* is a mixture of the phencyclidine derivative tiletamine hydrochloride (CI 634*) and flupyrazapon (CI 716*). In doses of 8-30 mg/kg injected intramuscularly it produces a rapidly-induced (1-2 min), relatively short-acting (0.5-3hr) dose related anesthesia characterized by a cataleptoid electroencephalographic (EEG) pattern. Recordings obtained among multiple sites on the cortex by chronically implanted electrodes showed that CI 744 induces a high voltage synchronization of EEG waves (1-3 hz band) in neocortical areas. Stereotaxically placed deep electrodes recorded similar waves from the reticular thalamus. EEG signs of recovery from effects of the anesthetic include a rapid change (30-60 sec) from almost exclusively slow wave activity to desynchronization typical to that of awakening. Spindling is never provoked by the drug in the intact brain but in animals with electrolytic destruction of midbrain ascending reticular activating system, the spindling as well as slow wave activity is increased. However, recruiting produced by low frequency electrical stimulation of the reticular nuclei of the thalamus is depressed by CI 744 but it blocked neither spindling resulting from interruption of ascending reticular activating system nor spindles elicited by pentobarbital. This evidence supports the concept that recruiting is probably an electrophysiological correlate of several neural activities, of which the spindles found in barbiturate anesthesia and the early stages of sleep are just one. Whereas EEG desynchronization could be induced during pentobarbital anesthesia by strong nociceptive stimulation, electrical stimulation of pain afferents and by electrical activation of the midbrain reticular formation, under CI 744 EEG arousal was entirely absent during these stimuli even though the flexion reflex and a pupillary reaction to light were clearly present. On the contrary, in lightly anesthetized animals a decrease in frequency of the basic slow wave pattern was the only EEG detectable response to arousing stimuli. This work partially supported by CNPq and FAPESP.

416 THE Q_{10} OF AUDITORY BRAINSTEM RESPONSES IN RATS UNDER HYPOTHERMIA.
John S. Williston and Don L. Jewett. Dept. Ortho. Surg., UCSF Sch. Med., San Francisco, Ca. 94143.

Changes in the latencies and heights of ABR (Auditory Brainstem Responses) in response to body cooling were studied in 38 Sprague Dawley rats ranging in age from 15 to 120 days. The animals were anesthetized with 2% gaseous halothane and presented 50μsec clicks at 10 to 80 clicks per sec, and at 10 to 60 db click intensities. Body temperatures were regulated by a temperature-controlled copper plate upon which the animals were placed. Signals were averaged by needle electrodes inserted into midline dorsal scalp at the interaural line and at the pinna of the stimulated ear.

Following a series of control recordings taken at 38°C the animal was cooled in stages and further records taken after body temperatures stabilized. Body temperature was monitored by thermocouples inserted into the ear canal of the nonstimulated ear (shown to be equivalent to intracranial brain temperature). Rectal temperatures were found to not accurately reflect temperature changes in the brain.

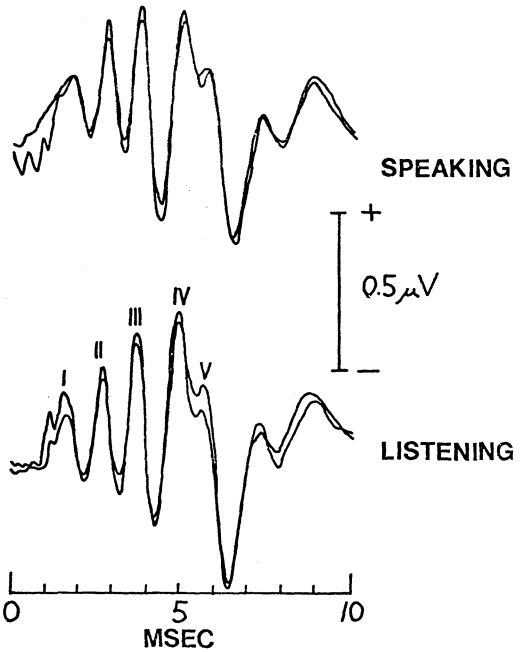
Although variability between animals was considerable (see ranges in Table I), there was very high repeatability in wave latencies and Q_{10} between runs taken at a constant temperature, high or low, in individual animals and changes in wave latency with cooling were very predictable within a single session. Changes in either repetition rate or intensity did not appear to interact with the effects of hypothermia. The large variability in these data suggest that it may not be possible to "correct" evoked response latencies for changes in temperature by the application of a single mean Q_{10} ratio obtained from a population, young or adult, despite the statistically significant change with age.

Table I. Q_{10} Values for Latencies of ABR Components at Different Ages.

Wave #	15-20 Days Old Median	(Range)	21-120 Days Old Median	(Range)	Wilcoxon's Sum of Ranks Test
I	1.87	(1.4-2.3)	1.63	(1.2-2.0)	P<.01
II	1.83	(1.5-2.4)	1.53	(1.4-1.8)	P<.002
III	1.88	(1.3-2.2)	1.57	(1.3-1.9)	P<.05
IV	1.57	(1.4-2.3)	1.55	(1.2-2.0)	P>.10

417 BRAINSTEM EVOKED RESPONSES DURING SPEECH PRODUCTION.
David L. Woods*, Robert Galambos and Steven A. Hillyard. Dept. Neurosci., UCSD, La Jolla, Calif. 92093.

We compared click-evoked brainstem responses (BERs) in subjects who were 1) producing speech and 2) listening passively to tape recordings of their own speech, to see if vocalization in man is accompanied by the same efferent inhibition of brainstem auditory relay nuclei as has been reported to occur in the bat (Suga, 1974). Two experiments were conducted, one where speech was fed back immediately to the speaker, and another where speech was fed back after a 200 msec. delay. In both experiments the BERs during speech production were indistinguishable from those during passive listening, suggesting that speech production does not engage special efferent inhibitory mechanisms in man.



EPILEPSY

418 THE INFLUENCE OF TRACE METAL CHELATION ON SEIZURE ACTIVITY IN THE SENEGALESE BABOON. M.C. Alley* and E.K. Killam*, Department of Pharmacology, School of Medicine; and G.L. Fisher*, (SPON: R.M. Joy). Radiobiology Laboratory, University of California, Davis, CA 95616.

Several clinical and experimental investigations have suggested a possible relationship between seizure activity and abnormal metabolism of copper and/or zinc. The finding of elevated titers of serum zinc in the seizure-prone baboon species, Papio papio, as compared to the non seizure-prone primate species, Papio cynocephalus and Macaca mulatta, led us to consider whether zinc status might be related to the higher degree of seizure proclivity in the former species. D-penicillamine, known to "selectively" chelate divalent metal cations which are present in excess, was found to exert significant anticonvulsant activity in several chronic phases of treatment. Daily oral doses of 80-120 mg/kg given over a four week period decreased the severity and spread of seizures induced by intermittent light stimulation (ILS). Lower doses of 40-80 mg/kg given over a nine week period were more effective than the shorter courses of high dose treatment, and were not accompanied by noticeable side effects. Moreover, azaribine, structurally unrelated to D-penicillamine, but known to induce "indirect chelation" of copper and zinc was found to exert a similar form of anticonvulsant activity in these baboons at daily oral doses of 25-50 mg/kg. Seizure latency was lengthened, while seizure duration and spread were progressively diminished or entirely blocked over consecutive weeks of treatment. Both agents promote a quieting effect upon behavior without signs of sedation. Blood and urine samples were collected during these studies and evaluated for trace metal content. The altered patterns of seizure response and serum trace metal titers observed during the courses of pharmacologic intervention will be discussed.

419 INHIBITION IN PENICILLIN -INDUCED EPILEPTIC FOCI. T.E. Anderson* and L.T. Rutledge. Neuroscience Program, University of Michigan, Ann Arbor, Michigan 48109.

Though topical application of penicillin is a widely used experimental model of epilepsy, the neuronal mechanisms responsible for development of epileptiform activity remain poorly understood. It was reported that the evoked potential recorded from cat precruciate cortex, subsequent to pyramidal tract stimulation, was altered after application of penicillin to the cortical surface. The early surface negative component (SN-wave, associated with recurrent inhibition) decreased in amplitude over time, but it recovered upon removal of the penicillin. It was proposed that a decreased effectiveness of recurrent inhibition was the basis for epileptogenicity in a penicillin focus. To study the proposed loss of inhibition at the neuronal level, and to assess possible sites of penicillin action, foci were made in chloralose anesthetized cats. The effect of pyramidal tract, epicortical and foot pad stimulation upon spontaneous activity of extracellularly recorded neurons was calculated prior to and at intervals subsequent to application of penicillin to precruciate cortex. Only neurons yielding stable recordings throughout the transition from normal to epileptogenic cortex were counted. Cells were categorized as pyramidal tract (PT) or non-PT on the basis of antidromic activation following stimulation of the cerebral peduncle. For PT cells, inhibition observed in normal cortex was less effective subsequent to establishment of an active focus, regardless of the stimulus mode. However, excitability of bursting non-PT cells (B-NPT) increased subsequent to penicillin application, again irrespective of the stimulus modality responsible for the initial excitation. Further, 68% of the B-NPT cells exhibited an increase in firing in response to pyramidal tract stimulation which preceeded SN-wave peak amplitude, firing behavior consistent with their involvement in recurrent inhibitory pathways. These results demonstrate a loss of inhibitory effectiveness at the pyramidal cell level, as implied by SN-wave alteration. However, the loss of inhibition occurs simultaneously with an increased excitability of neurons which appear to be involved in inhibitory circuits. Thus, penicillin is probably not acting to reduce excitability of inhibitory interneurons or efficacy of synaptic inputs to those cells. Penicillin likely acts to increase apical dendritic membrane resistance. Applied topically it would selectively enhance the influence of the more superficially terminating excitatory inputs; it would also reduce the passive superficial current sink and hence, the surface negative wave.

420 STIMULATION OF THE CEREBELLAR SURFACE AND ITS EFFECT ON THE ACTIVITY IN PENICILLIN FOCI. Heinrich Bantli and James R. Bloedel. Dept. Neurosurg., Med. Sch., Univ. Minnesota, Minneapolis, MN 55455.

The effect of stimulating the cerebellar surface on the activity in acute penicillin foci (20,000 units) was investigated in a statistically controlled study. At the onset of an experiment, the cats were assigned randomly to either the experimental group (stimulating electrode placed over the vermis of the anterior lobe) or to the control group (only the dura opened over the posterior lobe). Following surgery, the animals in the experimental group were again randomly assigned to either the stimulated or unstimulated group. The cerebellar stimuli were capacitatively coupled pulses applied at a frequency of 10/sec with current densities of.25 ma/cm^2 and durations of .1 ms. The stimuli were applied with a bipolar electrode consisting of two platinum plates with a surface area of 7.6 mm^2 per plate. In order to determine the effectiveness of the stimuli to activate the cerebellar tissue, the cerebellar evoked response was recorded from the sensorimotor cortex prior to the injection of the penicillin. The statistical analysis indicated that any difference between the means of the total number of seizures per animal or total seizure time per animal of the control and experimental groups could have occurred by chance with high probability. But the distribution of the durations of the seizures was significantly affected by the cerebellar surface stimuli. In addition, the correlation of the amplitude of the cerebellar evoked response with the total number of seizures indicated that these two parameters did not vary independently, indicating that stimuli evoking large-amplitude responses over the sensorimotor cortex produced a decrease in the number of seizures in the same animal, whereas stimuli that evoked small-amplitude responses produced an increase in the total number of seizures with respect to the mean number per animal in the control group.

421 CORTICAL EXCITABILITY CYCLES FOLLOWING INTERICTAL "PENICILLIN SPIKES" IN CAT. F. M. Barken* and E. L. Gasteiger. Section of Physiology, Div. of Biology and N.Y.S. Vet. Col., Cornell U., Ithaca, NY 14853.

Triggering of topical penicillin-induced interictal spikes was accomplished by orthodromic activation of a cortical focus through stimulation of nVL of the thalamus in cats anesthetized with urethane. Condition-test stimuli delivered to nVL produced paired penicillin (PCN) spikes (surface positive-negative waves) only when the stimulus interval exceeded 150 msec. Facilitation of the positive wave on the order of 120 to 140% peaked at an interval of 250 msec. whereas maximum facilitation of 120 to 200% occurred at 300 to 350 msec. for the negative component. At intervals of 800 msec. and greater no facilitation of the test penicillin spike was observed. Facilitation was demonstrated in 10 out of 13 animals.

Single stimuli to nVL were delivered at varying intervals following spontaneous PCN spikes. Spikes could not be triggered with a delay less than 150 to 200 msec. following the spontaneous discharge. Facilitation of both the positive and negative waves of the nVL-triggered PCN spike has been observed at 250 and 350 msec. respectively, after the spontaneous spike in 6 out of 9 animals. Spontaneous and triggered PCN spikes appear to behave similarly with regard to their excitability cycles.

Different underlying mechanisms of electrogenesis are indicated by the differing latencies for maximum facilitation of the positive and negative PCN spike components. We interpret this facilitation as originating from interacting thalamocortical influences, since after-discharges are seen at the cortex 200 to 250 msec. after PCN spikes and arise from reverberatory circuits between thalamus and cortex as demonstrated by reversibly cooling nVL.

422 EFFECTS OF EPILEPTIFORM DISCHARGES IN THE VISUAL CORTEX ON NEURONAL DEVELOPMENT IN THE LATERAL GENICULATE NUCLEUS AND SUPERIOR COLLICULUS OF YOUNG RABBITS. H. Dale Baumbach, K.L. Chow, Barry L. Gordon*, Dept. Neurol., Stanford Univ. Sch. Med., and David L. Glanzman*, Dept. Psychol., Stanford Univ., Stanford CA 94305.

The effects of an epileptogenic focus in the visual cortex on the development of receptive field properties of single cells in the dorsal Lateral Geniculate Nucleus (LGN) and Superior Colliculus (SC) were studied. 8 to 9 day old rabbits were chronically implanted with a stainless steel cannula on each hemisphere so as to rest on top of the dura overlying the VI area of the visual cortex. To create an epileptogenic focus, penicillin (200,000u/ml) was applied to the dural surface through one cannula twice daily beginning one day after implantation. Interictal spiking began 3-10 min following the initial application and continued for 6-12 hrs. As a control, penicillin (200,000u/ml) mixed in equal proportions with penicillinase was simultaneously applied through the second cannula. For the LGN study, penicillin applications were continued to 19-24 days of age and the animals were prepared for single unit recordings at 20-25 days of age. For the SC study, applications were continued to 21-26 days of age and animals prepared for recordings at 22-27 days of age. Both of these age ranges are well beyond the time at which previous work (Rapisardi, Chow, & Mathers, 1975; Fox, Chow & Kelly, 1976) has shown that receptive fields in each respective structure achieve adult-like characteristics. All drug applications were discontinued 24 hours prior to single unit recordings and no interictal spiking was present during the single unit recording sessions.

The development of receptive field properties of cells in the LGN ipsilateral to the epileptogenic focus was clearly disrupted. There was a significant increase in the proportion of cells which were either unresponsive or had indefinite receptive fields along with a significant decrease in cells with concentric receptive fields. The proportional distribution of receptive fields for cells sampled in the LGN ipsilateral to the control injections was normal. Preliminary data on the Superior Colliculus, on the other hand, indicates that its development is not affected by the presence of the epileptiform focus. All types of receptive fields were found in the SC ipsilateral to the epileptiform focus and the proportional distribution did not differ appreciably from normal.

The presence of cortical interictal events during early development appears, therefore, to disrupt normal development in Thalamic structures remote from but synaptically related to the focal area. 423 INFLUENCE OF 5-HYDROXYTRYPTOPHAN (5-HTP) AND DIMETHYL TRYPTAMINE (DMT) ON ISCHEMIA-INDUCED SEIZURES IN THE GERBIL. James C.H. Chan*, K.M.A. Welch, Eva Chabi*, and T-P.F. Wang.* Dept. Neurol., Baylor Coll. Med., Houston, Tx. 77030.

Ischemia-induced seizures in the gerbil were studied as a model of epilepsy. The entire gamut of seizure activity, from myoclonic jerks, turning and running fits, to tonic-clonic fits, was observed in over 70% of gerbils studied after a 30 minute episode of cerebral ischemia was produced by bilateral common carotid occlusion followed by reperfusion. Gerbils were observed for seizure activity for up to 5 hours after the ischemic insult. Fifty percent of animals that seized died during a tonic fit. The onset of seizure activity was marked by running fits which appeared at fairly discrete, equally spaced time intervals, clustered around 1.00, 2.25 and 3.50 hours after cerebral reperfusion.

Previous studies had shown depletion of monoamines in ischemic brain of the gerbil (Zervas et al., Nature 247, 283, 1974; Welch et al., Proc. Amer. Soc. Neurochem. 6, 156, 1975). When we subsequently investigated the differences in brain monoamine levels between animals with cerebral ischemia alone and animals with ischemia that developed seizures, we found that catecholamines were significantly depleted in the cerebral cortex of the ischemia plus seizure group but not in the group with ischemia alone (Welch et al., Trans. Amer. Neurol. Assoc., in press, 1977). Serotonin was decreased in both groups of animals. This raised the possibility that (1) decrease in catecholamine levels was a secondary effect of seizure activity, and (2) since pharmacological depletion or elevation of brain serotonin respectively facilitates or decreases seizure threshold in other epilepsy models (Maynert et al., in Freidlander, Adv. Neurol., Vol. 13, Raven Press, N.Y., 1975), the decrease of serotonin common to both the ischemia and ischemia plus seizure groups was a factor predisposing to the development of seizures in the latter. Serotonergic influence on seizure activity was therefore examined in the gerbil model by pharmacologic manipulation with 5-HTP (50-125 mg/kg I.P.) and DMT (10 mg/kg I.P.). Mortality, frequency and type of seizures did not differ significantly between drug and saline-treated animals. However, gerbils treated with 5-HTP showed a delay in the time of onset of seizures, whereas those treated with DMT seized earlier than the saline-treated controls. Experience with ischemia-induced seizures therefore supports previous studies in other epilepsy models which indicate an influence of serotonin on seizure threshold. (This work was supported by NIH NS 09287-07)

424 UNIT RESPONSES IN THE CAUDATE NUCLEUS DURING FOCAL PENICILLIN EPILEPTIC DISCHARGES. Charles M. Chuman*, E.J. Neafsey, Arthur A. Ward, Jr., Department of Neurological Surgery, University of Washington, Seattle, Washington 98195

Recent studies (e.g., Collins, et al. Arch. Neurol.,33:536, 1976) using the 2-deoxy-D-glucose method have demonstrated prominent activation of the basal ganglia during penicillin evoked epileptic discharge, confirming earlier observations using depth EEG recordings (e.g., Udvarhelyi and Walker, Arch. Neurol., 12:333,1965). The experiments reported here have extended these observations to the single unit level in an effort to understand more fully the processes involved in the spread and generalization of epileptic activity.

Experiments were performed on locally anesthetized, paralyzed cats. A 2 x 2 mm gelfoam pledget saturated with sodium penicillin (50,000 u/cc) was applied over cruciate sulcus. EEG was recorded at and remote from the focus with silver ball electrodes. Single unit activity was recorded in the ipsilateral caudate nucleus (A17,L5). Recording sites were verified histologically. Histograms of unit activity before ("background") and after interictal EEG spikes were accumulated on a CAT 400 computer. All 8 cats studied thus far showed similar responses.

Of the 108 caudate cells studied, 101 responded to cortical epileptic discharge. Five of these responded with bursts only during the clonic phase of seizures and were otherwise silent. The remaining 96 responded to cortical interictal EEG spiking as well, 78 with an initial high frequency burst of spikes and 18 with an initial decrease in firing rate. The burst in the caudate cells occurred at the onset of the cortical EEG spike. For 8 of the 78 bursting cells, the burst was followed by a long lasting (>500 msec) depression of firing rate. This figure (8/78) may be an underestimation because only 16 of the 78 bursting units had background firing rates high enough to permit detection of decreases, even with averaging. Of the 18 cells initially responding with a decrease in firing rate, 6 showed a later "rebound" increase in rate above their background activity.

In sum, the firing pattern of nearly all cells in the rostral portion of the head of the caudate nucleus is strongly affected by cortical epileptiform discharges. 82% fire a burst with at least 1/10 of these showing a later depression. 18% are initially decreased in firing rate with 1/3 of these showing a later "rebound" increase in firing. The dramatic effect of cortical epileptic discharge on the caudate nucleus suggests that this structure plays an important role in the subcortical spread and possible generalization of focal epileptic discharge.

425 EFFECT OF MATERNAL RESPERINE AND CHLORPROMAZINE ADMINISTRATION ON SEIZURE SUSCEPTIBILITY AND INTENSITY IN OFFSPRING RATS. John W. Dailey and Phillip C. Jobe, Department of Pharmacology, L.S.U. Medical Center, Shreveport, Shreveport, Louisiana, 71103.

Administration of reserpine or chlorpromazine to pregnant rats has been shown to impair the development of the restrained cold stress response in their offspring. This defect may be due to alterations in the development of noradrenergic neurons (Fed. Proc. 35: 585, 1976; Pharmacol. 18 (2): 331, 1976). Since noradrenergic systems have been shown to be important in the modulation of seizures (JPET 184: 1-10, 1973; Neuropharm. 13: 961-968, 1974) experiments were designed to determine if offspring from similarly treated dams have altered susceptibility to sound-induced seizures or if they have alterations in electrically-induced seizure patterns. Pregnant Sprague-Dawley rats received daily subcutaneous injections of either 7 mg/kg of chlorpromazine or 0.1 mg/kg of reserpine from day 8 of pregnancy until the pups were weaned at approximately 20 days postpartum. After they were more than 60 days of age, offspring from control and drug treated groups were exposed to a standardized sound stimulus. Offspring from reserpine treated dams had a seizure frequency significantly higher than control ($P<0.05$). Offspring from chlorpromazine treated dams were not different from control. Responses to supramaximal electroshock which was administered through corneal electrodes were not different between control and reserpine or chlorpromazine pretreated animals. There was also no difference among the groups in their response to electrically-induced spinal cord seizures. These data suggest that restrained cold stress is a more sensitive indicator of the reserpine and chlorpromazine induced neuronal deficits in these animals than is seizure susceptibility and intensity (Supported in part by National Foundation Grant #1-496).

426 EPILEPTIC CHICKENS AS A PHARMACOLOGICAL MODEL OF GRAND MAL EPILEPSY. H.L. Davis*, D.D. Johnson, and R.D. Crawford*. Dept. of Pharmacology, University of Saskatchewan, Saskatoon, Saskatchewan Canada S7N OWO.

Crawford reported a mutant causing epileptiform seizures in domestic fowl (J. Hered. 61: 185, 1970). Seizures can be evoked by intermittent photic stimulation (IPS). Acute dose-response studies with phenobarbital (PB), phenytoin (PH) and primidone (Pr) were conducted to determine the relationship between plasma levels and anticonvulsant effect in epileptic chickens. Complete protection against IPS-induced seizures was obtained with plasma PB levels > 14 µg/ml. Maximal anticonvulsant activity was obtained with plasma PH levels of 16 µg/ml, however complete protection could not be obtained at sub-toxic doses. Pr produced a significant reduction in seizure incidence for 24 h but is metabolized to PB. Concurrent administration of SKF-525A with Pr to prevent the generation of PB resulted in significant protection against IPS-induced seizures indicating that Pr itself possesses anticonvulsant activity. Phenylethylmalonamide (PEMA) levels of 49 µg/ml did not affect the incidence of seizures. The data revealed a high correlation between plasma PB, PH or Pr levels and anticonvulsant activity indicating that the epileptic fowl resemble human epileptics in terms of plasma anticonvulsant concentrations required for control of grand mal seizure activity. (Funded in part by an MRC post-doctoral Fellowship and MRC Grant #MA5893).

427 EFFECTS OF SEIZURE-PRODUCING STIMULATION ON PROTEIN PHOSPHORYLATION IN MEMBRANES FROM RAT CEREBRAL CORTEX. Y.H.Ehrlich, L. G. Davis* and E. G. Brunngraber. Mo. Instit. Psychiat., Univ. of Mo.-Columbia, Sch. Med., St. Louis, MO 63139.

Massive firing of neurons can be recorded in cerebral cortex following treatments that induce seizures, such as electroconvulsive shock or decapitation. Numerous studies have related this seizure activity to the increase in cerebral cAMP levels which are induced by these treatments. Cyclic AMP is known to exert its physiological functions by regulating phosphorylative activity. We have therefore investigated the phosphorylation of specific proteins in membrane preparations from rats in which cerebral cAMP levels were altered by seizure-producing stimuli. Osmotically shocked P_2 fractions were prepared from the cerebral cortex of rats sacrificed by head immersion in liquid nitrogen, and these served as controls. Corresponding fractions were prepared from cerebral cortex of rats whose head was immersed in liquid nitrogen after ECS or decapitation (experimental). Aliquots from the control and experimental groups were incubated with 3uM gamma-^{32}p-ATP for 10 sec. in the presence and absence of 5 uM cAMP. The specific protein substrates which incorporated labeled phosphate were identified by autoradiography of SDS-solubilized reaction products, electrophoretically separated in slab polyacrylamide gels. The results were quantitated by densitometric measurments of the autoradiograms. Specific differences which occurred in opposing directions were observed between the experimental and control groups. For example, phosphate incorporation into a protein band with approximate MW of 52K increased about two-fold after decapitation, while that of a band with MW = 47K showed a 50 % decrease. In fact, the ratio of phosphate content in these 2 proteins was inversed after treatment. It was 1.83±0.16 in the controls and 0.43±0.09 in the experimental group ($F = 72.74$; df= 1,8; $P < 0.001$). In addition, a marked stimulation by cAMP of the phosphorylation of two other bands (MW = 78K and 56K) was in evidence in membranes from seizured-cortex but not in controls. We have reported recently that endogenous phosphorylative activity towards the specific proteins mentioned above is characteristic for membranes of synaptic origin (Neurochem. Res., in press). It is possible, therefore, that the selective alterations in their phosphorylation as described here, are related to the changes in neuronal activity which occur during seizures. An inherent abnormality in protein phosphorylation systems may be investigated as one of the possible causes of epilepsy. (Supported in part by a grant from the Epilepsy Foundation of America).

428 ENDURING DOPAMINE DEPLETION AT THE SITE OF AMYGDALOID KINDLING STIMULATION. Jerome Engel Jr. and Nansie S. Sharpless* Depts. Neurol., Neurosci., & Psychiat., Albert Einstein College of Medicine, Bronx, NY 10461

Daily stimulations of the amygdala with brief currents that initially produce little or no behavioral responses gradually result in the development of generalized seizures. This kindled epileptogenicity is enduring since the typical seizure can still be evoked in kindled animals after many months without stimulation. The mechanisms accounting for these enduring alterations are unknown, although previous work in our laboratory and others has indicated a role for the catecholamine projection systems in the kindling phenomenon. In the present study, electrodes were implanted into the left amygdalae of 19 rats and 9 rats were kindled with daily amygdaloid stimulation until generalized seizures were evoked on three consecutive days, while 10 rats were handled daily but received no stimulations. One month after the last kindled seizure (kindled rats) or last handling trial (implanted control rats), the rats were killed, the brains removed, and noradrenaline (NA) and dopamine (DA) were measured radioenzymatically in both right and left amygdalae and hippocampi. NA and DA levels in the left (stimulated and/or implanted) and right structures were compared using Student's t-test for matched pair data. When compared to the right, nonstimulated side, there was a very significant decrease in both DA ($P<0.0005$) and NA ($P<0.005$) levels in the left, stimulated amygdala of the kindled rats. DA levels in the left amygdalae of the implanted control animals were not different from those in the right amygdalae. However, the NA levels were significantly lower ($P<0.05$) in the left amygdalae of the control animals. No left-right differences were found in the hippocampi of either group. When the mean percent difference between right and left amygdalae for kindled rats was compared with that for the implanted controls, there was a significant difference for DA ($P<0.05$) but not for NA. We conclude that amygdaloid kindling caused a consistent, specific, and persistent decrease in DA concentration in the left, stimulated amygdalae while the effect of amygdaloid kindling on NA concentration may not be greater than that produced by the electrode implantation alone. It is suggested that an enduring stimulation-induced decrease in DA mediated inhibition may be one mechanism underlying kindled excitability.
Supported by NIH Grants No. NS 09649 and NS 70209.

429 ALTERATION OF SINGLE UNIT RESPONSES TO VISUAL STIMULI IN THE RETICULAR FORMATION AND LATERAL GENICULATE INDUCED BY PENTYLENETETRAZOL. Carl L. Faingold and James Stittsworth*. Division of Pharmacology, Department of Medical Sciences, Southern Illinois University School of Medicine, Springfield, IL 62704.

Previous findings from this laboratory have demonstrated that pentylenetetrazol (PTZ) administration markedly alters the sensory responsiveness of units recorded in the mesencephalic reticular formation (MRF) (Faingold and Caspary, Neuropharm., 16:143, 1977). This study compared the effects of PTZ on visual responsiveness of units recorded in the MRF to the effects of this agent on the responsiveness of units simultaneously recorded in the lateral geniculate nucleus (LGN). Experiments were performed in acutely prepared, locally anesthetized, paralyzed cats. The data were examined using post-stimulus time histograms (PSTH's) with a bin width of 1 msec utilizing 50 presentations of light flashes at 1 per sec intervals. The results indicate that MRF units which did not respond to the visual stimuli became responsive after PTZ as shown by the emergence of the time-locked consistent peaks in the PSTH's. Units in the LGN were quite responsive to visual stimuli, and most of these units showed only minor modifications of the late components of the firing pattern after PTZ. These changes included the appearance of small multiple peaks at 100 to 200 msec after the stimulus. Some LGN units showed small increases in the height of the initial peak of the PSTH, while others showed no detectable change in firing pattern. Major modifications of MRF unit firing patterns were noted at subconvulsive doses of PTZ. However, changes observed in the responses of LGN units remained relatively minor even if PTZ was given to the point of seizure induction. The relative difference in the degree of PTZ-induced change in single unit responses to visual stimuli in MRF and LGN sites may explain previous findings which indicate that convulsant drugs enhance sensory evoked field potentials in non-primary sites to a much greater extent than in primary sensory sites (Faingold, Neuropharm., 16:73, 1977).

430 MATHEMATICAL PREDICTION OF HUMAN POST-TRAUMATIC EPILEPSY. Dennis M. Feeney and A. Earl Walker*. Depts. Psych., Physiol. and Neurosurg., Univ. New Mexico, Albuquerque, N.M. 87131.

The following equations estimate the probability of post-traumatic seizures given risk factors and for time between 1 wk and 5 yrs after the injury.

$P_n = P_0 (.925)^n$ where: /Equation 1/

n = number of months since the injury

P_n = probability a patient will have a seizure after time n

P_0 = estimate that a patient will have a seizure any time after brain injury, considering relevant risk factors. Let $P_0 = R_I$ and R_I is calculated using Equation 2.

.925= a constant estimating the probability that a patient will not have a seizure in any given month.

$R_{i+1} = R_i + \theta (1.2 - R_i)$ where /Equation 2/

initially; R_0=.01, lowest probability of post-traumatic seizures

θ = increment of R by a risk factor, the values are given below. Use no more than 4 in decreasing order of magnitude.

1.2 = a constant to adjust the final R or R_I to fit published data. So, with a limit of 4 factors, $.01 \leq R_I \leq .74$.

θ	Factor	θ	Factor
.05	unconsciousness/amnesia≥1 hr	.20	missile wound/dura tear
.10	persisting EEG abnormality	.05	linear skull fracture*
.20	hemiplegia, aphasia	.10	depressed skull fracture*
.20	hemorrhage (intracranial)	.25	central/parietal damage**
.15	fits in first wk	.15	temporal damage**
.10	prefrontal/occipital damage**	.10	infection (CNS)

*do not use with missile wounds unless dura intact.

**with multiple brain damage use the single highest θ.

Example: occipital wound, depressed fracture, 2 hrs coma (Equa.2)

R_1-depressed skull fracture θ=.10;R_1=.01+.10(1.2-.01)=0.129

R_2-occipital damage θ=.10;R_2=.129+.10(1.2-.129)=0.236

R_3-unconsciousness θ=.05;R_3=.236+.05(1.2-.236)=0.284

R_I=0.284 the probability of a fit any time after the injury. The probability of fits after 6 mos has declined and is calculated using Equation 1 with n = 6 and P_0 = 0.284.

$P_6 = 0.284 (.925)^6$

P_6 = 0.18 = the probability that the patient will have a seizure some time beyond 6 mos post-injury.

To determine the time to reach a given risk level, use Equation 1 and set P_n to desired risk and then solve for n.

These formulae, using a constant probability model, give results that fit published data and predict with 95% confidence the chance of post-traumatic epilepsy in single cases.

431 EFFECTS OF MONOAMINERGIC CHANGES ON POSTDECAPITATION CONVULSIONS IN RATS. P. F. Geiger, E. Greg Tubre*, P. C. Jobe. School of Pharmacy, Northeast Louisiana University, Monroe, LA 71209, and Department of Pharmacology and Therapeutics, Louisiana State University School of Medicine, Shreveport, LA 71130.

The present study investigated the role of spinal cord (SC) monoamines in convulsions (C) induced by decapitation in rats. The magnitude of postdecapitation C was quantitated by use of two single-plane acceleration transducers (Grass Instruments). Reserpine (5 mg/kg i.p. 24 hours prior to decapitation) treated animals exhibited a convulsive magnitude which was 0.7% that of normal saline treated subjects. Also, reserpine decreased the duration of convulsive activity from 0.29±0.04 minutes (controls) to 0.04±0.01 minutes. These effects of reserpine were determined at 24 hours postadministration, a time when maximal depletion of norepinephrine (NE), dopamine (DA), and 5-hydroxytryptamine (5-HT) is also observed. Two drugs which have relatively specific effects on 5-hydroxytryptamine stores were also tested: parachlorophenylalanine (316 mg/kg i.p. 3 days prior to decapitation) a potent inhibitor of tryptophan hydroxylase; and 5,7-dihydroxytryptamine (10 µg of the base intracerebroventricularly 10 days prior to decapitation) a substance which produces a neurotoxic effect on 5-hydroxytryptaminergic neurons. Neither of these drugs produced an effect on either the magnitude or the duration of postdecapitation C. In contrast, 6-hydroxydopamine (200 µg of the base intracerebroventricularly) produced an effect on postdecapitation C which was qualitatively and quantitatively similar to that of reserpine. This effect was determined 14 days after 6-OH-DA administration, a time when SC NE levels are markedly decreased. These data indicate that noradrenergic neurons in the SC may play a role in the modulation of postdecapitation C.

432 FOCAL PENICILLIN EPILEPSY IN AN ISOLATED HEMISPHERE: EEG AND INTRACELLULAR STUDIES. J. J. Hablitz and D. V. Wray*. Neurophys. Dept., The Methodist Hospital, Houston, TX 77030.

The cortex of an entire cerebral hemisphere was surgically isolated in the cat to allow assessment of the role of intrinsic regulatory mechanisms in focal epileptic activity. Topical application of small amounts of penicillin to the cortex has been shown to result in a spatially, well-delimited focus producing recurring interictal spikes. Neurons at the center of such foci are strongly excited during the paroxysmal discharge while cells in the surrounding cortex and controlateral homotopic cortex are markedly inhibited during the interictal discharge. We now report rapid spread of epileptic activity in isolated cortex associated with decreased cellular inhibition.

Prior to surgical isolation of the hemisphere a small penicillin focus was created on the marginal gyrus and spread of activity assessed by closely spaced EEG electrodes. After removing the pledget and rinsing the cortex with saline the hemisphere was isolated by sectioning all forebrain commissures and dividing the white matter at the level of thalamus and caudate nucleus. Animals were then allowed to recover for 3-5 days. Subsequently, a focus was created on the suprasylvian gyrus and spatial spread studied. Intracellular recordings were then made at the focus or at distances removed from it.

EEG recordings indicated that interictal spike activity in the normal cortex was maximal in the focus and markedly reduced in amplitude at distances of 5-7 mm. Activity in the isolated hemisphere was similar in morphology to the normal cortex but was characterized by the presence of large amplitude spikes 10-15 mm away from the focus. These distant spikes appeared early in the development of the focus and are not attributable to diffusion of penicillin. Intracellular recordings at the center of the focus and at distances up to 10 mm showed typical large amplitude depolarizing shifts with superimposed high frequency spike activity and spike inactivation (paroxysmal depolarizing shifts, PDPs).

Hyperpolarizing shifts were noted to follow termination of PDPs in most cells; considerable variation in amplitude and duration was seen. In the small number of cells sampled to date (N=50) no uninjured neurons were encountered which displayed purely hyperpolarizing responses without prior activation.

These results indicate that interictal spikes in isolated cortex are associated with the same patterns of cell discharges seen in intact brain. The greater spread of interictal spikes suggests that this preparation may be useful for studying intrinsic control mechanisms.

433 EPILEPSY AFTER ALUMINA EXCISION IN THE ABSENCE OF "MIRROR FOCI" A. Basil Harris and Joan S. Lockard. Department of Neurological Surgery, University of Washington, Seattle, Washington, 98195.

The role of intracortical alumina in sustaining experimental epilepsy in monkey and the matter of secondary independent epileptic foci are examined in this study. Staged surgical excisions were performed on 15 monkeys clinically epileptic 3 to 5 years. Four to six months elapsed between each procedure to allow stable seizure frequency observations. The first operation was the removal of the alumina granuloma and immediate 1 mm. of surrounding cortex. The second procedure was removal of a 1 to 1½ cm. rim of cortical tissue which surrounded the first excision site. The final procedure was removal of a 1 to 2 cm. circle of homotopic cortex followed by profusion of the brain. Serial EEGs were performed and each animal was monitored on videotape or polygraph to prove the frequency or lack of seizures. Electrocorticography was performed to map areas of epileptic activity at each operative procedure. Histological studies were done on each excised piece of cortical tissue and, finally, on the profused brains utilizing Cajal's astrocyte stain, Nissle and histochemical stains for aluminum.

In the majority of animals (13 of 15), the first excision resulted in a greater than 50% decrease in seizure frequency, but in only two did the epilepsy disappear. The second excision stopped seizures in all but two animals, one of which had subdural scarring from the operative procedure. The second animal received a third resection which terminated epileptic activity. In no animal was aluminum detectable after the first excision. Cortical astrocytes were hypertrophied throughout the epileptic tissue up to the peripheral border of the second excision. Contralateral or homotopic areas of cortex did not show astrocytic hypertrophy. No independent "mirror foci" were seen by EEG or electrocorticography. Alumina generates the epileptic focus by scarring in the cortex, but it is not necessary to maintain seizures once they have become established. This series of long-term epileptic animals did not have independent homotopic epileptic foci. (Supported by NINCDS Grants NS-09037, NS-04053 and Contract NO1-NS-1-2282).

434 EFFECT OF TAURINE ON INTRACEREBRAL ELECTROSHOCK THRESHOLDS IN AUDIOGENIC AND NON-AUDIOGENIC RATS. Ryan Huxtable* and Hugh Laird. Depts. Pharmacol. and Pharmacol. & Toxicol., Cols. Pharm. and Med., Univ. of Az., Tucson, Az. 85721.

Audiogenic (AS) and non-audiogenic (NAS) rats were bilaterally implanted in the inferior colliculi (IC) with bipolar electrodes for determination of intracerebral electroshock thresholds (IET). IET is defined as the minimum current, in μA, required to elicit consistently a convulsion. Graded intensities of electrical current administered as 60Hz sine-wave pulses of 5 seconds duration were used to obtain stable IET values in each side of the IC in all subjects. Following IET determinations, groups of AS and NAS rats were injected with taurine (Tau) into either the lateral cerebroventricle (LCV) or directly into the IC. Lateral cerebroventricular injection of Tau (8μmoles) into AS rats elicited a biphasic effect on IET values. Initially (3 min) Tau elevated IET 44% but this response returned to baseline at 1 day only to be followed on day 2 by a long-lasting increase in IET. The IET values for 2,3,5, and 6 days were 34%, 61%, 64%, and 64% respectively. By day 7 the IET had returned to baseline. The LCV injection of Tau also reduced the severity of the convulsions displayed by the AS animals but only at the 3 min time period. In contrast to the AS subjects, LCV Tau administration did not alter either IET values or seizure severity in NAS animals. The injection of Tau (200nmoles) directly into the IC caused a slow developing but persistent elevation of IET in AS rats. The initial IET elevation was obtained 12 min after Tau at which time there was a 70% increase. The peak effect was noted (99%) 24 hrs after injection, and a significant elevation in threshold persisted for 20 days. Even though there was a marked and long-lasting elevation of IET in the AS animals, at no time was there a reduction in seizure severity. By comparison, injection of Tau into the IC of NAS rats did not cause a change in either IET nor seizure severity at any time after injection. These data show that Tau exerts long-lasting anticonvulsant effect only in AS rats, a species that is genetically susceptible to seizures. Furthermore, Tau administered LCV produced a different response to Tau given IC, indicating that the site of action was not the same. Supported by USPHS HL 19394 and 20087.

435 EFFECTS OF RO 4-1284 (RO) ON AUDIOGENIC (AG) SEIZURE (S) SUSCEPTIBILITY (SP) AND INTENSITY (I) IN RATS. P.C. Jobe, John W. Dailey and R. Don Brown. VA Hosp and Dept of Pharmacol, L.S.U. Sch Med, Shreveport, LA 71130.

This study determined effects of CNS biogenic amine depletion on AG S SP and I in 2 types of Sprague-Dawley derived rats: the progeny of genetically susceptible parents (PGS) and of nonsusceptible parents (PNS). S SP was determined by comparing the number of animals responding to sound stimulation [with a running episode only (RE) or with running episodes and convulsions (RC)] to the total number of animals tested. S I was assessed by determining an AG response score (ARS) for each animal (each higher ARS represents a more intense S). Three PGS subgroups were selected for experimentation on the basis of responses to sound stimulation: Subgroup 1 (SG1) showed no signs of AG S SP (ARS=0) in 3 pretreatment tests (at least 1 week apart); Subgroup 2 (SG2) animals had an RE (ARS=1) in 1 or 2 of the 3 test sessions and had an ARS=0 in at least 1 session; Subgroup 3 (SG3) animals had an ARS=1 in all 3 test sessions. PNS were selected for use in the same way as SG1 of PGS. The table shows S SP and I values prior to treatment (controls), 45 min after RO (a time when monoamine depletion is maximal), and 19 days after RO (18 days after depletion has completely dissipated). These results show that effects of RO on PNS are minimal. In contrast, the drug caused a increase in SP and I in all 3 PGS subgroups. In the PGS tested 19 days after RO, a relatively high degree of S activity was still present. These observations suggest that CNS monoaminergic neurons function as determinants of AG S SP in animals which also carry some other genetically determined SP factor. A deficit in monoaminergic transmission is insufficient to cause SP in animals not carrying this other factor.

TEST GROUP		CONTROLS (Before RO)			RO (45 Min. After)			AFTER RO (19 Days Later)		
		SP		ARS	SP		ARS	SP		ARS
		RE	RC		RE	RC		RE	RC	
PNS		0/23	0/23	0.0	3/23	1/23	0.2	1/22	1/22	0.1
PGS	SG1	0/17	0/17	0.0	1/17	10/17	5.4	4/17	3/17	0.7
	SG2	6/6	0/6	.33	0/6	6/6	9.0	1/6	3/6	1.1
	SG3	2/2	0/2	1.0	0/2	2/2	9.0	0/2	2/2	2.0

436 ANISOMYCIN DELAYS AMYGDALOID KINDLING IN RATS. Viliam Jonec*, Susan Holm*, David Masuoka* and Claude G. Wasterlain* (SPON: Richard N. Lolley). Epilepsy Research Laboratory, VA Hospital, Sepulveda, CA 91343, Brain Research Institute and Department of Neurology, UCLA, CA 90024.

Twenty-six adult Holtzman rats received one daily electrical stimulation to the basolateral amygdala (500 uA, 1 sec, 62.5 Hz, 5 days/week) through chronically implanted bipolar stainless steel electrodes. Experimental animals received an intraperitoneal injection of anisomycin (60 mg/kg) 30 min before each stimulation. Preliminary experiments showed that this dosage inhibited rat brain protein synthesis by over 75% during the first hour after injection and produced no apparent toxicity. Little inhibition was observed later than two hours post injection. Control animals were injected with solvent (0.9% NaCl). Handling and stimulation were similar in controls and experimentals. Clinical response and electroencephalogram (shape and duration of afterdischarge) were recorded with every stimulation. Kindling was continued until the animal responded to five consecutive stimulations with stage 5 seizures (Racine, R.J., EEG clin.Neurophysiol. 32:, 281, 1972). Twenty-four hours after the last stimulation, the animals were killed and dopamine, norepinephrine and serotonine concentrations were measured in both cerebral hemispheres, cerebellum and brain stem.

Anisomycin-treated rats reached each stage of kindling more slowly than saline-injected animals, and development of stage 5 seizures was delayed ($P < 0.001$). Crossover of treatments after kindling revealed no anticonvulsant action of anisomycin. One possible interpretation of these findings is that enzyme induction is necessary to the establishment of the kindling process.

437 CEREBELLAR MODULATION OF HIGH PRESSURE NERVOUS SYNDROME SEIZURES P. G. Kaufmann and J. C. Farmer, Jr.*, Duke University Medical Center, Durham, N.C., U.S.A.

The high pressure nervous syndrome (HPNS) in mammals proceeds from jerky movements of the limbs to tremors and myoclonic jerks and finally to generalized convulsions. Subjective reports by human divers have also included a vestibular involvement, manifested by dizziness, nausea, ocular and limb tremors, and standing unsteadiness. Electronystagmographic evidence indicated that these symptoms are not due to unilateral dysfunction of vestibular end organs (Farmer, et al., Undersea Biom. Res., 1974, 1, A-11). It was postulated that decreased cerebellar modulation of brainstem vestibular nuclei could result in the reported symptoms. In view of existing reports that the cerebellum may play a role in inhibition of epileptic activity (Cooper et al., J. Amer. Geriat. Soc. 1974, 24, 40-43), we further examined its role in the development of HPNS seizures.

Electroencephalographic activity of the frontal cortex, cerebellar vermis, vestibular nuclear complex, hippocampus, and reticular formation was recorded in awake rats during simulated dry chamber ($He-O_2$) dives to 136 atmospheres at 40 to 80 atm/hr. Effects of compression varied from severe tremor and myoclonic jerks to tonic-clonic convulsive seizures and status epilepticus. The predominant seizure pattern observed was a spike-and-slow-wave pattern of 4-5/sec. Cerebellar ablation two weeks prior to the dive significantly lowered seizure threshold and increased the number of convulsions, but had no effect on the electrographic pattern evident during seizures. (Supported by ONR Contract N00014-75-C-0553).

438 EFFECT OF CONVULSANT DRUGS ON PHOTIC AFTERDISCHARGE. Gary A. King* (SPON: W.M. Burnham). University of Toronto, Department of Pharmacology, Toronto, Canada.

Photic Afterdischarge (PhAD) consists of a series of high amplitude, low frequency (6-8Hz), slow waves that appear in the visual cortex following normal light-flash evoked potentials. It usually lasts for 1-2 seconds.

Recent work on PhAD indicates a number of similarities to petit mal epileptic seizures: a) it often has a spike-and-wave pattern; b) it is suppressed by the arousal state; c) it is suppressed by anti-petit mal drugs but unaffected by anti-grand mal drugs; d) during its occurrence some behavioural responses are inhibited.

Work by previous experimenters has shown that PhAD is enhanced by metrazol. The present series of experiments, a dose-response investigation of the effects of picrotoxin, bicuculine and strychnine, in rat, indicates that it is also enhanced by drugs which interfere with GABA transmission in the CNS.

439 LOCAL CHANGES IN PO_2 AND PREDICTION OF METABOLIC RATE DURING INTERICTAL ACTIVITY IN EXPERIMENTAL PRIMARY AND SECONDARY EPILEPTOGENIC FOCI. Norman R. Kreisman, Thomas J. Sick* and Duane F. Bruley*. Departments of Physiology and Chemical Engineering, Tulane University, New Orleans, La. 70112.

Focal epileptogenic activity was produced in one hemisphere of the bullfrog telencephalon by microinjection of 10-100U of Na penicillin G. The electrocorticogram (ECoG) was monitored from each hemisphere with bipolar Ag/AgCl electrodes. Measurements of local PO_2 in one or both hemispheres were made polarographically with glass insulated, platinum-iridium microelectrodes with a tip diameter less than 1μ and an exposed tip length of 15-20μ.

The most frequently observed responses consisted of slow transient decreases in PO_2 which followed the penicillin-induced ECoG spikes and gradually recovered to control values with an exponential decay. The duration of these transient decreases in PO_2 ranged from 10-60 sec and the magnitudes were as large as 35mm Hg. As the frequency of ECoG spikes increased with further development of the penicillin focus, the PO_2 decreases summated, driving the PO_2 to lower values which often approached 0 mm Hg. Slowing of the ECoG spikes always resulted in a return of PO_2 levels to a value higher than control suggesting that penicillin or the interictal paroxysms may produce hyperemia. When the ECoG spikes were followed by afterdischarges the resultant PO_2 decreases recovered to control values more readily than before and were followed by a large overshoot. In contrast, small slow waves, often resembling afterdischarge with no preceding interictal spike, were followed by transient increases in PO_2. Simultaneous recordings from two polarographic microelectrodes revealed that the ECoG related PO_2 transients occurred intitally in the 1° focus and several minutes later in the 2° focus. Most often these transients occurred for varying periods of time in one hemisphere and then the other. This alternation appears analogous to the "flip flop phenomenon" first described by Morrell (Epilepsia 1:538, 1960).

Distributed parameter, non-linear partial differential equations representing oxygen convection and diffusion were used to calculate local metabolic rates based upon the PO_2 transients. The equations were solved using a pseudo dynamic technique on a hybrid computer by the parallel solution method. These mathematical models predict metabolic rate changes which are inversely proportional to the changes in PO_2 and directly proportional to superimposed simulated increases in local blood flow. Direct measurements of local blood flow are necessary to test the predictions of these models.

This work was supported by NIH grant NS-12419.

440 INTRACEREBRAL ELECTROSHOCK THRESHOLDS OF AUDITORY NUCLEI IN AUDIOGENIC AND NON-AUDIOGENIC RATS. Hugh E. Laird and Ryan J. Huxtable* (SPON: Lincoln Chin). Depts. Pharmacol. and Toxicol., and Pharmacol., Colleges Pharm. and Med., Univ. Ariz., Tucson, Ariz. 85721.

Intracerebral Electroshock Thresholds (IET) of the medial geniculate bodies (MG), inferior colliculi (IC) and ventral cochlear nuclei (VCN) were determined in groups of audiogenic (AS) and non-audiogenic (NAS) rats. The IET is defined as the minimum electrical current, in μA, required to cause a behavioral convulsion. Each subject was bilaterally implanted in one pair of auditory nuclei with bipolar stimulating electrodes. IET values were determined on each side by administration of graded intensities of electrical current as 60Hz sine-wave pulses of 5 seconds duration. Subjects were tested daily on alternate sides until stable thresholds were obtained. Stimulation of the auditory nuclei at the IET current elicits in both the AS and NAS rats behavior identical to that observed in the AS animal during sound-induced seizures. However, there is a marked difference in the convulsive pattern displayed by two strains of rat. The AS animal consistently shows a maximal (tonic extension), whereas the NAS animal displays only a minimal type of convulsion. Another difference between the AS and NAS subjects was observed in the IETs of the auditory nuclei. IET values in the MG, IC, and VCN of AS rats were significantly lower than the comparable thresholds in NAS subjects, as shown in the table.

INTRACEREBRAL ELECTROSHOCK THRESHOLD

LEFT	IC	MG	VCN
AS	43 ± 7	73 ± 14	48 ± 9
NAS	184 ± 39	525 ± 24	>1000
RIGHT			
AS	49 ± 7	112 ± 48	43 ± 8
NAS	193 ± 46	400 ± 39	>1000

These results may be summarized as follows: (1) Electrical stimulation of auditory nuclei in both AS and NAS rats elicited an audiogenic seizure response; (2) The AS animal had a more severe convulsive seizure; (3) IET values in all auditory nuclei are markedly lower in the AS rat. Supported by USPHS grants HL 19394 and HL 20087.

441 PATTERNS OF DEPTH SPIKING RELATED TO PSYCHOLOGICAL ASSESSMENT IN PATIENTS WITH EPILEPSY. Jeffrey P. Lieb, Rebecca Rausch*, and Paul H. Crandall*. (SPON: J. Rohrbaugh). Reed Neurological Research Center, UCLA, Los Angeles, CA 90024.

The statistical properties of depth spiking in the interictal EEG were assessed in 12 patients with intractable temporal lobe epilepsy in whom depth electrodes had been implanted for diagnostic purposes. Prior to the implantation surgery each patient was administered standard psychological tests. Following electrode implantation in medial temporal lobe depth sites, 1 to 4 EEG recording sessions, varying in length from 29 to 300 minutes, were analyzed with a computerized automatic spike recognition system in each patient. The mean rate of spike occurrence was measured bilaterally in the amygdala, pes hippocampi, and hippocampal gyrus. The total amount of spike activity in each patient (TA) was measured by computing the root mean squared mean spike rates across all sites bilaterally. The degree of lateralization of spike activity (LAT) in each patient was measured by computing the ratio of the root mean square of spike activity in the more active temporal lobe to TA. TA and LAT were correlated with the pre-implant psychological measurements. TA negatively correlated with intelligence (i.e. Wechsler Full Scale, Verbal and Performance I.Q.s). LAT, while not significantly related to the intelligence scores, correlated positively with a general memory score (i.e. the Wechsler Memory Quotient) as well as a rating of psychosocial independence. Age, sex, length of seizure history, or drug serum levels at the time of psychological testing did not correlate with the behavioral measurements.

Supported by NIH Grant NS 02808.

442 EFFECTS OF 1,4-BENZODIAZEPINES ON ANTIDROMIC INVASION INTO THE GIANT NEURON OF APLYSIA CALIFORNICA. M.F. Murphy* and N.R. Kreisman (SPON: A.W. Epstein). Depts. of Pharmacology and Physiology, Tulane University, New Orleans, LA 70112.

Repetitive neuronal discharge along synaptic pathways is an acknowledged mechanism for the spread of ictal activity and the establishment of secondary epileptogenic foci in mammalian CNS. The projection of this aberrant activity may occur in an orthodromic fashion or by antidromic invasion of normal soma through ectopic spike generation in nerve terminals of axons within primary foci (Gutnick & Prince, Science 176:424, 1972). The giant neuron of the invertebrate Aplysia (R2) can serve as a model for a presynaptic terminal due to its dependence on sodium and calcium for spike generation and its unique axon arborization at the spike trigger zone near the soma. Retrograde invasion into R2 by axon stimulation was assessed in the presence of two 1,4-benzodiazepine derivatives: diazepam, a psychotropic which aborts ictal spread and prevents the establishment of secondary epileptogenic tissue, and R05/4864 (7-chloro-5-(p-chlorophenyl)-1,3-dihydro-1-methyl-2H-1,4-benzodiazepine-2-one), a derivative devoid of significant pharmacologic effects in all mammalian test systems. Two KCl filled microelectrodes were inserted into the soma of R2, and the second connective, containing the axon of R2, was secured over a bipolar stainless steel electrode. One microelectrode was used to rigidly control the transmembrane potential of the cell just prior to axon stimulation while the second microelectrode recorded membrane potential during antidromic invasion. Stimulation of the right connective with a 20V, 0.5 msec pulse every 3 min yielded reproducible axon and soma spikes. Bath application of diazepam (10^{-4}M) produced an increase in latencies to both axon and soma spikes, an increase in soma spike width, and a marked decrease in soma spike height and afterhyperpolarization which was maximal at 1/2 hr post application. R05/4864 (10^{-4}M) for 1 hr produced either no effect or marginal changes opposite in direction to that seen with diazepam. The effects of diazepam and R05/4864 were reversible only with prolonged washing.

The effects of diazepam suggest a possible mechanism of membrane stabilization which could produce conduction blocks in regions of low safety factor such as points of axon bifurcation and dendritic arborization. Conduction block mechanisms could abort seizure spread and prevent the establishment of secondary epileptogenic foci independently of effects on neuronal activity in primary foci. (Supported by NIH Fellowship 4-F02-GM52664, the Southern Medical Association Research Project, and NIH grant NS-12419).

443 SYNCHRONOUS DISCHARGES IN NEOCORTEX ALTER THE EXCITABILITY OF INTRACORTICAL AXON TERMINALS. Jeffrey L. Noebels and David A. Prince. Dept. Neurol., Stanford Univ. Sch. Med., Stanford CA 94305.

During epileptogenesis produced by focal application of penicillin or strychnine to cat cortex, action potentials generated in the intracortical axons of thalamocortical relay (TCR) cells antidromically invade their parent cell bodies (Gutnick and Prince 1972, Schwartzkroin et al. 1975, Scobey and Gabor 1975). We have found that, in 89% of the TCR cell population of n. ventralis posterolateralis, the brief (20 msec) bursts of antidromic spikes following each isolated interictal discharge are greatly prolonged in duration (.1-1.5sec) during the interictal-ictal transition period. At this stage, axonal spike firing accounts for a majority of TCR cell activity, and is directly associated with the development of focal seizures. In order to determine whether the excitability change initiating repetitive firing in axons is dependent upon direct exposure of the intracortical axon terminals to convulsant drugs, or whether it might be a result of epileptiform activity in cortex per se, we studied the activity of identified TCR cells in nucleus ventralis posterolateralis of the cat during seizure activity initiated by brief trains of electrical pulses applied to postcruciate cortex. During the early stages of the cortical afterdischarge, bursts of regular (3-4msec) interval, constant amplitude spikes were recorded in TCR cell bodies. Burst spikes were proven to be of antidromic origin by demonstrating that they did not collide with cortically-evoked antidromic spikes. Antidromic bursts occurred only during afterdischarges, and could not be produced by subthreshold cortical stimulation. Intracellular recordings showed that antidromic bursts were often present in TCR cells immediately before the prolonged cellular depolarizations associated with each cortical discharge, indicating that prior orthodromic activity in the neuron was not necessary to trigger axon bursts. Within 10 sec of the onset of continuous cortical seizure activity, axonal spike generation ceased abruptly without any decrease in firing frequency. Since no synaptic contacts onto the intracortical segment of TCR axons are present, the results show that axon terminal excitability is modulated by endogenous events coincident with neocortical discharges. These and other data show that non-synaptic excitation and repetitive firing of intracortical axons occur in normal cortex during intense neuronal discharges, and may be presumed to be a general mechanism for increasing synchronization and excessive excitatory synaptic drive in cortical epileptogenesis. (Supported by NIH grant NS06477 from NINCDS.)

444 SELECTIVE ATTENUATION OF TRANSMITTER-INDUCED CHLORIDE CONDUCTANCE BY PENTYLENETETRAZOL (PTZ). Terry C. Pellmar and Wilkie A. Wilson. Epilepsy Center, Veterans Administration Hospital and Department of Physiology and Pharmacology, Duke University Medical Center, Durham, NC 27705

In the neurons of Aplysia californica, the synaptic actions of low concentrations (2 to 10 mM) of PTZ were studied. Iontophoretic responses were elicited by acetylcholine, dopamine, serotonin and GABA. Chloride-dependent, fast inhibitory responses to the neurotransmitters were reduced 50 to 60% by 2 mM PTZ. At the same concentration, PTZ caused an attenuation of the sodium-dependent, fast excitatory response by approximately 25% and of the potassium-dependent, slow inhibitory response by approximately 10%. The extent of attenuation of the responses did not vary with the neurotransmitter used to elicit them. Higher concentrations of PTZ (10 mM) further reduced all of the responses. At the concentrations of PTZ used, membrane actions were minimal. Two millimolar PTZ had no effect on the current-voltage (I-V) relationship of the cells while ten millimolar PTZ induced a small degree of non-linearity into the I-V curve.

These results indicate that the most potent action of PTZ is an attenuation of chloride conductance elicited by neurotransmitters in the cells of Aplysia. Since these effects are very similar to those previously described for penicillin (Pellmar and Wilson, Brain Res. 1977) a decrease in synaptic chloride conductance is postulated as a general mechanism of convulsant activity.

445 DICHOTOMOUS RESPONSE TO PENICILLIN-INDUCED INSTABILITY IN THE ALPHA-CHLORALOSE ANESTHETIZED CAT. S.R. Quint*, J.D. Charlton* and R.N. Johnson. Depts. Biomed. Engr. and Neurol., Sch. Med. Univ. of Virginia, Charlottesville, Virginia 22901

Active regulatory mechanisms have been implicated in the control and arrest of seizure activity, with subcortical sources of regulation activated by corticofugal influence. We have previously compared the effects of stimulation of subcortical structures and of common anticonvulsant drugs on excitability of the thalamocortical motor system. In this study we have investigated the influence of an active penicillin focus on the excitability of the thalamocortical motor system of the α-chloralose anesthetized cat.

Stimuli were presented in pairs to ventrolateral thalamus, varying both the amplitude of the second stimulus and the stimulus pair period. Resultant evoked responses from the computer generated stimuli were quantified and stored on-line. Multidimensional augmentation curves were then used to characterize the excitability of the system in its control state and after penicillin application.

Following the application of penicillin to cortex, homotopic to the recording site, one of two developments was observed, with equal incidence. In one group, an initial, unequivocal suppression of the response profile was accompanied by a relatively quiescent electrocorticogram (E.Co.G). Despite persistence of the epileptogenic focus, the response magnitude consistently returned to control levels, followed by considerable cortical spike activity and occasional seizurelike episodes of complete E.Co.G. disruption. Such intense epileptiform activity was followed by a return to the suppressed profile, an elevated threshold, or both. This modification of excitability suggests the presence of an active regulatory mechanism. The alternate development to the attenuated response was represented by a consistently magnified response profile, accompanied by moderate cortical spiking. However, intense epileptiform activity was never observed. The magnified response to the focus appears contingent upon a fundamental difference in the pre-penicillin response profile. These control profiles were obtained at a deeper level of anesthesia where augmentation showed less complex behavior. We assume that the mechanisms responsible for the complex modification of augmentation are not operative when this peculiar chloralose state is manifest. There is considerable evidence suggesting that cortical depression from α-chloralose may eliminate feedback to subcortical structures with an increase in convulsant threshold, while subcortical structures are facilitated, with resultant motor hyperexcitability. Such a selective elimination of corticofugal influence would provide a plausible explanation for the dichotomous response to penicillin-induced instability.

446 CONVULSANT ACTION OF MONOFLUORACETIC ACID: CORTICAL DISINHIBITION. W. Raabe and L. Zieve*. Dept. of Neurology, St. Paul-Ramsey Hospital, St. Paul, Minn. 55101, and Dept. of Research, VA Hospital, Minneapolis, Minn. 55417.

Monofluoracetate (MFA), which blocks the oxidation of citrate in the tricarboxylic acid cycle, is a well-known convulsant. However, the detailed mechanism of convulsant action is not clear. Because MFA increases cerebral ammonia concentrations just prior to convulsions it was suggested that the effects of ammonia, abolition of postsynaptic inhibition, initiate the convulsion.

The effects of intravenously administered MFA and ammonium acetate (AA) on cortical postsynaptic inhibition and cerebral ammonia concentrations were studied. Pentobarbital anesthetized and artificially respirated cats were used. Extracellular recordings were obtained from pyramidal tract cells. Cortical postsynaptic inhibition was measured as the efficacy of recurrent postsynaptic inhibition of pyramidal tract cells to suppress antidromic action potentials of pyramidal tract cells. As soon as the efficacy of inhibition was abolished the widely exposed cortical hemispheres were frozen with liquid nitrogen. Cerebral ammonia concentrations were determined with the Conway microdiffusion method.

As the first sign of neuronal toxicity MFA (1 mg/kg bodyweight) abolished the efficacy of cortical post-synaptic inhibition; at this time an electrocorticogram still showed no seizure patterns. MFA induced disinhibition occurred at cerebral ammonia concentrations (345 ± 275 S.D. nmol/gm wet weight, N=6) which were only slightly higher than in sham-operated animals (284 ± 191 S.D. nmol/gm wet weight, N=12). AA (1.4 - 3.3 mmol/kg bodyweight) abolished the efficacy of cortical inhibition at ammonia concentrations about three times higher (861 ± 156 S.D. nmol/mg wet weight, N=5) than in sham-operated animals.

MFA abolishes the efficacy of cortical post-synaptic inhibition like ammonia does. The effect of MFA on inhibition occurs independent of MFA induced increases of cerebral ammonia concentrations because MFA-disinhibition occurs at almost unchanged cerebral ammonia concentrations whereas AA-disinhibition requires about three times increased cerebral ammonia concentrations. Cortical disinhibition may account for the convulsant action of MFA.

447 *NEUROPHYSIOLOGICAL AND BEHAVIORAL CHANGES PRODUCED BY CEREBELLAR STIMULATION.* Lee T. Robertson, Mary Artero*, and Don Rushmer. Neurological Sciences Institute, Good Samaritan Hospital and Medical Center, Portland, Oregon 97209.

Electrical stimulation of the cerebellar cortex is being used for therapeutic control of selected cases of epilepsy and cerebral palsy. In monkeys (Macaca fascicularis) we have used similar electrode systems and placement in an attempt to quantify the physiological parameters and long-term stability of stimulation and to identify behavioral changes. The monkeys were trained to precisely touch three buttons in a left-to-right sequence. The analyses of the forelimb movement was by EMG, single-frame motion picture, and computer printouts of timing characteristics for each trial. The monkeys were then implanted with modified Avery electrodes over the intermediate cerebellar cortex and bonescrew electrodes for EEG were symmetrically placed over the cranium. Evoked responses were averaged (N=100-250) by a PDP-12 computer. The lowest threshold was for bilateral cerebellar stimulation, which produced a large amplitude evoked potential over the sensory-motor cortex. The shape of the potential consisted of two biphasic positive-negative waves; at higher current levels the amplitudes of the first two waves increased and a third positive wave also appeared. The shape of the response was consistent at various frequencies but an increased amplitude occurred at higher current levels or longer pulse durations. Contralateral stimulation required a slightly higher current threshold and ipsilateral stimulation produced no response. Cerebellar stimulation consistently affected the wave form of sensory evoked potentials. For example, one minute of bilateral stimulation surpressed the late component (23-40 msec) of an evoked response produced by electrical stimulation of the tail. The effect lasted up to five minutes. One week of continuous stimulation (1 min on/off) did not affect the shape or amplitude of any of the evoked responses. Bilateral cerebellar stimulation at slightly above threshold had no effect on the precisely timed forelimb movement. However, at slightly higher current levels a significant increase in the latency of the movement occurred during and immediately after stimulation. Contralateral stimulation produced only a small effect and ipsilateral stimulation resulted in no change. High-speed films of the movement indicated that stimulation produced a decrease in the velocity but did not disrupt the stopping, starting, or precision of limb placement. Possibly a beneficial effect of cerebellar stimulation in cerebral palsy patients is a slowing of phasic movements.

448 A RODENT MODEL OF CENTRENCEPHALIC EPILEPSY. Paul F. Robinson* and Shirley A. Gilmore. Dept. Anat., Univ. Arkansas Med. Sci., Little Rock, AR 72201.

A subpopulation of Charles River CD^{R} albino rats has been found to display behavior possessing certain characteristics of human petit mal epilepsy and of generalized penicillin epilepsy in the cat. These characteristics include cessation of spontaneous movement, staring, bilateral twitching of the vibrissae, nose and mouth, and augmentation by drowsiness. The ECoG tracings of these animals display trains of polyspike plus spike and wave discharges with average frequencies of 6-10 complexes per second and amplitudes of 300-700 μv. The ECoG findings differ from reports by McQueen and Woodbury (Epilepsia 16: 295, 1975) and Fariello (Epilepsia 17: 217, 1976) of the inability of the rat brain to produce spike and wave forms.

Such discharges appear spontaneously in approximately 20% of the subpopulation. They may be induced in the remainder of the subpopulation by parenteral injections of pentylenetetrazol (10 mg/kg body weight) and penicillin G (100,000 u/kg body weight/day for 1 to 5 days). Those discharges which are spontaneous or penicillin-induced are self-sustained in that they persist throughout the six-month duration of the study.

449 BRAIN EXTRACTS AND AUDIOGENIC SEIZURES: ENHANCEMENT OF SEIZURE RATE BY EXTRACTS FROM DBA/2J MICE AT PEAK SEIZURE SUSCEPTIBILITY. Robert A. Schreiber, Dept. Biochemistry, Univ. of Tennessee Center for the Health Sciences, Memphis, TN 38163.

Mice susceptible to sound-induced seizures (audiogenic seizures, AGS) have been considered an experimental model for the study of sensory epilepsy.

One major question is whether susceptible mice are synthesizing some unusual substance which makes them hyperreactive, or whether they lack some necessary substance which affords sufficient protection under normal circumstances. An experimental approach to this question is to prepare a brain extract from selected AGS susceptible or non-susceptible donor mice, inject it into selected recipients, and test the recipients for AGS. (It is assumed that any active fraction contains a substance not present in inactive fractions.)

The experiment reported here is the first attempt to alter susceptibility to AGS in a strain of mice intrinsically susceptible to AGS at particular ages. (Other published efforts to confer heightened sensitivity to acoustic stimulation have been performed on C57BL/6J mice subjected to audiogenic priming. Of these, only one demonstrated significant differences on an initial test for AGS in recipient mice[1].)

Previous data do not exclude the possibility that the substance of interest is a peptide. Brains of 21-day-old DBA/2J mice were removed and lyophilized. The freeze-dried brains were powdered then extracted with cold 1.0 M acetic acid for 2 hr, and centrifuged for 1 hr at 5° at 6000 rpm. The supernatant was lyophilized, taken up in .05 ml H_2O per mg of brain powder, and centrifuged as before. The supernatant was passed through a PM10 Amicon filter, again lyophilized, and resuspended in 0.20 ml H_2O per brain equivalent. Recipient 21 day old DBA/2J mice were injected i.p. with one brain equivalent, and tested for AGS at either 2 hr, 1 day, or 2 days, or 5 days after injection. No mouse was used more than once. The incidence of lethal seizures was significantly ($p<.05$) raised from a control level of 36% to an experimental level of 81% in mice tested 1 day later. There were no significant differences in any level of seizure observed between experimental and control (untreated) mice tested at 2 hr, 2 days, or 5 days. This experiment supports the hypothesis that some additional substance is present in the brain during a period of CNS hyperreactivity.

450 SOME NEUROCHEMICAL CORRELATES IN SEIZURE PRONE GERBILS. R. N. Seaman*, S. L. Seaman and A. Y. Sun*. Sinclair Comparative Medicine Research Farm, University of Missouri, Columbia, MO 65201.

The Mongolian gerbil (Meriones unguiculatus) has previously been reported to exhibit a spontaneous seizure response similar to that found in the human epileptic. Over 50% of the gerbils in our colony displays an epileptiform seizure characterized by (1) ear and vibrissae twitch, (2) eye blinking, (3) body tremor, (4) crouching, (5) myoclonic body jerks, (6) clonic-tonic seizures, (7) rapid running and finally a (8) quiescent period. The seizure was initiated either by handling or by exposing the animal to a foreign environment. The latency, duration and severity of the epileptiform response was variable. This behavioral condition appears to be inherited as an autosomal, dominant condition with incomplete penetrance. Three groups of female gerbils (10-14 months old) were injected intraventricularly with 5 μCi [^{14}C]-GABA and 5 μCi of [^{3}H]-NE. The animals were then sacrificed by decapitation five minutes after the radioisotope injection. The control, non-seizing animals displayed the greatest in vivo brain uptake of NE and GABA. The biogenic amine uptake was significantly lower in those animals injected prior to the onset of the seizure. A significant difference in NE-uptake was also observed between the pre- and post-seizure injected groups. In another experiment, male gerbils (10-15 months old) were decapitated during seizure and compared with non-seizure control animals. Seizing animals exhibited an elevated in vitro synaptosomal uptake of Ca^{2+}. There was no difference in synaptosomal (Na^{+} + K^{+})-ATPase or AChE activity. From these studies it appears that some membrane systems are altered during the seizure response. This animal model may prove useful in testing the neurochemical as well as physiological conditions resulting from epileptic seizure.

451 REDUCED SEIZURE SUSCEPTIBILITY TO MMH INTOXICATION FOLLOWING DENTATE AND VENTROBASAL THALAMIC LESIONS IN CATS. M. N. Shouse*, M. B. Sterman and J. M. Siegel. Dept. Anat., Sch. Med., UCLA, Los Angeles, CA 90024 and Neuropsychol. Res. and Neurophysiol. Res., VAH, Sepulveda, CA 91343.(SPON: Joel F. Lubar)

The present experiment attempted to clarify conflicting evidence on the relationship of 12-15 Hz sleep spindles to seizure activation. Seizure thresholds were calculated in minutes post-injection following IP administration of the convulsant drug monomethylhydrazine (MMH) to cats with lesions intended to enhance the occurrence of spontaneous 12-15 Hz sleep spindles recorded from sensorimotor cortex. Twelve cats with bilateral cortical and subcortical recording electrodes were divided into three groups receiving electrolytic lesions in the dentate nucleus (Group I), the ventrobasal (VB) thalamus (Group II), or in one of various "control" regions (Group III). Lesion sites in Group III animals avoided primary afferent pathways to VB thalamus, destruction of which has been found to enhance sleep spindle activity (Elliot and Sterman, Anatomical Record, 1975, 181: 352) and included cerebellar white matter, pyramidal tract, and ventral pontine tegmentum. Prior to the MMH trials, three baseline EEG's were obtained during pre- and post-lesion conditions. Following the MMH trial, lesions were verified histologically. Results of the MMH trial revealed that animals with dentate and VB thalamic lesions showed elevated seizure thresholds relative to those with control lesions. EEG analyses indicated that animals with reduced seizure susceptibility showed prolonged periods of slow wave sleep relative to their own pre-lesion baselines and to the pre- and post-lesion baselines of control animals. These findings are compatible with the view that sleep spindles do not facilitate seizure activation in epileptogenic neuronal populations (Wagner et al., Electroenceph. clin. Neurophysiol., 1975, 39: 499-506) and may, in fact, exert a protective influence, as suggested by our findings in both epileptics and patients with dorsal column injury.

452 UNIT ACTIVITY AND LOCAL CHANGES IN PO_2 DURING FOCAL EPILEPSY IN THE FROG. Thomas J.Sick* and Norman R.Kreisman. (SPON: J.P. Ellison). Department of Physiology, Tulane University School of Medicine, New Orleans, LA 70112.

Unit activity and local PO_2 were recorded from the primordium hippocampus of bullfrogs by glass coated platinum-iridium microelectrodes with a tip diameter of <1μ and an exposed tip length of 15-20μ. Focal epileptogenic activity was initiated by microinjection of 10-100U of Na penicillin-G and the electrocorticogram was monitored from bipolar Ag/AgCl electrodes placed on the surface of each hemisphere.

Units were classified according to the occurrence of firing in relation to ECoG spikes. Of 34 units recorded from 14 bullfrogs, 18 were excited, 12 were inhibited, 2 showed excitation followed by inhibition and 2 were unaffected during or immediately following the ECoG discharge. The four unit response classes correspond well with those reported by Wilder and Morrell (Neurology 17:1193, 1967). Occurrence of unit firing was also compared to ECoG related PO_2 changes. The most common response was a transient (10-60 sec) decrease in local PO_2 following the ECoG spike. This was accompanied by a short (500-1000 msec) high frequency unit discharge, the duration of which often coincided with the duration of the falling phase of the PO_2 transient. Units which were inhibited following the ECoG discharge were correlated with PO_2 decreases only when an excitatory response from another unit was recorded at the PO_2 microelectrode. Units unaffected during the ECoG discharge were rare and were never accompanied by a change in local PO_2.

Association of local PO_2 transients with excitatory unit responses suggests that these transients reflect increased oxygen consumption by those units and/or by neighboring glial cells. However, since local blood flow was not measured, a transient decrease in local blood flow associated with the excitatory unit response cannot be ruled out.

453 INCREASED SENSITIVITY TO MAXIMAL ELECTROSHOCK SEIZURES FOLLOWING SELECTIVE DESTRUCTION OF NORADRENERGIC NEURONS WITH 6-HYDROXYDOPAMINE (6-OHDA). R. L. Simonton* and R. A. Browning. Southern Illinois University, School of Medicine, Carbondale, IL 62901.

Despite a vast amount of pharmacological evidence showing seizure inhibitory effects of the central catecholamines, the relative contributions of norepinephrine (NE) and dopamine (DA) remain somewhat equivocal. In order to evaluate the relative importance of NE and DA in this regard, seizure susceptibility was examined in rats after selective destruction of NE or DA neurons with 6-OHDA. Pretreatment with benztropine mesylate (30 mg/kg, i.p.) and intraventricular 6-OHDA (100 + 50 μg) resulted in a 55-60% depletion of forebrain NE without altering DA or serotonin. Animals subjected to maximal electroshock stimulation (MES) 30 days following treatment with the benztropine + 6-OHDA combination exhibited a decrease in the latency for hindlimb extension ($P < .02$), an increase in the duration of hindlimb extension ($P < .05$), and a prolongation of recovery ($P < .01$). Moreover, the ability of acetazolamide (12 mg/kg, i.v.) and phenobarbital (8 mg/kg, i.p.) to abolish hindlimb extension in the MES test was markedly reduced in rats treated with benztropine + 6-OHDA. In contrast, rats treated with protriptyline HCl (20 mg/kg, i.p.) and intraventricular 6-OHDA (200 μg) failed to differ significantly from vehicle-injected rats in their response to MES 30 days post injection. The anticonvulsant effects of acetazolamide and phenobarbital were likewise unchanged in the rats receiving protriptyline + 6-OHDA. Monoamine analyses in animals treated with protriptyline + 6-OHDA revealed a 50-60% reduction in forebrain DA with no deficit in NE. These findings show that a selective reduction in brain NE can increase seizure susceptibility and antagonize the action of anticonvulsants, while a comparable reduction in DA does not have this effect. Although these data do not preclude the possiblity that DA functions as a modulator of MES-induced seizures, it indicates that NE plays a greater role in this regard.

454 EXPERIMENTAL EPILEPSY AND CEREBELLAR STIMULATION IN THE MONKEY. Henry V. Soper, Jeffrey P. Lieb, Thomas L. Babb, George M. Strain* and Paul H. Crandall. Brain Research Institute, UCLA, Los Angeles, CA. 90024.

An alumina cream model of temporal lobe epilepsy was developed in the monkey to try to determine the effect of cerebellar stimulation on such epilepsy. Five monkeys had fresh alumina cream (aluminum hydroxide) stereotaxically placed in the anterior and posterior hippocampus in successive surgeries with 8½ months between the surgeries. None developed chronic epilepsy after the first placement. Three more received one-stage bilateral placements. All monkeys received recording electrodes and #32 and #33 received 6.8mm^2 platinum stimulating electrode pairs on the paravermal cortex.

In three weeks the animals became anorexic, and within the next two weeks they began having psychomotor seizures. Five animals started having relatively mild seizures almost continuously (epilepticus partialis continua), appeared almost comatose, and required force-feeding; one died from an unrelated cause; and two continued to have seizures until they were sacrificed (113 and 432 days after surgery).

Of the animals which went into status, three died, and two (#80 and #33) were deteriorating with no evidence they would recover. Cerebellar stimulation electrodes were implanted in #80, and both monkeys were stimulated at 2.4 uC/phase at 10 hz for 10 min on and 10 min off. Over the first four days the most dramatic change in #80 was the reduction in the spread of seizure activity from the hippocampus to the cortex. The general condition of the animal improved and it began having clear interictal intervals. Unfortunately, it choked on its food and died shortly after this improvement. The other monkey (#33) also began improving after four days. After 2½ weeks the behavior was normal during interictal intervals, although it was still having seizures. Immediately after cerebellar stimulation was terminated, the state of the animal remained the same, but over the next two months it deteriorated. Again, after four days of stimulation there was some improvement and after 2½ weeks interictal behavior was normal. Following the end of stimulation this time the behavior remained relatively stable for the next 11 months and subsequent stimulation did not alter it.

These preliminary results suggest that bilateral, multifocal, alumina cream implantations in the hippocampus can induce a chronic model of temporal lobe epilepsy. In addition, although cerebellar stimulation does seem to have an effect on this epilepsy, it appears to be most effective in the severely epileptic monkey, takes about four days to show any effect, and has its primary effect on improving the general interictal condition of the animal. Supported by NIH Contract NS 4-2331.

455 PREVENTION OF SEIZURE-INDUCED INCREASE IN BRAIN WATER IN THE DEVELOPING RAT BY STEROID DRUG THERAPY. Norma J. Starr and David Holtzman*. Dept. Neurology, Stanford U. School of Medicine, Stanford CA 94305

Previous studies in our laboratory have shown an increase in brain water and electrolytes, as well as a decrease in both brain and body weight in rat pups exposed to repetitive seizures between 11-15 days after birth. Furthermore, a frequent pathologic finding after prolonged seizures in young children is cerebral edema. If indeed the production of cerebral edema is involved in the encephalopathy resulting from repetitive seizures, then the use of drugs which reduce brain water, (e.g. steroids) may be useful in the management of young children who seize.

In order to study the effects of steroid drug therapy on animals subjected to seizures early in life, litters of rat pups were divided into weight-matched halves, with one-half receiving daily injections of either corticosterone (25 or 50 µg/g) or dexamethasone (1 or 5 ng/g) between 1-21 or 10-21 days of age. On days 11-15, 'seizure' litters received 2 electroshocks per day (150 V., 1 sec, AC) to study the effects of repeated seizures on brain weight and water content and body weight. Control litters, with animals receiving the same dose had the electrodes attached, but with no current passed.

Our results indicate that chronic treatment with a steroid drug can prevent the increase in brain water and the decrease in brain and body weights observed after seizures alone. Differences between the two drugs were seen in terms of the relative effectiveness of different treatment regimes. After corticosterone treatment (1-21 days) both the 25 and 50 µg doses could attenuate the increase in brain water and electrolytes, with no loss of brain or body weight. After treatment from 10-21 days, only the 50 µg dose was effective. Dexamethasone treatment, at both doses tested, and under both treatment schedules resulted in the prevention of the seizure-induced increase in brain water and changes in brain weight.

Thus it appears that chronic treatment with optimal doses of a steroid drug may be effective in the prevention of post-seizure encephalopathy in the developing brain. (Supported by (NIH Research Grants, NS 12151 and ES 01197 to D.H. and IT 32NS-02012-02 to N.S.)

456 EFFECTS OF CENTRAL CORTICAL EEG FEEDBACK TRAINING ON EEG CHARACTERISTICS AND SEIZURE INCIDENCE IN POORLY CONTROLLED EPILEPTICS. M. B. Sterman and L. R. Macdonald. V. A. Hospital, Sepulveda, CA 91343 and University of California, Los Angeles, CA 90024.

This study examined the effects of central cortical EEG feedback training on seizure incidence in poorly controlled epileptics. After baseline recordings patients were trained in the laboratory and then initiated on a double crossover, ABA design using portable equipment at home, with bimonthly laboratory test sessions. EEG data were recorded polygraphically and on magnetic tape. Performance at home was monitored by a strip chart recorder within the portable unit. Training was based upon the simultaneous detection of two central cortical (C_3-T_3) EEG frequency bands (6-9 Hz and either 12-15 or 18-23 Hz), with reward provided for the occurrence of one in the absence of the other. The ABA design used consisted of successive 3 month periods of training, with reward contingencies reversed after each period and without the subject's knowledge. EEG response evaluations (power spectral analysis) and seizure incidence records were compared before, during and after the ABA design.

Results to date indicate significant redistribution of EEG power spectral densities in direct relation to training contingencies, with reversed contingencies producing reversal in power spectral distribution. Epileptics were found to be consistently deficient in power above 8 Hz, and particularly in the 12-15 Hz band during stage 2 sleep. Six of the eight patients reported significant reductions in seizures initiated during or in strict relationship to reward for 12-15 Hz or 18-23 Hz in the absence of 6-9 Hz central cortical activity. EEG changes associated with seizure reduction reflected a normalization of waking and sleeping EEG patterns.

These data are interpreted as indicating that significant and specific changes in EEG characteristics, and therefore in the neural substrates of the cortical EEG, can be achieved in epileptics with operant conditioning procedures. The reinforcement of normal thalamocortical conduction patterns with certain training contingencies is felt to account for both the reduction in EEG abnormalities and the apparent elevation of seizure thresholds observed.

457 THE EFFECTS OF PHENYTOIN ON SENSORY EVOKED RESPONSES IN THE CAT. James D. Stittsworth, Jr.,* Robert Teece* and Carl L. Faingold. (SPON: J.Donald Easton). Southern Illinois University School of Medicine, Springfield, IL 62708

The effects of phenytoin (PHT) administration on auditory and visual evoked responses were studied in unanesthetized, paralyzed cats. Responses evoked by visual or auditory stimuli were recorded from primary sensory structures (cortex, lateral geniculate, inferior colliculus) and reticular formation. Phenytoin was infused intravenously either in commercial diluent (consisting of 10% ethanol and 40% propylene glycol) or in saline solution at rates of 1-2 mg/kg/min. Arterial blood samples were drawn and analyzed for PHT serum levels, using gas-liquid chromatographic methods (Kupferberg, Clin. Clim. Acta.29:283, 1970). Complete and long-lasting abolition of all auditory evoked responses was seen with a total dose of 20-25 mg/kg of PHT in commercial diluent. Doses in a range of 22-56 mg/kg of PHT in saline were required to induce the same degree of reduction in auditory evoked responses. Although the doses required to cause the reduction of responses differed with the two solutions, the serum PHT levels were found to be consistently in the range of 30-40 µg/ml in both cases. At these serum levels of PHT primary visual evoked responses were not consistently altered. Although the responses evoked in reticular formation by auditory stimuli were abolished, the responses to visual stimuli in the same site were unaffected. Thus, PHT appears to have a preferential effect on the responses to auditory stimuli. The commercial diluent appears to enhance the effectiveness of PHT on auditory evoked responses. In addition, at the higher dose rate of PHT in the commercial vehicle EEG changes were noted that would be consistent with the induction of sleep. Since drowsiness is induced by PHT in patients only when it is administered intravenously, the diluent may play a role in the production of this symptom. Previous reports have shown that auditory evoked responses enhanced by the administration of the epileptiform "anesthetic chloralose are also abolished by PHT administration (Herman and Bignall, Electroenceph, clin. Neurophysiol. 23:351, 1967). Responses to sensory stimuli are also enhanced in a variety of other seizure models (Faingold, Neuropharm. 16:73, 1977), and the reduction of the auditory responses by PHT may play a role in the ability of PHT to reduce seizure susceptibility.

458 EFFECTS OF CEREBELLAR STIMULATION ON SEIZURE THRESHOLDS. George M. Strain*, William G. Van Meter* and William H. Brockman* (SPON: J. P. Lieb). Biomedical Engr. Prog. and Dept. Vet. Anat., Pharm. and Physiol., Iowa State Univ., Ames, IA 50011.

Cerebellar stimulation (CBL) and standard anticonvulsant drugs were compared for their abilities to elevate seizure thresholds. Generalized EEG seizures were elicited in conscious, acute New Zealand albino rabbit preparations by 10 or 15 mg/kg intravenous (IV) injections of pentylenetetrazol (PTZ) or by electrical stimulation of the frontal cerebral cortex at 50 Hz, 1 msec monophasic pulse duration and 4.0-7.6 volts for 2 seconds (ELEC).

After establishing control seizures, one of three anticonvulsant treatments was applied: IV injection of (1) phenobarbital (PHE) 25 mg/kg or (2) diphenylhydantoin (DPH) 30 mg/kg, or (3) transhemispheral electrical stimulation of the simplex and ansiform lobes of the cerebellum. Seizures were repeatedly induced with regular increments in PTZ dose or ELEC voltage until a seizure was evoked that approximated the control in severity and duration.

Cerebellar stimulation parameters of 10 Hz, 1.5-2.0 msec biphasic pulse duration, and 3-4 volts were found to be effective in attenuating PTZ-induced EEG seizure activity. Deviation from these parameters markedly decreased the effectiveness of the stimuli.

Analysis used six blocks of data: elevations of ELEC seizure thresholds by PHE, DPH or CBL, and elevations of PTZ seizure thresholds by PHE, DPH or CBL. ELEC seizure thresholds were found not to be elevated by CBL, and PTZ seizure thresholds were not elevated by DPH. In each of the remaining four cases the seizure threshold elevations were significant at a level of $p < 0.025$ or greater.

Elevations of seizure threshold (percent change in dose or voltage) were compared to evaluate the efficacy of CBL in comparison with PHE and DPH as antagonists of generalized seizures. At a significance level of 0.05, the elevation of PTZ seizure thresholds by PHE was greater than that of CBL and greater than the elevation of ELEC seizure thresholds by DPH. No differences existed at the 0.01 level of significance.

The failure of CBL to elevate ELEC seizure thresholds was attributed to a possible need for chronic cerebellar stimulation and/or differences in the seizure-inducing mechanisms of PTZ and ELEC.

It is concluded that the inhibition of generalized seizure activity on an acute basis by CBL does not differ significantly from that seen with DPH or PHE.

459 EFFECTS OF ELECTRICAL STIMULUS INTENSITY ON HIPPOCAMPAL POST-ICTAL PHENOMENA. H.S. Swartzwelder*, C.M. Eccles* and R.S. Dyer. (SPON: L.D. Fechter). Dept. Environmental Health Sciences, Johns Hopkins Univ., Balto., Md. 21205.

Electrical Stimulation of the hippocampus may produce afterdischarges (AD's) which can be recorded in the absence of obvious behavioral manifestations. Little attention has been given to the electrical changes which occur immediately following an AD, or to the influence of stimulus intensity upon these changes. Casual observation has revealed that the latter stages of the well known post AD EEG flattening (depression) are often characterized by a brief period of bilateral synchronous spiking, which we call the rebound AD. The AD, depression and rebound are often characterized by the appearance of behavioral episodes similar to wet dog shakes known to accompany such phenomena as morphine withdrawal (Psychopharm., 1976, 46, 191) and generalized motor convulsions (Psychopharm., 1975, 44, 33). The present study was designed to determine the influence of stimulus intensity upon the properties of hippocampal AD and post-AD phenomena. Sixteen Long-Evans male rats had bipolar nichrome wires implanted into the dorsal hippocampi for stimulation and recording, and skull screws implanted for grounding. Two weeks were allowed for recovery, whereupon thresholds for producing AD's were determined by the method described by Racine (EEG, 32, 1972). The animals were then matched according to threshold levels and divided into two groups, one receiving daily stimulation at 115% of threshold, and the other receiving daily stimulation at 400% of threshold. Results indicated that the post-AD depressions associated with AD's in the high intensity group lasted significantly longer than did those associated with AD's in the low intensity group. High stimulus intensity was inversely related to AD duration. Wet dog shakes occurred most frequently during the rebound AD, and their frequency was not related to stimulus intensity, AD duration, depression duration or rebound duration. When present, these wet dog shakes tended to occur immediately following or during the latter third of the AD and rebound AD. This research was supported in part by NIH grants HL 054053 and EHS 00454.

460 DRUG EVALUATION OF EXPERIMENTAL PSYCHOMOTOR STATUS EPILEPTICUS: A NEW ANIMAL MODEL. Katherine Taber*, S.F. Zornetzer and B.J. Wilder. Dept. Neuroscience, College of Med. U. of Fla., Gainesville, Fl., 32610.

Recently a new animal model of psychomotor status epilepticus, produced by a variant of the kindling paradigm, was reported (EEG Clin. Neurophysiol., in press). Self-sustained seizures (SSS) were induced by the repetitive application of electrical stimulation via depth electrodes chronically implanted into the dorsal hippocampus of male Swiss ICR mice. The stimulus parameters used were a 1.0 sec pulse train at 60 Hz, using 1 ms square-wave biphasic pulses at an intensity of 400 ua (constant current). The interstimulus interval was 60 sec.

Application of 100 to 150 stimulations to subfield CA3 of hippocampus results in the induction of non-lethal SSS. These seizures continued unabated for several hours after termination of electrical stimulation. Non-lethal SSS is characterized electrophysiologically by a slow spiking of 2-3 Hz and a dome or spike and dome wave form. Behaviorally these mice exhibit frequent automatisms or stereotyped behavior. These characteristics parallel the behavioral and electrophysiological observations of human psychomotor status epilepticus.

To test further the validity of this proposed animal model for human psychomotor status, drug challenges with antiepileptic drugs were performed. A double blind format was employed for all drug trials. Drugs were administered IP 20 min. after the onset of SSS and observations were continued until the cessation of SSS. The effect of diphenylhydantoin (DPH) (20mg/kg), phenobarbital (25mg/kg) and trimethidione (150 mg/kg), were evaluated on the behavioral and electrophysiological manifestations of non-lethal SSS. Results support the hypothesis that non-lethal SSS is a useful model for human psychomotor status epilepticus in so far as the pharmacological response of SSS in the mouse closely parallels the human clinical data. The implications of these data for future experimentation will be discussed.

461 EFFECTS OF PHENOBARBITAL ON SEIZURE ACTIVITY IN THE GERBIL. Kathy S. Watanabe*, Richard J. Schain and Beva G. Bailey*. Depts. Pediat. and Neurol./NPI, Sch. Med., UCLA, Los Angeles, CA 90024.

Phenobarbital is used extensively in the treatment of febrile seizures and epilepsy. Its popularity stems from its reported lack of adverse side effects on major organ systems. However, little is known about its influence on the central nervous system. Of particular concern is the developing brain, whose vulnerability to external events is well documented. Previous work in this laboratory has demonstrated a brain growth retardation in immature rats subjected to chronic phenobarbital administration. The present study was concerned with the effect of chronic phenobarbital treatment on seizure behavior in a strain of Mongolian gerbils (Meriones unguiculatus) that is predisposed to spontaneous seizures. Subcutaneous injections of 60 mg/kg phenobarbital were given daily to the experimental animals from 1 to 5 months of age. Control animals received equivalent doses of vehicle. At the termination of treatment (5 mo.), animals were tested regularly for seizure susceptibility until one year of age. Phenobarbital-treated animals exhibited an intensification of seizure activity both during and after the period of drug treatment. All animals receiving phenobarbital had one or more spontaneous seizures during the treatment period; 67% of the controls seized. During this time phenobarbital-treated animals had an average of 10.5 seizures with a mean seizure degree of +3.2 (scale of 1-5), whereas the controls had an average of 3.5 seizures with a mean seizure degree of +2.4. During the entire 7 month post-treatment period, the phenobarbital-treated animals displayed a mean seizure degree of +3.4 as opposed to +2.3 for the controls; drug treatment gerbils exhibited more frequent unstimulated seizures (66%) than did controls (37%). The latency to seize was shorter for the phenobarbital-treated animals (142 sec.) than for controls (233 sec.), and experimental animals had seizures of greater duration (231 sec.) than did controls (107 sec.). (All comparisons are significant at the 0.001 level.) These studies reveal that chronic phenobarbital administration enhances seizure activity in the gerbil. This enhancement persists long after termination of phenobarbital treatment. The explanation for this paradoxical effect may lie in the effects of phenobarbital upon the development of brain inhibitory mechanisms.

462 EFFECTS OF ELICITED SEIZURES ON LEARNING IN THE PAPIO PAPIO BABOON. Susan B. Weinberger* and Eva K. Killam* (SPON: A. Gabor). Departments of Pharmacology, University of California, Davis, CA 95616 and Boston University, Boston, MA 02118.

The contribution of seizures to the performance deficits that have been reported in human epileptics has been difficult to assess directly. This question has therefore been investigated experimentally by evaluating the effects of elicited seizures on learning in the epilepsy-prone baboon, Papio papio. Using three prepubertal animal subjects, learning performance was measured with a repeated acquisition task that required the animals to learn and perform a different sequence, or chain, of lever presses on a three-lever behavior panel each day. For each animal, the length of the chain started at two elements each session and increased stepwise as mastery of a chain was demonstrated.

When seizures were elicited twice weekly in each animal over a period of three weeks, mean performance levels (as assessed by efficiency, total errors, and time to criterion for each chain length) did not differ from preceding control values. However, learning performance was found to be significantly better at 18 hours than at 42 hours after each individual seizure, suggesting some type of cyclic phenomenon. When seizures were elicited at 24-hour intervals for 7 days, this cyclic phenomenon could not be evaluated, but the performance data demonstrated no overall or cumulative effect of these more frequent seizures on learning. Additionally, no changes in the baboons' spontaneous behaviors were observed over the course of this study.

Since limited numbers of seizures did not produce sustained impairment of learning performance, it was concluded that sources other than the sequellae of seizures themselves should be considered as the cause of performance deficits in epileptics.

463 EFFECT OF TRANSVERSE CORTICAL LESIONS ON AFTERDISCHARGE THRESHOLD, DURATION AND SPREAD. Howard J. Williams*, John H. Ferguson, M.D. and Gene H. Barnett*. (Spon: P. Bart Vrtunski). Division of Neurology, Case Western Reserve University School of Medicine and Cleveland Veterans Administration Hospital, Cleveland, Ohio 44106

A series of experiments were carried out to determine the effects of transverse (subpial) cortical lesions (TCL) of the cat suprasylvian gyrus (SS) on electrically induced Afterdischarge Threshold(ADT), Afterdischarge Duration (ADD), and Afterdischarge Spread (ADS).

Seventeen cerveau isole animals were studied. Lesions were performed 11 to 60 days earlier under sterile conditions. Platinum balled electrodes were placed over the SS bilaterally such that each gyrus was divided into two halves (four quadrants). Peak current ADT (50 Hz 5 sec train of biphasic pulses, 2 msec duration, 2 msec separation) for each quadrant was measured. Steps of 0.1 ma were used until ADT was obtained.

Results indicate that: 1. In the 6 control cats (no lesions) mean ADT was .57 ± .03 ma compared to a mean of .55 ± .03 ma in the 11 experimentals (1-8 transverse lesions). 2. ADD at threshold in control cats was 4.09 ± .52 sec compared to 11.93 ± 2.88 sec in experimentals. TCL did not seem to prevent ADS from stimulated lesioned areas, but did limit spread into lesioned areas from stimulation of non lesioned SS quadrants.

Contrary to data from chronically implanted and stimulated animals (Ferguson et al Neurosci. Abst. 2:245, 1976) the present experiments suggest that TCL does not significantly effect ADT. Furthermore, the fact that they increase ADD suggests an enhancement of epileptogenicity.

464 EPILEPTIFORM DISCHARGE INDUCED BY FERROUS AND FERRIC CATIONS. L. J. Willmore , G. W. Sypert , and J. B. Munson. VA Hospital Dept. of Neurology, Div. of Neurosurgery, and Dept. of Neuroscience, University of Florida, College of Medicine, Gainesville, Fl. 32610.

Application of epileptogenic agents such as penicillin, ouabain, and cobalt to pial surface of rat isocortex have been utilized to assess neural mechanism associated with the initiation of epileptiform discharge. However, the neuropathologic mechanisms associated with the development of human focal epileptic lesions may not be reproduced in models of epilepsy requiring such chemical application to brain. Implantation of metallic iron into monkey motor cortex induces activation-sensitive focal epileptiform discharge. This observation, combined with the known convulsant effect of subarachnoid injection of erythrocyte contents suggests that the presence of the metallic compounds of whole blood within cortical tissue may be important in epileptogenesis.

In the present study a solution containing 100 mM $FeCl_2$ (Fe^{++}) or $FeCl_3$ (Fe^{+++}) was iontophoresed on the pial surface of rat sensorimotor isocortex with a 5 μA current for 5 min from a pool of ionic solution contained within a plexiglass footplate having a 500 μM orifice. Electrocorticograms (ECoG) were continously recorded via bipolar metallic electrodes in contact with the pial surface ipsilateral to the site of iontophoresis. Multiunit extracellular recordings were obtained from various depths within the isocortex with a glass micropipette placed through the central perforation of the iontophoretic well.

After variable latency, high amplitude epileptiform discharge was observed in the ECoG. During iontophoresis of both ionic species extracellular microelectrode recording within isocortex revealed progressive unit synchronization at the time of epileptogenesis, with superficial layers of isocortex affected prior to the deeper lamina. Fe^{++}-induced epileptogenesis was associated with more prominent unitary burst activity than with Fe^{+++}. Furthermore, there appeared to be a greater disinhibition with Fe^{++} than Fe^{+++}. Depth of cation penetration was identified by specific histochemical staining for iron compounds.

465 BURST GENERATION AND CALCIUM MEDIATED SPIKES IN HIPPOCAMPAL CA3 NEURONS. Robert K.S. Wong* and David A. Prince. Dept. Neurol., Stanford Univ. Sch. Med., Stanford CA 94305.

The finding that hippocampal CA3 neurons act as pacemakers for epileptogenic discharge in the penicillin-treated slice preparation led us to study the behavior of guinea pig CA3 neurons in the normal slice. In contrast to CA1 cells, a large proportion of CA3 neurons exhibit spontaneous bursting activity. Bursts consisted of 2-11 spikes riding on a slow depolarization of up to 27mV. In bursts of more than 3 spikes, 2 phases of activity could be recognized. The early phase consisted of 2-4 rhythmic spikes whose interspike interval, spike height, and duration showed little variability from burst to burst in a given cell. Events in the late phase of the burst at the peak of the slow depolarization consisted of single or repetitive slow spikes with multiple humps or peaks. These spikes had longer durations (4-5msec), smaller amplitudes (up to 30mV), and longer, more variable, interspike intervals than the first few spikes of the burst. Short duration (2msec) intracellular depolarizing current pulses could evoke the whole train of spikes. Brief intracellular hyperpolarizing pulses of sufficient intensity to block a single spike, applied at various intervals after the first spike of a burst, would abort the subsequent spikes in the train. This and other evidence suggest that the burst-generating mechanism is an intrinsic property of CA3 pyramidal cells. When slices were treated with TTX (10^{-6}g/cc), intracellular depolarizing current pulses evoked slow spikes (4-5msec duration) with multiple humps and peaks. These TTX-resistant spikes appeared at levels of membrane depolarization comparable to those which evoked spikes in the late phase of the burst. Increasing the stimulating current decreased the latency of these responses and elicited rhythmic repetitive spike activities of increasing frequency. The slow high threshold spikes were reversibly blocked by locally applied Mn^{++}. In control experiments we found that single but not repetitive TTX-resistant spikes could be evoked in CA1 neurons; no such potentials have been seen in granule cells to date.

These data suggest that Ca^{++}-mediated spikes in CA3 pyramidal cells participate in normal bursting behavior. There is a striking similarity between the bursts studied and those recorded in CA3 and CA1 neurons during penicillin epileptogenesis in the slice. There is also a parallelism between the capacity to generate Ca^{++} spikes and the degree of involvement in penicillin epileptogenesis among the 3 major cell groups in the hippocampus. We would speculate that generation of Ca^{++} spikes may contribute to development of the depolarization shift and spike bursts in hippocampal "epileptic" neurons. 466 STATISTICAL ANALYSIS OF SINGLE UNIT DISCHARGES IN GENERALIZED PENICILLIN EPILEPSY. D. V. Wray* and J. J. Hablitz (SPON: R. P. Borda). Neurophys. Dpt., The Methodist Hospital, Houston,TX 77030.

Generalized paroxysmal discharges in cortical and subcortical structures can be induced in cats by parenteral administration of penicillin. Spontaneous bursts of paroxysmal activity occur against a background of otherwise normal activity. Microelectrode analysis of the paroxysms has revealed the presence of altered neuronal activity; we now report statistical studies which suggest altered single unit-EEG relationships during time periods not encompassed by paroxysms.

Extracellular single unit recordings were obtained from neocortex and cerebellum of awake cats with simultaneous recording of cerebellar and cortical EEG activity. Paroxysmal events in cerebellum were associated with increased unit activity in 39% of all cells (N=59) analyzed while excitatory/inhibitory sequences were seen in 30.5%. Seven percent showed a non-specific slowing during cerebellar paroxysms, while the remainder were not affected. In cortical recordings, approximately 80% (N=283) demonstrated altered firing rates during paroxysms. Ongoing activity was interrupted and replaced by bursts of action potentials coincident with the spike portion of the paroxysm followed by cessation of activity during the wave. For statistical analysis artifact-free segments of EEG activity (80 sec) were randomly sampled by a digital computer and the amplitudes obtained sorted into discrete voltage categories. The same segment of EEG activity was then systematically sampled at times related to the occurrence of each single unit discharge. Comparison of the unit related histogram to the random histogram is then made.

Using quantitative comparison of statistical data (mean, median, mode) generated by these procedures, it was found that during penicillin epilepsy cortical EEG activity was significantly related to the time of occurrence of cortical unit discharges, a relation which did not obtain in the normal non-penicillin state. Similarly cerebellar EEG was correlated with cerebellar unit activity. Analysis was also made of the relation of cerebellar unit activity to cortical unit discharge; significant correlations were obtained. These effects were seen prior to time of occurrence of spike discharges rather than after as might be expected if simple propagations were involved. No consistent relation between cortical EEG and cerebellar unit activity was seen.

These results demonstrate the usefulness of a statistical approach to analysis of single unit data, and suggest that not only is there a significant relationship between paroxysmal events and neuronal activity in generalized penicillin epilepsy but an overall trend to closer synchronization of EEG and unit discharge.

EXTRAOCULAR MOVEMENTS

467 UNITS IN THE SUPERIOR COLLICULUS AND UNDERLYING TEGMENTAL STRUCTURES RESPONDING TO PASSIVE EYE MOVEMENT. V. C. Abrahams and G. Anstee*. Department of Physiology, Queen's University, Kingston, Ontario, Canada. K7L 3N6.

In previous experiments (Rose and Abrahams, Brain Research, 97, 95, 1975) a quantitative study was made of passive, nasally directed eye movements that led to unit activity in the superior colliculus and which was presumed to derive from receptors in extraocular muscle. At the time a population of units was examined which was only excited by large eye movements, usually greater than 20°. A second population of units were also found in the superior colliculus which was excited by small eye movements. The response of this type of unit have now been examined in detail as has the response of units to vertical as well as horizontal movements.

An opaque contact lens was cemented to the cornea of one eye of a chloralose anaesthetized cat and this lens in turn was cemented to a device which could be used to produce vertical or horizontal movements in either direction at controlled velocity and from any initial position. The presence of large displacement threshold units was confirmed and they were found to respond to both vertical and horizontal movements. The majority of units in the superior colliculus have now been found to respond to small eye movements. Movement threshold ranged from 2 to 8° and was initiated by an applied corneal force of 1 to 15 g. Response was independent of initial eye position, and movement in either direction (upward or downward, right to left, or left to right) normally caused the same unit to discharge. The units so activated lie mainly in the intermediate and deep layers of the superior colliculus with some in the underlying tegmentum. Cells of origin of the tectospinal tract lie in this area and can be antidromically activated by stimulation in the contralateral upper cervical cord. Sixty per cent of cells so identified respond to passive eye movement.

One group of units were found located in the region of the mesencephalic nucleus of V and the tegmentum lateral to this nucleus which respond to passive eye movement. Attention was first drawn to these units because of their short latencies and great sensitivity. Horizontal movements of the eye of less than one degree and a load on the cornea of less than one gram is sufficient to activate these units. The response is not of retinal origin as it was present after the optic nerve had been severed. Responses were not elicited by corneal touch with Von Frey hairs with thresholds up to one gram. It may be that this eye movement induced activity may arise in jaw muscle spindles, a possibility strengthened by the fact that these same units are extremely sensitive to vibration.

468 EXCITATORY AND INHIBITORY EFFECTS OF DORSAL NECK AND EXTRAOCULAR MUSCLE AFFERENTS IN FRONTAL EYE FIELD REGIONS IN THE CAT. H. Barbas, B. Dubrovsky, D. Williams* and M. McCormack. Neurophysiol. Lab., Allan Mem. Inst., McGill Univ., Montreal.

We have shown that dorsal neck and extraocular muscle afferents project and converge onto neurons in regions corresponding with the frontal eye field (FEF) of the cat (Dubrovsky and Barbas Exp. Neurol. 1977, In Press). We now report that these muscle afferents also have inhibitory effects on FEF neurons, as was shown by testing these stimuli against a background of neural activity induced through iontophoretic release of glutamate. A sample of 115 neurons was recorded either in response to peripheral nerve stimulation or to iontophoretic release of glutamate. These included 83 units which responded to stimulation of one or more dorsal neck and/or extraocular muscle nerves, 22 which were inhibited, and 20 which were not affected by these muscle afferents. Out of 70 units tested, 56 responded to both extraocular and dorsal neck muscle afferents. This degree of convergence (80%) onto FEF neurons was higher than that observed with stimulation of the nerves of different dorsal neck muscles (22%), and two or more extraocular muscle nerves (59%). Although neurons in the FEF generally responded to more than one of the muscle nerves tested, subsets of this sample appeared to be selectively affected by pairs of extraocular and/or dorsal neck muscle afferents. Thus, whereas 9 units were excited with stimulation of the superior rectus on one side, they were inhibited by the homologous contralateral muscle nerve. Excitatory and inhibitory responses of 4 FEF neurons were also observed with stimulation of two groups of dorsal neck muscles, which involved, respectively, the contr. biventer cervicis/complexus, and the contr. rectus capitis dorsalis major/obliquus capitis caudalis muscles. Another 4 FEF units were inhibited by the contr. biventer cervicis/complexus of the neck, and also by either the contr. lateral rectus, or the contr. superior rectus muscles of the eye. Also, 5 units were inhibited by one extraocular or dorsal neck muscle nerve, but were otherwise unresponsive to any of these afferents. The latencies of excitation by one input and those of inhibition by another overlapped in 36% of the cases and were 8-35 ms, while in 20% of the cases inhibition occurred later. Inhibition of units which were otherwise unresponsive to any dorsal neck or extraocular muscle afferents occurred either as early as 10-20 ms, or as late as 45-180 ms. The majority (70%) of the units were situated within the upper and lower lip of the lateral cruciate gyrus. The converging input of afferents from muscles that move the eyes and the head, and their specific excitatory and inhibitory interactions onto these FEF regions suggest a role of these afferents in coordinated eye-head movement.

469 EFFECT OF REARING IN STROBOSCOPIC ILLUMINATION ON FIXATION AND SMOOTH EYE MOVEMENTS OF CATS. Janet L. Conway*, George T. Timberlake*, and Alexander A. Skavenski* (SPON: Frank H. Duffy). Dept. of Psychology, Northeastern University, Boston, MA 02115.

Rearing in a stroboscopically illuminated environment disrupts the velocity analyzing capacity of cat cortical and collicular neurons by denying experience with continuous retinal image movement. We examined whether the types of eye movements known or suspected to be driven by retinal slip velocity would also be disrupted by similar kinds of plastic changes at the input stage of oculomotor control. To find out, the magnetic-field search-coil technique was used to record 2 dimensional eye movements of 3 kittens reared from birth in an environment illuminated about 8 times per sec by a 4 microsec strobe flash. During strobe rearing there was surprisingly little change in oculomotor performance. Specifically, the frequency, velocity and trajectory of saccades were normal. Optokinetic nystagmus was also normal as evidenced by slow phase eye velocities that were approximately 90% of drum speed for speeds below 15 deg arc/sec. In addition, smooth pursuits, which can be elicited only with difficulty in normally reared cats, could also be obtained from strobe reared animals. Consequently, the cells providing the retinal velocity signals for these visually guided smooth movements are not modifiable by lack of experience with continuous motion. However, strobe rearing dramatically altered the animal's ability to fixate stationary objects. In particular, fixation, which is quite stable in normal cats, is characterized by a conjugate pendular nystagmus in strobe reared animals. This nystagmus is large (about 3 deg arc peak to peak amplitude), fast (4 to 5 Hz), always seen during fixation in either strobe or continuous illumination and frequently seen in total darkness. In addition, this nystagmus is superimposed on a wandering drift which is similar in the light and dark. These results show that experience with continuous retinal image movement is essential for the development of accurate fixation in the cat.

470 BRANCHING AXONS TO "FUNCTIONALLY INDEPENDENT" MUSCLES IN THE CAT OCULOMOTOR SYSTEM. W. F. Crandall, Jr.,* J. S. Wilson* and S. J. Goldberg (SPON: P. Bach-y-Rita). Smith-Kettlewell Institute, San Francisco, CA 94115 and Department of Anatomy, Medical College of Virginia - VCU, Richmond, VA 23298.

The Retractor Bulbi (RB) muscles in the cat are composed of four slips inserting on the equator of the globe. Both Lateral Rectus (LR) and RB muscles are innervated by the VI cranial nerve branching to the RB muscle before entering the LR. Although the motoneurons of the RB and LR originate in the same nucleus, it is generally assumed that these muscles are functionally distinct. The RB is thought to be protective in producing a reflexive globe retraction allowing the nictitating membrane to sweep over the globe. The LR is the primary muscle involved in lateral eye movement. Such a muscle system would require completely separate innervation. Contrary to this view we found that in many cases intracellular stimulation of abducens motoneurons resulted in simultaneous contraction of several muscles in the abducens system.

Multiple motoneuron stimulation may be precluded for the following reasons: a) Standard intracellular techniques were employed, b) Intracellular threshold activation of all muscles for a multiple muscle unit occurred simultaneously, c) Conversely, termination of an induced spike due either to motoneuron injury or electrode displacement resulted in simultaneous termination of muscle contractions, d) High current stimulation of these units produced multiple spikes of equal amplitude along with an increase in muscle force output, however, no new muscles were brought into contraction by the higher currents.

Of the 56 units studied in three experiments, stimulation of 44 (79%) of these units resulted in contraction of more than one muscle in the abducens system. Co-contraction of the LR and slip(s) of the RB were seen in 8 (14%) of these units. In each of these eight cases only the lateral two retractor slips were found to contract. This synergistic behavior of the lateral muscles suggests an involvement of the retractor bulbi in normal rotary eye movements.

Supported by N.I.H. grants EY 01442 and EY 01474-01.

471 ANATOMY AND PHYSIOLOGY OF IDENTIFIED INTERNUCLEAR NEURONS IN THE ABDUCENS NUCLEUS OF THE CAT. J. Delgado-García*, R. Baker, S.M. Highstein and R. Maciewicz*, Dept. Physiol., NYU Med. Ctr., New York, N.Y. 10016 and Dept. Neurosci., Kennedy Ctr. for Research, Albert Einstein Coll. Med., Bronx, N.Y. 10461.

Injection of HRP into the oculomotor complex has suggested the presence of a population of non-motoneuronal, internuclear (Int) neurons within the abducens (Abd) nucleus. Electrophysiological studies have demonstrated that Int neurons respond like Abd motoneurons (Mns) to orthodromic vestibular and reticular inputs. The Int neurons have been shown to terminate on medial rectus (MR) Mns exclusively in an excitatory fashion. We have further characterized the Int pathway by placing HRP in the cut axons of the ascending MLF and intracellularly injecting HRP in antidromically identified Int neurons. Reconstructions of the Abd nucleus have shown that Int neurons have a morphology and distribution similar to Abd Mns. In addition, the axons of all Int neurons cross the midline at the level of the Abd nucleus with no observable axon collaterals and ascend in the dorsal medial part of the contralateral MLF. To identify and compare Int and Abd Mn activity in the alert cat stimulating electrodes were placed in the contralateral MR subdivision of the oculomotor complex and on the ipsilateral Abd nerve. Of 47 neurons antidromically isolated in the Abd nucleus, 18 were activated only from MR stimulation and 29 from only Abd nerve stimulation. As determined by recording EOG's from each eye, Int activity was found to be qualitatively identical to that of Abd Mns during all horizontal conjugate eye movements. Quantitatively the two populations of neurons were markedly different. Typically, eye position thresholds were lower and maximum firing frequency higher for Int neurons than Abd Mns. Plots of eye position vs. firing frequency for Int neurons showed a steep, non-linear increase in contrast to the linear relationship exhibited by Abd Mns. Modulations of Int neurons preceded saccadic eye movement in the ON and OFF direction by an average of 10 and 20 msec, respectively. During monocular eye movements Int activity closely paralleled changes in only contralateral eye position and velocity profiles. Int firing frequency during 2-4° vergence movements was not altered following the change in eye position. In contrast, Abd Mn firing was modulated during all vergence and versional movements. From this data, we propose that vergence movements are produced by a separate supranuclear input to MR Mns. We infer that horizontal burst-tonic fibers recorded in the MLF are axons of Int neurons from the Abd nucleus. Thus, we conclude that they are the source for relaying conjugate horizontal eye movement signals to the contralateral MR Mns for saccades and fixation. (Supported by EY-01074, EY-10003 and EY-10670).

472 TECTAL CONNECTIONS WITH THE EXTRAOCULAR MOTOR NUCLEI. Stephen B. Edwards and Craig K. Henkel. Dept. Anat., Sch. Med., Univ. of Va., Charlottesville, VA 22901.

Direct and indirect projections from the superior colliculus to the extraocular motor nuclei were studied using the orthograde autoradiographic tracing method, the retrograde HRP technique, and Golgi methods. After injections of ^{3}H-leucine into the superior colliculus, transported label was found either within the extraocular motor nuclei or in nuclear regions directly adjacent to them. Within the oculomotor region, a focus of label was present in the central gray matter directly overlying the nucleus all along its rostrocaudal extent. This label was always more dense than that in the interstitial nucleus of Cajal or the nucleus of Darkschewitsch-purported accessory oculomotor structures. No label was present in the oculomotor nucleus itself. Golgi material revealed that dendrites of many oculomotor cells extend dorsally into this tectal terminal zone, thus providing the opportunity for direct tecto-oculomotor contacts. Horseradish peroxidase injected into the abducens nucleus produced retrograde labeled neurons clustered specifically in the tectal terminal zone overlying the oculomotor nucleus. This finding suggests that cells in this zone provide indirect tectal input to the abducens nucleus. Within the trochlear region, isotopic label transported from the colliculus was focused in a cell group directly ventrolateral to the trochlear nucleus. The projections of this labeled cell group were not studied. Within the abducens region, transported label was concentrated mostly in the reticular formation directly ventral to the nucleus. In six cases, however, label was present within the nucleus itself, though it was always sparse. The presence of this label is strong evidence for a direct, though small, tecto-abducens connection. Tectal labeling in the extraocular motor regions was present only after isotope injections in the deep gray layers of the colliculus and was heaviest in those cases with rostrally placed injections. Label in the abducens and trochlear regions was densest after injections into the stratum griseum intermedium, and thus appeared to have a preferential origin from this layer.

473 SINGLE UNITS IN THE CAT THAT PAUSE FOR SACCADES. C. Evinger,* C.R.S. Kaneko and A.F. Fuchs (SPON: T. Kennedy). Dept. Physiol and Biophysics, and Regional Primate Research Center, Univ. Wa., Seattle, WA 98195.

Although both anatomical and electrophysiological studies have begun to reveal the connectivity of brainstem oculomotor structures in the cat, very little is known about the functional properties of these neurons. In order to examine the roles of brainstem neurons in eye movements, the activity of single units in the region of the abducens nuclei were recorded in cats trained to a visual tracking task. This study deals with one group of neurons, the pausers, found clustered around the midline, anterior to the abducens nuclei that appear to be significant in the generation of saccadic eye movements.

Pausers are tonically active and cease their discharge just prior to and during saccades. The pause in firing begins 12-20 msec before the onset of the saccade. The pause duration usually lasts longer than saccade duration, and pause duration increases linearly with saccade duration. In the majority of the units the tonic firing level varied between 50 and 160 spikes/sec and was not related to eye position.

Pausers are also modulated by visual input. If the cat fixates a stationary target surrounded by a visual noise background sinusoidally oscillating in the horizontal plane, the cells' firing rate is modulated such that minimal firing frequency occurs during maximal background velocity during both left and rightward background movement. Retinal slip velocities of 20-40 deg/sec produced maximal unit modulation but retinal slip velocities in excess of 100 deg/sec also modulated pauser activity.

Microstimulation at the site of pauser recordings specifically inhibited both horizontal and vertical saccades. Continuous 30μA pulse trains (300 Hz, bipolar, .1 msec square wave) prevented all saccades but did not interrupt smooth eye movements in response to a sinusoidally modulated optokinetic target. Brief (10-50 msec) 20μA pulse trains triggered by the onset of a saccade interrupted that saccade for a period equal to the stimulus duration.

474 RESPONSES OF NECK MOTONEURONS TO STIMULATION OF THE INTERSTITIAL NUCLEUS OF CAJAL. K. Fukushima, N.G. Pitts and B.W. Peterson. Rockefeller Univ., New York, N.Y. 10021.

The interstitial nucleus of Cajal (INC) has been considered to be particularly important in vertical and rotatory gaze control. Since both head and eye movements contribute to the shifts of gaze observed when the region of the INC is stimulated (Hassler & Hess, 1954), it seemed reasonable to expect that interstitiospinal fibers might establish synaptic connections with neck motoneurons. To detect such connections, we have studied the responses of antidromically identified neck motoneurons to stimulation of the INC in cats under chloralose anesthesia. Multi-electrode arrays consisting of 5 electrodes, 1-1.5 mm apart in a mediolateral direction, were inserted into the mesencephalon so that the central electrodes recorded antidromic responses (0.6-8 msec latency) of INC neurons to stimulation at the C_4 spinal segment. Histology showed that these electrodes were in the INC. The other electrodes were used to delimit the effective area of stimulation. 100μA, 100μsec monopolar pulses were applied to the electrodes and responses were recorded intracellularly from neck motoneurons.

Stimulation within the INC evoked EPSPs at latencies of 0.7-1.4 msec in many neck motoneurons. If 0.5 msec is allowed for conduction time, these latencies suggest monosynaptic connections. The effective area for evoking these EPSPs corresponded well to the INC and thresholds were often 10-50μA. No monosynaptic PSPs were evoked by electrodes located 1.0 mm or more from the INC or interstitiospinal tract. Monosynaptic EPSPs were evoked from the ipsilateral INC in 27/27 biventer-cervicis-complexus (BCC), 10/15 splenius (SP) and 4/10 trapezius (TR) motoneurons and from the contralateral INC in 6/11 BCC, 1/10 SP and 2/7 TR motoneurons. INC stimulation also evoked later, presumably disynaptic, EPSPs in BCC and TR, and mixed EPSPs-IPSPs in SP motoneurons. The excitatory responses evoked by INC stimulation were considerably greater in BCC motoneurons than in TR or SP motoneurons.

Simultaneous stimulation of the INC and medial vestibular nuclei or ponto-medullary reticular formation produced monosynaptic PSPs that exhibited simple summation. Hence monosynaptic EPSPs evoked by INC stimulation do not appear to be mediated by bifurcating vestibular or reticular axons. Thus our results indicate that the INC directly excites many neck motoneurons. The pattern of consistent excitation of dorsal neck extensors and weaker, mixed excitation and inhibition of lateral flexors and muscles with a more complex action is consistent with the view that the INC causes movements resulting in vertical and rotatory gaze shifts. 475 ANATOMICAL ORGANIZATION OF CAT ABDUCENS MOTONEURONS RELATED TO SINGLE MOTOR UNIT MECHANICAL CHARACTERISTICS. S.J. Goldberg and H.P. Clamann. Depts. Anat. and Physiol., Med. Coll. of Va.-VCU, Richmond, VA. 23298.

There is histological and physiological evidence indicating diverse types of extraocular muscle fibers. Electrophysiological studies have shown functional differences in extraocular motoneurons related to impulse firing rates. Although it is generally accepted that most motoneurons in a particular nucleus can participate in all types of eye movement (saccades, pursuit and fixation), individual cells may exhibit firing frequencies better correlated with specific types of eye movement. This study was undertaken to determine if abducens nucleus (ANu) - lateral rectus muscle (LR) motor units displayed any features which might further the clarification of extraocular functional characteristics.

Cats were anesthetized and the abducens nerve was stimulated within the brain stem. ANu motoneurons were identified by their antidromic responses to VIth nerve stimulation. Single motor units of the LR were activated with short current pulses delivered through an intracellular micropipette penetrating a single motoneuron, and the mechanical responses in the LR were recorded with a sensitive strain gauge attached to the freed LR in the orbit.

A total of 30 ANu motoneurons were studied intracellularly, but all mechanical parameters of each motor unit could not always be examined. We found that the motor units had a wide range of twitch tensions (1.3 - 50 mg.), but units with contraction times slower than 6.5 msec. had a tendency towards twitch tensions of less than 15 mg. Motoneurons encountered deeper than 1.7 mm. beneath the floor of the IVth ventricle also tended to feed motor units with twitch tensions of less than 15 mg. But the most striking feature was a clear trend from fast (3.5 msec.) to slow (10.3 msec.) twitch contraction times as we penetrated motoneurons from dorsal to ventral in the ANu. Further investigations are needed to understand the possible functional significance of this motor unit organization.

476 EYE AND HEAD MOVEMENTS EVOKED BY STIMULATION OF CAT SUPERIOR COLLICULUS. D. Guitton, A. Roucoux+ and M. Crommelinck+ (SPON: M. Meulders). Univ. Louvain, B - 1200 Brussels. Belgium.

The lower layers of the superior colliculus (SC) contain a motor map which, in monkey, is in register with an overlying retinotopic projection. Saccades evoked by stimulating a point in the deeper layers are coded in retinal coordinates: they have constant amplitude and direction, independent of the eye's initial position in the orbit. In cat, the situation is less clear : 1) eye movements, that are goal directed with respect to the head, have been reported[1,2]; and 2) the sensory map covers more than 60° of visual field whereas eye movements are limited to 25° from central gaze position. These facts suggest that cat SC might also code head movements. Monopolar stimulation of the deep layers of the SC was performed in chronic cats with head fixed or free. Currents ranged between 5 and 15 µA. Eye and head movements were accurately recorded (to .1°) using the search coil in magnetic field technique. Results differed according to the location of the stimulated site with respect to the following zones of the overlying retinotopic map. Zone 1 (approximately the central 12°). With head fixed, evoked saccades with about 25 msec latency were retinotopic and similar to those observed in monkey. With head free, a slow head movement accompanied in the same direction the evoked saccade with similar short latency. This result differs from monkey. Zone 2 (about 12 to 25°). With head fixed, stimulation of a single point in SC brought the eye to a single point in the orbit: saccades were goal-directed. With head free, the evoked saccades were slightly preceded by a rapid (100-200°/sec) head movement. The direction of the evoked head movement was constant and independent of the head's initial position. Zone 3 (far periphery). With head fixed, centering eye movements were evoked. When the head was released, the evoked head movements were very rapid and goal directed with respect to the body. Results suggest that in cat, unlike in monkey, 1) the oculomotor and visual maps are not necessarily in register and 2) the SC is directly implicated in head motor control.

477 CANCELLATION OF THE VESTIBULOOCULAR REFLEX DURING ACTIVE AND PASSIVE HEAD MOVEMENTS IN THE NORMAL CAT. G.M. Haddad* and D.A. Robinson. Dept. Ophthal., Sch. Med., Johns Hopkins, Baltimore, MD 21205.

Circuit diagrams of the oculomotor system are frequently developed by correlating functional performance to single cell activity in the alert monkey and explaining this correlation by structural interconnections found in the depressed cat. However, common laboratory experience suggests that normal oculomotor performance in the cat may be quite different from that of monkey. This could cause serious errors in extrapolating cat anatomy to monkey behavior. This research addresses two questions in the cat for which we have answers in the monkey: 1) do saccades (quick phases) and vestibular velocity commands just add during vestibular nystagmus and 2) when cats track objects with their heads do they cancel their vestibulooocular reflex (VOR)?

Three normal adult cats were studied. Eye movements and head movements were measured by the technique of coils moving in a magnetic field. The gain of their VOR (slow phase eye velocity/ head velocity) in the dark was normal (e.g., .92).

Peak velocities (eye in head) of saccades ranging from 5-15 degrees were measured with the head stationary, the head passively rotated (~ 100 deg/sec) and the head actively moving (~ 50 deg/sec). Saccade velocity was always higher during either active or passive head movements than with the head stationary. For example, the cats typically made 10 deg saccades, head stationary, whose average peak velocity was 86 deg/sec. The same amplitude saccades during active 50 deg/sec head movements had an average peak velocity of 122 deg/sec and during passive rotation at 100 deg/sec, the average peak velocity was 142 deg/sec. All cats showed the same effect, i.e., saccades during head movements were faster than saccades with the head stationary. This result implies that saccadic and vestibular velocity commands do not just add. If they did, one would expect that saccades made during head rotation would be slower than saccades made with the head stationary. We found the opposite effect.

We also measured intersaccadic gaze velocities (eye velocity in space) during active and passive head movement as the cats looked about the room. Cats used their VOR to keep intersaccadic gaze velocity essentially zero despite head movements as fast as 90 deg/sec. Mean gaze velocity for one cat on one day was 0.6 deg/sec, $\pm$ 5.7 (s.d.). However these cats were also able to cancel the VOR during head tracking (of food). During tracking the ratio of gaze velocity to head velocity (which would be 1.0 for perfect cancellation) was about 0.7 (0.6 s.d.) for head velocities ranging from 3-60 deg/sec. Gaze velocity matched or was higher than head velocity about 40% of the time.

478 CELLS RELAYING LABYRINTHINE SIGNALS TO THE IIIRD NUCLEUS THROUGH THE BRACHIUM CONJUNCTIVUM IN THE RABBIT. S.M. Highstein, M. Yamamoto*, I. Shimoyama*, R.J. Maciewicz* and A. Steinacker*. Albert Einstein Col. Med., Bronx N.Y., Univ. of Tokyo; Faculty of Med., Tokyo, Japan.

Excitatory signals from the labyrinth to oculomotor neurons are conveyed by the Medial Longitudinal Fasiculus (MLF) as well as by the Brachium Conjunctivum (BC). The BC pathway relays anterior canal (AC) excitation to the ipsilateral superior (iSR) and the contralateral inferior oblique (cIO) extraocular muscles. However, the cells of origin of this BC mediated excitation are in question. To elucidate the location of these cells, a morphophysiological approach was undertaken.

The brainstems of anesthesized paralyzed rabbits with bilaterally transected MLFs were systematically tracked with a recording microelectrode during stimulation of the AC and IIIrd nucleus. Locations of units ortho- and antidromically activated were marked with fast green FCF iontophoresed from recording pipettes and later plotted on reconstructed brainstem sections.

Horseradish peroxidase (HRP) was iontophoresed into the IIIrd nuc. of rabbits with intact brainstems or with lesions of the MLF or BC. After 24 hours animals were sacrificed and brainstem sections reacted with diaminobenzidine and H_2O_2. Cells labeled with HRP reaction product were plotted on photographs of brainstem sections. Morphological and physiological results suggest that there is a group of cells in the dorsal portion of the superior vestibular nucleus which project through the BC to the IIIrd nuc. These cells presumably mediate the excitatory signals from the AC to the motoneurons innervating the iSR and cIO extraocular muscles. Further, cells in the center of the superior vestibular nuc. project to the IIIrd nuc. via the MLF and apparently mediate inhibitory labyrinthine signals to ipsilateral oculomotor neurons.

To elucidate other components of the BC pathway the Y group and lateral cerebellar nucleus were tracked during whole VIIIth nerve and IIIrd nuc. stimulation. Y group and lateral nuc. cells were antidromically activated from IIIrd nuc. but required multiple VIIIth nerve shocks for orthodromic activation.

To confirm these pathways superior vestibular, lateral nuc. and Y group cells were injected intracellularly with HRP and their axonal and dendritic projections traced.

BURSTING EYE-MOVEMENT RELATED NEURONS RECORDED IN THE BRAINSTEM OF THE ALERT TRAINED CAT. C.R.S. Kaneko, C. Evinger*, and A.F. Fuchs. Dept. Physiol. & Biophys. and Regional Primate Res. Ctr., Univ. Washington, Seattle Wa. 98195.

In order to provide information on the possible function of cat ocular motor structures presently being studied by intracellular and anatomical techniques and to provide some support for the untested assumption that feline and simian ocular motor systems are similarly organized, we recorded from single midline pontine neurons in the alert cat. We surveyed the types of eye-movement neurons and mapped their anatomical locations. Quantitative characterization of the firing parameters of these neurons correlated with eye-movement parameters was employed to discern possible causal relationships. This report deals with neurons in the region of and anterior to the abducens nucleus which fire a burst of action potentials for fast eye movements.

Extracellular recordings from cats trained to track moveable visual targets have revealed several types of bursting neurons. Burst units may be divided into those that have a tonic level of firing and those that do not. The former may be subdivided into medium-lead and long-lead bursters with latencies from first spike to eye-movement of 6 to 14 and 15-30 msecs respectively. Burst frequencies were as high as 350 spikes/sec and durations varied from 1 spike to several hundred msecs in length. The former group tended to be located more anteriorly than the latter.

The on-direction (angle) of eye movement associated with maximal firing of the neuron) varied from purely ipsilateral to omni-directional for either medium-lead or long-lead bursters. Unlike analogous neurons in simian brainstem, these units were not uniquely related to fast eye movements but might fail to fire for on-direction movements or might fire in the absence of an eye movement. We have not recorded from units uniquely related to eye movements, nor have we found burst units which burst following fast eye movements as has been demonstrated for the monkey.

Burst parameters such as average frequency or number of spikes are significantly correlated with horizontal components of saccade parameters such as amplitude and size but not with vertical components.

Neurons showing a tonic firing were either units whose tonic level was eye-position sensitive or was not. The former will not be considered here. The latter appear to be an eye-movement related neuron unique to the cat, although they are rare. These units burst for fast eye movements in a large range of directions. Such units are apparently akin to omni-pausers but fire a burst instead of pausing for fast eye movements. A detailed analysis of the extent of this similarity is under way.

481 AN UNEXPECTED EFFECT OF EXPECTATIONS ON SLOW OCULOMOTOR CONTROL Eileen Kowler*, Robert M. Steinman, and Barbara J. Winterson*. Dept. Psychol., Univ. of Md., College Park, Md. 20742.

Eye movements were recorded (sensitivity < 1') while subjects used saccades to track square-wave motion of a bright point moving in darkness. They tracked for 20 seconds at a particular frequency (0.25, 0.375, or 0.5 Hz) with amplitude (p-p) set either at 12', 25', 50' or 100'.

Anticipatory drifts were observed in well over half of the tracks. These drifts moved the eye smoothly in the direction of the expected target step before the step occurred. Such anticipatory drifts were common with both vertical and horizontal target steps. They began long before the target stepped—as much as one-half second. Their velocities were high, frequently 40'/sec and faster. These anticipatory drifts did not depend on initial eye position or directional idiosyncracies of slow control.

Anticipatory drifts are "natural" eye movements in the sense that they were observed in all subjects beginning with the first 20 second trial and continued throughout a long series of measurements. N.B. None of the subjects could make directed smooth eye movements in the absence of an afterimage or smoothly moving target. However, they all made anticipatory drifts when they expected a target step.

Much to our surprise anticipatory drifts did not go away when the target stepped on a highly structured stationary background. There were more surprises when we attempted to find out whether the expectation of the target step or the expectation of making a saccade caused the eye to drift in the direction of the expected target step. We found that both expectations were essential. Anticipatory drifts were largely abolished when subjects were required to keep the eye in place while the target stepped back and forth. They were also largely abolished when the stepping point was replaced by 2 stationary points and the subject was required to saccade from one to the other in time with a periodic auditory signal.

Anticipatory drifts are not restricted to square-wave target motions. Predictable ramps (2.2°/sec and 4.4°/sec) often have negative latencies of several hundred msec. Unpredictable ramps do not.

Our observations, admittedly mysterious as well as unexpected, have implications. They show that expectations can be a powerful input to the slow oculomotor subsystem. This is news. They also raise questions about the independence of the fast and slow subsystems because anticipatory drifts are activated only when saccades will be made.

480 CRITICAL STRUCTURES FOR DOWNWARD GAZE IN MONKEYS. Detlev Kömpf*, Tauba Pasik and Pedro Pasik. Dept. of Neurology, Mount Sinai School of Medicine, CUNY, New York, N.Y. 10029.

Only two patients with isolated downward gaze palsy can be found in the literature, and both had widespread bilateral pathology in the medial thalamus, subthalamus and rostral midbrain. In the attempt to delineate the critical region for downward eye movements, ten monkeys (M. mulatta) were stimulated through bipolar concentric electrodes placed stereotactically on each side of the midline under light barbiturate anesthesia. Stimuli consisted of a single 1-3 sec train of 0.5 msec pulses at 250 Hz. Stimulations were made unilaterally, and bilaterally in homotopic points every mm between the H+9 and the H-2 planes. The A planes between +5 and +13 were explored from 1.5 to 6 mm from the midline. At the completion of each experiment, bilateral or unilateral electrolytic lesions were made in placements where stimulation had elicited downward eye movements.

Bilateral simultaneous stimulations caused straight conjugate downward gaze from an extended area in the ventral mesodiencephalic junction from A+7 to A+11, up to 6 mm from the midline, and from H+3 to H+1. Unilateral stimulation of these points resulted in straight down, oblique down and contralateral, or no deviations at all. Bilateral lesions caused impairments of vertical gaze which were more pronounced in, and in one animal were restricted to the downward direction. Oculocephalic reflexes, however, were preserved. Electrooculograms of optokinetic nystagmus with stimuli moving in the horizontal, vertical or oblique planes, and of vestibular nystagmus elicited by caloric and turning tests, showed marked decrease or absence of responses in the direction of the defective gaze. Oblique optokinetic stimulation elicited a perverted response in the horizontal plane. Bilateral simultaneous warm caloric irrigations with the monkey in the erect position produced a strong upward deviation of the eyes. In some cases, there was also a shimmering or weak downward nystagmus, which, however, never reached below the horizontal meridian. Double cold irrigations failed to produce the tonic deviation downward in most animals and elicited in some cases an upward nystagmus. Similar findings were obtained by turning the animals while lying on the right side. The postrotatory response after clockwise rotation was equivalent to that elicited by bilateral warm irrigation. All responses in the horizontal plane were consistently normal. Recovery occurred in all types of vertical eye movements except in rapid deviations below the horizontal meridian which were absent during the entire 3-month follow up period. A unilateral lesion had no effect. These findings indicate that both sides of the ventral mesodiencephalic junction contain critical structures for downward rapid eye movements. Aided by N.I.M.H. Grant # MH-02261.

482 SMOOTH PURSUIT TRACKING OF PERIODIC AND NON-PERIODIC TARGETS IN MAN. S.G. Lisberger, L.C. Evinger* and G.W. Johanson.* Regional Primate Research Center, Univ. Washington, Seattle, WA and Universität München, Germany.

The purpose of these experiments was to re-evaluate the human smooth pursuit system in the light of recent experiments suggesting it might not function in the same way as the velocity-servo demonstrated by Collewijn in rabbit. For periodic tracking subjects were asked to track a sinusoidally moving target at a variety of amplitudes and frequencies. Gain was computed (after Meiry) as the average peak-to-peak amplitude of 25 cycles of de-saccaded eye position (E) divided by the peak-to-peak amplitude of target position (T). When gain was plotted as a function of frequency (f) or peak target velocity ($VT=(2\pi f)T$) each amplitude of target movement formed a different characteristic with greater gain for smaller target amplitude at any given frequency. When gain was plotted as a function of peak target acceleration ($AT=(2\pi f)^2T$) all data from all frequencies (0.4 to 2.1 Hz) and all amplitudes (±5 to ±25 deg) fell along the same characteristic. Similarly, when eye velocity (VE) was plotted as a function of retinal error velocity (REV=VT-VE), each target amplitude produced a different characteristic, but when eye acceleration was plotted as a function of REV, all data points fell along the same characteristic. For non-periodic tracking, subjects were asked to track a "random walk of sinusoids" in which the probability that the target changed direction at a peak or trough was reduced to 0.5. However, 1 of each 4 cycles (on the average) was a full sinusoid and could be analysed using the techniques applied to periodic tracking. Thus this target movement greatly reduced predictability, but at the same time allowed easy analysis. Although tracking capabilities in this paradigm were only 10 to 16% of periodic values and eye position lagged target position by up to 55° deg at 1 Hz, the results were qualitatively the same as for predictive tracking. Gain was best described as a function of target acceleration and eye accelaration was better related to REV than eye velocity was. Our results suggest that one basic property of the human smooth pursuit system is that target slip on the retina causes eye acceleration. Therefore, our results support the corollory discharge model of smooth pursuit in which a neural positive feedback pathway would sustain eye velocity while visual input would cause corrective changes in eye velocity, or eye acceleration. (Supported by Grants RR00166, EY00745 from NIH, USPHS)

483 CONTROL OF CHAMELEON SACCADE TIMING. J. W. B. Mates* (SPON: J. M. Horowitz). Dept. Biology, Univ. Oregon, Eugene, OR. 97403.

African chameleons scan their environments by saccadic movements of their eyes. But saccades of left and right eyes of these lizards often occur at different times. Thus, one chameleon generates two sequences of eye movement times, one for each eye.

An automatic saccade recognition system recorded saccade time sequences from taped EOG records. Sequence durations exceeded four hours. Sequences contained several thousand saccade times each. The recognition system found all saccades with horizontal amplitudes in excess of 1°, and the system specified saccade times to within 2 msec. Ten chameleons of three species (C. dilepis, C. jacksoni, and C. hohnelii) provided more than 200,000 saccadic eye movements for analysis.

Histograms of intervals between successive saccades invariably had exponential tails. This result suggested that, following a saccade, the likelihood of a second saccade settled after about 1 sec to a constant low value per unit time (ca. 0.5/sec). I conjectured that visual environment changes would cause changes in the slopes of the exponential tails.

First-, second- and third-order statistics, taken from whole and segmented saccade sequences, confirmed that (except for the 1 sec neighborhood effect) chameleon saccade generation was a constant probability (i.e., Poisson) process. But saccade timing statistics of left and right eyes were always closely similar, despite exposure to differing left and right visual environments. Even chameleons with one or both eyes occluded did not alter the time constants of their saccade generating processes. I concluded that chameleons in static visual environments made most saccadic eye movements by a constant probability stochastic process unaffected by visual input.

484 PLASTIC ADAPTATION OF SACCADIC DYSMETRIA. Lance M. Optican* and David A. Robinson (SPON: M. H. Goldstein, Jr.). Dept. Biomed. Eng. and Ophthal., Johns Hopkins Sch. Med., Baltimore, MD 21205.

The innervation for a saccade is a pulse to move the eye rapidly against viscous drag and a step to hold the eye against the elastic restoring force. If the pulse is not matched to the step, the eye will drift exponentially at the end of the saccade. When the pulse and step match, but are both either too big or small for the retinal error, saccadic dysmetria occurs. This study shows that both types of disorder are repaired by the brain.

Trained Rhesus monkeys had the position of both eyes monitored by a scleral search coil in a magnetic field. Each eye was calibrated seperately. Under anesthesia the horizontal recti of one eye were tenotomized and the eye was patched. After a few days the muscles reattached but were weaker. With the normal eye viewing, the weak eye made saccades hypometric by about 50% and drifted with initial velocities up to 50°/sec. The patch was then switched. Over the next few days saccades of the weak eye slowly grew until they became almost orthometric and post-saccadic drift was greatly diminished. Simultaneously, saccades in the patched, normal eye became hypermetric with a drift in the opposite direction to the original drift in the weak eye. Thus, both the size of the step and the pulse had been independently adjusted to compensate for the peripheral disorder.

A mechanical gain for the eye was defined as the ratio of the change in position of the weak eye to that of the normal eye. The gain of the saccadic system was defined as the ratio of the amplitude of the saccade to the retinal error. Results indicate that mechanical gains as low as 0.4 can be compensated, and gains for the saccadic system (monitored through the normal eye) can go as high as 2.3. Drifts caused by pulse-step mismatches as high as 40% can be suppressed by independently adjusting the gains of the pulse and the step. These changes occur with an exponential time course over 3 to 5 days. If the patch is switched back so that all visual experience comes from the normal eye, the gains will revert to their original values in another three to five days.

This adaptive ability of the saccadic system can be summarized: 1) With monocular viewing, the central compensation caused the gains of the saccadic system for the left and right eyes to change together, similar to Hering's Law; 2) the gains change with a time constant of about one day; 3) the gains for leftward and rightward movements can be adjusted independently; 4) the gains for the step and the pulse of the saccadic system can be adjusted independently.

485 ADAPTIVE GAIN CONTROL IN VESTIBULO-OCULAR REFLEX OF GOLDFISH. J.O. Schairer* and M.V.L. Bennett, Dept. of Neuroscience, Albert Einstein College of Medicine, Bronx, N.Y.

Unanesthetized goldfish were restrained with their heads centered in a clear cylindrical tank on a sinusoidally rotating platform. An optokinetic drum surrounded the tank. Eye position was monitored with a magnetic search coil. The velocity gain (gain = eye velocity/fish velocity) of the vestibulo-ocular reflex (VOR) was measured in the dark and in the light. Three fish were first rotated for at least 1/2 hour in the light at 0.16 Hz. with the optokinetic drum stationary in order to establish a baseline gain. In the dark the gain ranged from 0.33 to 0.55. In the light gains were higher, ranging from 0.43 to 0.66. Then the fish and the drum were rotated together in the light for six hours (except for brief periods of dark testing). The gain measured in the dark dropped with a time constant ranging from 1.3 to 2.5 hours during the first two hours. This was followed by a continued slower drop in gain to between 7 and 33% of the baseline value at the end of six hours. The fish were then rotated with the drum stationary again. The dark gain recovered with a time constant of from 0.5 to 1.5 hours. Control experiments showed the VOR did not change significantly during six hours rotation in the dark at this frequency. Large variations in the difference between vestibulo-ocular gain in the dark and in the light were seen. During the first two hours of adaptation one fish had an average difference between dark and light gains of 0.23. The drop in gain over the same time period had a time constant of 2.5 hours. The second fish had an average difference of 0.02 over the first 2 hours with the same time constant of adaptation. The third fish had an average difference of 0.17 with a time constant of 1.3 hours. It is odd that these differences in the visual effect on eye movements showed little correlation with speed of adaptation. During recovery light gain was always substantially greater than dark gain. At least 5 other fish showed similar changes in gain during less extensive experimental runs. These data extend to a lower vertebrate the demonstration of adaptative gain control in the vestibulo-ocular reflex. The relatively rapid learning exhibited here and the previously proven capacity for intracellular recording from rotating alert fish make this an attractive preparation for studying the electrophysiology of VOR gain control.

486 DYNAMIC OVERSHOOT IN SACCADIC EYE MOVEMENTS. Lawrence Stark, Alan B. Scott*, and Robert V. Kenyon*. University of California, Berkeley, and Smith Kettlewell Institute of Visual Science, San Francisco.

Dynamic overshoot was first predicted from theoretical consideration of the time optimal control strategy for saccades (Clark and Stark, IEEE Trans. AC-20: 345, 1975). Optimal control theory developed by Pontryagan, Bellman, Smith and Athans determines the number of switchings of maximal controller signals from the order of the plant. The plant is the eyeball and eye muscle model as developed by Cook and Stark (Arch. Ophthal. 79: 428, 1968) and by Clark and Stark (Math. Biosci. 20: 191,213, 239, 1974) that features reciprocal innervation and nonlinear force velocity relationships.

Using careful recording techniques, dynamic overshoot was found in human eye movements as predicted by theory (Bahill, Clark and Stark, Exp. Neurol. 48: 107, 1975). Since dynamic overshoots are caused by neurological control signal reversals, they therefore should be experimentally observable in neurophysiological studies in man. They would be most clearly apparent with bursts of single unit EMG activity in antagonist muscle at the end of its pause for the main saccade. Preliminary results using single unit EMG recordings in a limited sample of patients do indeed show such bursts as predicted from time optimal control theory and eye movement recording results.

Although published neurophysiological studies on primates and other mammals had not shown dynamic overshoot neural signal reversals, we understand that several laboratories are now finding such controller signal patterns. This is an exciting confirmation of the ability of neurological control studies to provide interaction with neurophysiological recordings in animals.

487 OSCILLATORY EYE MOVEMENTS WITH POSSIBLE VISUAL FUNCTION IN BIRDS
Joseph Turkel and Joshua Wallman. Dept. Biol., C.C.N.Y., New York, N.Y. 10031

A characteristic of eye movements in at least some birds is the frequent occurrence of a type of movement never seen in most mammals. These movements, which were first recorded in pigeons, consist of bursts of rhythmic, large amplitude oscillations of the eyes, often associated with eye blinks. Nye (Vis. Res. 9:133, 1969) termed these movements "polishing movements" with the implication that they are involved in grooming the eye. We have investigated these oscillatory eye movements in order to determine the role of these unique ocular movements in avian vision.

Oscillatory eye movements were measured in chicks using electro-oculograms, filmed records of movement made with a light-lever technique, and eye movement records made with a magnetic coil technique. In general, the visual axis traced a series of roughly elliptical paths with major orientation in approximately the horizontal plane during the course of a burst of eye movement. The bursts of movement typically occurred synchronously in both eyes and lasted for 100-300 msec., during which the eye oscillated at a frequency of 20-30 Hz with an amplitude of up to 15°. Both amplitude and frequency were usually greatest at the beginning of an eye movement burst. Movements of the nictitating membrane were always accompanied by oscillatory eye movements; oscillatory eye movements occurred, however, about twice as frequently (20-30/min.). Further, while local anesthesia of the eye did not affect the frequency of occurrence of these eye movements, it significantly reduced the number of membrane movements.

The relation of oscillatory eye movements to visual stimulation was also explored. In a stationary visual environment these movements occurred about as often as in the dark. During optokinetic nystagmus they invariably occurred during the quick phase. We did not find a relationship between the path traced by the eye and the spatial pattern of the stimulus, either with moving or stationary stimuli.

Oscillatory eye movements appear then to at least be under some visual control in chicks in that they are triggered by visual stimulation, and not necessarily related to movements of the nictitating membrane. An additional finding which supports the idea that these oscillations are involved in visual processing is that the occurrence of bursts of eye movement are synchronized to an ongoing tectal EEG rhythm of 3-5 Hz.

488 INTERACTIONS BETWEEN THE EYES IN OPTOKINETIC NYSTAGMUS OF CHICKENS.
Josh Wallman, Joseph Turkel, David H. Eastzer*, and Mok Hin-Kiu*. Biology Dept., City College, CUNY, New York, N.Y. 10031.

In most mammals, visual pursuit is accomplished by equal movements of both eyes. Even when it is dysfunctional, as when one eye is blind or partially paralyzed, the motor output to the muscles of both eyes is equal (Hering's Law).

By recording the movement of the eyes and the head with small search coils in an alternating magnetic field, we have found that in chickens the movements of each eye are much more independent than in mammals and have an interesting relation to each other.

Both the quick and slow phases of optokinetic nystagmus occur synchronously in the two eyes. The velocity of the slow phase of optokinetic nystagmus is usually very different in each eye. If one eye is closed, the closed eye makes normal movements but with much lower velocity than the open eye. Even if both eyes are open, the velocities of each may differ by a factor of 2 or more, with the eye for which the stimulus direction is temporal-to-nasal moving at higher velocities.

The following evidence argues that these phenomena result from partially independent programming of the movements of the two eyes rather than from shifts in the proportion of motor output to the two eyes: (1) The ratio of slow-phase velocities of the two eyes depends on the stimulus velocity; (2) The slow-phase velocity of the eye moving in the temporal-to-nasal direction is less variable (lower coefficient of variation) than that of the other eye; (3) In a stimulus situation in which the stripes move in opposite directions for each eye, the bird makes normal nystagmus movements, synchronously in both eyes, but in opposite directions; (4) In a stationary environment, or in the dark, saccades are always synchronous, but are more often disjunctive than conjugate, and more often unequal than equal in amplitude.

Studies on the development of these interactions and the effect of monocular visual deprivation are in progress.

489 EYE AND HEAD MOVEMENTS TO AUDITORY TARGETS.
Douglas A. Whittington* and Marie-Claude Hepp-Reymond. Dept. Psychol., M.I.T., Cambridge, MA. 02139 and Institut für Hirnforschung, CH 2029 Zurich, Switzerland.

Rhesus monkeys were trained to direct their gaze toward hidden auditory targets consisting of single clicks or click-trains delivered through small loadspeakers located along a perimeter arc in the horizontal plane in front of the monkeys. The monkeys received a water reward when they directed their gaze to within five degrees of the target. The experiments were conducted under two conditions; one in which the monkeys' heads were restrained, and the other in which they were free to rotate in the horizontal plane.

When the monkeys' heads were restrained, and auditory targets were presented at various locations along the perimeter arc, the animals responded by making saccades toward those targets. These saccades differed from saccades to visual targets in that their latency averaged 118 ms. (n=238, σ=44 ms.), while saccades to visual targets taken during the same recording sessions had an average latency of 215 ms. (n=45, σ=46 ms.). Since the animals were not constrained to have their eyes in a specific position when each auditory trial started, the saccades elicited began from a variety of initial positions, and it was found that the accuracy of the saccades was independent of the initial position of the eye. If one accepts the concept of a retinocentric coordinate system for saccadic movements, the preceding observation argues that a remapping takes place in which the head-referenced auditory target position is remapped into retinocentric coordinates by taking into account the initial position of the eye in the orbit.

When the monkeys were allowed to move their heads as well as their eyes in attempting to fixate an auditory target, they used a strategy which appears to be the same as that used to fixate visual targets. That is, they made a saccade toward the target and, as the head began to rotate to the target, the eye performed a compensatory movement which kept the gaze on target during the head movement. This strategy was employed when the auditory stimulus was present throughout the movement as well as when the stimulus was extinguished just prior to the onset of the eye and head movement, thereby removing the contribution of auditory feedback. The most striking difference between the responses to auditory and to visual targets was that the latencies for both eye and head movements were markedly shorter for auditory targets. (Research supported by NIH grant NS09343 and NASA grant NGR 22-009-798.)

490 THE EFFECT OF PULVINAR AND LATERAL POSTERIOR NUCLEUS STIMULATION ON CELLS OF THE ABDUCENS NUCLEUS.
J.S. Wilson* and S.J. Goldberg (Spon.:J.H. Johnson). Dept. of Anat., Med. Coll. of Va. - VCU, Richmond, Va. 23298.

Electrical stimulation of the pulvinar-lateral posterior nucleus (Pul-LP complex) in the alert cat produces contraversive, conjugate, saccadic eye movements. The exact nature of Pul-LP complex's input and pathway to the abducens nucleus is unknown. The purpose of this study was to determine the intracellular response characteristics of abducens cells to Pul-LP complex stimulation.

Cats were anesthetized during surgery and immobilized with gallamine triethiodide prior to recording. The vermis of the cerebellum was aspirated to expose the floor of the 4th ventricle. The abducens nucleus was identified by antidromic field potential responses to stimulation of the abducens nerve in the orbit. Bipolar stainless steel stimulating electrodes were inserted into the Pul-LP complex contralateral to the abducens nucleus recording site. The Pul-LP complex was stimulated with either single or trains of monopolar rectangular pulses. The location of all stimulation sites was confirmed histologically.

Preliminary results include a study of 43 motoneurons (MN's), 24 of which responded to Pul-LP stimulation. Pul-LP stimulation produced action potentials in 17 MN's with latencies generally between 15-30 ms. All latencies were measured from the first stimulus pulse. Intracellular records in six of these MN's showed EPSP's with latencies between 8-25 ms. Six other MN's also showed EPSP-IPSP sequences with EPSP latencies between 8-25 ms. Seven cells appeared to receive a purely inhibitory input. 19 MN's did not respond to Pul-LP stimulation. 11 of these were recorded intracellularly.

Five interneurons, which were orthodromically activated by abducens nerve stimulation, showed action potentials in response to Pul-LP stimulation. Their latencies were between 13-28 ms. Their threshold to Pul-LP stimulation was about half that needed to drive the MN's.

The pulvinar-LP complex appeared to have a predominantly excitatory polysynaptic input onto contralateral abducens motoneurons, although 19 cells showed no response and 6 were inhibited. Studies are in progress to determine if particular Pul-LP sites effect abducens neurons differentially and if the ipsilateral Pul-LP complex has a predominantly inhibitory input.

FEEDING AND DRINKING

491 CHANGES IN FOOD-ASSOCIATED DRINKING FOLLOWING PERIVENTRICULAR LESIONS OF THE ANTERO-VENTRAL THIRD VENTRICLE (AV3V). Steven L. Bealer. Dept. Psychol., Univ. of Iowa, Iowa City, IA 52242.

Lesions of the periventricular tissue of the antero-ventral third ventricle (AV3V) have been shown to produce a temporary post-lesion period of adipsia and chronic drinking deficits to thirst challenges (Buggy & Johnson, Am. J. Physiol., in press). The present experiment was designed to examine the effects of AV3V lesions on meal associated water intake in the rat. Ad lib eating and drinking responses were monitored continuously for several days before and after electrolytic lesioning of the AV3V periventricular tissue. After an initial period of post-lesion adipsia, spontaneous fluid consumption returned in most animals. It was found that in neurologically intact (pre-lesion) animals, there was a significant positive correlation between the volume of water associated with a period of eating and the size of that meal. This was previously reported by Fitzsimons and Le Magnen (JCPP, 1969, 67, 273-283). However, following the lesion, after daily intakes of water had returned to pre-lesion volume, the correlation between the amount of water associated with a meal and meal size was not significant. These data indicate that ablation of AV3V periventricular tissue attenuates the rats' ability to respond with appropriate volume intakes to hydrational challenges evoked by the consumption of food.

492 FAILURE OF GLUCOSE INJECTIONS TO INHIBIT FOOD INTAKE IN WEANLING RATS WITH DORSOMEDIAL HYPOTHALAMIC NUCLEUS LESIONS (DMNL). LARRY L. BELLINGER AND LEE L. BERNARDIS. Dept. Physiol., Baylor Coll. Dentistry, Dallas, Tx 75246 and Depts. Surgery and Path., SUNY at Buffalo, N.Y. 14215.

Compared to sham operated controls, rats with DMNL are hypophagic and have a reduced body weight and linear length. In a previous study (Fed. Proc. 36:561.1977) we observed that after insulin injection rats with DMNL did not initially increase their food intake comparable to the controls. The DMNL rats were also insensitive to the food intake stimulating properties of 2-Deoxy-d-glucose. In this investigation we observed whether glucose injections would depress the food intake of DMNL rats. A total of 54 rats received bilateral lesions (1 mAmp, 8 sec.) destroying primarily the DMN while 33 rats were sham operated for injections. The animals were divided into three groups: Gr. 1, saline; Gr. 2, 1.36 mg glucose/ gm body weight and Gr. 3, 2.72 mg glucose/ gm body weight. Fifteen days after the operation food was removed from the rats. The next day the animals received, intraperitoneally, their respective injections. Food was returned and then measured hourly for the next four hours. Because the DMNL rats are hypophagic compared to sham operated animals the food intake data was normalized by expressing the amount consumed during each hour as a per cent of that animal's previous 24 hour intake. The results show the hourly intakes did not differ between DMNL and the sham operated rats after the saline injections. After the glucose injection the control rats of Gr. 2 and Gr. 3 significantly ($P<0.01$) depressed their food consumption during the first hour post injection when compared to the saline controls. Their food intake during the first hour of refeeding was also significantly ($P<0.02$) less than that of the DMNL rats receiving glucose. Compared to their saline controls the glucose injections did not depress the food intake of the DMNL rats at any measurement time. The results suggest that DMNL disrupts the animals ability to monitor internal changes in glucose that normally would effect food consumption.

493 BODY WEIGHT AND FOOD INTAKE REGULATION IN RATS WITH DORSOMEDIAL HYPOTHALAMIC LESIONS WITH PRE-OPERATIVELY REDUCED BODY WEIGHT. Lee L. Bernardis, Larry L. Bellinger and Stephen Brooks*. Depts. Surg. and Path., SUNY at Buffalo, Buffalo, N.Y. 14215 and Dept. Physiol. Baylor Coll. Dent., Dallas, Texas 75246.

Mature male rats were placed on a partial starvation regimen to gradually lower their body weight below that of ad libitum-fed rats. Bilateral electrolytic lesions were placed in the dorsomedial hypothalamic area, primarily destroying the dorsomedial hypothalamic nuclei (DMN), Sham-operated rats served as controls. Food intake, body weight and obesity index were measured for 27 postoperative days. Rats that had been fed ad libitum prior to the DMN operation (AL-DMNL) showed the previously reported postoperative hypophagia and reduced body weight. Rats that had been pre-starved to a body weight 100 gm below that of the ad libitum-fed rats prior to the DMN operation (PS-DMNL) showed a significant increase in food intake only on the first postoperative day, whereupon their food intake gradually decreased to a constant level by the 10th postoperative day. At this point, and from then on, it coincided with that of the AL-DMNL rats. The body weight of the PS-DMNL rats increased steadily from the day of operation, but their obesity index was below that of the controls. Since both PS-DMNL and AL-DMNL rats had similar food intakes from the 10th day on while the body weight of the PS-DMNL rats was at that time lower than that of the AL-DMNL rats it is suggested that the postoperative food intake changes are not an active process to adjust the weight to a new set point, as has been demonstrated for the rat with lateral hypothalamic lesions. It is concluded that the lowered set point in both PS-DMNL and AL-DMNL rats is determined by the consequences of the lesions and not by the previous body weight. It is postulated that the DMN lesions have lowered the set point for both food intake and body weight, which appear in homeostatic synchrony. The above data speak for an otherwise "normal" rat that is, however, reduced in size. Possibly, then, the DMN lesion has lowered food intake and body weight set point simultaneously so that the animal is now capable of subsisting on smaller amounts of substrate. The lack of endocrine (growth hormone, insulin), substrate (glucose, lactate, pyruvate, acetoacetate, triglyceride, cholesterol) and metabolic (glucose and palmitate oxidation and incorporation and gluconeogenesis), and the ability to compensate for additionally supplied calories seem to support this hypothesis.

494 LIMITED DAILY ACCESS TO FOOD DRIVES--BUT FAILS TO ENTRAIN--CIRCADIAN RHYTHMS IN RATS. Ziad Boulos*, Alan Rosenwasser* and Michael Terman* (SPON: Parvati Dev, MIT). Dept. Psychol., Northeastern Univ., Boston, MA 02115.

Rats maintained under constant light with free access to food and water showed free-running circadian rhythms of feeding and drinking with periods greater than 24 h. Access to food was then limited to 4 h per day over 3-8 wk, while water remained continuously available. Under the feeding schedule the drinking rhythm rapidly assumed 24-h periodicity, with most of the animals' daily water intake occurring during the feeding segment. When food was subsequently made freely available both feeding and drinking assumed their original free-running periods. However, the phase of these free-running rhythms was not determined by the phase of the preceding food-access schedule. Rather, the rhythms assumed the phase they would have shown had they been free-running throughout the feeding schedule. Under true entrainment (as with light-dark schedules), free-running rhythms would be expected to assume an initial phase set by the preceding cyclic environmental agent. The results indicate that the daily feeding schedule controlled the overt phase of the feeding and drinking rhythms, but did not alter the free-running characteristics of the underlying circadian pacemaker(s). The 24-h periodicity shown during the feeding schedule would seem to result from a temporary uncoupling of the behaviors from their pacemaker(s), allowing ingestion to be passively driven.

495 THE EFFECT OF SUPRACHIASMATIC NUCLEUS LESIONS ON CIRCADIAN RHYTHMS IN THE SQUIRREL MONKEY (Saimiri sciureus). C.A. Fuller, F.M. Sulzman*, M.C. Moore-Ede*. Dept. Physiology, Harvard Medical School, Boston, MA 02115.

The suprachiasmatic nucleus (SCN) of the hypothalamus is postulated to be a key element in the neural control of circadian rhythms in mammals. Studies in nocturnal rodents have demonstrated there is a direct retinal-hypothalamic tract (RHT) from the retina to the SCN and that lesions which destroy the SCN result in loss of organization of circadian rhythms within the animal.

We have studied the role of the SCN in the circadian timing system of the squirrel monkey, a diurnal primate with a documented RHT leading to the SCN. This primate offers particular advantages in that the circadian timing system is well documented and we have the capability to measure circadian rhythms in multiple variables simultaneously (Moore-Ede, et al., Am J Physiol 232: R31-37, 1977). Unrestrained squirrel monkeys were maintained in an isolation chamber where environmental lighting, temperature and sound were controlled. Intact animals confined all of their active behavior to the lights-on portion of a 24-hr light-dark cycle (LD 12:12 hr, 600:<1 lux). Upon being placed into constant light (LL 600 lux), each of these rhythms persisted with a free-running period of ∿25 hrs.

Bilateral electrolytic (4 mA, 15 sec) hypothalamic lesions were located in the SCN using stereotaxic coordinates confirmed by X-ray visualization of the third ventricle using a radio-opaque dye (Conray) infused into the ventricles. The mean level of the behavioral variables did not change after the lesion. In LD there was a less precise phase control of the rhythms. However, most activity was still confined to the lights-on portion of the cycle, with greater phase control than seen in similarly lesioned rodents. After 8-hr phase-delays of the LD cycle the animals took ∿3 times longer to resynchronize with the new LD phase than they did before the lesions. In LD and LL there was a large reduction in the circadian amplitude as measured by 24-hr sine wave fitting. Visual inspection of the record also showed a marked alteration in the circadian organization of these variables. This preliminary evidence indicates that the SCN plays a key role in the multioscillator circadian timing system of the squirrel monkey. 496 EFFECTS OF VAGOTOMY ON FEEDING FOLLOWING GLUCOSE INFUSION. Paula J. Geiselman, James R. Martin, and Donald Novin. Department of Psychology and Brain Research Institute, UCLA, Los Angeles, CA 90024.

Female rabbits were duodenally cannulated and subdiaphragmatically vagotomized (vagx). Additional animals were cannulated but not vagotomized. Subsequent to either 0-hour or 24-hour food-deprivation conditions, animals were intraduodenally infused with either .9% saline or a solution of 5%, 10%, or 20% glucose (10 ml/3 kg BW). Amount of food ingested and meal patterns were monitored for the following three-hour period.

Cumulative food intake at 1, 2, and 3 hours postinfusion indicated that, after 24-hour food-deprivation, neither intact nor vagx rabbits showed suppression of feeding in response to glucose infusions. When free-feeding, however, 5% glucose suppressed cumulative food intake in the intact rabbit at 2 and 3 hours postinfusion (p's < .01). The 10%-glucose solution was ineffective in the intact rabbit. The 20%-glucose infusion produced suppression when measured at 2 hours postinfusion (p < .05), although the effect at this concentration may have been due to toxicosis. In contrast, free-feeding vagx rabbits showed no suppression of food intake to any concentration of glucose. Furthermore, the vagx rabbits showed only a 3.7-minute latency to the first meal following infusion of 5% glucose, while intact subjects showed an 18.0-minute latency. The initial satiety ratio (number of minutes to next meal/meal size) for the vagx rabbits after 5%-glucose infusion was only 4.9 as compared with 7.4 for the intact animals.

Thus, the above results provide evidence that 5%-glucose solution administered into the duodenum of a free-feeding, intact rabbit is effective in the suppression of short-term food intake; but a simple monotonic relation between glucose amounts and degree of feeding suppression was not found. While glucose suppression of feeding was again demonstrated to be vagally dependent, the mechanism of glucose-induced suppression is complex and effects on pancreatic secretion may be involved in an explanation of the effects of different glucose loads.

497 EFFECTS OF CHRONIC INTRAVENTRICULAR ADMINISTRATION OF ANGIOTENSIN II ON DRINKING BEHAVIOR AND BLOOD PRESSURE. Robert J. Gronan & Donald H. York, Dept. of Physiol., Sch. of Med., Univ. of Missouri, Columbia, Mo. 65201.

Angiotensin II (AII) stimulates drinking behavior and appears to increase blood pressure and ADH release through actions on the central nervous system. Evidence has been presented that these actions of AII are mediated at sites adjacent to the brain ventricles. Since an increase in plasma AII is associated with the development of certain forms of hypertension, increased levels of AII acting on the brain over a period of days may be involved in this process. It was thus of interest to determine the effects of long term infusion of AII intraventricularly (IVT). This procedure has been facilitated by the introduction of implantable osmotically driven minipumps (Alza).

AII was delivered continuously into the right lateral ventricle of Sprague-Dawley rats (400-500 g) using subcutaneously implanted osmotic minipumps connected to ventricular cannulas with PE tubing. AII was delivered in a volume of 1 µl/hr of saline vehicle at a dose of 10 ng/hr for one week. Water consumption and urine output were measured daily. Blood pressure was determined once daily in unanesthetized animals via catheters chronically implanted in the abdominal aorta. Water consumption was greatest during the second day of IVT AII infusion, reaching 209 ml/day, as compared with a mean of 44 ml/day in rats infused with AII subcutaneously (SC), and 38 ml/day prior to AII infusion. After the second day, water consumption decreased to approximately 160-180 ml/day with continued IVT infusion. Urine output followed a similar pattern. Blood pressure showed little change during the first two days, and increased after the second day a modest 10-15 mm Hg in rats receiving AII IVT. Blood pressure in the AII SC group did not differ from the pre-infusion level of 100 mm Hg. These results demonstrate a substantial increase in drinking behavior with continued IVT administration of a low dose of AII, and the possible development of tolerance or some other adaptive process, and a delayed, but small, increase in blood pressure with prolonged infusion into the lateral ventricles. (Supported by PSH HL 07094).

498 INGESTIVE REFLEXES OF THE SUCKLING RAT. W. G. Hall and Jay S. Rosenblatt.* North Carolina Dept. Mental Health, Raleigh, NC 27611 and Inst. Animal Behav. - Rutgers, Newark, NJ 07102.

The infant rat has two distinctly different ingestive reflexes. One of these is a rapid form of intake that occurs when the suckling pup receives milk-deliveries from its mother's nipple, and during which it makes a dramatic extensor response but no mouthing movements. The pup's other ingestive reflex, obvious lapping and swallowing, can be experimentally elicited by placing liquid diet in the pup's mouth when it is not suckling. The relationship of these two ingestive responses has been investigated using an intra-oral cannula that opens onto the back of the pup's tongue. With this preparation liquid diet can be delivered when the pup is attached to the nipple of its anesthetized mother and suckling, or when it is away from the mother.

The ingestive response the pup displays depends on whether or not it is suckling. When liquid-diet injections were made into the mouths of 5-day old pups suckling at the nipples of their anesthetized mothers, pups rapidly consumed diet and showed the stereotypic ingestive response associated with this form of ingestion. When the identical diet was injected into the mouths of pups which were not suckling; lapping, swallowing, and diet spillage occurred.

Intake regulation also differs for these two modes of ingestion. When 5-day old pups (6 hr food deprived, n=10) were allowed to freely consume diet (delivered in pulses through the intra-oral cannulae, 0.1cc/min) while suckling from their anesthetized mother, they virtually drowned themselves before rejecting the nipple, consuming 100% of the injected diet (11.2% body weight). Similarly treated pups (n=6) fed the same diet away from the mother consumed only a portion of the injected diet and showed no general behavioral response to the diet-deliveries (e.g. on a 1-10 scale with 10 being highest activity, activity count before deliveries start, $\bar{X}$=2.3; during deliveries, $\bar{X}$=2.1). If deprivation was increased to 22 hr, however, the intake of suckling pups declined, while the intake of pups fed away from the nipple increased. Significantly, these pups now also showed a behavioral activation in response to diet-delivery (activity count before deliveries start, $\bar{X}$=3.4, during deliveries, $\bar{X}$=7.1, and pups now vigorously licked the floor).

Thus, the context of whether or not the pup is attached to the nipple appears to determine which of two ingestive responses the pup will emit when liquid diet is delivered intra-orally. Little or no intake regulation occurs when the 5-day old pup consumes diet in the suckling mode. Intake accomplished by elicited lapping and swallowing shows an adult-like increase to prolonged deprivation and suggests an early nutritional control of this precursor to adult ingestive behavior.

499 REDUCED TOLERANCE TO d-AMPHETAMINE-INDUCED ANOREXIA AFTER 6-HYDROXYDOPAMINE INJECTIONS WHICH DEPLETE BRAIN DOPAMINE. Thomas G. Heffner* and Lewis S. Seiden, Department of Pharmacological & Physiol. Sci., U. of Chicago, Chicago, IL 60637

Development of tolerance to the anorexic effect of d-amphetamine was examined in rats given a 6-hydroxydopamine (6-HDA) treatment designed to selectively destroy central dopaminergic neurons. Groups of rats were given i.p. injections of pargyline (50 mg/kg) and desmethylimipramine (25 mg/kg) prior to intraventricular injections of either 200 ug 6-HDA or the vehicle solution (controls). Assays for telencephalic catecholamines performed at the end of these experiments revealed that the pargyline, desmethylimipramine and 6-HDA treatment reduced the levels of dopamine by 75-85% with no change in norepinephrine levels. Beginning two weeks after these treatments, all rats were restricted to 4 hr access to food daily and intake was measured after the first hr. d-Amphetamine was injected i.p. 30 min prior to the start of the access period. In phase I of the experiment, dose-effect functions for d-amphetamine were established with three non-drug days separating each test day. As previously reported,rats given 6-HDA showed resistance to d-amphetamine-induced anorexia (ED_{50}=2 mg/kg) compared to controls (ED_{50}= 0.9 mg/kg). In phase II, all rats were given daily injections of the d-amphetamine dose that reduced food intake by an average of 80% in phase I (1.5 mg/kg for controls, 3.0 mg/kg for rats given 6-HDA). Controls rapidly developed a partial tolerance to d-amphetamine-induced anorexia; food intake rose from 22% of pre-drug levels on day 1 to approximately 55% of pre-drug levels on days 4-21. However, food intake in rats given 6-HDA was only 25% of pre-drug levels after 21 days of d-amphetamine injections. In phase III, dose-effect functions for d-amphetamine were redetermined while giving the same d-amphetamine doses used in phase II on non-test days. Control rats showed a shift to the right in the d-amphetamine dose-effect curve (ED_{50}=1.8 mg/kg) as compared with the dose-effect curve determined in phase I. On the other hand, the dose-effect curves determined in phases I and III for rats given 6-HDA were identical. The failure of rats given 6-HDA to display tolerance to d-amphetamine does not seem to be due to a general inability of such animals to display tolerance to anorexic agents since another group of rats given the same 6-HDA treatment as above showed complete tolerance to the anorexic effects of fenfluramine over the same time course as controls. These data suggest that central dopaminergic neurons are involved in the development of tolerance to the anorexic effects of d-amphetamine. (Supported by PHS MH-11191-12; RCDA PHS MH-10562-11; MH-14274-02, Trng).

500 MUTUAL SUPRA-ADDITIVE FACILITATION OF CONTRALATERAL SELF-STIMULUATION AND STIMULATION-INDUCED FEEDING. Luis Hernandez* and Bartley G. Hoebel, Dept. of Psychol., Princeton University, Princeton, N.J. 08540

In previous experiments we found that lesions of the medial or lateral hypothalamus (LH) affected free feeding and contralateral self-stimulation alike. For example, unilateral electrolytic lesion of the LH decreased temporarily both feeding and contralateral LH self-stimulation, and both recovered in parallel. It is also known that self-stimulation of one side of the hypothalamus facilitates self-stimulation of the other side. We reasoned that because feeding and self-stimulation (SS) are correlated and SS exhibits bilateral facilitation, then electrically elicited feeding should be facilitated by contralateral, suboptimal self-stimulation trains and vice versa, self-stimulation-bound feeding (SBF) trains. Methods: Rats with bilateral monopolar LH electrodes that produced SS and SBF at both electrode placements were used in the experiment. For self-stimulation we used .5 sec trains of 100 Hz,.1 msec pulses. These short trains would not produce SBF. For SBF we used 5 sec trains alternated with 5 sec off. Current intensity was considered suboptimal for SBF when it produced less than five feeding responses in ten presentations, and suboptimal for self-stimulation when it produced less than half of the maximal rate of lever presses during a 20 min test. There were four bilateral interaction tests: a) SS plus auto-SS: each rat pressed a lever for suboptimal SS at one electrode while suboptimal SS coincident trains were also automatically delivered to the other side. b) SS plus SBF: again the rats worked for SS, but this time suboptimal SBF current was delivered continuously for 20 min to the other side. c) SBF plus auto-SS: SBF with suboptimal current was tested while coincident SS trains at 0.5 sec on, 0.5 sec off, were delivered contralaterally. d) SBF plus SBF: again SBF was tested, but with contralateral, coincident SBF trains. Results: SS on one side of the hypothalamus was facilitated significantly by either SS or SBF trains delivered to the other side. The opposite also occurred; SBF on one side was facilitated by either SS or SBF trains on the other side. The important point is that the behavioral response with bilateral stimulation was 4.5 to 7 fold greater than with unilateral stimulation in each of the four cases. This suggests that, similar to facilitation of spinal root stimulation, unilateral hypothalamic stimulation produces facilitation by means of a "subliminal fringe" of excitation in a network common to both sides and common to both SS and SBF. It is concluded that contralateral feeding and reward elements interact synergistically at a common site of convergence.

501 MICROINJECTIONS OF GABA OR BICUCULLINE INTO BRAINSTEM SITES: EFFECTS ON FEEDING. J. Kelly*, G.F. Alheid*, A. Newberg*, and S.P. Grossman. Dept. of Behavioral Sci., Biopsychology Section, Univ. of Chicago, Chicago, Ill. 60637.

Microinjections (100 ng in 1 ul) of bicuculline methiodide into the lateral hypothalamus of rats reliably increased the intake of sweetened milk. Animals with placements in the ventromedial hypothalamus displayed opposite, inhibitory effects of bicuculline on food intake and marked facilitatory effects of microinjections (100 ng in 1 ul) of GABA. Animals with cannula placements in the ventral tegmental area reduced food intake after GABA. Bicuculline injections into this region sharply increased the general level of activity and this, in turn, interfered with drinking. Neither bicuculline nor GABA affected food intake when administered to the substantia nigra. Repeated injections of bicuculline resulted in extreme and persistent hyperactivity accompanied by unidirectional "barrel rolling". GABA injections reversed these effects within a few minutes. The pattern of drug effects suggests that the effects of direct or indirect manipulations of hypothalamic catecholamines on food intake may be mediated, at least in part, by GABAergic mechanisms.

502 EFFECT OF LATERAL HYPOTHALAMIC LESIONS ON INGESTIVE BEHAVIORS IN RHESUS MONKEYS. Joseph W. Kemnitz, Gary W. Kraemer, Richard E. Keesey and Robert W. Goy. Primate Research Center, Univ. of Wisconsin, Madison, Wisconsin 53706.

There is a voluminous literature documenting the effects of lateral hypothalamic (LH) lesions in rats. In this species, LH lesions normally produce transient aphagia and/or anorexia, chronically reduced body weight, and altered responsiveness to a variety of hunger and thirst challenges. However, virtually no data exist regarding the sequelae of LH lesions in primates. With these considerations in mind, this preliminary study is being conducted.

Bilateral radiofrequency lesions were made in the LH of four young adult male rhesus monkeys. The electrodes were acutely placed in the LH utilizing an x-ray ventriculographic procedure. Brief electrical stimulation at the lesion site prior to producing the lesions elicited a small increase in blood glucose ($\bar{X}$= 9 mg%, n=3) measured 15 min. after stimulation.

Following surgery, all animals were hypophagic for at least one week. When animals would refuse to in-quest their usual fare of Purina biscuits, they would eat preferred food such as fresh fruit whenever it was offered. Idiosyncratic behaviors associated with eating (e.g., biscuit rubbing) were not affected by the lesions.

Fluid intake was also reduced for at least several days postlesion. Two animals were drinking normal amounts of tap water within one week following surgery, one animal would reliably drink only flavored water (orange Tang) for several weeks postlesion, and one animal would not drink more than 100 cc/day (i.e., about 10% of normal) of the tap water or flavored water for two weeks postlesion.

Other behavioral and physiological measures are currently being taken, including body weight, fasted levels of blood glucose and several hormones, glucose tolerance, insulin challenge, and catecholamine turnover. Glucose tolerance functions obtained while the animals were sedated with ketamine were not different in intact and lesioned animals 2-5 weeks postlesion.

503 FRONTAL NEOCORTEX AND FEEDING BEHAVIOR IN RODENTS. Bryan Kolb, A. Nonneman and Ian Q. Whishaw. Dept. Psychology, University of Lethbridge, Lethbridge, Alberta, Canada T1K 3M4.

In recent studies we have suggested that the frontal cortex of rodents plays an important role in feeding and drinking. We have extended the examination of this role in 5 different ways: 1) Discrete lesions to subregions of the frontal lobe demonstrated that the ventral lateral frontal (VL) cortex was the focus of feeding deficits in rats, hamsters, and guinea pigs. There was no significant correlation between the amount of cortical tissue removed and length of aphagia unless the VL cortex was removed. The feeding deficits were not due to a general deterioration of motor functions, a failure to initiate behavior, or sensory neglect. However, the animals may be unable to chain together the sequences of motor acts necessary for feeding. 2) Manipulation of body weight affected the length of aphagia. Preoperatively fattening rats to 120% of original weight significantly prolonged the aphagic period whereas dieting the rats to 80% had little effect. Both fattened and dieted rats assumed a chronic postoperative weight level that was independent of preoperative weight level and was 25% of control level. 3) Removal of all of the frontal cortex in neonates (less than 10 days of age) or juveniles (25 days of age) failed to alter food intake, induce motor deficits or chronically lower body weight. Complete decortication at 7 days of age also failed to produce aphagia or motor deficits although the rats had a chronic weight drop of about 35% of control level. 4) Animals with lateral hypothalamic (LH) lesions induced 30 days after VL frontal lesions failed to show aphagia or adipsia whereas rats with prior frontal cortex lesions which spared the VL tissue exhibited the complete "lateral hypothalamic syndrome". This phenomena of recovery after VL lesions could be interpreted in terms of concepts such as denervation supersensitivity. However further work suggests it could be at least partly due to the original drop in body weight. If rats with VL lesions are fattened to control level prior to the LH lesion, they are aphagic. 5) Finally, combination LH and contralateral VL lesions produce aphagia and adipsia similar to that observed after bilateral VL lesions whereas unilateral LH or VL lesions have little effect on feeding.

These results are discussed in terms of cortical-brainstem interactions as well as cortical and subcortical reorganization of function.

504 CHOLECYSTOKININ (CCK) INHIBITS TAIL-PINCH INDUCED EATING IN RATS. Morris A. Lipton, Albert J. Osbahr, III,* Charles B. Nemeroff Gloria D. Jahnke,* Garth Bissette* and Arthur J. Prange, Jr.* Biological Sciences Research Center and the Dept. of Psychiatry, Univ. North Carolina School of Medicine, Chapel Hill, North Carolina 27514.

Cholecystokinin (CCK) is a peptide hormone of intestinal origin which stimulates the secretion of glucagon and insulin. It consists of 33 amino acids, though the C-terminal octapeptide possesses all of the biological activity of the parent compound. When administered IP, CCK induces behavioral satiety in rats and monkeys (Gibbs et al., 1973, Nature 245:323; Smith and Gibbs, 1975, Pharmacol. Biochem. Behav. 3:135). In the present study the effect of the C-terminal octapeptide on tail-pinch-induced ingestive behavior in the rat has been evaluated. The tail-pinch paradigm utilized was that of Antelman and Szechtman (Science 73, 731, 1975). Adult male Sprague Dawley rats (200-250 g) were initially screened with a 2 minute tail-pinch and rats not responding with the characteristic tail-pinch behavior (eating and gnawing) were discarded. On the day of testing rats were randomly divided into 2 groups ($n \geq 6$) and injected IP with CCK (0.1-100 µg/kg) or vehicle (0.9% NaCl, pH 7.5). Five minutes later rats received tail-pinch for 10 minutes (approximately 80 psi) in a stainless steel surgical bowl in the presence of 5 grams of food (45 mg pellets). An experienced observer, unaware of the treatment regimen, measured the food consumed during the 10 minute tail-pinch or quantified chewing of wood chips. Peripherally administered CCK in a dose-dependent manner markedly reduced tail-pinch-induced eating. Results are shown in the Table below.

Treatment (IP)	N	Food (grams) Consumed/10 Minute Tail-pinch (χ±SEM)	p<
Saline	24	2.01 ± 0.94	
CCK 0.1 µg/kg	6	1.81 ± 0.50	ns
CCK 1.0 µg/kg	6	1.19 ± 0.38	<0.05
CCK 10.0 µg/kg	16	0.71 ± 0.18	<0.001
CCK 100.0 µg/kg	6	0.20 ± 0.10	<0.01

The incidence of stereotyped chewing of wood chips observed during tail-pinch was not reduced in CCK-treated rats. Peripherally administered bradykinin (100µg/kg) a peptide approximately the same size as the C-terminal octapeptide of CCK had no effect on tail-pinch induced eating. Lateral ventricular injection (n=13 per group) of CCK-octapeptide (500ng) also reduced tail-pinch-induced eating by approximately 50% ($p<0.05$). This is the first demonstration that CCK exerts behavioral effects after central administration. (Supported by NINCDS NS-05722, HD-03110, MH-22536 and MH-15631).

505 VAGAL MEDIATION OF A VISCERAL DRINKING SYSTEM IN THE RAT. James R. Martin, Paula J. Geiselman, and Donald Novin. Department of Psychology and Brain Research Institute, UCLA, Los Angeles, CA 90024.

Following recovery from bilateral subdiaphragmatic vagotomy (vagx), rats showed a lower daily water intake than did laparotomized controls. Daily food intake in the vagx rats, however, did not differ from control levels. In both groups, intraperitoneal injection (1 ml/100 g BW) of 4.5% NaCl resulted in a shorter latency to drink and greater water consumption during a .5-hour testing session than did .9% NaCl. No difference was found between groups following injection of .9% NaCl; however, the vagx rats showed a greater latency and lower intake than did the controls subsequent to injection of 4.5% NaCl. Maintenance of vagx and control rats on a liquid diet did not alter the deficit observed in the vagx group, thus precluding the possibility that the attenuated response of vagx rats to a hypertonic challenge could have been due to excessive gastric retention, which is characteristic of vagx rats fed a solid diet. Using a more selective procedure, vagal fibers joining the liver immediately below the diaphragm were transected; however, this intervention had no effect on drinking elicited by intraperitoneal administration of 4.5% NaCl.

In further experimentation, total vagx and control rats were implanted with either a chronic hepatic-portal or jugular cannula and were infused with buffered Ringer's solution, which included either .9% NaCl or 4.5% NaCl (.5 ml/100 g BW). In comparison to isotonic infusion, latency was shorter and water intake was greater following hypertonic infusion in both vagx and control rats. Isotonic infusion via the two routes in vagx and control rats did not result in any differences in latency or magnitude of drinking. The quantity of water consumed by the vagx and control animals following hypertonic infusion via the two routes did not differ appreciably. However, the latency to drink was shorter subsequent to the administration of the osmotic stimulus via the hepatic-portal route in control animals than in the other groups.

In summary, this series of experiments provided evidence for a vagally-mediated visceral osmosensitive drinking system. The role of this peripheral system will be discussed within the context of the previously established brain osmoreceptor system.

506 THE EFFECT OF TRIGEMINAL DEAFFERENTATION ON FOOD AND WATER INTAKE IN THE RAT. Maria G. Miller* (SPON: R. M. Wylie). Walter Reed Army Institute of Research, Washington, DC 20021 and Barnard College, Columbia University, New York, NY 10027.

To study the relative roles of peripheral and central factors in controlling food intake I selectively deafferented the oral cavity of rats. A method was developed for individual sectioning of the alveolar, palatine and lingual branches of the trigeminal nerve that convey somatosensory inputs from the mouth. Proprioceptive and motor innervation of the mastication musculature is spared as well as taste carried by the VIIth and IXth cranial nerve. (1) Deafferentation of either the lower part of the oral cavity including the tongue or the upper part led to a reduction in average food intake (mash) lasting for several weeks and to retardation of recovery of the lost body weight. Variability of intake from day to day was increased. (2) After partial deafferentation affecting both the upper and lower part of the mouth the animals failed to eat mash. If offered four diets differing in texture and palatability the animals continued to ingest the preoperatively most preferred semi-liquid cereal and to a lesser degree moist pellets though in insufficient amounts for maintaining their body weight. Water intake was severely depressed or abolished. Intake sufficient to lead to recovery of body weight began only after weeks but then occurred abruptly. (3) Complete deafferentation of both the upper and lower part of the mouth including tongue led to adipsia and aphagia lasting a minimum of five weeks at which time some animals started to recover. These findings establish that peripheral trigeminal deafferentation of the oral cavity significantly impairs the rat's ability to maintain adequate intake.

Behavioral tests and observations demonstrated that the animals were able to bite, chew and swallow. I observed no evidence of general debility or deafferentation neuralgia. However, impairment in coordination of the consummatory act was suggested by a reduction of ingestion rate and inappropriate oral behavior in biting tests and during exploration of food. By increasing the duration of feeding partially deafferented animals compensated for these deficits but not sufficient to maintain normal body weight. Completely deafferented animals failed to show compensation making only few and short attempts to eat and drink. Therefore, it is concluded that in the rat peripheral trigeminal deafferentation also affects the propensity for feeding and drinking.

507 THIRST NEURAL CIRCUITRY: EFFERENT CONNECTIVITY OF THE SUBFORNICAL ORGAN DETERMINED BY AUTORADIOGRAPHY. Richard R. Miselis, Peter J. Hand and Robin Berger*. Animal Biol., Sch. Vet. Med. and Inst. of Neur. Sciences, Univ. of Penn., Phila., PA 19104.

Little is known of the neural connectivity of the subfornical organ(SFO), one of the circumventricular organs of the brain. Its functions have been speculative up until the demonstration of the SFO as a receptor site for angiotensin II in the induction of thirst(Simpson and Routtenberg. Sci. 181: 1172, 1973). A study of the efferent projections of the SFO offers an opportunity to identify neural circuitry involved in thirst and related physiological mechanisms. In addition, identification of the efferent projections may suggest new functions by virtue of the terminal fields found. The autoradiographic technique of tracing labeled amino acids within axons to their synaptic terminations was used to reveal the SFO's efferent projections. 20 nl of a ^{3}H-leucine solution(25 μCi/μl) was slowly infused(25 min) through a 33 gauge beveled cannula(bevel facing caudad) stereotaxically aimed for the mid-dorsal border of the rat SFO. The time to sacrifice and commencement of autoradiographic-histological procedures was 2 days. Control injections were made in adjacent septal nuclei and in the cerebral ventricles. The septum and preoptic, anterior and lateral hypothalamus were examined for sites of terminal transport. The SFO projects to the nucleus medianus(NM), the organum vasculosum lamina terminalis(OVLT) and the supraoptic nucleus(SON) bilaterally. Injections that involve the SFO unilaterally showed greater grain densities over the ipsilateral SON. The increased grain densities appeared to have occurred via axonal transport and not via vascular or ventricular routes since neighboring vascular endothelium and ependyma did not show increased grain densities. Projections to septal nuclei could not be demonstrated nor excluded. Control injections into septal nuclei did not label the above sites. Ventricular injections produced increased grain densities in the OVLT and medial preoptic region but was mostly confined to the ependyma. These data suggest the involvement of the NM and OVLT in neural mechanisms of thirst. They also suggest a modulatory role of the SFO on the SON. (Supported by NS-06716)

508 Degenerated Neuroanatomical Pathways Associated With Aphagia And Adipsia Following Lateral Hypothalamic Lesions. Elliott Mufson* and Walter Riss, Program in Biological Psychology, and Department of Anatomy and Cell Biology, Downstate Medical Center, Brooklyn, New York, 11203.

The importance of the lateral hypothalamus(LH) in the regulation of ingestive behavior is well established. Bilateral electrolytic damage of the LH at the level of the ventromedial hypothalamic nucleus (VMH) disrupts feeding (aphagia) and drinking (adipsia) (Anand and Brobeck, 1951;Teitelbaum and Epstein, 1962).

Several authors have stressed that ingestive behavior depends on the interaction of the lateral hypothalamus with other levels of the neuraxis. This concept is supported by data demonstrating that feeding and drinking are disrupted by damage to extra hypothalamic areas such as the amygdala, the central gray matter, and the reticular formation. The present investigation is a correlative behavioral and anatomical analysis of the neural substrate underlying aphagia and adipsia following LH damage. Specific attention is directed towards the anatomical interfaces between the LH and other areas known to be involved in the acts of feeding and drinking. Adult rats of both sexes were used. The strategy was to place bilateral electrolytic lesions varying in size in the LH at the level of the VMH and correlate post-operative ingestive deficits with the pattern of degeneration revealed by the Fink-Heimer I or II procedure (1967).

Daily food and water consumption were recorded both pre and post-operatively. Lesion parameters were 1 ma for 3,7 and 10 sec. Animals were allowed to survive for 1-14 post-operative days. Only the 7 and 10 sec. groups were aphagic and adipsic. Since the pattern of degeneration was qualitatively similar for all lesion groups the data described is from the smallest effective LH lesion (i.e., the 7 sec. group).

Degeneration was traced from the lesion to the central amygdaloid nucleus, lateral preoptic area, medial and lateral septum, nucleus accumbens and lateral habenular nucleus. Descending degeneration coursed to the tectum, midbrain central gray, substantia nigra pars compacta and reticulata,mesencephalic tegmentum and midbrain raphe nuclei. Degenerated fibers entered the medial pontine gray at the level of the mesencephalic-metencephalic junction. Further caudally, degenerated axons were observed in the dorsal and ventral parabrachial region and motor and mesencephalic nuclei of the trigeminal nerve. All lesions damaged the medial edge of the internal capsule producing degeneration in the crus cerebri-pyramidal fiber system. In certain brains fibers were seen in the VMH nucleus. Many of the structures which receive a projection from the LH complex are also involved in the regulation or expression of ingestive behaviors, judging by existing evidence.

509 ALCOHOL CONSUMPTION FOLLOWING HIPPOCAMPAL LESIONS IN MICE. J. N. Pasley* and E. W. Powell. Dept. Physiol. and Anat., UAMSC, Little Rock, AR 72201.

Thirty mature wild-derived male house mice were selected for this study. Ten animals sustained bilateral lesions to the posterior (hilar) segment of the hippocampus. Ten other animals sustained bilateral lesions to the amygdala, or ventral hippocampus. After a 7 day surgical recovery period, the mice, including an additional ten unoperated animals, were given access to both water and a 5% solution of ethyl alcohol in a free-choice situation. Ethanol consumption in animals which sustained bilateral lesions of the posterior hippocampal area averaged from 34% to 69% of their total fluid intake over the two week test period. The control group which sustained lesions in parahippocampal structures did not exhibit this differential and their proportion of alcohol intake to total consumption was nil (0-4%). The ten unoperated mice also rejected the 5% ethanol solution. Thus, it may be possible to attribute a degree of voluntary alcohol consumption in mice to select limbic system balances.

510 ARE THE CENTRAL EFFECTS OF ANGIOTENSIN DUE TO PERIPHERAL ANGIOTENSIN II CROSSING THE BLOOD BRAIN BARRIER? M. Ian Phillips, Pushpa Deshmukh & William Larsen. Dept. Physiology, Dept. Anatomy University of Iowa, Iowa City, Iowa, 52242.

Angiotensin II (AII) injected into the brain ventricles (IVT) causes a blood pressure increase, drinking and vasopressin release to ensue. AII injected i.v. however, does not elicit vasopressin release and there are subtle differences in the i.v. and IVT effects of the peptide on BP and drinking. Autoradiographic studies indicated that the AII i.v. crosses the blood brain barrier (BBB) and gains access to the ventricles. In these studies the doses used were extremely high (2 μg+).

To investigate if AII at high doses was causing a change in the BBB we used 68 male, adult rats injected with horseradish peroxidase (HRP), 1-50mg, Sigma type VI, alone or with AII, i.v. and IVT. Blood pressure was recorded. Ten minutes after injection, the rats were perfused with glutaraldehyde and the brains sectioned for reaction and light and electron microscopy.

HRP injected i.v. alone lowered BP. The peroxidase reaction product was seen in the blood vessels and pericytes, and in the tissue of the circumventricular organs (CVO) and choroid plexus, as Brightman, Cancilla and others have shown. With 2μg AII + HRP i.v. there was a rise in BP (70mmHg) and the reaction product was observed outside the blood vessels in additional areas of the striatum and hypothalamus. This increased permeability of the BBB could allow AII to reach ventricular receptor sites from blood.

HRP injected IVT penetrated the ciliated ependyma wall but not the CVOs. With AII + HRP IVT, penetration was deeper into the brain parenchyma, but not into the CVOs.

Freeze fracture of the rat ventricular wall showed gap junctions at the apical tips of ciliated ependyma. It is possible that AII causes greater penetration by altering the state of the gap junctions. In the CVOs more tight junctions are found and we report here the finding of a type of tight junction in the subfornical organ. Tight junctions would resist entry of AII from the CSF.

Although the evidence with HRP (MW43000) is indirect, it suggests that a smaller molecule such as AII (MW1000) injected i.v. could cross the BBB if blood pressure is substantially raised. With lower doses, however, peripheral AII would not reach the same sites as AII injected centrally. Thus the central effects of AII IVT injections may be due to stimulation of receptors which are not reached by low levels of peripheral AII.

511 METABOLIC CORRELATES OF DISSOCIATED FEEDING RESPONSES INDUCED BY HEPATIC-PORTAL AND DUODENAL INFUSIONS (HPI and DI) OF SMALLER AND LARGER LOADS (SL and LL) OF ISOTONIC GLUCOSE. EFFECTS OF SOMATOSTATIN (SRIF) AND CYCLOHEXIMIDE.
M. Rezek, V. Havlicek, and H. Friesen, Dept. of Physiology, U. of Manitoba, Winnipeg, Manitoba, Canada.

Hepatic-portal infusions of SL (10 ml) and LL (30 ml) of glucose, which had previously been shown to have little or no effect on food intake in rabbits (Rezek et al., Am. J. Physiol. 1975), produced an immediate, sharp rise in glycemia which peaked briefly at the end of the respective infusions (10 min and 30 min) and then declined rapidly. Maximal increases in glycemia for SL and LL were 22% and 53% resp. Serum insulin responses were also rapid, rising quickly to their respective peaks at the end of the infusions (SL at 10 min = 17 μU increase; LL at 30 min = 30 μU increase). The post-peak decline of insulin levels was rapid and reached steady state at 30 min (SL) and 60 min (LL). In contrast, the responses of blood glucose and insulin to duodenal infusions of SL and LL, which in chronic experiments produced satiety (SL) or paradoxically stimulated food intake (LL), were considerably different. The glucose response to SL was immediate: it peaked briefly (23% increase) at the end of the infusion (10 min) and then declined more slowly than it had after portal SL and reached steady state at 60 min. On the other hand, the glucose response to LL, although immediate and fast rising initially, required 60 min to peak (> 80% increase); the subsequent decline was slow so that at the end of the test period (3 hrs) glycemia was still considerably elevated. The insulin response to SL was immediate and rapid although slower than after HPI (max. increase 21 μU at 30 min); however, the subsequent decline was rapid transiently and at 60 min it had practically reached steady state. Thereafter the decline toward the preinfusion baseline level required an additional two hours. In marked contrast, the insulin response to LL, although initially immediate and rapid approached its maximum gradually and at a considerably higher level (max. increase 55 μU at 60 min). Its decline was rather slow and as a result the insulin level in the end of the 3rd hour was still markedly elevated (> 30 μU). This prolonged, intesified insulin response represents the main difference when compared with responses to DI of SL as well as to HPI of SL or LL and correlates with the dissociation of the corresponding feeding responses. This marked and prolonged insulin increase as well as the paradoxical overeating induced by DI of LL are both reduced or eliminated by pretreatment with SRIF and cycloheximide. These data suggest that the expression of paradoxical overeating may be dependent on the prolonged release of insulin from both the acute as well as chronic insulin pools. Supported by MRC Canada.

512 A PHARMACOLOGICAL ANALYSIS OF CHOLINERGIC AND PEPTIDERGIC DRINKING AT THE SUBFORNICAL ORGAN. John B. Simpson and Michael L. Mangiapane* (SPON: Nancy J. Kenney), Department of Psychology, University of Washington, Seattle, WA 98195

The subfornical organ (SFO) has been identified as a particularly sensitive site of drinking elicited by intracranial cholinomimetics (Simpson and Routtenberg, Brain Research, 79, 1974) and by the hormone, angiotensin II (Simpson and Routtenberg, Science, 181, 1973). An important question is that of the relationship between the receptors for the two dipsogenic substances. Further, the identification of the SFO as a structure of unique sensitivity for both forms of elicited drinking makes it amenable to pharmacological analysis of a degree of specificity which is not possible at alternative loci, such as the cerebral ventricles. Carbachol (CBC) drinking at the SFO was characterized by pretreatment at the structure with various cholinergic antagonists (in 0.5 ul) prior to CBC (100 ng/0.5 ul). The nicotinic antagonists hexamethonium and decamethonium did not affect CBC drinking at molal ratios of antagonist:agonist of 1:1, 10:1, or 100:1. Drinking was also unaffected by equimolal pretreatment with d-tubocurarine prior to CBC. Alternatively, the muscarinic antagonist atropine significantly reduced or eliminated drinking to CBC at molal ratios of antagonist:agonist of 1:1, 1:10, and 1:100. Hence, cholinergic thirst at the SFO is mediated by muscarinic cholinergic receptors. The drinking induced by angiotensin II (A II; 10 ng/0.5 ul) at the SFO was significantly reduced by the A II antagonist, Saralasin Acetate, at molal ratios of antagonist:agonist of 1:1 and 10:1. Hence, A II drinking at the SFO is mediated by A II specific receptors.

The interaction between CBC and A II drinking at the SFO was evaluated by using demonstrated antagonists for each dipsogen in competition with the alternative dipsogen. It was found that atropine did not significantly antagonize A II drinking, even at molal ratios of antagonist:hormone of 10:1, 100:1, or 1,000:1 (doses which antagonized CBC drinking). Likewise, Saralasin did not antagonize CBC drinking at the SFO (at doses of antagonist which completely blocked A II drinking). It is apparent, therefore, that drinking induced by cholinomimetics and by A II at the SFO may employ activation of parallel, nondependent receptors. The significance and nature of this apparent pharmacological independence of thirsts at the SFO remains unclear.

513 SHORT AND LONG TERM EFFECTS OF PARA-CHLOROAMPHETAMINE ON CONSUMMATORY BEHAVIORS. J.M. Stein*, M.J. Wayner, K.M. Kantak* and R.C. Cook*. (SPON: C.S. Weiss). Brain Res. Lab., Syracuse Univ., Syracuse, NY 13210.

The possible role of serotonin in eating and drinking was investigated using a single administration of the serotonin neurotoxin para-chloroamphetamine (PCA). Female hooded rats were housed individually and had free access to food and water. Following a baseline period, 0.9% saline or 1.0,2.0, 5.0 or 10.0 mg/kg of PCA was injected intraperitoneally. Twenty-four hr food intakes were decreased 40-60 % of baseline levels on the day immediately following administration of all PCA doses. Food intakes returned to baseline levels within 48 hr of PCA administration and remained stable for the next 30 days. Twenty-four hr water intakes were decreased 50-60 % of baseline levels on the day immediately following administration of all PCA doses. Significant increases in water intakes, 110-150 % of baseline, were observed following the initial decreases. No further changes in water intakes were recorded during the next 30 days. Additional data will be presented in which the responsiveness of PCA injected animals to salt arousal of drinking and insulin induced eating was investigated. These results will be discussed in terms of the short term changes and lack of long term changes in food and water consumption following PCA.

514 DEVELOPMENTAL PLASTICITY IN RETINO-HYPOTHALAMIC CONNECTIONS AND THE ENTRAINMENT OF CIRCADIAN RHYTHMS. F. K. Stephan* and A. A. Nunez* (SPON: A. Wesley). Dept. Psy., Florida State Univ., Tallahassee, Fl 32306.

The role of retino-hypothalamic pathways in the re-entrainment of drinking rhythms after a 12-hr phase shift in the light-dark cycle was investigated by comparing the rate of re-entrainment of the following groups of rats: (1) unilaterally enucleated as adults (AE), (2) unilaterally enucleated within 24 hr of birth (NE), (3) intact controls (C). As previously reported, AE rats required more days to invert drinking rhythms than controls. On the other hand, NE rats were not significantly different from controls. Previous anatomical observations indicate that neonatal enucleation results in a nearly equal distribution of retinal input to both suprachiasmatic nuclei. Therefore, the results are consistent with the hypothesis that the unequal distribution of retino-hypothalamic fibers in AE rats interferes with the entrainment process. Compared to controls, AE and NE rats showed a smaller reduction in water intake during a 24 hr exposure to constant light. This response, believed to be mediated by the inferior accessory optic tract, was not affected by age of enucleation.

515 THE RENIN-ANGIOTENSIN SYSTEM AND THIRST: A RE-EVALUATION. Edward M. Stricker. Depts. Psychol. & Life Sci., Univ. Pittsburgh, Pittsburgh, PA 15260.

Ligation of the inferior vena cava, and administration of isoproterenol, have been shown to stimulate renin secretion and to augment water intake in rats. Both effects are abolished by bilateral nephrectomy. These results have been used to support the popular hypothesis that the renin-angiotensin system is largely responsible for the mediation of thirst following the two treatments. However, recent experiments suggest that the plasma renin activities produced by caval ligation or isoproterenol treatments do not account for more than 20 percent of the observed drinking behavior. Direct measurements of arterial blood pressure further indicate that nephrectomized rats go into hypotensive shock after either treatment. Drinking can be elicited in these hypotensive animals by systemic injection of hypertonic NaCl solution, renin, or Pitressin, or by intracranial injection of angiotensin, but in each case a rapid increase in blood pressure also is observed. Thus, it would appear that nephrectomy reduces water intake in these animals by undermining their general capacity to behave, rather than by removing a specific dipsogenic stimulus. (Indeed, it is difficult to explain why the removal of the renin-angiotensin system should abolish thirst after caval ligation or isoproterenol treatments, since both treatments would still activate vascular baroreceptors that have been assumed to stimulate thirst during hypovolemia.) These and other results suggest that the renin-angiotensin system contributes little to the direct mediation of drinking that is elicited in rats by caval ligation or isoproterenol.

516 THE ROLE OF THE HYPOTHALAMIC SUPRACHIASMATIC NUCLEUS AS A CIRCADIAN OSCILLATOR IN RAT. Anthony N. van den Pol. Dept. Psychol. Yale Univ.,New Haven, Ct. 06520.

Several previous studies (e.g. Moore & Eichler Brain Res. 42: 201, 1972;Stephan & Zucker PNAS 69:1583,1972) have demonstrated convincingly that the area of the suprachiasmatic nucleus (SCN) is involved in the maintenance of circadian rhythms, but these studies have not ruled out the possibility that fiber systems adjacent to SCN or anterior hypothalamic tissue near the nucleus are also involved in the control of these rhythms. The present experiment evaluated such a possibility using minute radiofrequency (RF) lesions. Lesions about 25 times smaller than those used in earlier experiments were made in and around SCN in 76 male Fischer rats. Other animals received knife cuts (n=14) placed in the SCN area or served as sham-operate (n=15) or blinded (n=10) controls. Drinking and feeding were monitored electronically over a seven week period.

Neural damage restricted to SCN with little or no extra-SCN insult was sufficient to eliminate circadian rhythms of feeding and drinking ($p<.01$). Lesions immediately posterior to SCN had a similar effect, presumably by interupting axonal projections from SCN(Krieg, JCN 55:19,1932). Damage restrictedto the supraoptic commissures, optic chiasm, tractus infundibularis, or the hypothalamic area anterior or lateral to SCN had little influence on circadian rhythms.

As an independent check on the direct lesion analysis, a computer-assisted three-dimensional reconstruction of each rat's RF lesion was made, and the numerical description (autocorrelation) of each rat's postoperative circadian rhythm was correlated with its lesion description. All rats with RF lesions were used. This computer procedure confirmed that damage of the SCN caused a severe impairment of circadian rhythms. A positive correlation ($r=.68$)between the anatomical loci involved in feeding and drinking rhythms was found. Drinking rhythms seemed more resistant to perturbation by SCN lesions than did feeding rhythms. The anatomical area subserving drinking rhythms seemed slightly smaller than that for feeding rhythms when the same autocorrelation criterion was used.

Rats with partial (greater than 10%, less than 85%) SCN damage showed some decrease in circadian rhythm as judged by autocorrelation analysis. Ten rats with more than 50% SCN destroyed showed significant ($p<.05$) eight hour feeding or drinking rhythms; no other rats showed this infradian rhythm.

An additional 107 rats were used to examine SCN with Nissl, Golgi, and ultrastructural methods. The anatomical integrity of SCN in comparison to the surrounding hypothalamus will be discussed. (Supported by PHS AM 11551; ACS IN 31-0-5).

517 DIETARY SELF-SELECTION FOLLOWING DESTRUCTION OF THE LATERAL HYPOTHALAMUS. Dennis A. VanderWeele and Paula J. Geiselman. Depts. of Psychology, Occidental College, Los Angeles, CA 90041, and UCLA, Los Angeles, CA 90024.

Animals sustaining subdiaphragmatic vagotomies have been shown to decrease daily intake of sucrose and increase fat and protein intake compared to preoperative levels (Fox, Kipp, and VanderWeele, Am. J. Physiol. 231:1790-1793, 1976). An afferent vagal-hypothalamic circuit has been postulated to explain the decreased sucrose intake in vagotomized animals (Fox et al., 1976). The present experiments were conducted to assess the effects of destruction of the lateral hypothalamus (LH) on dietary self-selection.

Subsequent to LH damage, rats were evaluated for intake of fat and sucrose while maintained on a protein-Alphacel diet. A significant inverse correlation was found between amount of sucrose consumed and severity of LH syndrome. Comparable analyses for fat intake and daily caloric intake yielded non-significant effects. Severity of LH syndrome was assessed on the basis of final body weight (the lower, the more severe the syndrome) and number of days aphagic (the more days, the more severe the syndrome). In the second study, effects of LH destruction were investigated by comparing preoperative and postoperative consumption of sucrose, casein hydrolysate, and olive oil. LH animals were allowed to recover to Stage II (would ingest wet cookies) at which time measurement of macronutrient intake was resumed. Results indicated that, while there was a tendency for fat intake to decrease, neither protein nor caloric intake was systematically affected by LH destruction. Sucrose ingestion, however, was again found to be inversely correlated with the severity of the LH syndrome. In comparison to preoperative intake, animals that were characterized by a less severe LH syndrome were found to increase sucrose consumption; while sucrose intake in animals with a more severe LH syndrome did not differ from preoperative levels.

In many instances, the vagus and the LH have been found to subserve similar functions. Contrary to prediction, however, the effects of the vagus and the LH on daily sucrose intake are not the same. Results will be further discussed in relation to size and histology of LH destruction.

518 INHIBITION OF SUCKLING IN THE WEANING AGE RAT BY A DEVELOPING NEUROTRANSMITTER SYSTEM. Christina L. Williams*, Bruce Nock*, and W. G. Hall (SPON: F. S. Kraly). Institute of Animal Behavior, Rutgers Univ., Newark, N.J., and North Carolina Dept. of Mental Health, Raleigh, N.C.

Previous studies have demonstrated the emergence of an inhibitory control of suckling behavior in the infant rat between the 10th and 15th day of life. Prior to this age, nutritional state is not a factor controlling suckling, and all pups will attach and suckle from the nipples of their anesthetized mother, whether deprived or nondeprived. After 15 days of age, only deprived pups will suckle. Since biochemical and behavioral evidence suggest a maturation of serotonergic neural function at this time, we treated 20-day old rat pups with methysergide (20 mg/kg), a putative serotonin (5-HT) receptor antagonist, and immediately observed their suckling behavior with their anesthetized mother for 1 hr.

Methysergide treatment produced a dramatic increase in the suckling of nondeprived pups, compared to saline injected controls (methysergide 37.5 ± 5.6 mins, saline 17.5 ± 8.0 mins, $p<.05$, $n=8$). In addition, methysergide-treated pups, like younger pups, tended to suckle from a single nipple while deprived controls shifted from nipple to nipple.

In order to further assess serotonergic involvement in the mediation of suckling, we treated 20-day old, deprived pups with the putative 5-HT receptor agonist, quipazine (10 mg/kg), alone or with a methysergide (20 mg/kg) pretreatment and observed their suckling behavior 30 mins following quipazine treatment. Quipazine alone, clearly inhibited nipple attachment in deprived 20-day old pups. Pretreatment with methysergide 15 mins prior to quipazine, blocked the inhibitory effects of quipazine on suckling behavior (quipazine 7.5 ± 6.1 mins, methysergide/quipazine 55.6 ± 2.3 mins, $p<.01$, $n=8$).

We have evidence that the reinstatement of suckling which we report, is not simply the result of making the nondeprived pups hungry. Methysergide reliably stimulates suckling in 30-day old pups, but at this age, even 24 hrs of food deprivation fails to activate suckling. Also, given the choice between non-nutritive suckling or food pellets, methysergide-treated pups prefer to suckle while deprived controls prefer to eat food pellets.

In young pups, suckling has the appearance of a fixed reflex behavior. However, in the brief preweaning period, this relatively simple behavior sequentially develops internal controls. The pharmacological stimulation and inhibition of suckling in 20-day old rat pups which we report, suggest that in part, the development of these controls may be related to the emergence of an inhibitory serotonergic system.

INVERTEBRATE NEUROBIOLOGY

519 TWO TYPES OF NEUROMUSCULAR JUNCTIONS IN COCKROACH MUSCLE FIBERS. S. Aizu* (SPON: A. Hess). Dept. Anat., Rutgers Med. Sch., CMDNJ, Piscataway, N.J. 08854.

Different muscles of the coxa of the cockroach, Periplaneta americana, are known to be physiologically fast or slow and to be innervated by fast, slow or inhibitory nerve fibers. Previous investigations of these diverse muscle fibers have thus far failed to find any striking morphological differences in the nerve endings on these muscles. Muscles numbered 177A, 177B, 177C, 177E (e and e'), and 182 have been studied in the electron microscope. Others have shown physiologically that muscles 177A and C receive only fast nerve fibers. The nerve terminals on the fibers of these muscles contain many spherical clear synaptic vesicles and contact the muscle fiber for only a short distance. On the other hand, muscles 177B and 182 are innervated physiologically by three kinds of nerve fibers: fast, slow and inhibitory. In these muscles, two types of neuromuscular junctions are observed. One type is the same as the above mentioned short-contact terminal. The nerve terminal of the other type contains many clear polymorphic synaptic vesicles, and the membranes of nerve terminal and muscle fiber are apposed for a relatively long distance. Muscle 177e receives a dual innervation of slow and inhibitory fibers and both types of neuromuscular junction occur. From the above study, it appears that excitatory terminals of both fast and slow nerve fibers are of the short-contact type, while the inhibitory terminal is of long-contact type. An exception to this conclusion is muscle 177e' which is innervated by fast and slow fibers only (no inhibitory fibers), but in which, nevertheless, both types of terminals have been found. However, it is suggested that muscle 177e' is indeed innervated by inhibitory nerve fibers, which have not yet been found electrophysiologically. Further study of the internal structure and histochemical enzyme patterns of these insect muscle fibers and the nerve terminals on them is under way to attempt to correlate morphologically types of muscle fiber with the type of innervation.

520 INTERACTION OF CHEMOSENSORY, VISUAL AND STATOCYST PATHWAYS IN *HERMISSENDA CRASSICORNIS*. Tadashi Akaike*, Daniel L. Alkon* and June Harrigan* (SPON: J. Atema) Sec. on Neur. Systems, Lab. of Biophysics, NINCDS, NIH, MBL, Woods Hole, MA 02543.

Synaptic interaction between the visual and statocyst pathways of the nudibranch mollusk *Hermissenda crassicornis* has been recently defined with simultaneous intracellular recordings from neuron pairs during physiologic and electrical stimulation (Alkon 1973, 1975, 1976). To investigate the interaction of chemosensation with sensory perception mediated by the visual and vestibular pathways, intracellular neuronal responses were recorded while stimulating the *Hermissenda* tentacles with palpable food substances, extracts thereof, or amino acids (natural stimulation). Intracellular responses from the same neurons were also recorded during electrical stimulation of the tentacular nerve. Neurons investigated included those with specific loci on the cerebropleural ganglia, photoreceptors within the eyes, optic ganglion cells and statocyst hair cells. Many small neurons depolarized when the tentacle was perfused with squid extract, egg yolk solution or amino acids (glycine, L-proline, D, L-methionine with threshold concentration of 10^{-8} -10^{-10}M). These same cerebropleural neurons depolarized with a fixed latency (5-10 msec) in response to electrical stimulation of the tentacular nerve. Other cerebropleural neurons hyperpolarized with electrical and natural stimulation of the tentacular pathway. The five photoreceptors of each eye hyperpolarized in response to electrical and natural tentacle stimulation. Type A were much less responsive than Type B photoreceptors (e.g. with electrical stimuli Type A hyperpolarized 2-5 mV vs 5-10 mV for Type B). This hyperpolarization of the photoreceptor was associated with a 30-40% increase in membrane conductance as measured by simultaneous impale of single photoreceptors with two microelectrodes. Since the conductance changes were measured within a linear portion of the photoreceptors' current-voltage relation, they cannot be attributed to rectification of the photoreceptor membrane. The hyperpolarization was reversed by hyperpolarizing the photoreceptor, was reversibly eliminated by perfusion with 20 mM $CoCl_2$, and fatigued with repetitive stimulation at 0.2 Hz. Tonic inhibitory potentials in statocyst hair cells were eliminated by natural and electrical tentacle stimuli. These IPSP's most likely arise from ipsilateral optic ganglion cells which were also inhibited by natural and electrical stimulation. Such intersensory interaction may provide a neural basis for a behavioral hierarchy in *Hermissenda* and related species (cf. Davis, 1973). For *Hermissenda*, a positive chemotaxis as well as a positive phototaxis were substantially suppressed when a choice between food substances or a light source was possible (N = 30, $p<.01$).

521 PROLONGED INHIBITION AND EXCITATION IN THE *HERMISSENDA* EYE. Daniel L. Alkon*, and Yoram Grossman* (SPON: T. MacNichol). Sec. on Neur. Systms., LB, NIH, MBL, Woods Hole, MA 02543.

Within each eye of the nudibranch mollusk *Hermissenda crassicornis* there are two Type A and three Type B photoreceptors, distinguished by numerous morphologic and electrophysiologic criteria (Alkon 1973, 1976). Since the somata are only passively invaded by action potentials arising (~80μ away) in the distal axon, the generator response can be studied in the absence of impulses and synaptic interactions (which occur at the terminal branches) by cutting the distal axon (Cut N). Intracellular records from all five photoreceptors (Cut N) after at least fifteen minutes dark adaptation, showed a depolarization for 4-6 minutes after a 30-sec. light step (10^3 ergs/cm^2 -sec). This long-lasting depolarization (LLE), which increased with longer and brighter light steps, was associated with a two to three-fold decrease in membrane conductance although membrane conductance was substantially increased throughout the depolarizing response during the light stimulus. LLE could be eliminated by hyperpolarizing the photoreceptors during the light. Injection of large depolarizing current steps was associated with an increased membrane conductance and was not followed by LLE. Cutting the axon distal to the impulse initiation zone removed all synaptic interactions, but did not alter LLE for either Type A or Type B photoreceptors. When completely intact, the lateral Type A photoreceptor unlike its neighbor, the medial Type A, gave a light response which was followed by almost no LLE and usually hyperpolarized. This long-lasting inhibitory undershoot (LLI) closely paralleled the LLE of simultaneously penetrated Type B and medial Type A photoreceptors. Unitary IPSP's within the LLI followed, one-for-one, impulses of simultaneously penetrated Type B cells. The LLI was eliminated by synaptic blockade with 20 mM $CoCl_2$ or eserine (10^{-3}M). It was associated with small decreases and in some cases slight increases of membrane conductance. This suggested that an increased conductance at the synaptic endings during the LLI added to and mostly cancelled a decreased conductance at the lateral Type A soma. Additional observations (including reduction of LLI by ipsilateral statocyst removal) indicated that the increased firing of Type B cells during their LLE inhibit the lateral Type A by both monosynaptic and polysynaptic (via statocyst hair cells) inhibition. When excitation of these hair cells by rotation was paired with a light step, the LLE of Type B cells was substantially enhanced and the number of unitary IPSP's during the LLI of the lateral Type A was correspondly increased. This enhancement of LLE and LLI can be explained by changes of known synaptic interactions and may help explain previously observed neural and behavioral changes produced by associative training of intact *Hermissenda* (Alkon 1975).

522 ACTIVATION OF A STOMATOGASTRIC MOTOR PATTERN GENERATOR BY DOPAMINE AND L-DOPA. William W. Anderson* and David L. Barker, Bio. Dept., U. of Oregon, Eugene, OR 97403.

Biochemical and histochemical data indicate that neurons in the spiny lobster stomatogastric ganglion (SGG) are innervated by dopaminergic fibers originating from the paired commissural ganglia (CG) (Barker and Hooper, Neurosci Abst 1:395, Kushner and Maynard, Brain Res, in press). When the nerve connecting the CG and SGG is cut, the pyloric motor output from the SGG decreases 2-4 fold in frequency and only 3 of the 13 pyloric motorneurons remain active (Russell, J Exp Biol, in press). To assess the role of dopamine (DA) in the activation of pyloric motor output, the isolated SGG was bathed in saline containing DA or its precursor L-DOPA. L-DOPA was used with the aim of inducing excess synthesis and spontaneous release of DA at the proper synaptic sites. We found rapid conversion of ^{3}H-DOPA to ^{3}H-DA; ^{3}H-norepinephrine synthesis was not detected.

Both DA (50-200 μM for 30 min) and L-DOPA (20-200 μM for 2 hrs) induced gradual activation of three pyloric motorneuron types (2-PD, LP, 8-PY) beginning after 2-5 min in DA and 9-30 min in L-DOPA. Although the degree of activation was variable, depending in part on the time between CG removal and stimulation, the pyloric output of strongly activated preparations was nearly identical whether induced by DA or L-DOPA, and was similar in many respects to the intact CG-SGG preparation. The previously silent LP and PY neurons began rhythmic firing in the normal PD-LP-PY sequence, and cycle frequency of the PD bursting pacemaker neurons increased to CG-SGG levels. However, IC activation was rare, VD activity often decreased, and the number of PD spikes/burst was less than in the CG-SGG preparation. During washout, DA activated preparations returned to control levels within 30 min, while L-DOPA activated preparations continued to increase their activity for 2-3 hrs and required at least 5 hrs to reach control levels. The differences in time course indicate that L-DOPA does not act by directly stimulating receptors, but through conversion to, and release as, DA.

Our results suggest that dopaminergic input could be a major component of CG activation of the pyloric motor pattern generator, and that tonic release of a particular neurotransmitter may activate the coordinated rhythmic output of several neurons in a pattern generator. 523 PHOTORESPONSIVE NEURON ON THE VENTRAL SURFACE OF THE ABDOMINAL GANGLION OF APLYSIA CALIFORNICA. Michael C. Andresen* and Arthur M. Brown (SPON: D. C. Eaton). Dept. of Physiol. & Biophysics, Univ. of Texas Medical Branch, Galveston, Texas 77550.

A number of neurons in the central nervous system of Aplysia respond directly to illumination. Most of these neurons require fairly high light intensities. This report describes a ventral photoresponsive neuron (VPN) whose threshold light requirement is 1000x's lower than for the photoresponse of R_2 and is comparable to the threshold for the Aplysia eye. When VPN is voltage clamped near the resting potential, brief (100 msec) illumination increases the membrane conductance and produces an outward light-induced current (I_L) lasting about one minute. The reversal potential of I_L and its shift with changes in external potassium are consistent with the Nernst equation for potassium. The I-V curves for I_L are nonlinear and agree with the constant field equation. The recovery phase of the I_L response consists of two exponential components with time constants of 12 and 50 seconds. When illuminated, the pigmented lipochondria in the cytoplasm of VPN undergo morphological changes similar to those found in R_2 and associated with a release of calcium. The similarities of the photoresponses of VPN and R_2 suggest that an identical mechanism is responsible for the phototransductive properties of these neurons.

524 BIOSYNTHESIS OF NEURO-DEPRESSING HORMONE (NDH) IN THE NERVOUS SYSTEM OF THE CRAYFISH. Hugo Aréchiga, Casimiro Cabrera-Peralta, Alberto Huberman* and Irene González* Dept. Physiol. Ctr. Adv. Stud., IPN, México, and Dept. Biochem. Inst. Nutr. Dis., México, D.F.

The nervous system of the crayfish contains a neuro-hormone of peptidic nature, which depresses neuronal excitability. The greatest amount of this substance is contained in the sinus gland, a neuro-haemal organ in the eyestalk, wherefrom it is released (Aréchiga, Huberman and Martínez-Palomo, Brain Res., 1977 In Press). The purpose of this work is to locate the site(s) of synthesis of this hormone. In a first stage, 200 adult specimens of Procambarus bouvieri (Ortmann) of either sex were subjected to eyestalk ablation, and the content of NDH in blood and in the remaining of the nervous system was determined at 24-hour intervals. NDH was separated from crude extracts, passing the material successively, though Sepahdex G-25 and G-10 columns, and identifying by bioassay, the active fraction thus separated from other peptides. The activity was meassured as the decrement in spontaneous firing rate in a set of identified motoneurons in the 3d abdominal ganglion. NDH content gradually diminished both in the nervous system and in blood after eyestalk excision until nearly disappearing in 4 days. Yet, some recovery was apparent at the end of one week. A similar time course was found in a second group of animals in which the eyestalks were ligated and left in place. In order to test the possibility of synthesis in vitro, the eyestalk ganglia were excised, and incubated in culture medium (Eagle's MEM) at 20°C for variable periods of time. Two types of preparations were used; a) intact ganglia, devoid of sinus gland, and b) homogeneized ganglia, from which NDH originally contained was removed by dyalisis. In this latter preparation, incubation was ended by heating at 75°C for 3 min followed by centrifugation for 1 min and the supernatant was taken and passed to Sephadex. In both, NDH was present after a few hours, and in the intact ganglia, NDH activity was also present in the culture medium. These results indicate that the neurosecretory apparatus of the eyestalk synthesize NDH, and that normally it is the main source of this hormone. That it is not the sole source is suggested by the recovery of NDH activity in eyestalkless animals.

525 SHORT AND LONG-TERM ERG CHANGES IN BRAINLESS CRAYFISH. Baltazar Barrera-Mera and B. Fuentes-Pardo. Depto. de Fisiología, Facultad de Medicina, Universidad Nacional Autónoma de México, México 20, D.F. MEXICO

Cerebral ganglion lesion studies (Barrera-Mera, 1976) have shown a close dependence between ERG circadian activity and the integrity of neurohemal system-cerebral ganglion sinus gland of the crayfish P. bouvieri. It was proposed that the lack of humoral neurosecretions, is the mechanism through which changes in ERG circadian oscillations in brainless crayfish are brought about. In this paper we report the effects of surgical removal of the cerebral ganglion on short and long-term ERG activity. Light-dark (L-D) adaptation reactions (60 min each) as well as the retinal shielding pigments (RSP) position were determined in intact and in brainless animals, during both rest (ρ) and activity (α) phases of continuous ERG recordings. In contrast with intact animals the time course of ERG voltage during L-D adaptation consists of one component only, probably due to the lack of the movilization of distal RSP. That is, also observed in these animals. These findings an increase in frequency of ERG oscillations and the change in α/ρ ratio value seen in these preparations suggest a central modulatory influence on short and long-term ERG activity in these animals.

526 LACK OF CENTRIFUGAL EFFECTS ON SPEED OF PHASE SHIFTING IN THE APLYSIA EYE. Gene D. Block and Terry L. Page*. Hopkins Marine Station, Stanford University, Pacific Grove, CA 93950.

The eye of Aplysia contains a circadian pacemaker (Jacklet, 1969). This oscillator is entrainable by light both in vitro, when isolated in culture medium (Eskin, 1971), as well as in vivo (Jacklet, 1969). However, there are differences in the speed of entrainment of eyes exposed to light cycles in vivo when compared to exposure in vitro (Eskin, 1971). Enhanced rates of entrainment in vivo might be due to neural or hormonal factors absent in vitro or might reflect deficiencies in the culture medium. The assistance of extraocular neural inputs in phase shifting the ocular rhythm is made plausible by the presence of efferent fibers in the optic nerve (Eskin, 1971). In order to evaluate whether efferent fibers are responsible for enhanced entrainment rates 16 Aplysia were placed on white light cycles (Light:Dark, 12hr:12hr) for 5-7 days. One optic nerve was then surgically cut and the Aplysia placed back on the same light schedule. After 2 additional days the intact and denervated eyes of 4 Aplysia were removed and recorded to ensure that both eyes of the operated animals were in steady-state entrainment. At this time the light cycles were phase advanced by 10 hr. Aplysia were sacrificed at the end of each successive photoperiod and recordings of optic nerve activity made by means of suction electrodes attached to the optic nerves of eyes maintained in filtered seawater at 15.0 + .5°C. in constant darkness.

The results indicate that efferent information does not influence entrainment speed. At the end of the first photoperiod of the advanced light cycles the mean shift for intact eyes was 3.5 hr and 3.6 for denervated eyes when compared to the unshifted controls. After the second photoperiod the mean shift was 9.0 hr for intact and 9.0 hr for denervated while after the third photoperiod, 10.3 hr for intact and 11.5 hr for denervated eyes. There was no additional advance after the 4th photoperiod indicating the pacemakers were in steady state. Additional Aplysia with both optic nerves intact showed similar entrainment rates. Taken together, these results demonstrate that differences in entrainment rates in vivo and in vitro are not due to efferent neural inputs via the optic nerve. Supported by N.I.A. AG00490-02 and N.I.H. IF32NS5035-02.

527 HOURS-LONG INHIBITION PRODUCED BY PEPTIDE-SECRETING BAG CELLS OF APLYSIA, INCLUDING INHIBITION OF CELLS CONTROLLING INKING BEHAVIOR. Philip Brownell* and Earl Mayeri. Dept. Physiol., Sch. Med., UCSF, San Francisco, CA 94143

Previous work indicates that a peptide released from the neuroendocrine bag cells induces egg laying in intact animals. In the isolated abdominal ganglion, bursts of bag cell spike activity lasting 5-40 min can be triggered by local electrical stimulation. We have found that bag cell activity triggered in this manner produced several types of neural changes, both excitatory and inhibitory, that lasted several minutes or hours. Slow inhibition, the most widespread type of change, occurred in 21 of the identified cells we surveyed, including the giant cell R2, white cells R3-R14, the left upper quadrant cells L2-L6, and ink-gland motorneurons L14 A,B & C. It also occurred in several unidentified cells on the ventral surface of the ganglion.

We have begun a detailed study of bag cell-induced slow inhibition in two of these cells, L3 and L6. Hyperpolarization of L3 and L6 typically began 2-8 sec after onset of bag cell activity, and reached a peak amplitude of 10 to 20 mV within 20 sec. For 30 min to 3 hr or more thereafter,both the burst rate and average firing rate of these burster neurons were decreased. The inhibition was (1) contingent on bag cell activity and not on the electrical stimulus that triggered bag cell activity; (2) the response was inverted when the cells were hyperpolarized by direct current injection; (3) the reversal potential was near -80 mV, the potassium equilibrium potential; and (4) the response was not attenuated by tetraethylammonium and curare at concentrations that blocked cholinergic inhibition of these cells. These results strongly indicate that the bag cells produce slow inhibition that involves an increase in membrane conductance to potassium ions. Since bag cells release peptides when they are activated, it is possible that the slow inhibition is mediated by a peptide.

Slow inhibition that occurs in the ink-gland motorneurons L14 A, B&C is similar to that described above. These cells are part of a well-defined neuronal circuit controlling a fixed act, the all-or-none release of ink from the purple gland (Carew and Kandel, JNP, May 1977). Our results predict that in intact animals the threshold for inking is elevated during egg-laying. Thus bag cell activity that produces inhibition of the ink-gland motorneurons might serve to suppress one stereotyped behavior, inking, at the same time bag cell activity induces another behavior, egg laying.

528 DIFFERENTIAL SENSITIVITY OF APLYSIA AXONS TO PHARMACOLOGIC AND IONIC MANIPULATIONS. Hugh Bryant, Anatomy Department, School of Medicine, UCLA, Los Angeles, California 90024.

The axons of cells R1 and R2 are the largest in the Aplysia right pleurovisceral connective (PVC), and their extracellular field potentials can be readily recorded and distinguished one from the other. This preparation, therefore, offers the possibility of studying the differential responsiveness of these axons to various experimental manipulations. The pleural-pedal ganglion, right PVC and visceral ganglion were mounted in a multi-compartment chamber. Stimulation and recording in oil were accomplished on either side of a 2 cm compartment which contained the experimental medium. For example, in a Na^+-deprived medium (40-50%) the axon of R2 does not conduct in an all-or-nothing fashion but conducts with decrement (Bryant and Decima, 1976, Soc. for Neurosci. Abst.). R1, on the other hand, conducts uniformly until the Na^+ is reduced to approximately 20-30% of its normal value, at which point it also begins to conduct with decrement. The above conclusions are true only for stimulus frequencies below 2-4/sec. At higher frequencies (5-10/sec), R2 paradoxically resumes uniform conduction, and R1 begins to conduct with decrement (even with 40-50% normal Na^+). Following a tetanus in a 40-50% Na^+ medium, the original decrement in R2 is augmented for several minutes, whereas R1 quickly recovers and conducts uniformly. In a "low Ca^{++}, high Mg^{++}" solution whichpurportedly blocks chemical synaptic transmission (Byrne et al., 1974, J. Neurophysiol. 37, p. 1041), conduction in R2 and several smaller axons occurs with decrement. Providing stimulus frequencies are kept low, R1 and still other small, unidentified axons will continue to conduct uniformly. This medium is, in fact, also a Na^+-deficient medium (~46%) and would be predicted to cause conduction with decrement in some, but not all, axons (see above). Its use in Aplysia to separate synaptic from non-synaptic neuronal activation is, therefore, seriously compromised. Finally, the R1 and R2 axons also have different sensitivites to xylocaine. Although the precise concentrations which cause R1 and R2 to conduct with decrement vary slightly from one preparation to another (10-30mM), R2 is always depressed at lower concentrations than R1. Whether or not R1 or R2 conduct uniformly or with decrement during local anesthesia depends on several factors in addition to anesthetic concentration, most notably time of exposure and stimulus frequency. These results: 1) add further support to the classical concept of decremental conduction as the proper description of conduction in narcotized peripheral nerve; 2) demonstrate similarities between conduction in narcotized nerve and certain synaptic phenomena; 3) suggest caution in the generalization of results from one preparation (i.e., cell) to another. Supported by NIH grant MH 10083.

529 HABITUATION OF CEREBRAL NEURONS MEDIATING TENTACLE RETRACTION IN THE LAND SLUG ARIOLIMAX. Christopher Y. Chan* and Stacia Moffett (SPON: F. A. Young). Dept. Zool., W.S.U., Pullman, WA 99164.

The tentacles of Ariolimax columbianus are inverted by tentacle retractor muscles when the slug experiences a novel or aversive stimulus. We have studied cerebral neurons that mediate retraction of the major tentacles in semi-intact preparations and in the isolated central nervous system. The efferent units that mediate the retraction response are found in the cerebral retractor nerve (CRN). Because the large efferent units are few in number (1-3 on each side) and distinguishable by characteristic spike heights, the response of each cell can be quantified in extracellular recordings.

Repetitive electrical shocks delivered to the minor tentacle nerve or other cerebral nerves cause an exponential decline in the number of action potentials reflexly activated in the efferent units. The reflex response recovers spontaneously with rest and shows dishabituation and habituation of the dishabituating stimulus pathway. No generalization of the habituation from one pathway to another has been found. The interval that produces the most rapid habituation is around 45 to 60 sec., which is approximately the time required for the reflex to be completed and the retractor muscle to relax. Short stimulus intervals, as well as high stimulus strengths tend to produce sensitization of the response.

We have identified two symmetrically positioned cerebral neurons as retractor efferent units on the basis of one-to-one correspondence of action potentials in the soma and CRN, and antidromic action potentials following stimulation of CRN. Intracellular recordings from these neurons show that they are reflexly activated by inputs from all cerebral nerves. The response habituates and can be dishabituated in a manner similar to that found in extracellular recordings. Sensitization is also evident as an increase in the general level of activity of these neurons. Each neuron is the dominant unit in the ipsilateral tentacle retraction reflex. When the neuron is depolarized to fire action potentials, no effect of its activity is recorded on the contralateral CRN. We are currently studying the mechanism of habituation in these neurons and attempting to identify other elements in their reflex pathways.

530 MUTATIONS AFFECTING THE FLIGHT NEUROMOTOR SYSTEM IN DROSOPHILA John C. Coggshall*, (SPON: William Pak). Dept. Biol., Yale Univ., New Haven, CT 06520

An extensive, ongoing, mutagenesis has been conducted yielding a large number of flightless mutants, primarily on the X-chromosome.

The technique of fate-mapping using mosaic flies has been used to distinguish between mutants with primary defects in the nervous system as opposed to primary defects in the muscles. The incorporation of an autonomous, external, marker for the nervous system, namely a temperature-sensitive paralytic, has been incorporated into the mosaic generation system, thus allowing the detection of internal mosiacism within the nervous system without resorting to the use of internal enzyme markers requiring tedious, time consuming, histochemistry.

Results suggest that two general classes of neural mutants can be distinguished; functional mutants and neurotrophic mutants.

Functional mutants appear to have a defect in the nervous system that disrupts the functioning of the nervous system itself. Of five X-chromosome flightless mutants which have been fate-mapped, three have been shown to have defects in the nervous system. Electrophysiological, anatomical, and behavioral data suggest that these are indeed functional mutants. The other two mutants have wing and muscle defects.

A neurotrophic mutant is defective in a function that is necessary for the development and/or maintenance of a particular set of muscles. A potential neurotrophic mutant on the third chromosome has been studied. The phenotype consists of the elimination of one specific set of flight muscles, the dorsal longitudinals, in the adult. Mosaic data indicate that the primary defect is in the nervous system.

531 IN VIVO RECORDING OF REFLEX ACTIVITY FROM LOBSTER CLAW MOTOR NEURONS. Walter J. Costello and Fred Lang, Boston University Marine Program, Marine Biological Laboratory, Woods Hole, Massachusetts 02543.

Crustacean neuromuscular systems possess a large repertoire of synaptic activity. Depending on the neuromuscular properties there can be summation, facilitation, or anti-facilitation. A salient feature of these responses is the fact that patterned pre-synaptic stimuli can be more efficient in eliciting motor responses than unpatterned (equally spaced, constant frequency) stimuli. We have investigated the normal motor pattern of the fast and slow axons to the claw closer muscles by recording intracellularly from muscles of restrained animals.

First, using isolated claws we determined the distribution of the fast and the slow excitor axons to the closer muscle of the cutter and the crusher claws in the lobster. Preliminary results reveal that specific areas of the muscle are innervated by only one of the two single motor axons. Thus it is possible to observe the activity of each axon by monitoring a known area.

These results were utilized to ascertain in vivo reflex activity of the neuromuscular system in the lobster claw closer muscle. Small holes were drilled in the claws of restrained animals; microelectrodes were inserted into the holes to record from individual muscle fibers. Reflex activity was evoked by stimulation of the sensory hairs on the dactyl and propus. Claw closure was accompanied by one or a few excitatory postsynaptic potentials (EPSP's) in the fast motor axon. A fast twitch was accompanied by a pair of EPSP's with an interval of less than 9 msec. The second EPSP was greatly facilitated and usually evoked a graded membrane response.

Slow claw closure was accompanied by a burst of EPSP's from the slow motor axon. These occasionally contained paired EPSP's with interpulse intervals of 9-15 msec but no active membrane responses were observed.

Therefore it appears that claw closure can be achieved by only a few impulses from the fast motor axon. When these are patterned into paired pulses, two closely spaced stimuli give sufficient synaptic facilitation to evoke an active membrane response which will, in turn, result in a rapid twitch.

532 MEASUREMENTS OF OXYGEN PARTIAL PRESSURE AND SINGLE-UNIT ACTION POTENTIALS IN THE ABDOMINAL GANGLION OF APLYSIA CALIFORNICA. P.E. COYER *(SPON: R.J. Bradley). Department of Neurology, University of Alabama Medical Center, Birmingham, Al 35294.

Intracellular determinations of oxygen partial pressure and simultaneous recordings of single-unit action potentials have been obtained from identifiable neurons in the isolated ganglion of Aplysia californica with polarographic current measurements using gold microelectrodes. Previous combined oxygen level and action potential recording techniques relied on inferential spectrophotometric measurements from heme-protein-containing cells during penetration with intracellular microelectrodes (Chalazonitis and Arvanitaki, 1970). In those experiments many neurons were reported to respond to hypoxia by a decrease in pigment oxygen saturation usually followed by an increase in spike frequency and sometimes by membrane depolarization. Both membrane potential monitoring and single-unit action potential recording are being undertaken with 3M KCl -filled pipettes and gold microelectrodes from the same identifiable neuron to ascertain the effects of hypoxia on membrane potential and spiking patterns.

This report concentrates on intracellular oxygen level determination from unpigmented neurons (R_{15}, R_8 and L_7) and that of supporting tissue surrounding them. Beating and bursting pacemaker activities have been attributed to single neurons in isolation from the ganglion by several other workers. I report intracellular oxygen levels which have been obtained from ganglionic neurons in conjunction with their characteristic patterns of spiking activity. Attempts are being made to experimentally manipulate the ganglion tissue level in vitro to those reported in vivo. It is hoped that once the link between the level of intracellular oxygen supply and single-unit activity is known that further parameters underlying oxygen diffusion into the interior regions where these identifiable neurons are found can be established.

533 ACQUISITION AND RETENTION OF A LONG-TERM BEHAVIORAL CHANGE IN *HERMISSENDA CRASSICORNIS*. T. Crow and D. Alkon*. Sect. on Neur. Systems, Lab. of Biophys., NINCDS, MBL, Woods Hole, MA 02543.

The nudibranch mollusk *Hermissenda crassicornis* is attracted to a light source. It has been shown previously for groups of animals that this attraction to light can be modified by the paired presentation of a light stimulus and a rotational stimulus (Alkon, 1974). The number of animals reaching and entering a spot of light is significantly smaller for groups that received paired stimulation immediately before testing as compared with groups receiving light or rotation (Alkon, 1974). We now have shown that this behavioral change to a light stimulus is long-term, lasting several days. The effects of paired and single stimulus presentations were assessed at the end of each training session by examining changes in the animals response latencies to enter a light spot. Four groups were trained and tested for seven consecutive days. One group received 40 trials each day of light (30 seconds) paired with rotation (30 seconds). An additional group received 15 trials each day of the same light and rotational stimuli. Control groups received 40 or 15 trials of light and 40 or 15 trials of rotation. The groups that received paired light and rotation took significantly longer to reach the light spot as compared with the respective control groups ($p<.001$). In addition, there was a significant increase in response latencies over the seven training days for the groups that received paired stimulation ($p<.01$) while this was not observed for the respective control groups. We next investigated the retention of this behavioral change. Subjects received a pre-test to light to establish baseline response latencies. One group received 50 trials of light paired with rotation for three consecutive days. The response latencies to enter the light were measured at the end of training day three. These subjects exhibited significantly longer latencies as compared with their own pre-training baseline ($p<.005$) and the respective control groups that received 50 trials of light or 50 trials or rotation ($p<.005$). The subjects were then divided into two groups, one received a retention test two days following the last training session and the other received a retention test four days after the last training session. The experimental groups showed significant retention at two days and four days ($p<.005$) as compared with the control groups and baseline response levels. Two additional retention tests examined changes in light responsiveness on two subsequent days following retention tests 2 and 4. These results revealed that response latencies gradually declined such that the latencies were not significantly different from controls or baseline levels on the last retention day. These results suggest that the changes in response latencies following paired stimulation are long-term and resist repeated testing.

534 DESCENDING CONTROL OF COCKROACH GIANT FIBERS DURING WALKING Darryl L. Daley* (SPON: F. Delcomyn). Program in Neural and Behavioral Biology, Univ. of Illinois, Urbana, IL 61801.

The ventral nerve cord (VNC) of the American cockroach contains about 16 giant fibers (GF's), commonly associated with some aspect of escape behavior. Delcomyn (J. Insect Physiol. 22:1223, 1976), monitoring activity from the VNC of a tethered cockroach capable of normal walking, has found certain giant fibers are activated during walking. This finding was unexpected because activity in GF's had been thought to occur mainly before and possibly during the escape run, and not during slow walking.

To further investigate GF activity during walking in the cockroach, experiments have been performed using tethered walking preparations. Giant fiber activity was monitored en-passant with suction electrodes from the connectives of the VNC. The results demonstrate the existence of at least two distinct populations of GF's under descending control during walking. The first population consist of those GF's shown by Delcomyn to be active during walking but near silent during rest. Activity of a second population of giants can be evoked by presenting the animal with 10-12 Hz auditory clicks. The activity of these GF's is inhibited during walking, coincident with the activation of the first population of GF's. Murphey and Palka (Nature 248:249, 1974) have described a similar inhibitory influence on cricket giant fibers. Both excitatory and inhibitory influences on giant fiber activity are unilateral and appear to originate in part from thoracic or higher central nervous centers. After establishing the two modes of GF control active during walking, experiments were done to examine these influences upon single GF's. The results of intracellular recordings from identifiable GF's during walking in tethered animals allowed specific inhibitory or excitatory influences to be uniquely associated with individual giant fibers.

The findings reported here support the ideas that giant fibers are under two separate modes of descending control during walking and that they do not all function exclusively in escape. This research was supported in part by RIAS NSF grant SER 76-18255, NIH grant NS12142 to F. Delcomyn, and HEW PHS grant GM-1076 to the author.

535 SYNAPTIC GROWTH IN A CRUSTACEAN MUSCLE. Richard A. DeRosa and C. K. Govind. Scarborough College, University of Toronto, West Hill, Ontario, Canada M1C 1A4.

The absence of a terminal molt in a lobster allows its muscle fibers to continue growing in length and diameter throughout the animal's life span. If it is desirable to have uniform depolarization of the muscle fiber at all stages of growth, then changes must occur in their synaptic properties, electrical properties, or in both. These changes have been examined in the proximal head of the limb accessory flexor muscle of the lobster by comparing two distinct age groups, viz., adult (1 lb) and old (6 lbs) lobsters.

During growth of the muscle fiber from adult to old lobsters the input resistance (R_{in}) decreased according to the fiber diameter$^{3/2}$. However, postsynaptic potentials and facilitation ratios were similar for comparable muscle fibers in both age groups and were independent of R_{in}. Furthermore, muscle fibers in both age groups have similar values for membrane time constant, specific membrane resistance, membrane capacitance and sarcoplasmic resitivity. Consequently, the equivalent levels of depolarization seen in adult and old lobsters must be due to increased quantal output (m) in older lobsters. The quantal output increased to 3.4 in old lobsters compared to values of 2.2 in adult lobsters.

Ultrastructural analysis suggests that the increases in m values from adult to older synapses are due to increases in total synaptic area and dense body accumulations. Also it was observed that the structural properties of sarcomere length, A-band length and total sarcomere number were still growing in the oldest of lobsters examined (12 lbs).

It is concluded that the accessory flexor muscle maintains similar levels of depolarization throughout its life span. This is accomplished by increasing the quantal output rather than changing the electrical properties of the muscle fiber.

536 IDENTIFICATION OF HORIZONTAL AND VERTICAL MOVEMENT DETECTION SYSTEMS IN INSECTS. Hendrik E.A.Eckert.USC, Dept.Biol.Sci.,Los Angeles. CA 90007.

The iontophoretic injection of the fluorescent dye Procion Yellow has yielded the anatomical identification of two groups of neurones in the flies Phaenicia Sarcophaga,which respond selectively to either horizontally or vertically moving patterns. These cells are located in the third optic ganglion (lobula plate) with their axons extending into the protocerebrum (homolateral elements)or crossing the midline and extending to the contralateral side of the brain and contralateral lobula plate (heterolateral element)

Vertically sensitive fibers were split into two groups:(1) 9 giant homolateral elements (V-cells) respond with a depolarizing DC-membrane potential shift (mps) to downward, and with a hyperpolarizing mps to upward movement of a pattern. Elements with anterior receptive fields in the eye exhibit only this response behaviour; cells with lateral and posterior receptive fields possess an additional sensitivity to progressive pattern motion (front to back) by responding with a depolarizing mps; regressive motion elicits a hyperpolarizing mps. (2) Another element VS1 which crosses the midline of the brain (hetrolateral element) generates spikes and exhibits a preference sensitivity to downward movement and a slightly weaker response to progressive motion. It is believed to be postsynaptic to the 9 V-cells on anatomical and physiological grounds.

Horizontally sensitive cells are also split into two groups:(1) 5 giant cells of two different types, one type (2 centrifugal horizontal cells) only conducting discrete excitatory and inhibitory graded potentials, the other (3 H-cells) conducting graded potentials and action potentials, the latter potentials believed to be the output of these cells controlling the yaw torque response via descending neurones.Both types are homolateral elements with binocular receptive fields.(2) One heterolateral spike conducting element was identified responding to ipsilateral regressive pattern motion with strong excitation and to progressive pattern motion with inhibition over the background spike frequency. Response properties of this cell resemble those of the class IIa1 motion fibers studied by extracellular recording techniques.

537 PHOTOSENSITIVITY OF TONIC FLEXOR MOTONEURONS OF THE CRAYFISH ABDOMEN. Donald H. Edwards, Jr.* (SPON: N. A. Newby). Dept. of Biol. Sci., Stanford Univ., Stanford, CA 94305

Light incident on any one of the five rostral ganglia of the crayfish (Procambarus clarkii) evokes an increase in the spontaneous discharge frequency of the tonic flexor motoneurons which have cell bodies in the illuminated ganglion. The spike frequency of the tonic extensor inhibitor of the same segment also increases in response to the light. The tonic extensor motoneurons are unaffected by light stimuli. Stimulation of the caudal photoreceptor neuron with light directed at the sixth abdominal ganglion evokes no change in the discharge of rostral tonic flexor motoneurons. The tonic flexor motoneurons are most sensitive to blue (436 nm.) and green (546 nm.) monochromatic light and less sensitive to longer wavelengths. Dark adaptation increases the sensitivity of the light response, while light adaptation, or repeated brief exposures to light stimuli, decreases the sensitivity. When thoroughly dark adapted, blinded intact animals are consistently observed to flex their abdomens in response to light directed at the ventral side of their extended abdomens.

538 CHEMOSENSORY NEURONS IN APLYSIA. Dennis G. Emery and Teresa E. Audesirk*. Dept. Zoology, Iowa State University, Ames, IA 50011 and U. of Washington, Friday Harbor Labs, Friday Harbor, WA 98250.

Behavioral and physiological studies have shown that Aplysia makes use of chemical cues in several activities, including food finding, feeding, and possibly mating. Behavioral observations and ablation studies indicate that the chemoreceptors involved are located in the anterior tentacles, rhinophores, and the circumoral area (lip). These organs were examined with light and electron microscopy to identify and characterize the sensory neurons. The rhinophores and tentacles have dark-pigmented grooves that are sensitive to chemicals. The epithelium of these grooves and of the lip is made up of ciliated columnar cells. Below the epithelium are ganglia containing a few to several dozen neurons each. A slender dendrite arises from the distal pole of each neuron, extends through the epithelium and terminates in a tuft of cilia at the surface. The dendrites have pale cytoplasm containing many microtubules and are thus easily identified among the epithelial cells. Each sensory ending bears up to thirty cilia which may arise from a shallow, subterminal invagination. Axons arise from the proximal end of the ganglion and merge to form major nerve trunks. On the basis of light microscopy there appear to be two morphological types of receptors. One type has only one or two cilia while the other has many. This observation has not been confirmed with electron microscopy, but physiological studies indicate the presence of both mechanoreceptors and chemoreceptors in these organs. This might account for the two morphological types among the sensory cells.

The arrangement of the sense cells in discrete subepithelial ganglia might make it possible to record directly from the sensory ganglia with microelectrodes. Such recordings have been made from the nerves, and from identified central neurons to which they project. It may be possible to study electrical activity in this system at the receptor, nerve, and central neuron levels simultaneously. This sensory system might thus be useful for studying both sensory processes and the role of sensory neurons in behavior.

539 ENTRAINING A CIRCADIAN RHYTHM FROM THE ISOLATED EYE OF APLYSIA: THE INVOLVEMENT OF CHANGES IN MEMBRANE POTENTIAL. Arnold Eskin, Dept. Biol., Rice Univ., Houston, TX 77001.

The circadian rhythm of nerve activity from the Aplysia eye can be photoentrained in vitro. For entrainment, the environmental information must be absorbed by a photopigment, coded into a form which can be propagated, and then decoded by the circadian oscillator (CO) resulting in a phase shift of the rhythm. The information may be translated into a transmembrane potential change as it flows from the environment to the CO, or, the CO may be associated with photoreceptors and receive information directly from the photochemical reaction. Entrainment information seems to be translated into changes in membrane potential since there is a correlation between those treatments which blodk phase shifting by light and the effects of these treatments on the ERG (Eskin, J. Neurobiol., in press). Also, a depolarizing stimulus, increased K_o^+ (HiK), produces a response curve with both advance and delay phase shifts (Eskin, J. Comp. Physiol. 80:353, 1972).

To further explore the involvement of changes in membrane potential and the CO, we investigated whether other types of depolarizing stimuli could phase shift the rhythm. Strophanthidin (ST), a Na-K pump inhibitor, and Li^+, which is transported poorly by the Na-K pump, were used. Four hr. treatments of either 100% LiCl:0 NaCl or 50% LiCl:50% NaCl caused phase shifts in the rhythm, whereas treatments of 10% LiCl:90% NaCl did not. A phase response curve which contained only delay phase shifts was obtained using 100% LiCl treatments. The response curve obtained using ST (4 hr., $6x10^{-7}$M) contained both advance and delay phase shifts. An inward Na^+ flux seems to be involved in the ST produced phase shift since the effect of ST was abolished by treating the eye with ST ($1.2x10^{-6}$M) in the presence of a low Na^+ (35mM) solution. Release of neurosecretory substances does not seem to be involved since ST phase shifts were not diminished when the eye was exposed to ST in the presence of a high Mg^{++} (125mM) low Ca^{++} (.1mM) solution.

The qualitative similarity in the HiK and ST phase response curves strengthens the case for a coupling between the membrane potential and the CO. Also, ion concentrations may be important. If so, at least Na^+ and K^+ must be involved since the HiK and ST treatments should produce different changes in each ion. The difference between the response curves of LiCl and of HiK and ST point to a different effect of LiCl on the CO. LiCl may change intracellular concentrations of divalent ions. This might be true since the shape of the LiCl response curve is similar to others obtained using agents known to produce such effects. (Eskin and Corrent, J. Comp. Physiol. in press). 540 MODIFICATION OF TACTILE RESPONSES IN APLYSIA FOLLOWING FOOD CHEMICAL PRESENTATION. Steven M. Fredman and Behrus Jahan-Parwar. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

Mechanical and chemical stimuli elicit very different behaviors in Aplysia. Tactile stimulation of a tentacle usually causes a withdrawal response. Chemical stimuli such as seaweed extracts (SWE) elicit very different behavior such as head waving and mouth opening which are part of the feeding sequence. Tactile stimuli presented after a chemosensory stimulus produces an altered response. Instead of withdrawal there is an orienting response consisting of bending toward the stimulated side. To determine how the mechano-and chemosensory modalities are distinguished and how the different behaviors they mediate are controlled, the responses of neurons in the identifiable A and B clusters of the cerebral ganglion were examined. The isolated CNS of Aplysia with the anterior tentacles attached was used. Each tentacle was placed in its own sealed compartment. Tactile stimuli were presented by a solenoid. Chemical stimuli consisted of 1 ml of SWE presented 1 cm from the tentacle. An interval of 20-30 min was allowed between tests which were each preceded by a control stimulation with seawater.

Tactile stimuli produced phasic excitatory responses in the B neurons. The A neurons were usually inhibited at a longer latency. Stimulation with SWE produced strong tonic firing in the B neurons. Both excitatory and inhibitory A neuron responses were obtained, all at longer latencies. A neuron responses to tactile stimulation were altered following chemosensory stimuli. After the presentation of SWE a subsequent tactile stimulation caused A neuron firing. It was not necessary to have SWE present. These results could be obtained even after the SWE had been washed out. This suggests that some type of gating or arousal mechanism is involved. The excitatory A neuron responses appear to be the result of a polysynaptic pathway from the B neurons to the A neurons. Strong firing of the B neurons might raise the level of excitation of the interneurons involved sufficiently to produce A neuron firing, or if below threshold, raise the level of excitation enough that a subsequent tactile stimulus triggers the A neurons. Since the A neurons appear to be motor neurons producing body movements, their activity may be a correlate of the orienting response. This possibility and the mechanisms underlying the modification of A neuron responses are being investigated.

541 ON THE MECHANISMS OF MIGRATION OF PIGMENT GRANULES OF THE RETINULA CELLS OF THE CRAYFISH. Eugenio Frixione*†, Victor Tsutsumi* and Hugo Aréchiga. Depts. Neurosc. and Physiol. CIEA, IPN, and Dept. Electr. Microsc. Reg. Nac. Anat. Patol., SSA, México, D.F.

The retinula cells of the compound eye of the crayfish contain a set of accessory pigment granules, the position of which is a function of the intensity of illumination. In a fully dark-adapted eye, the granules migrate longitudinally away from the cell bodies and accumulate along the axons, whereas the opposite occurs under light-adaptation. The mechanism underlying this photomechanical response is at present poorly understood. In isolated eyestalks or retinas of the crayfish Procambarus bouvieri, the position of pigment granules was determined after fixation at different times of light- or dark-adaptation. The time course of granule migration was quite different under light than in darkness. While the light-induced migration proceeds in a sigmoidal fashion, being complete in about 30 min, depending on light intensity, the migration in darkness shows two distinct phases: an initial stage, during which the granules move from the distal regions of the cell body to the middle zone, with a time constant of 6 min, ends on a short plateau from which a further rapid movement clears up the pigment from the proximal regions of the cell body and takes the granules deep into the axon. The full dark-adaptation is over in about 45 min. The migration in either direction is temperature-dependent with a Q_{10} of approximately 2.0 Hypoxia and metabolism-blocking agents, like cyanide (2 mM), prevent the second stage of dark-adaptation and induce distal migration in the absence of light. The effect of oxygen deficiency has shown to be reversible. Electron microscopy reveals a close correlation between the intracellular arrangement of pigment granules and a central bundle of microtubules present in the middle and proximal regions of the cell body but being most prominent in the axon. Treatment for 2 hs with 10 mM colchicine or 90% D_2O blocks the second phase of migration in the dark but, although by itself does not promote distal migration, it does not interfere either with the movement towards the cell body induced by exposure to light.

These results suggest the existence of two different mechanisms of migration of pigment granules in the photoreceptor cells of the crayfish, dark-adaptation showing greater metabolic requirements than light-adaptation and being dependent for its completion upon a microtubule-involving mechanism of granule translocation.

542 INTRACELLULAR ANALYSIS OF PRESYNAPTIC INHIBITION IN THE CRAYFISH CLAW OPENER. Paul A. Fuchs, Neuroscience Program, Stanford University, Stanford, California, 94305.

Presynaptic inhibition of excitatory transmission in the claw opener neuromuscular junction proceeds by a reduction in the number of quanta released by an action potential (Dudel, J., and S.W. Kuffler, 1961c, J. Physiol. 155:543.). The mechanism by which this reduction comes about is not entirely clear. In other systems, such as the spinal cord and the tactile afferents of crayfish, presynaptic inhibition is seen as a depolarizing potential in the excitatory terminals, which in some manner reduces the ability of the excitatory spike to release transmitter. Intracellular recording from the excitor axon on the ventral surface of the opener muscle reveals hyperpolarizing IPSPs in response to action potentials in the inhibitor. These IPSPs are 100 - 200 uV in amplitude and approximately 80 msec in duration. They are presumably a summed potential from the many synaptic contacts of the inhibitor onto the excitor. Thus, in contrast to primary afferent depolarization, presynaptic inhibition at this synapse is mediated by a hyperpolarizing potential.

The action potential of the excitor axon is typically 100 uV in amplitude, overshooting the 70 mV rest potential. The action potential is followed by a depolarizing after potential of 5 to 10 mV amplitude and approximately 80 msec duration. When the excitor axon is stimulated at 40 Hz., each spike rides on the afterpotential of the previous spike, producing a depolarizing shift of several millivolts during the train. When excitor action potentials are elicited during stimulation of the inhibitor, the depolarizing after potential is partially shunted by the IPSPs, and trains of excitor spikes do not shift up to the same extent. Finally, during trains of excitor spikes, the duration of the action potential increases by 20% (for 10 spikes at 40 Hz.). Presynaptic inhibition has little effect on this process. Observed postsynaptically, presynaptic inhibition reduces ongoing transmitter release but has little effect on the progress of facilitation. This observation, taken in conjunction with those above, prompts further investigation into the role of use-dependent axonal conduction in the processes of facilitation and presynaptic inhibition at this neuromuscular junction.

543 LENGTHENING THE PERIOD OF A CIRCADIAN RHYTHM IN PROCAMBARUS BY HEAVY WATER. Beatriz Fuentes-Pardo and F. Félix-Durán*. Depto. de Fisiología, Fac. de Medicina, UNAM. México 20, D.F. MEXICO

Deuterium oxide lengthens the period of several endogenous circadian rhythms. Heavy water also produces a reversible slowing of several biological rhythms with periods in the millisecond range. In order to obtain information about the role of this substance on the clock mechanism underlaying the circadian electroretinographic rhythm, we have obtained long-termed records of the ERG of both, intact crayfish and isolated eyestalk of crayfish which exhibit high frequency cycles (Sánchez and Fuentes-Pardo, 1976). Heavy water lengthens both, the circadian and the ultradian rhythms with a dosage dependent character. Since the high frequency oscillations have been taken as the expression of a splitting of the circadian rhythm (i.e. the loss of sinchrony between at least two oscillators), the experimental results suggest the possibility that the changes observed in the circadian rhythm associated with the presence of deuterium oxide, are a consequence of the changes produced on the ultradian cycles.

544 SENSORY INPUTS TO A MOLLUSCAN FEEDING MOTOR PROGRAM. Alan Gelperin, Joseph Jin Chang and Stephen C. Reingold. Dept. of Biology, Princeton University, Princeton, N.J. 08540

A preparation of the lips, cerebral ganglia and buccal ganglia of the terrestrial slug Limax maximus has been developed which allows us to quantitatively elicit bouts of feeding motor program (FMP) by applying defined chemical stimuli to lip chemoreceptors. Expression of the FMP was monitored by extracellular recording of efferent activity in buccal nerves and intracellular recording of activity in buccal motoneurons and cerebral interneurons. The two autoactive salivary burster neurons provide a particularly clear monitor of the FMP as their bursting is rigidly phase-locked to the protraction-retraction cycle during feeding (Prior and Gelperin, J. Comp. Physiol. 114: 217, 1977).

A variety of pure chemical stimuli and food plant extracts have been tested for the vigor and reliability of the motor response which they elicit. The most effective stimuli found to date are extracts of the most attractive food plants (mushroom, potato, carrot). Application of secondary plant substances such as nicotine sulfate (6% wt/vol), quinine hydrochloride (1% wt/vol) and colchicine (0.01 M) give weak feeding responses when first applied. The feeding response to colchicine decrements rapidly after 2-3 applications. Colchicine can suppress a feeding response previously triggered by an attractive food plant extract. Rebound excitation of the FMP is observed when colchicine is removed.

One minute of chemical stimulation elicits a bout of FMP which can last for 3-4 minutes. Variations in the nature or concentration of the chemical stimulus affect the peak frequency of biting, the mean frequency of biting and the duration of the FMP episode. The basic coordination of activity phases of identified motoneurons is not altered significantly.

In addition to chemosensory stimuli which affect the feeding motor program, mechanical stimuli from the buccal mass may also alter on-going feeding rhythms. Bite frequency is significantly greater when an animal feeds on soft food than on hard food. In a lip-brain preparation in which the buccal musculature is left intact and innervated, we have found sensory units in the buccal mass which are responsive to deformations of buccal muscles. These units also fire rhythmically in phase with contractions of the buccal mass during bouts of feeding.

545 INTRACELLULAR Ca^{2+} CHANGES IN A MOLLUSCAN PACEMAKER NEURON MEASURED WITH ARSENAZO III. A. L. F. Gorman and M. V. Thomas* Dept. Physiol., Sch. Med., Boston U., Boston, MA 02118

Changes in free intracellular Ca^{2+} were measured in the neuron R-15 in the abdominal ganglion of Aplysia during spontaneous bursting pacemaker activity and during depolarizing voltage clamp steps. The soma was injected with the Ca^{2+} sensitive dye Arsenazo III and changes in dye absorbance were used to detect changes in $[Ca]_i$. We find that $[Ca]_i$, but not $[Mg]_i$ increases during each depolarizing pacemaker cycle. Our results suggest that the increase in $[Ca]_i$ during the pacemaker cycle occurs as a result of Ca^{2+} influx rather than from release from intracellular stores. Part of the influx is associated with each of the action potentials during a burst. The change in $[Ca]_i$ occurs in steps coincident with each action potential. A second part of the influx is associated with the slow depolarizing pacemaker wave. The absorbance changes are greatly reduced, but not abolished, when action potentials are blocked by the adding of TTX to the external media and reducing $[Ca]_o$ from 10mM to 1mM. In voltage clamped cells, held at -50mV, step depolarization as small as +5 to +10mV are sufficient to cause a Ca^{2+} influx and thereby increase $[Ca]_i$. This influx is reduced by the addition of 10mM Co^{2+} or Mn^{2+} and abolished by the addition of 1-3mM La^{3+} to the external media. We calculate that the total increase in $[Ca]_i$ during the burst is approximately 5 x 10^{-8}m. (supported by NIH Grant NS11429)

546 NON-SPIKING SYNAPTIC TRANSMISSION BETWEEN SPIKING NEURONS. Katherine Graubard, Jonathan A. Raper* and Daniel K. Hartline. Dept. of Zoology, Univ. of Washington, Seattle, 98195 and Depts. Neuroscience and Biology, UCSD, La Jolla, Calif. 92093

Graded synaptic transmission exists between spiking neurons of the lobster stomatogastric ganglion. These neurons have action potentials which cause IPSPs in their postsynaptic cells; however, it is often possible to demonstrate inhibition in the postsynaptic cells caused by subthreshold depolarization of the presynaptic neurons (Fig. 1). The synaptic connections studied were PD to LP, PD to PE (early PYs), PD to PL (late PYs), and LP to PD. Reversal potentials were similar for graded release and for spike-evoked IPSPs.

When $2X10^{-7}$M TTX was used to eliminate action potentials, the response to a suprathreshold presynaptic voltage step was a two-component (peak-plateau) hyperpolarizing waveform in the postsynaptic neuron (Fig. 2 inset). Both peak and plateau increased in amplitude with increasing presynaptic depolarization (Fig. 2 graph). All the studied cell pairs with strong synaptic connections in normal Ringer displayed graded release in TTX, suggesting involvement of the same synaptic terminals in both types of interaction. PD neurons often had a release threshold more negative than the resting potential (in TTX), so that presynaptic hyperpolarization caused a postsynaptic depolarization by disinhibition.

Preliminary work indicates that hyperpolarizing PL electrotonically hyperpolarizes LP, reducing graded release from LP onto PD. Depolarizing LP causes graded release which hyperpolarizes PD, thereby reducing graded release of PD onto PE.

In addition to spiking, these cells are characterized by large amplitude oscillations in membrane potential (15-20 mV) during normal cyclic activity. The resulting modulation of graded release may contribute to the phasing of units within the cycle.

547 OPTICAL MONITORING OF ACTIVITY IN BARNACLE NEURONS IN RESPONSE TO LIGHT STIMULATION OF THE MEDIAN PHOTORECEPTORS. A. Grinvald* and L. B. Cohen. Dept. of Physiology, Yale University School of Medicine, New Haven, CT 06510.

The changes in light absorption that occur in stained neurons in response to changes in membrane potential have been used to monitor spontaneous activity in cell bodies of the supraesophageal ganglion of Balanus nubilus (Salzberg et al, J. Neurophysiology, in press). We have now used this technique in a preliminary effort to localize ganglion cells which respond to light stimulation of the photoreceptors of the median ocellus. The ocellus and ganglion were in separate sections of a black lucite chamber; the light stimulus (510 nm) and the optical recording of membrane potential (720 nm using the merocyanine-oxazolone dye, NK 2367) did not interfere with each other. Two suction electrodes were used for electrical recording of activity in a root and a connective.

We were concerned about the possibility of pharmacological effects of the dye. (The dye concentration in the incubation solution was 2×10^{-3} molar.) However, in most stained preparations, the electrically recorded off-response to a light stimulus was similar to the response observed in unstained preparations. While such comparisons are difficult because the preparations tended to deteriorate with time, it seemed that pharmacological effects of the dye were not large even when the responding neurons were second or higher order.

In experiments where the ocellus was stimulated and fifteen neurons were monitored simultaneously, most neurons remained silent. Using the simultaneous optical and electrical measurements it was possible to specify the location and axon pathway for those neurons that did participate in the off-response. It would be easier to locate responding neurons if all the neurons were monitored simultaneously instead of just fifteen. We are presently trying to construct such an apparatus.

548 HAIR MOVEMENTS, VOLTAGE NOISE AND GENERATOR POTENTIALS IN STATOCYST HAIR CELLS. Yoram Grossman*, Eliahu Heldman and Daniel L. Alkon* (SPON: A. Fein). Section on Neural Systems, Laboratory of Biophysics, NINCDS, NIH, MBL, Woods Hole, MA 02543.

To elucidate mechanisms of mechanotransduction, hair movements, membrane potential fluctuations (voltage noise) and generator potentials were analyzed for hair cells in the statocyst of the nudibranch mollusk *Hermissenda crassicornis*. Scanning electronmicrographs and visualization with Nomarski optics revealed that the statocyst is a sphere consisting of 12-13 cells whose luminal surfaces are covered by motile hairs (12-15 hairs/100 μ^2). The mean movement frequency of free hairs as determined by a stroboscope was 10 Hz (at 20°C) and was reduced to 7 Hz when the hairs experienced the weight of the crystals (statoconia) within the statocyst lumen. Intracellular recordings from hair cells revealed that cells in front of a centrifugal force (produced by a rotating table) depolarized up to 25 mV (with a maximum stimulus of 1.7 g) and showed up to 400% increase of resting voltage noise amplitude. Cells behind the force vector hyperpolarized (max. 12 mV) and the voltage noise was almost eliminated. Both the increase in voltage noise amplitude and depolarizing generator potential were associated with an increase of membrane conductance within a limited range of membrane potential. Increases in voltage noise amplitude and hair cell generator responses elicited by rotation were similarly dependent on the level of membrane potential. Perfusion of the statocyst with zero external sodium eliminated the generator potential and the voltage noise without noticeable effect on the hairs' movements. Voltage noise, generator potentials, and the movement of the hairs and the statoconia were reversibly eliminated by perfusion with 5-10 mg/ml chloral hydrate, a known anesthetic. Lowering the bath temperature from 20° to 10°C and perfusion with 2600 mOsmoles hypertonic solutions reduced the hairs' frequency of movement (25% and 50% respectively) and similarly reduced the voltage noise amplitude. The results of this study demonstrate that the movements of the hairs themselves, although necessary, are not sufficient to produce substantial voltage noise. It is thus the collision of statoconia with the motile hairs which produces most of this voltage noise. The results also indicate that the voltage noise and hair cell generator potential have a common origin: exertion of force on statocyst hairs by the weight of the statoconia. Thus it is suggested that hair cell depolarizing generator potentials arise from summation of depolarizing waves within the voltage noise, in a manner that may resemble the production of photoreceptor generator potentials from summation of voltage noise events associated with quantal photon capture.

549 THE EXTENSION PHASE OF THE CRAYFISH ESCAPE RESPONSE. Grace Hagiwara* and Jeffrey J. Wine. (SPON: Angela C. DiBerardino) Dept. of Psych., Stanford U., Stanford, CA 94305.

Perhaps the most basic patterned activity generated by nervous systems is the sequential activation of antagonistic muscles. We investigated neural mechanisms underlying such coordination in the crayfish 'tailflip' response.

It has long been known that the giant axons of crayfish are command neurons that trigger tail flexion and reextension (Wiersma, J. Neurophysiol. 1947). Flexion is produced directly by monosynaptic activation of flexor motoneurons, but the neural basis of reextension is unknown. We recorded intracellularly in extensor motoneurons and inhibitors to establish the following points: (1) In an isolated abdomen, the only effect of the command neurons on the extensor system is inhibition. (2) Command-derived inhibition operates at three levels: (i) Extensor motoneurons are inhibited at short latency via an unknown pathway; (ii) Extensor muscles are inhibited by the peripheral inhibitor; and (iii) The muscle receptor organs (MROs), which are stretch sensitive proprioceptors in parallel with the extensor muscles, are inhibited via their accessory innervation.

Since no command excitation of extensor motoneurons could be demonstrated, we looked for sensory pathways to the extensor motoneurons. Two were found. (1) The tonic and phasic MROs excite the extensor motoneurons. The connections are chemical and meet most criteria considered to be indicative of monosynaptic transmission. The connections are extensive; at least three of the five extensor motoneurons in each hemiganglion are contacted by the MRO axons, which then bifurcate and make weaker connections with extensor motoneurons in the anterior and posterior ganglia. (2) A polysynaptic pathway to the extensor motoneurons was found that can be activated by any sensory root in the abdominal nervous system. The pathway causes excitation of extensor motoneurons that peaks 25-35 msec after the stimulus and is associated with the discharge of sustained sensory interneurons.

In summary, the results show that although a command neuron impulse can trigger a flexion-extension sequence in an intact animal, only inhibition of extensor motoneurons is seen in an isolated abdominal cord. Excitation occurs as a result of sensory feedback. The source of the polysynaptic sensory input and the contribution of the rostral nervous system to the organization of extension are now being investigated.

550 EQUILIBRIUM RECEPTORS IN THE COCKROACH ARENIVAGA. H. B. Hartman, W. W. Walthall*, L. P. Bennett*, R. R. Stewart*. Dept. Biol. Sci., Texas Tech Univ., Lubbock, TX 79409.

Pendulous sensilla located on the ventral surface of the cerci of the burrowing desert cockroach Arenivaga are adapted specifically for the detection of changes in the insect's equilibrium. Each sensillum (tricholith) consists of a dense sphere positioned at the distal end of a slender shaft, the latter inserting into an innervated socket. The tricholiths generally occur in pairs, the number varying with the developmental stage of the animal. Adults have as many as eight pairs per cercus.

The information from the tricholiths is integrated by two pairs of giant interneurons in the ventral nerve cord. On roll left, the two interneurons in the right connective are active. The two interneurons in the left connective respond to roll right. Pitch forward evokes activity from the two smaller interneurons of both connectives, whereas pitch backward prompts activity from the two larger units. Rotations between roll and pitch are signalled by variations in the ratio of activity of the two pairs of interneurons. In each instance, the frequency of firing is proportional to the angular displacement. The animal's orientation as related to gravity is therefore determined by which interneurons are active, the ratio of their activity, and the frequency of firing.

Immobilization of the tricholiths on one cercus inactivates the large interneuron on the ipsilateral side and the small interneuron on the contralateral side. If the tricholiths of both cerci are immobilized, the interneurons no longer respond to positional changes.

This is the first report of specific receptors and interneurons responsive to gravity orientation in insects.

551 ELECTRICAL COUPLING AND BILATERAL INTERACTIONS OF BAG CELLS IN APLYSIA. J.T. Haskins and J.E. Blankenship. Marine Biomedical Inst. and Dept. Physiol. and Biophysics, Univ. Tex. Med. Br., Galveston, TX 77550.

Two bilateral clusters of bag cells in the abdominal ganglion of Aplysia release an egg-laying hormone when they fire in prolonged afterdischarges of synchronous action potentials. Conventional intracellular recording from pairs of bag cells in A. dactylomela was used to demonstrate directly that electrical coupling underlies bag cell synchrony. Depolarizing or hyperpolarizing current pulses passed through the electrometer bridge into one cell produced electrotonic potentials of reduced amplitude and extended time course in the other. Coupling ratios for 63 pairs of cells ranged from 0.0004 to 0.087 with a mean of 0.057. At frequencies of 1 Hz, stimulating pulses of 100 msec duration produced summated responses in coupled follower cells that could be twice the amplitude of single responses. A single cell was often coupled to more than one other cell and in one case to five cells. Cells in opposite clusters were found to be weakly coupled. Extracellular recording indicated that the bag cell neurites in A. dactylomela do not extend as far along the pleurovisceral connective as they do in A. brasiliana and A. californica, suggesting that the coupling site is nearer the somata in A. dactylomela.

Simultaneous intra- and multiple site extracellular recordings also were used to examine bilateral interactions, synchrony and direction of propagation of bag cell spikes during spontaneous and evoked afterdischarges in A. brasiliana and A. dactylomela. Bag cell spikes were typically initiated on one connective near the terminations of the neurites and propagated toward the somata. This activity crossed the abdominal ganglion to the opposite cluster where impulses were usually initiated very near the somata and traveled outward toward the ends of the neurites. The sides on which this sequence of propagation was initiated could change many times during an afterdischarge. Tight synchrony across the abdominal ganglion was rare, however, because of backfirings, blockades and multiple sites of spike initiation. Prepotentials which potentiated to full spikes in one cluster could arise from improved invasion of action potentials from the contralateral cluster. 552 EVIDENCE FOR CHOLINERGIC TRANSMISSION AT PHOTORECEPTOR SYNAPSES IN *HERMISSENDA*. Eliahu Heldman, Yoram Grossman*, Terry J. Crow and Daniel L. Alkon*. Section on Neural Systems, Laboratory of Biophysics, NINCDS, NIH, MBL, Woods Hole, MA 02543.

Each of the two simple eyes of the nudibranch mollusk *Hermissenda crassicornis* contains five photoreceptors (two Type A and three Type B, distinguished electrophysiologically). Each of the two optic ganglia contains thirteen second order visual cells. We attempted to identify neurotransmitters within this visual system. When the circumesophageal ganglia were incubated with labelled precursors for putative neurotransmitters and the products were extracted and analyzed by high voltage electrophoresis, four neurotransmitter candidates were shown to be synthesized and accumulated within the ganglia: acetylcholine (ACh), serotonin (5-HT), dopamine (DA) and histamine (HA). Direct enzyme assays suggested that the amount of neurotransmitter accumulated during 1-4 hours is directly proportional to the corresponding enzyme activity as measured in homogenates of the circumesophageal ganglia. When isolated eyes were incubated with labelled precursors for the above putative neurotransmitters only ACh was synthesized and accumulated at a detectable level (1-5 pmoles). Intense histochemical staining for acetylcholinesterase was observed in the region of the photoreceptor terminal branches. Histofluorescence localization of DA and 5-HT indicated that only one second order visual cell within each optic ganglion contained dopamine. The photoreceptors themselves did not fluoresce. Clear round vesicles were observed in endings of identified photoreceptors injected intracellularly with horseradish peroxidase. Intracellular recordings from identified photoreceptors were made while the nervous system was perfused with neurotransmitter agents: carbachol, DA, 5-HT, GABA, HA, and glycine. Only carbachol and HA had significant effects. Carbachol produced hyperpolarization of 5-15 mV accompanied by a drop of 10-60% in the input resistance. The reversal potentials for carbachol as calculated from the IV curve (-70 to -75 mV for Type A, and -85 to -90 for Type B photoreceptors) were similar to that of IPSP's which followed, one for one, neighboring photoreceptor impulses elicited either by light or intracellular current injection. HA produced hyperpolarization of 10-20 mV accompanied by a drop of 20-25% in the input resistance. Reversal potential for HA as estimated from IV curve was -90 to -100 mV. Eserine (10^{-3}M) reversibly eliminated or greatly reduced all photoreceptor interaction and increased membrane conductance 20-40%. The evidence presented here suggests that ACh serves as neurotransmitter for at least some of the photoreceptors in *Hermissenda*. Although HA was not synthesized by the photoreceptors, it may serve as a transmitter for other presynaptic neurons.

553 WEAK NEGATIVE COUPLING BETWEEN THE CIRCADIAN PACEMAKERS OF THE EYES OF APLYSIA. David J. Hudson* and Marvin E. Lickey. Dept. of Psychol., University of Oregon, Eugene, OR 97403.

The concept of a master biological clock controlling circadian rhythms is giving way to models involving multiple circadian pacemakers (PMs) which are coupled internally. The circadian system in Aplysia may be a case in point. There is a PM in each of the eyes and at least one more elsewhere. In the current experiments we asked whether the two ocular PMs are coupled. Forty-three Aplysia were released into very dim LL or DD. After 0 to 62 days both eyes were dissected and the phase of their rhythm was measured in DD by determining the time of the peak firing rate of CAPs in the optic nerve. Pairs of eyes removed after 0 to 7 days were always nearly synchronized; the time difference between the peaks of given pairs ($\delta\phi$) was between 0 and 1 h. Between 8 and 28 days, 77% of the pairs had $\delta\phi$ of 0 to 4 h and 15% had $\delta\phi$ of 10 to 12 h. After 29 to 62 days, 26% had $\delta\phi$ of 1.5 to 4.5 h and 61% had $\delta\phi$ of 9.5 to 12 h. In all 43 pairs only 14% had $\delta\phi$ between 4 and 8 h, none of which were in the range of 4.5 to 7 h, a span of potential phase angle differences which apparently is forbidden. Inhibitory neural connections are known to exist between the eyes, and it has been suggested that the eyes are neurosecretory. It is not farfetched, therefore, that the eyes might behave as PMs with weak negative internal coupling. This hypothesis predicts that after a long time in LL the majority of pairs of eyes should be in exact antiphase. Our data show, however, that in the majority of pairs the modal $\delta\phi$ is only 11.5 h, and occasionally as little as 9.5 h. Entrainment theory may explain even this small discrepancy. When we dissected a pair of eyes and prepared it for recording, we exposed it to a brief pulse of light. If the eyes were in exact antiphase, one of them would have been in its subjective day and the other in its subjective night. A generalized phase response curve (PRC) would predict that the light pulse should evoke a larger phase shift in the eye dissected in its subjective night than in the other eye. This asymmetric action would reduce the observed $\delta\phi$ of the pair from 12 h to some lesser value which is dependent on the amplitude and shape of the specific PRC for the light pulses of dissection. We therefore measured the PRC for dissection and found that its amplitude was about $\pm$ 2 h during the middle of the subjective night decreasing to nearly zero at the middle of the subjective day. This PRC goes a long way toward explaining the departure from 12 h shown by the pairs of eyes tested after long exposure to LL. A similar argument can be made for those pairs of eyes in which $\delta\phi$ departed slightly from zero. We believe that this is the first physiological demonstration of internal weak coupling between circadian PMs in a nervous system. NS 12374

554 PEDAL AND PARAPODIAL MOVEMENTS ELICITED BY CEREBRAL GANGLION NEURONS IN APLYSIA. Behrus Jahan-Parwar and Steven M. Fredman. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

Locomotion in Aplysia involves coordinated rhythmic activity in both the foot and parapodia. As an initial step in analyzing the neural mechanisms underlying this activity we have examined several pathways that elicit reflex contractions of both organs and the role of several groups of neurons in the peri-esophageal ganglia. We have found that neurons in the identifiable A and B clusters of the cerebral ganglion mediate some pedal and parapodial movements. A semi-intact preparation was used. Aplysia were pinned rostrally and caudally and the foot longitudinally hemisected. Each parapodium was severed at its base with its connections to the pedal and pleural ganglia left intact, isolating it mechanically from the foot. Foot and parapodial movements were monitored via tension transducers.

The parapodia and foot both exhibited spontaneous rhythmic contractions. Those in the parapodia were abolished by cutting the pleuro-abdominal connectives; pedal contractions were not. This indicates that the rhythms are controlled independently. Reflex contractions of both organs could be obtained by touching the anterior tentacles or stretching either one hemi-foot or parapodium. Thus both direct and crossed reflexes are present. That all these reflex contractions could be obtained with the foot hemisected and the parapodia isolated suggests that a peripheral nerve net is not necessary for their spread or coordination and that control of the parapodia and foot resides in the CNS.

Intracellular stimulation of A and B cluster neurons caused both ipsilateral and bilateral pedal and parapodial contractions. Units recorded extracellularly from the parapodial nerves followed the driven somatic spike in the A neurons 1:1. Electrical stimulation of parapodial and pedal nerves caused antidromic spikes in both A and B neurons. Parapodial contractions evoked by A neurons persisted when synaptic transmission was blocked by adding Co^{++}. In addition, filling parapodial and pedal nerves with Co^{++} filled the somas of some A and B neurons. These results suggest that the A and B neurons are presumptive pedal and parapodial motor neurons.

The B neurons are active during reflexes elicited by tactile stimulation of the tentacles which suggests that they may help mediate them. Neither the A or B neurons fire significantly during proprioceptive reflexes. These are presumably mediated by neurons in the pedal and pleural ganglia.

555 CELLULAR LOCALIZATION OF CHOLINE ACETYLTRANSFERASE IN MOTOR-NEURONS FROM ASCARIS. Carl D. Johnson*, and Antony O.W. Stretton (Spon: P. Claude). Dept. of Zoology, Univ. of Wisconsin, Madison, WI 53706

We have begun to study the metabolism of putative neurotransmitters in the large parasitic nematode Ascaris lumbricoides by examining those motorneurons in the ventral nerve cord which send isolated circumferential commissures to the dorsal nerve cord. These include five of the seven different types of somatic motorneurons. Three of these neurons are excitatory to muscle in the dorsal half of the body, one is inhibitory to dorsal musculature and the fifth is inhibitory to ventral musculature (see Abstract by Walrond, Kass, Donmoyer, Moses and Stretton).

In order to isolate single commissures, the muscles and other internal organs are detached from the cuticle and hypodermis by treatment with bacterial collagenase. Processes of single motorneurons are then dissected as transverse strips of hypodermal tissue containing motorneuron commissures. These strips are incubated with [H^3]-choline and cold acetylCoA. Compared to hypodermal strips containing no commissure, elevated levels of acetyl-[H^3]-choline (ACh) are synthesized by strips containing a commissure of any of the three excitatory motorneuron types. Strips containing only commissures of inhibitory motorneurons do not synthesize elevated levels of ACh. This suggests that all of the excitatory motorneurons to the dorsal musculature are cholinergic and that the inhibitory motorneurons do not use ACh. (Supported by NSF Grant BNS 76-09641 and a Postdoctoral Fellowship from the Muscular Dystrophy Association)

556 A CHORDOTONAL ORGAN-LIKE STRUCTURE IN THE UROPODS OF CRAYFISH. Stanley R. Johnson* and Richard L. Roth* (SPON: Marion E. Smith). Dept. Biol. Sci., Stanford University, Stanford, CA. 94305.

In the rostromedial quadrant of both the exopodite and endopodite of the crayfish uropod there are patches of cuticular hairs which are longer and more densely packed than are hairs known to be sensitive to near-field water disturbances. These hair patches are overlapped by adjacent members of the tail fan so that they are protected from ordinary perturbations of the environment, but are sheared by promotion and remotion of the uropods. Consequently, neurons innervating these hairs have been assumed to signal postural changes of the tail fan, and ascending interneurons have been found which are especially sensitive to deformation of the patch of hairs on the endopodite (R. Fricke, personal communication).

We have recently discovered a chordotonal organ-like structure within the protopodite of the uropod of Procambarus clarkii which may reasonably be expected to supplement or complement the postural information supplied by the hair patches. This structure consists of a strand of connective tissue which inserts medially in the hard cuticle of the proximal end of the endopodite and laterally in the soft cuticle of the articulation between the endopodite and exopodite. A small branch of the 3rd root of the 6th abdominal ganglion enters the connective tissue strand at about one-third of the distance from the medial to the lateral insertion. Thus, the whole structure is Y-shaped, the base of the "Y" being the lateral insertion of the connective tissue strand. The structure, as a whole, contains about 26 neuronal somata of which the 10 largest (20-30 X 35-50 micrometers) lie near the site of nerve entry. The smaller cells (about 8 X 15 micrometers) lie, for the most part, towards either end of the connective tissue strand. Cobalt outfills of the 3rd root routinely fill most or all of the large cells, but few of the smaller cells.

We are beginning a physiological assessment of this presumed chordotonal organ and are engaged in selective labeling of its constituent cells and of other components of the 3rd root in order to establish whether there is an anatomically discernible segregation of different sorts of afferents within the ganglionic neuropil.

557 CYCLIC AMP IN APLYSIA GILL: INCREASES BY PUTATIVE NEUROTRANSMITTERS. Procerfina R. Kebabian*, John W. Kebabian*, John W. Swann* and David O. Carpenter. Armed Forces Radiobiology Research Institute and National Institutes of Health, Bethesda, Maryland 20014.

Dopamine (DA) is found in substantial amounts in the gill of the marine mollusc Aplysia. When perfused, it induces contractions and also greatly facilitates transmission from identified motor neurons, some of which are clearly not dopaminergic (Neurosci. Abst. 2:508, 1976). Because of the possibility that at least the modulation of neuromuscular transmission might be mediated through cyclic adenosine monophosphate (cAMP), we have determined the ability of several putative neurotransmitters to affect cAMP levels in gill tissue.

Slices of gill tissue were incubated in seawater (30°C) for 20 min. The amines were added immediately prior to addition of the tissue to the seawater. At the end of the incubation period, the tissue was rapidly removed and frozen on dry ice. Subsequently, the tissue was homogenized; cyclic AMP was measured with the method of Brown et al. (Adv. Cyclic Nucleo. Res. 2:25, 1972).

Both DA (30 µM) and serotonin (5-HT) (100 µM) caused increases in cAMP levels to values 10 times control. Carbachol (100 µM) showed no significant effect. The half-maximal concentration of DA for this effect was 10 µM. While the 5-HT stimulation was immediate and approached maximal within 5 min, the stimulation by DA was slower and approached maximal only at about 20 min. Neither the DA- nor 5-HT-induced increases in cAMP levels were decreased when the experiment was performed in the presence of elevated Mg^{++} concentrations (200 mM), which is known to depress synaptic transmission. These results suggest that both transmitters are acting directly and not through activation of some intermediate receptor. In addition, the maximally stimulating effects of DA and 5-HT were additive, indicating the presence of two independent receptor types.

The increases in cAMP induced by both DA and 5-HT was blocked by both fluphenazine and cis-fluphenthixol. These drugs were essentially equipotent and gave nearly 100% inhibition at 100 µM. While neither fluphenazine nor cis-fluphenthixol had effects on resting cAMP levels, trans-fluphenthixol was unexpectedly found to stimulate basal cAMP levels and not block the action of either DA or 5-HT. The three ergot drugs tested--ergonovine, ergotamine, and lergotrile--did antagonize the effects of DA but, unlike their action in mammalian systems, they caused an accumulation of cAMP in absence of either amine. Although the site of the receptors has not been identified, our observations are not inconsistent with the hypothesis that DA may cause modulation of neuromuscular transmission by a cyclic nucleotide mediated modulation of contractility of smooth muscle fibers.

558 AN INTERNEURON IN DROSOPHILA SYNAPSES WITHIN A PERIPHERAL NERVE ONTO THE DORSAL LONGITUDINAL MUSCLE MOTOR NEURONS. David G. King. Yale University, New Haven, CT 06520.

Flight in flies is powered by a set of indirect flight muscles, including the dorsal longitudinal muscles (DLM). Activity in a pair of giant neurons descending from the brain reaches the indirect flight muscles and the jump muscle (TDT), apparently triggering an escape response to initiate flight (King, Neuroscience Abstracts 2:628; Tanouye, Neuroscience Abstracts 3).

Each giant neuron activates the DLM motor neurons through an interneuron (incorrectly labelled a motor neuron in last year's abstract, King, NA 2:628). After contacting the giant neuron this interneuron crosses the midline and exits the ganglion through the posterior dorsal mesothoracic nerve (PDMN), whereupon it synapses onto the five DLM motor axons.

The synaptic region is anatomically quite simple and is easily located in histological sections. In the proximal segment of the PDMN, within 50µm of the ganglion, are found nine large axons and numerous small axons. Three of the large axons (the TDT motor axon and its two accessory axons) are isolated from the remainder of the PDMN and soon separate laterally to innervate the TDT. The other six large axons consist of the five DLM motor axons surrounding the peripheral interneuron. Each of these six axons is typically a simple cylindrical process; synapses are formed by direct contact of the axons rather than by collateral branches or spines. Reciprocal synapses from the DLM axons onto the peripheral interneuron are occasionally observed; their function is obscure.

Distal to these peripheral synapses the interneuron terminates and the DLM axons increase in diameter. Thus the interneuron appears to be specialized for rapid conduction from the giant neuron into the periphery, bypassing the dendritic tree of the DLM neurons. Synapses onto the DLM axons occur at a region of relatively high input resistance (small diameter); the DLM axons then increase in diameter for rapid conduction to the muscles.

These peripheral synapses may prove useful in developmental or genetic studies of synaptic connectivity in which identification of specific contacts between identified neurons will be necessary. Thorough physiological analysis of this system should also be possible since the same synaptic contacts have been observed in other larger Dipterans (Valentino, Neuroscience Abstracts 3).

559 SYNAPTIC MODULATION OF ENDOGENOUS ACTIVITY IN WHITE CELLS OF THE ABDOMINAL GANGLION OF APLYSIA CALIFORNICA. W. Michael King*, Michael F. Murphy*, and Norman R. Kreisman. (Spon: L.T. Happel) Depts. of Physiology and Pharmacology, Tulane University School of Medicine, New Orleans, La. 70112.

It has been reported that the white cells of the abdominal ganglion of Aplysia Californica receive weak inhibitory synaptic input resulting from stimulation of ganglionic nerves and connectives but no spontaneous synaptic input has been observed to date. The spontaneous activity of these cells is characterized by a regular spike output which is controlled by an endogenous pacemaker mechanism. This beating pattern often shows periods of waxing and waning of frequency and also periods when spiking ceases. In the course of other work in this laboratory, intracellular recordings have been made from the rostral and caudal white cells (R3-R15). Simultaneous recordings from two white cells at a time revealed that periods of cessation of activity were coincident. This cessation of activity appeared to result from a small hyperpolarization of 1-4 mV in amplitude which lasted up to several min. In some cases, the hyperpolarizations were preceded by a shorter duration 1 mV depolarization. When spiking resumed, it was at a lower frequency than normal and gradually returned to its previous rate over a period of minutes.

One explanation for the coincident periods of cessation of spike activity could be the presence of an inhibitory synaptic input from a common source. In order to test this possibility, simultaneous recordings were made from two rostral white cells until several coincident periods of spike inhibition were observed. The electrode from one white cell was then withdrawn and inserted into cell L11, which receives input from interneurons I and II. It was found that the periods of inhibition in the remaining rostral white cell were always coincident with a burst of action potentials in L11 which is characteristic of the action of interneuron II. In other experiments, simultaneous recordings were made from R14 and R15. R15 receives a biphasic postsynaptic potential (ILD-E) from interneuron II. Inhibitory periods in cell R14 were always coincident with ILD-E in R15, but not every ILD-E in R15 was coincident with inhibition in R14. These results indicate that the white cells R3-R14 receive synaptic input from interneuron II which can have both short term and long term modulatory effects on the firing rate of these cells, including complete cessation of spike activity. Stimulation of the right connective and nerves produces effects similar to those attributed to interneuron II in R15 as well as in the white cells. It is therefore possible that in each case the effects of nerve or connective stimulation are the result of excitation of interneuron II. (Supported by NIH grant NS 12419)

560 ANALYSIS OF THE FLIGHT PATTERN OF THE DORSAL LONGITUDINAL FLIGHT MUSCLE IN DROSOPHILA. J. H. Koenig* and Kazuo Ikeda. City of Hope National Medical Center, Duarte, CA 91010.

Simultaneous intracellular recordings were made from all 6 ipsilateral dorsal longitudinal flight muscle fibers (numbered 1 to 6, ventral to dorsal) in Drosophila while the animal was in stationary flight. The salient characteristic of the pattern generated by these 6 muscles is that they tend to fire at about the same frequency but at different times, with the exception of #5 and #6, which fire synchronously. An interval correlation analysis of this pattern reveals that the mechanisms involved in spacing of the firing of these muscles includes a combination of both "excitation" (so that a muscle fires earlier than it normally would have fired) and "inhibition" (so that a muscle fires later than it normally would), depending on which 2 muscles are involved.

Specific pairs of these muscles have stronger and more stereotyped interactions than other pairs and also show a higher frequency correlation. Thus, muscle pairs #1-2 and #3-4 exhibit the strongest interactions, which cause them to fire either in antiphase to each other or occasionally almost synchronously (within 1 msec). To effect synchronous firing, it can be seen that #1 fires earlier than it normally would have fired so that it fires within 1 msec of when #2 fires. No. 2's firing time appears unchanged. To maintain antiphase firing, it can be shown that #1's firing interval is shortened by about 30% while #2's concurrent interval remains the same or is lengthened by a variable amount. These interactions only occur when #1 and #2 would have fired within a relatively short interval of each other. This interval is equivalent to the "exclusion bands" in the phase histograms which have been reported by Wyman (1969). In addition, #1 usually fires slightly faster than #2. The same relationships are seen between #3 and #4, with #3 being equivalent to #1 and #4 equivalent to #2. Weaker but similar interactions are also observed between any other pair of muscles #1 through #4; but in this case, either muscle of the pair may exhibit a shortened or lengthened interval. Interactions of #1-4 with #5 and #6 are quite weak and difficult to define.

Underlying these spacing interactions, a common input is observed to drive all 6 dorsal longitudinal muscle fibers. (Supported by USPHS NIH grant NS 07442)

561 NEURAL CONTROL OF CIRCADIAN BEHAVIOR IN LIMAX MAXIMUS: ABSENCE OF AN ENDOGENOUS RHYTHM IN ISOLATED BRAINS. Stephen N. Kogge and Phillip G. Sokolove. Dept. of Biol. Sci., U. of Md. Baltimore County, Baltimore, MD 21228.

In experiments with intact giant garden slugs (Limax maximus), 24 hour temperature cycles ($15^{o}/10^{o}/15^{o}$C) were capable of entraining a locomotory circadian rhythm. The free-running rhythm was always observed to persist after the temperature cycle was discontinued (T constant = 15^{o}C). Similar experiments conducted on isolated brains showed no evidence of similar persistance of rhythmicity in pedal nerve output.

Formulation of a tissue culture medium matching the ionic and osmotic properties of slug blood allowed the continuous recording with suction electrodes from nerve trunks of isolated Limax maximus brains for periods of up to two weeks.

Brains held at constant temperatures, in closed and dark containers, showed no inherent rhythmicity of neuronal activity. When we alternately cycled the bath temperature from 10^{o}C to 15^{o}C and back (12 hours at each temperature), strong periodic responses developed by the end of 2-3 cycles. Typically, pedal nerve activity, measured as numbers of action potentials per two hours, increased during the high temperature phase and fell during the low temperature phase. In some cases non-pedal nerves showed the opposite response: neural activity clearly increased during the low temperature phase and decreased during the high temperature phase. When the temperature was held constant for 72 hours or more following at least 3 temperature cycles, no obvious rhythmicity in spontaneous activity was found in any trunk. Resumption of the temperature cycle always resulted in the same periodic output as has been seen earlier.

Two features of the in vitro neural activity are inconsistent with the circadian behavior of intact slugs: (1) activity in pedal nerves is normally greatest during the high phase of a temperature cycle whereas locomotor activity is greatest during the low phase; (2) no evidence of endogenous rhythmicity is found in vitro following cessation of a temperature cycle whereas the locomotor rhythm clearly persists. It is therefore unlikely that the Limax locomotor circadian rhythm is controlled by an endogenous neuronal oscillator located in the CNS.

562 RESISTANCE OF A CRAYFISH SENSORY INTERNEURON TO HYPER-INNERVATION. Franklin B. Krasne and Sun-Hee Lee*. Dept. Psychol., UCLA, Los Angeles, CA 90024.

Interneuron A (hereafter A) of the crayfish abdominal nerve cord normally receives synaptic input from mechanoreceptor neurons distributed over the side of the tail fan ipsilateral to A's axon and unilateral dendrites. We have found that: (1) When the 5 roots carrying mechanoreceptor axons of one side of the tail fan into the last abdominal ganglion are cut and the central and peripheral pieces sutured together, regeneration and reinnervation of ipsilateral A occurs over 2-6 weeks. (2) If cut roots from the contralateral tail fan are instead sutured to the ipsilateral central stumps, reinnervation by these "foreign" afferents occurs equally expeditiously. (3) If cut roots from one side of the tail fan are tied to roots on the intact opposite side of the body, the cut axons grow into the last ganglion along the roots to which they have been tied but they do not form synapses on A, which already has a normal complement of inputs; moreover, the axons do not cross through the neuropile to reinnervate A of their own side. (4) If roots of the intact side from the preceding experiment are now cut (after 6 weeks), the contralateral roots, which had already grown into the ganglion, rapidly (starting in about 1 week) form functional connections with the A whose normal inputs are now degenerating. We conclude that synapse numbers remain constant on A despite availability of acceptable regenerating afferents.

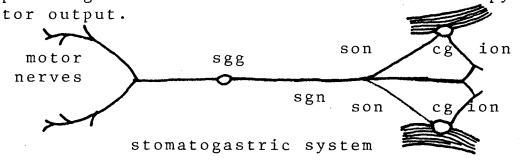
563 DIBUTYRYL CYCLIC AMP: PHARMACOLOGICAL MODULATOR OF THE AXONAL MEMBRANE SODIUM CHANNEL. Barry J. Kraynack, Major L. Cohn and Linda L. Kraynack*. Dept. Anesthesiology, Univ. Pgh. Sch. Med., Pittsburgh, PA 15261.

Local anesthetic agents produce nondepolarizing conduction blocks by inhibiting sodium ion flux through axonal sodium channels. The fact that pre and postsynaptic neural function is modulated by adenosine 3':5' monophosphate (cAMP) led us to examine in the present study whether at the axonal membrane level, the dibutyryl analog of cAMP (db cAMP) antagonizes blocking effects of agents which 1) bind specifically at or near the exterior opening of the sodium channel (tetrodotoxin 1 µg/.3 ml); 2) act strictly by a physicochemical mechanism (benzocaine 20 mg/ml, amobarbital 50 mg/ml); 3) act both through physicochemical means and at the axoplasmic receptor site of the sodium channel (procaine 15 mg/ml, chloroprocaine 20 mg/ml, lidocaine 20 mg/ml, mepivacaine 20 mg/ml, bupivacaine 2.5 mg/ml, tetracaine 10 mg/ml, naloxone 40 mg/ml, meperidine 25 mg/ml, ketamine 100 mg/ml). In groups of 12 naive male Sprague-Dawley rats (100 g) sciatic nerve blocks were produced by injecting .2 ml of the test drug around the sciatic nerve trunk at the junction of the biceps femoris and gluteus maximus. A frequency of 100% was obtained with all the local anesthetic agents tested; onset was very rapid (1-2 min). However, tetrodotoxin produced only a 60% frequency and a slow onset (10-15 min). Frequency and onset were unchanged by the addition of 2 mg of db cAMP to the test drug; however, db cAMP significantly shortened blocks induced by all the structurally unrelated drugs tested. Our findings agree with those of other investigators who reported that in isolated sciatic nerve preparations, conduction blocking effects of local anesthetic agents are antagonized by db cAMP. Moreover, we have found that db cAMP does not alter reabsorption of C^{14} lidocaine, administered in the subarachnoid space of cats and monkeys. Our study shows that the antianesthetic action of db cAMP is not contingent upon either the mechanism of action or the membrane sites where local anesthetic agents act. Therefore, we propose that db cAMP exerts its anti-anesthetic action by reestablishing the function of the axonal membrane sodium channel.

564 LOCALIZATION OF CATECHOLAMINES IN THE STOMATOGASTRIC NERVOUS SYSTEM OF THE CRAYFISH (PACIFASTACUS LENIUSCULUS T.). Pinky Drosten Kushner* (SPON: E.A. Maynard). Dept. of Biology, U. of Oregon, Eugene, Oregon 97403.

Dopamine appears to be present within the nerves and ganglia of the spiny lobster stomatogastric system (SGS) and may activate the pyloric motor output of the stomatogastric ganglion (SGG). To determine if dopamine is also present in the SGS of crayfish, isolated SGS nerves and ganglia were freeze-dried and heated in the presence of formaldehyde vapors. Whole mounts of the tissue displayed formaldehyde-specific fluorescence when viewed with UV light. As in the spiny lobster, fluorescence occurred in cell bodies of the two commissural ganglia (CG), in neuropil regions of the SGG, and in nerves connecting these ganglia. The fluorescence appeared catecholaminergic because of its green-yellow color, which did not fade rapidly when exposed to UV light, and because the areas of fluorescence were preferentially enhanced by pretreating the tissue with exogenous dopamine. As in lobster, fluorescent fibers projected from the CG to the SGG via the superior esophageal nerves (SONs) and the stomatogastric nerve (SGN). The crayfish ganglia were also linked by fluorescent fibers in the inferior esophageal nerves (IONs) and SGN, a pathway not found in the lobster.

Extracellular recordings of the crayfish SGS motor output showed that the pyloric rhythm was disrupted and slowed six-fold upon cutting the IONs; subsequent cutting of the SONs destroyed the residual rhythm. In contrast, lobster pyloric rhythm is essentially identical with and without the IONs but slows down several fold if the SONs are cut. It remains to be determined if the catecholaminergic fibers in the IONs in the crayfish are involved in the disruption of pyloric rhythm when the IONs are cut. These comparative observations are consistent with the hypothesis that dopaminergic neurons in the CG modulate SGG pyloric motor output.



565 INHIBITORY EFFECTS OF ESCAPE COMMANDS ON THE POSTURAL MOTOR SYSTEM OF THE CRAYFISH. John Y. Kuwada* and Jeffrey J. Wine. (SPON: Paul Lennard.) Dept. of Psych., Stanford U., Stanford, CA 94305.

The crayfish abdomen contains phasic and tonic motor systems. The phasic system is responsible for the initiation and coordination of the tail flip escape response. It is composed of a well-characterized neural circuit which includes command neurons. An action potential in a command neuron results in an escape response (Wiersma, J. Neurophysiol., 1947, 10, 23-28). The tonic system controls the postural activities of the abdomen. It contains two sets of antagonistic muscles, tonic extensors and flexors, and their associated motoneurons and command cells (Kennedy, Evoy, and Fields, Symp. Soc. Exp. Biol., 1966, 20, 75-109). One motoneuron of each set is a peripheral inhibitor which inhibits its respective muscle.

Previously, it was thought that the tonic and phasic systems were parallel but relatively separate and independent (Kennedy and Takeda, J. Exp. Biol., 1965, 43, 211-246). We have investigated interactions between those two motor systems in the isolated abdominal nervous system of the crayfish. Electrically-evoked escape commands in the phasic system inhibit ongoing activity of tonic flexor motoneurons centrally for up to several hundred milliseconds and drive the tonic flexor and extensor peripheral inhibitors with latencies of 5 to 10 milliseconds. In addition, electrical stimulation of sensory axons activates tonic flexor motoneurons but not the inhibitor. This activation is also inhibited by escape commands which immediately precede the sensory stimulation. This demonstrates that escape commands effectively prevent activation of the tonic system due to afferent inflow resulting from an escape response. Because of the slow time course of the tonic system, it is inferred that the role of this inhibition is to suppress postural behavior which would interfere with swimming often observed after an escape response. Furthermore, the response of the tonic system to sensory input exhibits rapid habituation upon repetitive stimulation of sensory axons. Another effect of the escape command initiated inhibition is to prevent such habituation. Thus, escape commands may preserve the excitability of postural reflexes as well as suppress incompatible behavior.

566 SEPTATE JUNCTIONS AND ACTIVE NEUROMUSCULAR SYNAPSES IN EMBRYONIC LOBSTER HOMARUS AMERICANUS. Fred Lang and James J. Cole*. Department of Biology, Boston University Marine Program, MBL, Woods Hole, Massachusetts 02543.

Development of neuromuscular connections was studied in the abdominal muscles of embryonic lobsters using electrophysiological and ultrastructural techniques. Female lobsters extrude and fertilize several thousand eggs in August-September and brood them under the abdomen until the following May-June, when all embryos on a female hatch within 1-2 days. Development is essentially arrested when water temperature falls below 10° C (December-April).

Embryos were removed from females between December and April (eye index 350-400 µm), freed from the egg membrane and fixed for E.M. Myogenesis appears to follow the pattern of myoblasts fusing to form myotubes which then mature to myofibers. A growing neuron, characterized by a high density of granular vesicles, was observed to form a septate junction with a myoblast. Growing neurons were often observed in close proximity to myotubes. In this area, growth cones or "microspikes" are evident and the neuron is characterized by the presence of granular and dense cored vesicles, by "wavy" microtubules and by vesicular structures which may be continuous with intracellular tubules. These endings were only rarely observed near mature muscle fibers.

Excitatory and inhibitory neuromuscular junctions were observed on maturing and fully developed myofibers. These were often indistinguishable from adult synapses. Axoaxonal synapses have not yet been observed.

Recording from the abdominal muscles revealed resting membrane potentials of 50-80 mV. In 64% (91 penetrations in 13 preparations) of the penetrations, spontaneous miniature excitatory postsynaptic potentials (EPSP's) of up to 1.5 mV were observed. Large EPSP's (5-30 MV) could be evoked by tactile or electrical stimulation to the abdomen. The former stimulus would often elicit several tail flips in succession demonstrating that the circuitry for this reflex is present early in development.

567 AN ELECTROPHYSIOLOGICAL AND ANATOMICAL INVESTIGATION OF THE GENITAL GANGLION IN APLYSIA CALIFORNICA. F.J. Lebeda and J.E. Blankenship. Marine Biomedical Inst. and Dept. Physiol. and Biophysics, Univ. Tex. Med. Br., Galveston, TX 77550.

The genital ganglion is located caudal to the abdominal ganglion along the genital nerve and contains approximately 20-30 neurons in the major cluster. Most of these cells can be backfilled with cobalt chloride via axonal iontophoresis of the caudal region of the genital nerve. Very few neurons, however, can be filled via the rostral portion of the genital nerve. Neurons are also found in one or more minor clusters or as individual cells scattered along the genital nerve. Nerve branches can be observed arising from the clusters toward the large and small hermaphroditic ducts and the receptaculum seminis.

Electrophysiological properties of the genital ganglion neurons have been examined using conventional stimulating and recording techniques. Intracellular recordings reveal that the neurons in the major cluster have a large resting membrane potential (-55.2 ± 1.1 (SEM) mV, n=43) and a high input resistance (19.4 ± 1.7 MΩ, n=24) which is constant over a wide range of hyperpolarizing potentials (Musgrave, unpubl. obs.). With sufficiently large hyperpolarizations, an after-potential is observed whose amplitude and polarity is voltage-dependent (Connor and Stevens, J. Physiol. 213: 31, 1971). Typically these neurons are silent at rest and have little synaptic input. In addition the cells are electrically coupled. Direct intracellular stimulation produces overshooting action potentials. Increasing the duration of the stimulus pulse causes repetitive firing whereupon the cell undergoes a long lasting period of accommodation. Most of these electrical properties are qualitatively similar to those of the L14 group in the abdominal ganglion (Kandel, Cellular Basis of Behavior, Freeman, 1976).

Stimulation of the caudal genital nerve elicits potentials 20-30 mV in amplitude (A-spikes) in the soma. Rostral genital nerve stimulation can often produce biphasic postsynaptic potentials comprised of an early, fast excitatory potential followed by a slow inhibitory response; both phases appear to increase membrane ionic conductance. With repetitive stimulation (5-10 Hz) several action potentials can initially be recorded intracellularly. Thereafter EPSPs and irregularly occurring action potentials may be observed. It is possible that both the accommodative property of the postsynaptic membrane and the slow inhibitory potential may play a role in the early cessation of the regenerative activity that occurs during repetitive stimulation. [Supported by NIH grant NS 11255, award NS 70613 to JEB and award NS 08531 to FJL and NSF grant PCM 76-18936.]

568 CRITERIA FOR CELL IDENTIFICATION: APPLICATION TO CENTRAL NEURONS OF PLEUROBRANCHAEA. Richard M. Lee and Reinhard Palovcik.* Dept. Neurol. and Behav. Sci., Edsel Ford Institute, Detroit, MI 48202.

Certain neurons of invertebrate species can be easily identified because they have unusual, externally observable properties, such as large size, atypical coloration or shape. In order to identify other cells, which do not have such unusual features, we have established methods which allow objective identification with an estimate of confidence.

We assume that in a large invertebrate ganglion, certain cells are unique and identifiable and possibly others are indistinguishable from one another. The basis for our identification system is the development of a fixed list of properties and a method which can be used for comparing cells. We define an "identified cell" as one for which average values can be specified for its properties, the variability in these properties can be specified, and it is distinguishable from other cells in the ganglion. In order to apply this definition, certain mathematical formulations must be developed, such as an "index of cell similarity." Such an index can be based upon distributions for parameters so that the probability that the sets of parameters for two cells are not accountable by chance variation can be computed.

In practice, a number of cells are penetrated in each of several preparations. For small ganglia, a particular cell found in the first prep. is said to be unique and identifiable if there exists one and only one very similar cell in each of the other preps. For large ganglia, where sampling methods must be employed, the following formula can be used for determining the number of preps required for a given level of confidence:

$$\frac{\text{LOG } (1-C)}{\text{LOG } (1-(SP/G)^2)}$$

where C is the confidence level, S is the number of cells studied per prep, G is the size of the population of cells sampled from, and P is the probability that the cell is in that group. SP/G may also be determined empirically by noting the number of occurrences of the cell in question for a given number of preps.

These methods were tested using a group of left ventral cells of the cerebropleural ganglion of Pleurobranchaea. An average of eight cells were penetrated in each of 11 preps. Parameters included soma size, location, synaptic input, spike shape measures, axons in brain roots, etc. -- a total of 40. Several variations of the procedures described above were evaluated. The resulting method led to the classification of three cells as "identifiable" with a confidence level of more than 95%.

569 NATURE OF INHIBITION ONTO GIANT INTERNEURONS IN THE CRICKET ACHETA DOMESTICUS. R.B. Levine, S.G. Matsumoto, R.K. Murphey. Dept. Biol. Sci., SUNYA, Albany, NY 12222.

Deafferentation during post-embryonic development in the cercal afferent to giant interneuron system of the cricket Acheta domesticus causes an increased effectiveness of inhibition onto giant interneurons (Murphey, Matsumoto, Mendenhal, 1976). This same increase also occurs when interneurons are non-surgically deprived of presynaptic activity (Matsumoto & Murphey, 1977). We are, therefore, currently studying the nature of cercal mediated inhibition in normal animals.

Giant interneurons in this system range from those which are not inhibited by cercal stimulation, to those receiving almost exclusively inhibitory input from the cerci. The lateral giant interneuron (LGI) receives excitatory input from cercal afferents ipsilateral to its axon and unilateral dendritic field. There is no sign of cercal inhibition onto this cell. Two giant interneurons with bilateral dendritic fields, the medial giant interneuron (MGI) and neuron 10-3, receive excitation from the cercus ipsilateral to their axons and inhibition from the contralateral cercus. Neuron 10-2, which is spontaneously active, receives mainly inhibition from both cerci. Thus its spontaneous activity is shut off upon stimulation of either cercus.

Intracellular recordings from the somata of 10-2 and MGI reveal a slow hyperpolarization in response to stimulation of the appropriate receptors. In the case of 10-2 this can be changed in size by a current intracellularly injected into the soma. Recordings from the dendrites of MGI reveal a burst of ipsps in response to stimulation of the contralateral cercus. These apparently unitary ipsps can also be changed in size by passing current. We conclude that the inhibition is post-synaptic.

Bath applied picrotoxin (10^{-6} to 10^{-5} M) causes MGI, which normally responds phasically to cercal stimulation, to become tonic. We are currently testing the effects of picrotoxin on the observed inhibitory potentials in the giant interneurons. Thus, the inhibitory pathway which is intimately involved in the plastic response of these neurons to various forms of deprivation is a chemical synapse impinging on the interneurons themselves and it is picrotoxin sensitive.

Supported by NSF research grant #BNS7523454 to Rodney K. Murphey.

570 INITIATION OF ESCAPE STREAMLINING IN THE CRAYFISH. Joseph Margiotta* and B. Walcott. Anat. Sci., Health Sciences Center, SUNY at Stony Brook, Stony Brook, N. Y. 11794.

Crayfish commonly escape from threatening stimuli by employing a sequence of rapid abdominal flexions and extensions. The rapid abdominal flexions provide propulsion. Motorneurons supplying abdominal flexor muscles are reliably excited by monosynaptic electrical input from either pair of medial (M.G.) or lateral giant (L.G.) interneurons. These giant interneurons integrate sensory information and are considered "decision fibers" crucial for the initiation of escape. During escape, the abdominal flexions are accompanied by postural adjustments of the thoracic appendages which may streamline the animal's body in its trajectory through the water. We have found that activity in the cheliped's coxopodite promotor muscle (mPro) contributes to the streamlining of this appendage. Using electromyography, we observe that cheliped promotion and tail flexion are always initiated simultaneously when escape is evoked via the M.G. circuit. Wiersma (J. Neurophysiol. 10:23, 1947) found that stimulation of M.G. or L.G. produced abdominal flexion and thoracic appendage promotion. These observations suggest that the different, yet complementary, thoracic and abdominal motor outputs may be initiated by impulses in the same giant interneuron.

We have evidence that supports this hypothesis. Intracellular stimulation of an abdominal M.G. produces a single or compound, short latency EJP in every ipsilateral fiber of mPro tested. An upper limit of the delay at the central M.G.-cheliped promotor motorneuron synapse was calculated to be less than 0.5 mSec. This suggested electrical coupling between the cells, and a neural organization similar to that responsible for abdominal flexion.

Extracellular stimulation of M.G. recruits several short latency spikes in axons of a nerve rootlet which appears to supply only mPro. When this rootlet is backfilled with 0.5 M $CoCl_2$, the cell bodies and complete arborizations of two large motorneurons reliably stain. The large central processes of these cells abut the edge of the M.G. axon in the first thoracic ganglion, just as the giant flexor motorneurons do in forming electrical synapses in abdominal connectives (Mittenthal and Wine, Science 179:182, 1973). Intracellular recordings from these promotor motorneuron processes are now in progress to determine the synaptic mechanisms underlying their excitation by the M.G.

571 CENTRAL NERVOUS SYSTEM CONTROL OF THE GAIN OF A COMBINED MUSCLE AND SENSORY ORGAN IN THE CRAYFISH CLAW. J.D. Marrelli* and D. Angaut-Petit*(SPON : W.H. Evoy). CNRS,INP.10, Marseille, France.

The myochordotonal organ (MCO) of the crayfish claw is a combined muscle and sensory organ. The sensory cells discharge to movement about the Merus-Carpus (MC) joint of the limb. Activity of the motoneuron to the accessory flexor (AF) muscle associated with the sensory cells produces activity in these cells in the absence of any joint movement and also alters the receptive field of these cells. The effect of single AF spikes occurring in a train of spikes on MCO discharge has been studied under conditions of different joint positions, velocity and levels of active tension in the receptor muscle. In general a single AF spike activated most of the sensory cells, both flexion sensitive and extension sensitive cells, both tonic and phasic. Flexion units responded at high frequency (> 200 hz.) and short latency (<25 ms.). Extension units responded at also a high frequency (200 hz.) but a longer latency (>75 ms.). The activity of extension sensitive MCO cells normally excites the AF motoneuron and the activity of the flexion sensitive cells inhibits the activity of the AF motoneuron. Thus the action of the AF spike is to first produce negative feedback on to itself through the MCO system followed by a positive feedback. This possibly unstable situation is under the influence of the level of the active tension in the AF muscle. Low levels of active tension in the AF muscle resulted in shorter latency and higher frequency discharges in the MCO sensory cells to an AF spike. As active tension increases, the influence, both positive and negative, of AF motoneuron upon itself declines, to be replaced by greater sensitivity of the MCO organ to MC joint movement. This greater sensitivity to MC joint movement is due to the increase in AF muscle stiffness (the coefficient of displacement dependent force), and viscosity (the coefficient of velocity dependent force) that occurs with AF activity. As a result of these changes in AF muscle the receptive fields of the sensory cells of the MCO are increased in their size and shifted towards the position of greater MC joint extension. At this new level of AF muscle tension additional increases of AF activity influence MCO output not by direct action but through changes in AF muscle properties which improve the transmission of the MC joint movement to the sensory cells.

Thus the activity of the MCO sensory cells is under direct control of the CNS via the AF motoneuron in the early period of the AF motoneuron activity. However the primary stimulus of the MCO sensory discharge rapidly becomes the movement about the MC joint. The significance of the positive feedback of AF motoneuron onto itself may lie in the need for a rapid rise in the AF muscle tension at the onset of AF activity. This possibility is currently under investigation.

572 DIFFERENTIAL SENSITIVITY OF CRICKET CENTRAL NEURONS TO SENSORY DEPRIVATION. S.G. Matsumoto. Dept. Biol. Sci., SUNYA, Albany, NY 12222.

The response properties of two large primary sensory interneurons in the abdominal nervous system of the cricket Acheta domesticus were examined following prolonged periods of sensory deprivation. In an earlier study Matsumoto and Murphey (J. Physiol. 1977, in press), demonstrated that the medial giant interneuron (MGI) was sensitive to sensory deprivation. The deprivation procedure involved immobilizing the mechanoreceptive sensory hairs with a thin layer of facial cleansing cream (Clinique Cleansing Cream). MGI normally receives powerful excitatory inputs from mechanoreceptive hairs located on its ipsilateral cercus, and inhibitory and weakly excitatory inputs from sensory receptors on its contralateral cercus. Therefore, blocking the sensory inputs from a single cercus silences the major excitatory inputs to the ipsilateral MGI but the contralateral inhibitory and excitatory inputs remain functional. Chronic unilateral deprivation depresses the responsiveness of the MGI ipsilateral to the treated cercus. This depression results from an enhancement of the untreated contralateral inhibitory inputs and a decrease in the efficacy of the deprived excitatory inputs.

The effects of deprivation on another primary sensory interneuron with a different pattern of cercal innervation has now been studied. I have determined that the lateral giant interneuron (LGI) receives sensory inputs only from its ipsilateral cercus. Therefore, immobilizing the mechanoreceptive hairs on a single cercus completely abolishes any response in the ipsilateral LGI. No contralateral inhibition has been detected.

Unilaterally deprived specimens were reared and both MGIs and LGIs were tested intracellularly for their sensitivity to sound stimuli using a standard tone pulse of 500 Hz at 80 db. In 14 specimens the deprived MGIs were significantly depressed compared to their homologs. The LGIs of these specimens were not affected by the deprivation procedure. The data is summarized below:

	No. of Action Potentials			
	Right (treated)		Left (control)	
	X ± SD		X ± SD (10 trials)	
MGI	0.28	0.09	3.52	1.37
LGI	1.12	0.86	1.22	0.82

The results suggest that the lack of competition from inhibitory inputs prevents any depression of LGI. Supported by NSF research grant #BNS7523454 awarded to R.K. Murphey.

573 DETERMINATION OF GABA IN APLYSIA GANGLIA AND INDIVIDUAL NEURONS. Marilyn W. McCaman* and Bruce N. Colby*, (Spon: J.K. Engelhardt). City of Hope National Medical Center, Duarte, CA 91010.

GABA was determined in ganglia and individual neurons of Aplysia californica as the dinitrophenyl ethyl ester using gas chromatography-mass spectrometry. It was identified by retention time and by the relative abundances of 3 major ion fragments. Quantitation was achieved using isotope dilution GCMS with GABA-d_2 as an internal standard. The sensitivity of the procedure was less than 1 pmole.

Levels of GABA in ganglia varied over a 5-fold range (0.30, 0.60, 0.61, 1.03 and 1.60 pmoles/µg protein for abdominal, pedal, pleural, cerebral and buccal, respectively). When various parts of the ganglia were analyzed, most of the GABA was found in the nerves and in the neuropil. Only a small fraction was found in cell soma.

Numerous individual, identified neurons were also analyzed. Most of these neurons contained no detectable GABA (less than 0.2 pmoles/µg protein). However, a few, including two bilaterally-represented neurons in the buccal ganglion, tentatively identified as B3, contained measurable amounts (0.5-1.5 pmoles/µg protein). The values reported here for ganglia and for identified neurons are considerably lower than those obtained using the GABAase procedure.

574 HISTAMINE AS A MULTIACTION NEUROTRANSMITTER IN THE CNS OF *APLYSIA CALIFORNICA*. Richard E. McCaman and David G. McKenna*, Div. of Neurosci., City of Hope Medical Center, Duarte, CA 91010.

Previous studies from this laboratory revealed that histamine is present in measurable quantities in only certain specific neurons within the CNS of *Aplysia* (Weinreich et al, Brain Res., 84, 341, 1975). Further studies by Weinreich and Yu (J. Neurochem., 28, 361, 1977) have demonstrated that the histamine-containing neurons (HNs) are also unique in their content of a specific histidine decarboxylase. We will present electrophysiological evidence in support of the role of histamine as a neurotransmitter in the central nervous system of *Aplysia*.

The HNs have been found to form synaptic connections with several different follower neurons within the *Aplysia* cerebral ganglion. The monosynaptic nature of these connections have been assessed by a variety of criteria including a) the augmentation of the evoked post-synaptic potentials (PSPs) after injecting TEA in the HN; b) the persistence of the PSPs in artificial sea water containing high levels of Ca^{++} which blocks polysynaptic pathways; and c) the reversible graded reduction of the PSPs in artificial sea water containing elevated levels of Mg^{++}.

Each HN appears to form direct synaptic connections with at least nine different follower cells. The follower cells can be subclassified according to the PSPs elicited by the connections they receive from the HNs. There appear to be five distinct types of PSPs: IEPSPs, IIPSPs, EIPSPs, EEPSPs and EPSPs. Application of histamine (by iontophoresis or by pressure ejection techniques) to the post-synaptic cell mimics the synaptically-evoked response in the different types of post-synaptic cells tested thus far (i.e., those exhibiting IEPSPs, EPSPs and EIPSPs).

Thus, the neurotransmitter role of histamine is supported by: 1) the unique cellular chemistry of the presynaptic neurons (HNs); 2) the evidence for the monosynaptic nature of the connections between the HNs and their follower cells; and 3) the ability of applied histamine to mimic the synaptically-evoked PSPs of specific follower neurons.

This work was supported in part by grants from the Public Health Service (NS 9339) and the National Science Foundation (GB 35417).

575 SYNAPTIC DIVERSITY OF A MOTOR AXON INNERVATING A HOMOGENOUS POPULATION OF LOBSTER MUSCLE FIBERS. Dennis E. Meiss and C. K. Govind. Scarborough College, University of Toronto, West Hill, Ontario, Canada M1C 1A4.

Properties of the synapses and muscle fibers of the singly innervated distal accessory flexor muscle were examined in the first and second walking legs of the lobster, Homarus americanus. The synapses differ in physiological properties such that low release, highly facilitating synapses occur on proximally located muscle fibers and high release, poorly facilitating synapses occur on distally located fibers. Synapses along a single muscle fiber are similar even though they may arise from more than one separate primary axon branch. Also, a single primary branch may form the full complement of synaptic types. Muscle fiber input resistances, R_{in}, were correlated with synaptic properties such that low output, highly facilitating synapses occurred on fibers with low R_{in} (mean 101.1 kΩ) and high output, poorly facilitating synapses occurred on fibers with higher R_{in} (mean 131.7 kΩ). All muscle fibers were similar for other membrane electrical properties including time constants and membrane capacitances. Regression analyses show that R_{in} has little or no influence on the size of the intracellularly recorded synaptic potentials or on their facilitation properties. Thus, differences in muscle membrane properties cannot account for the observed synaptic diversity. Instead diversity is based on differences in transmitter output recorded by focal analysis of single synaptic foci. Thus, proximal muscle fibers are innervated by low quantal output synapses ($\bar{m}$ = 0.16) and distal fibers by high quantal output synapses ($\bar{m}$ = 2.90). Preliminary ultrastructural analysis of the diverse synaptic terminals suggest that the high-output, poorly facilitating terminals are characterized by a large area of presynaptic dense bodies compared to low output, highly facilitating terminals with a smaller area of dense bodies. (Supported by the Muscular Dystrophy Association of Canada.)

576 DISRUPTION AND STABILITY IN THE COMPOUND EYES OF CAVE-DWELLING CRAYFISH. DeF. Mellon, Dept. of Biology, University of Virginia, Charlottesville, 22901.

Severe degenerative changes of a structural and functional nature characterize the visual system of Procambarus erythrops, a Floridian cave-dwelling crayfish. The compound eyes of P. erythrops are reduced in overall size compared to those of a related epigean (surface-dwelling) species, P. clarkii. The relative corneal area has been diminished by roughly 80%, and all traces of ommatidial faceting have been lost. Histological studies reveal a reduction in ommatidial number and structural complexity, including the absence of crystalline cones. Four remnant optic ganglia are present, but cell counts are down, neuropile is truncated, and no laminar organization remains. Electroretinigrams recorded from the cornea of P. erythrops eyes show response amplitudes of about two orders of magnitude smaller than those recorded from P. clarkii eyes in response to light stimuli of identical intensity. In contrast to these severe visual deficits, the oculomotor system apparently is structurally and functionally intact. Eye-withdrawal and retina-stabilizing reflexes can be evoked by appropriate non-visual inputs. All of the eye muscles and all identifiable oculomotor neurons in P. clarkii are also present in the cave species. Although the motor system of P. erythrops has a stable functional organization which is in contrast to the disrupted nature of the visual pathway, a pronounced size reduction of oculomotor axons and eye muscles has occurred, and this suggests that the efferent organization may also be responding to the selective pressures of the cave environment. Our present detailed electrophysiological and fine structural observations of neuromuscular organization in the cave crayfish eye may suggest mechanisms through which these matching cellular changes in axons and muscle fibers are evolving.

577 THE ROLE OF PERIPHERAL INHIBITION IN THE TIMING OF A PHASIC BEHAVIOR. Dyane C. Mistick and Jeffrey J. Wine, Dept. of Psych., Stanford U., Stanford, CA 94305.

We have been investigating neural mechanisms responsible for temporal coordination of a simple, stereotyped behavior: the crayfish tailflip. A tailflip, which consists of a rapid flexion and reextension of the abdomen, occurs in less than a tenth of a second and so requires precise timing of antagonistic muscles. We wanted to know how peripheral inhibition, whose function in this system was heretofore obscure, could help coordinate the response.

The phasic abdominal flexor muscles are innervated by at least two excitatory axons and one inhibitory axon. We recorded intracellularly in the soma of peripheral inhibitor of the flexors and in flexor muscle fibers to establish the following points: (1) The peripheral inhibitor is effective in blocking muscle spikes and reducing tension. (2) During escape behavior, which can be initiated by a single impulse in an identified central command cell, the peripheral inhibitor often fires a delayed burst of impulses. Both the delay and the formation of the inhibitor's burst are centrally programmed. (3) Delay is the result of a polysynaptic pathway from the escape command cell to the inhibitor; the pathway includes the flexor motoneurons and a set of corollary discharge interneurons. (4) All of the synapses in the pathway from the command cell to the inhibitor appear to operate electrically, yet the response of the peripheral inhibitor shows marked 'facilitation' to a pair of command cell impulses as a result of temporal summation and the consequent recruitment of additional interneurons. (5) The peripheral inhibitor also receives monosynaptic, chemical EPSPs from the muscle receptor organs. The muscle receptor organs are stretched during flexion; their accelerating input sums with central excitation to enhance the burst in FI.

Thus, the flexor muscles are first excited and then inhibited in rapid succession. The central and peripheral connections to the peripheral inhibitor cause varying amounts of peripheral inhibition to be recruited, so that the intensity of peripheral inhibition is appropriate to both the intensity of the initial motor discharge and to the speed of flexion and reextension. The consequence of this arrangement seems to be that a brief but powerful flexion is insured in spite of variations in the output of the motor circuits.

578 PHYSIOLOGICAL AND MORPHOLOGICAL IDENTIFICATION OF PEDAL NEURONS IN THE PULMONATE SNAIL MELAMPUS. Stacia Moffett and Linda Kahan.* Dept. Zool., WSU, Pullman, WA 99164.

The primitive pulmonate snail Melampus bidentatus crawls by utilizing the columellar muscles in repetitive crawl-step movements. This behavior is coordinated within the central nervous system and is therefore accessible to analysis at the level of neuronal interactions. A first step towards this goal has been the identification of efferent units in extracellular recordings. A relatively complex motor pattern has been obtained from tethered, crawling snails. Twenty efferent units are distinguished on the basis of spike height, nerve distribution and onset and pattern of activity within the crawl-step cycle. Probable functions for many of these units have been determined by correlating their activity with the snail's behavior.

In order to find the position of these efferent units in the central nervous system, the prominent pigmented somata in the pedal ganglia have been visually mapped. There is no evidence of symmetrically positioned cells or cell clusters in the two ganglia. Cobalt chloride backfilling allowed the somata of neurons with axons in each pedal nerve to be identified on the map. The majority of backfilled cells are found in the ipsilateral pedal ganglion but some are in the contralateral ganglion and a few are in the cerebral, pleural and visceral ganglia.

The activity of cells identified by the backfilling technique is being recorded intracellularly in whole-animal preparations. Suction electrodes positioned on the appropriate nerves allow identification of one-for-one action potentials in the soma and extracellular recordings. Correlations between the activity of the penetrated neurons and the movements of the snail provide clues to the function of each cell. The neurons identified thus far are driven by bursts of excitatory or alternating excitatory and inhibitory synaptic inputs during locomotion. (Supported by NSF Research Grant #BNS 76-09706 and by the NIH Biomedical Research Grant to WSU).

579 WHITE NOISE ANALYSIS OF ELECTROTONIC JUNCTIONS IN LEECH GANGLIA. G. P. Moore, B. M. Frazer*, C. M. Lent, J. A. Boles*. Dept. BME, U.S.C., Los Angeles, CA 90007, and Dept. Biol. S.U.N.Y., Stony Brook, N.Y. 11794.

We have investigated two junctions in the leech nervous system, that between the paired Leydig cells and that between Retzius cells, using white noise current-injection techniques. In most experiments currents having a Gaussian amplitude distribution (rms value about 1 nA) and a flat spectrum were injected into one of the paired cells while the transmembrane potential response of the homologous cell was recorded. In some experiments the injected current had a zero mean, while in others a hyperpolarizing or depolarizing DC bias was added. Bandwidths of injected currents varied between 10 and 50 Hz. Input (current) and output (voltage) were treated as continuous variables and first- and second-order Wiener kernels (cross-correlations) were calculated from several hundred seconds of data in each run. The first-order kernels were used to estimate the pulse response of the junction, and Fourier transformed to estimate frequency response characteristics. These characterizations were then independently checked against the response to positive and negative pulses of current, and to sinusoidally modulated currents. Second-order kernels were calculated to provide a characterization of the rectifying properties of the junction. Our results show that both junctions act as low-pass filters, but only the Leydig cell junction has rectification which depends upon the amplitude and frequency of the injected current. Such junctional properties are not predictable by measurements using DC currents alone. (A grant from Mr. Y. Nishimoto in support of this work is gratefully acknowledged).

580 DEVELOPMENT OF AN IDENTIFIED NEURON: MORPHOLOGICAL EFFECTS OF BLOCKING PRESYNAPTIC ACTIVITY OR REMOVING PRESYNAPTIC NEURONS. Rodney K. Murphey. Dept. Biol. Sci., SUNYA, Albany, NY 12222.

The development of a large abdominal interneuron, the medial giant interneuron (MGI), in the CNS of the cricket Acheta domesticus was studied. Both partial deafferentation and altered afferent activity levels, produced early in development, are known to alter the response properties of the MGI. The morphological consequences of these procedures have been examined by intracellularly injecting the neurons with cobaltous acetate and intensifying sectioned material using the Timm's method.

When the pair of homologous MGI's were injected in control specimens the neurons were seen to be very similar to one another. Three types of processes were found to project from the main dendrites. "Dendritic collaterals" which are cylindrical and may themselves branch. "Club Collaterals" which are approximately spherical and are mounted on a stalk do not branch. "Spines" which are similar to those found on vertebrate neurons and are distributed on all other types of dendritic process. The dendritic collaterals, club collaterals, and spines, while not identical, are similar in length and number on the bilaterally homologous neurons.

The paired MGIs in a specimen unilaterally deafferented at hatching are quite distinct from one another. The main dendrites of the deafferented neuron are shorter than controls, as reported earlier (Murphey et al., 1975, J. Comp. Neurol. 159:407). A dramatic alteration which could not be detected in the previous work, was a reduction in the length and number of dendritic collaterals and a reduction in the number of spines. Dendrites of the same neuron which are not deafferented are spared and may be expanded relative to controls.

Blocking afferent activity throughout postembryonic development alters the adult response properties of MGI. However, the main dendrites of the two MGIs in unilaterally treated specimens are identical in length and diameter. At the time of writing no conclusive evidence is available regarding differences at the level of dendritic collaterals or spines. The data is presently being collected. Thus it appears that it is the presence of the presynaptic connections, not the activity on the presynaptic neurons, which determines the morphology of MGI.

581 OPTOKINETIC TRACKING OF OSCILLATING DRUMS BY THE CRAYFISH, *PROCAMBARUS CLARKII*. Richard F. Olivo. Dept. Biol. Sci., Smith College, Northampton, MA 01063.

Optokinetic tracking experiments are usually performed using a continuously rotating drum, which a crayfish or other crustacean tracks with slow eye movements that follow the drum and periodic rapid flickbacks that return the eyes to their starting positions. If a sinusoidally oscillating drum is used instead, the eyes under appropriate circumstances track the drum without flickbacks, and the amplitude of tracking can be used as a quantitative measure of the stimulus's effectiveness, as we have shown in color discrimination experiments (Neurosci. Abstr. 1:902, 1975).

In the present experiments, we further explored the response to oscillating drums by using a standard stimulus and systematically varying its parameters. The drum consisted of a high-contrast array of 20° opaque (black) stripes and bright translucent stripes that were lit from outside by a red source (650 nm, stripe luminance 5 ft.c.). Sinusoidal oscillations of 22 - 0.4 cyc/min (0.37 - 0.007 Hz) were imposed by an eccentric drive and variable speed motor; the standard oscillation amplitude was 36°. Eye movements were monitored by a capacitative transducer on the left eye.

Decreasing the oscillation frequency (in steps), starting at 22 cyc/min, produced an increase in the amplitude of tracking; tracking amplitude increased linearly as the log of the frequency decreased. At frequencies lower than 5 cyc/min, flickbacks appeared; the number of flickbacks per cycle increased as the oscillation frequency was made lower. Since the total excursion of the eye is limited by flickbacks, the tracking amplitude reached a maximum (about 20°) at low oscillation frequencies (<1 cyc/min). Decreasing the luminance of the stripes (with ND filters at the source) or reducing the horizontal extent of the stimulus (with screens placed between the animal and the drum) substantially depressed the tracking amplitude and the number of flickbacks per cycle, but did not shift the oscillation frequency at which flickbacks first appeared. Similarly, decreasing the drum's amplitude of oscillation depressed the flickback rate but did not shift the frequency at which flickbacks were initiated.

In these experiments, the animals were restrained and usually remained quiescent. Occasionally, animals initiated locomotory movements that were accompanied by large-amplitude movements of the eyes. The cessation of the spontaneous locomotory and eye movements revealed a tracking response of increased amplitude, which then declined to normal levels over a period of several minutes. These findings provide support for the hypothesis that the main function of the optokinetic system is to correct eye movements that are generated non-visually during locomotion.

582 A PRESSURE SYSTEM FOR INTRACELLULAR AND EXTRACELLULAR EJECTIONS OF PICOLITER VOLUMES. Joyce K. Ono*, Richard E. McCaman, and David G. McKenna*. (Spon: J.T. Holden). Div. of Neurosciences, City of Hope Medical Center, Duarte, CA 91010.

We are attempting to isolate and characterize neuroactive substances endogenous to neural tissues by using the responses of identified neurons in the CNS of a marine mollusc, Aplysia californica as a bioassay. We have developed a pressure ejection system which delivers picoliter volumes of test solutions to the soma and proximal axonal areas of various Aplysia neurons. This pressure ejection system utilizes short duration pulses (milliseconds) generated by conventional laboratory stimulators. A time marker whose polarity and amplitude are adjustable and whose duration is proportional to the ejection pulse duration is provided. Conventional micropipettes are utilized in this system and simultaneous intracellular recording from the pressure micropipettes is possible for intracellular injections. The amount of substances ejected can be directly quantified since the ejected volumes are linearly related to the adjustable parameters of pulse pressure and duration.

Comparisons of the responses of various neurons in Aplysia to acetylcholine delivered by iontophoresis and by the pressure ejection system demonstrate that the pressure system may be used in place of iontophoresis and has several advantages over iontophoresis: a) un-ionized substances may be ejected; b) reproducible responses are more readily obtained since problems of desensitization and the need for braking currents are circumvented; and c) the amount of substance ejected can be directly quantified. The pressure system has also been used for cobalt staining of individual Aplysia neurons to demonstrate its use in intracellular injection.

583 SYNAPTIC MODULATION BY AN IDENTIFIED OCTOPAMINERGIC NEURON IN THE LOCUST. Michael O'Shea* and Peter Evans* (SPON: M. Burrows). Zool. Dept., Cambridge University, England.

Enzymic assays for octopamine were performed on a physiologically identified and isolated neuron in the third thoracic ganglion of the locust. It is unpaired, has a central cell body and projects via two axons bilaterally to the paired jumping muscles of the hind legs. These muscles also receive input from each of just three pairs of motoneurons: a fast and slow excitor and an inhibitor. The unpaired cell is not a motoneuron. Its soma and axons contain significant amounts of octopamine, the concentration in the axons being approximately four times that in the soma. The motoneurons do not contain octopamine.

We have shown that octopamine applied to the muscle in low concentration potentiates the force and facilitates the EJP produced by the slow excitatory motoneuron and, in contrast, that it reduces the amplitude of the inhibitory motoneuron's IJP. These and other effects can also be obtained by direct intracellular stimulation of the modulatory octopaminergic neuron. Neuromuscular transmission involving the fast motoneuron appears not to be affected.

Spikes in the unpaired cell can be elicited by natural stimulation in a variety of sensory modalities including visual, tactile and auditory. Left and right axons each have their own site of impulse initiation and although spikes are normally initiated together, they can arise independently in one or the other axon. By means of a single cell it is therefore theoretically possible to modulate motor activity independently in left and right members of a pair of muscles.

The ganglion contains several similar unpaired neurons which innervate other muscles. The transmitter has not yet in each case been identified although some contain octopamine and all are probably aminergic. Central connections made by these cells are the subject of current research and preliminary results suggest a modulatory function similar to that in the periphery.

This work was supported by the Science Research Council, the Agricultural Research Council and a Nuffield Research Grant awarded to Dr. M. Burrows.

584 LOAD COMPENSATION IN THE CRAYFISH ABDOMEN. Charles H. Page. Dept. Physiology, Rutgers University, Piscataway,N.J. 08854.

Application of a load to oppose postural extension of the crayfish abdomen evokes a load compensating increase in the discharge of the excitatory superficial extension motorneurons (SEMNs). Unit analysis of these SEMN responses during extensions generated by stimulation of command fibers indicates that most or all of the excitatory SEMNs increase their discharge in response to the load stimulus.

It has been suggested (Fields, J. Exp. Biol., 44, 455, 1966) that the load excites the tonic sensory neuron (SR1) of the muscle receptor organ which reflexly elicits a load compensating increase in the activity of one of the smaller SEMNs (#2). However, in the present experiments the SR1 was silent during most of the extensions against a load. In the few extensions where the SR1 was active, its activity contributed to the extension since it was proceeded by an increase in SEMN #2 discharge; these extensions were accompanied by increased discharge in the other excitatory SEMNs as well.

To test whether SR1 activity evoked the observed increases in SEMN discharge, the load was restricted to a single abdominal joint and the unit discharge of the SR1 and SEMNs from the joint were monitored. In 6 of the 7 preparations the SR1 was silent while the SEMNs increased their discharge when extending against a load.

It is concluded that the principle load sensors in the abdomen are not the MROs. The load compensating responses of the SEMNs must result from the activity of an unidentified load sensitive sensory system.

585 NEUROBIOLOGY OF HOMEOTIC MUTANTS IN DROSOPHILA. John Palka, Dept Zoology, Univ. Washington, Seattle, WA. 98195.

In the homeotic mutants of Drosophila, structures of a given segment are transformed into those of a different segment. I have studied the central projections of the peripherally located sensory cells of several mutants affecting the thorax: bithorax (bx, anterior meta- to anterior mesothorax); postbithorax (pbx, posterior meta- to posterior mesothorax; bx and pbx combined to produce flies with 4 wings (instead of 2 wings and 2 halteres) and 2 pairs of mesothoracic legs, plus a strong though incomplete transformation of the central regions of the thorax; and Contrabithorax (Cbx, meso- to metathorax), a mutant with variable expressivity which in extreme cases yields flies with 4 halteres and 2 pairs of metathoracic legs.

I studied the sensory projections of wings and halteres by backfilling the purely sensory wing and haltere nerves with cobalt. Each appendage has a characteristic distribution of fibers within its own segment, and also produces tracts which travel longitudinally, some as far as the head.

In bx flies (anterior wing/posterior haltere), a supernumerary anterior-directed tract is produced medial and ventral to the wild-type haltere tract which continues to be present. pbx flies (anterior haltere/posterior wing) have normal looking projections as would be expected from the fact that in the wing all the receptors are located in the anterior region and the mutation therefore introduces none of them into the metathorax.

In 4-winged flies (bx/pbx), a wing-like projection occurs in the metathorax as well as in its usual location in the mesothorax. However, many fibers which follow the course typical of the wild-type haltere are present, even though no haltere tissue can be identified on the fly's surface.

In 4-haltere flies (Cbx), the wing projection within the mesothorax is lost and fibers with at least some of the branching and staining characteristics of haltere axons are introduced.

The mutants thus show a mixture of appendage-specific and segment-specific projection patterns. Further analysis based on mosaics in which the cns is wild-type and the appendage mutant, or vice versa, is under way.

This work was initiated during the tenure of a Guggenheim grant with Dr. Peter Lawrence (MRC Labs of Molecular Biology, Cambridge, England) and is now supported by PHS grant NB07778.

586 PRESYNAPTIC INHIBITION OF DESCENDING MOVEMENT DETECTING NEURONS IN THE LOCUST. K.G.Pearson and C.S.Goodman*, Dept. of Physiology, Univ. of Alberta, Edmonton, Canada and Dept. of Zoology, Univ. of California, Berkeley, Ca. 94720.

The descending contralateral movement detector interneuron (DCMD) in the locust receives visual input in the brain and has an axon descending the contralateral connective to the thoracic ganglia. Intracellular recordings from the axon of this neuron in the meso- and metathoracic ganglia demonstrate the spontaneous occurrence of postsynaptic potentials (PSPs). These PSPs can be either hyperpolarizations or depolarizations at resting potential, but usually they are only observed as depolarizations after hyperpolarizing the axon with injected current. PSPs are evoked in the axon by stimulation of the contralateral connective, the cerci and sensory axons in the leg. PSPs follow 1:1 action potentials in the DCMD in the opposite connective. Intracellular injection of chloride ions increases the amplitude of the PSPs in the depolarizing direction, while chloride-free saline and picrotoxin abolishes them. Thus the generation of the PSPs appears to a conductance to chloride ions, the equilibrium potential is close to resting potential, and the putative transmitter is GABA. The conductance changes underlying these PSPs may either decrease transmitter release or block transmission through the terminal branches of the axon. Two observations indicating that presynaptic inhibition can occur are (1) in many animals there can be a prolonged or transient block of transmission across the monosynaptic junction from the DCMD to the fast extensor motoneuron (FETi), and (2) high frequency stimulation of the contralateral connective (which evokes PSPs in the DCMD terminal axon) can transiently block transmission from DCMD to FETi.

587 THE PHYSIOLOGY AND ANATOMY OF AN ARTHROPOD MUSCLE WITH POLYNEURAL INNERVATION. Christine E. Phillips, Dept. of Biology, University of Oregon, Eugene, OR 97403.

The well studied classical arthropod muscles are considered to have a simple frequency modulated neural control because they receive only one or two excitatory axons and one inhibitor. One group of muscles, the multiply innervated flexors of arthropod walking legs, prove to be an exception to this rule. Not only do they receive input from more motorneurons, they appear to be the effectors driven by a central pattern generator during walking, while their antagonists, the extensors, follow reflexively.

The metathoracic flexor tibiae of the locust was chosen for study. It has previously been shown to receive innervation from 7 excitatory motorneurons (3 fast, 2 intermediate, 2 slow) and 2 inhibitory neurons. An eighth excitatory flexor tibiae motorneuron (fast) has been found over the course of this study. The peripheral distribution of these neurons was not known. Flexor motorneuron somata were impaled, identified, and orthodromically stimulated while a second microelectrode was moved to monitor excitatory junction potentials in the muscle. No localization of endings was found in any region of the muscle, rather endings from each motorneuron were found throughout the muscle. These findings are in agreement with electron micrographs of axon profiles in the major nerve branches to the muscle, in which eight to ten axons are seen in each branch. Further, single muscle fibers receive at least three and as many as seven different post synaptic potentials. Thus, there is no apparent organization of motorneuron endings on the muscle.

The proximal and distal regions of the muscle are different, both in structure and function. When tension production is compared in the proximal and distal halves of the muscle, the fibers in the proximal half have faster rise times to peak tension (150 ms-prox., 350 ms-dist.) and fatigue more readily than those in the distal half. Ultrastructural differences are also present. Sarcomere lengths are shorter in the proximal region of the muscle (5.3 u-prox, 6.9 u-dist, $\pm$ 0.5 u). Actin to myosin ratios also vary from 2.4:1 in the proximal region to 5.3:1 in the distal region. Thus the flexor tibiae, in having one region for rapid contraction and another region for sustained tension production, is effectively a combination of the classical phasic and tonic muscle types. (This work was supported by PHS 5 T32 MH 14281-02 and NSF BMS75-00463).

588 STRUCTURE OF NEURONAL AND GLIAL MEMBRANES AT THE SQUID GIANT SYNAPSE. D. W. Pumplin and T. S. Reese. LNNS, NINCDS, NIH, Bethesda, MD 20014 and Marine Biol. Lab., Woods Hole, MA 02543.

The synapse between the 2nd order giant axon and the most distal of the 3rd order giant fibers in the stellate ganglion of the squid, L. pealei, was examined with the freeze-fracture technique. Stellate ganglia were excised and fixed in 2.5 percent glutaraldehyde in buffered 0.8 M sucrose. The postsynaptic axon was then injected with ruthenium red to aid in locating the "giant" synapse during freeze-fracturing. Examination of thin sections from comparable preparations confirmed previous reports (Young, Phil Trans Roy Soc B, 229:465; Hama, Z Zellforsch, 56:437) that a continuous glial and connective tissue sheath separates the pre- and postsynaptic axons, except where it is penetrated by thin processes (1-2 μm in diameter) of the postsynaptic axon. These axonal contacts were characterized by bands of fuzz, subjacent to each membrane and in the clefts between them, and by clusters of synaptic vesicles in the presynaptic axon. Further evidence of their synaptic nature was provided by stimulating the presynaptic axon at 20 Hz, while recording postsynaptically. This resulted in depletion of the synaptic vesicles near synaptic junctions. The structure of the membranes at these synaptic junctions was similar to that of many other types of excitatory synapses in that the distribution of particles on pre- and postsynaptic membranes was different. The presynaptic membrane had a disk-shaped aggregate of loosely clustered large particles (10 nm) approximately 0.3 μm in diameter. The postsynaptic membranes had coextensive aggregates of similar particles which, unlike the presynaptic ones, were on the external membrane leaflet; the concentration of particles in these aggregates approached 2000/μm^2. Thus, the postsynaptic membrane at this synapse resembles that at excitatory synapses in the mammalian brain but differs from excitatory cholinergic synapses on muscle and sympathetic ganglion cells. Two types of glial processes were readily distinguished from axonal membranes by the size, concentration and distribution of their membrane particles. Clusters of particles on the cytoplasmic leaflet of glial membranes in exact register with clusters of particle imprints on adjacent membranes were presumed to be components of intercellular junctions. These junctions closely resembled gap junctions in vertebrates but differed from those in arthropods where the constituent particles are on the external leaflet of the membrane. Thus, there may not be a distinct type of "invertebrate" gap junction.

589 NEURAL CONTROL OF THE PENIS RETRACTOR MUSCLE OF APLYSIA. M.K. Rock*, J.E. Blankenship, and F.J. Lebeda. Marine Biomedical Inst. and Dept. Physiol. and Biophysics, Univ. Tex. Med. Br., Galveston, TX 77550.

The excitatory innervation and physiology of the penis retractor muscle of A. californica have been examined using combinations of intracellular, extracellular and tension recording from neurons in the right pedal ganglion and from the muscle. The mean resting potential from 48 individual muscle fibers recorded with microelectrodes was -65 mV ($\pm$7 mV, SD). Simultaneous intracellular recording and stimulation from pairs of muscle fibers revealed that the fibers are electrically coupled. Almost all fibers have spontaneously occurring excitatory junctional potentials (ejps) of varying amplitude and time course.

Axonal iontophoresis of cobalt chloride applied to the cut end of the nerve innervating the retractor muscle has resulted in the backfilling of neurons in restricted regions of the right pedal ganglion. Impaled homologues of the neurons in one of these clusters were shown to be excitatory motor neurons innervating several muscle fibers directly with one-to-one constant latency ejps. Fibers receiving direct ejps also had other spontaneous ejps which could represent input produced by direct innervation by other motor neurons or electrotonic spread of ejps produced in coupled fibers. The innervation of the muscle is thus diffuse and polyneuronal. Directly produced ejps were seen to facilitate strongly to motor neuron stimulus frequencies of up to 10 Hz. Repetitive motor neuron activity elicited a contraction which was blocked when the muscle alone was perfused with sea water containing elevated magnesium concentrations; contractions could not be blocked when either the ganglion alone was perfused with elevated magnesium sea water or when the muscle alone was perfused with sea water containing elevated calcium concentrations. Motor neurons have a spontaneous irregular firing pattern and this, along with the innervation pattern and coupling among the fibers, accounts for the rich tonic excitatory input seen in this slow smooth molluscan muscle. Work supported by NIH grant NS 11255, award NS 70613 to JEB and award NS 08531 to FJL and NSF grant PCM 76-18936.

590 ACTIONS OF SEVERAL PUTATIVE NEUROTRANSMITTERS ON THE GILL OF APLYSIA. Peter C. Ruben*, John W. Swann* and David O. Carpenter (SPON: D. Evans). Armed Forces Rad.Res.Inst.,Bethesda, Md. 20014

Nerve-muscle interaction in the gill of Aplysia constitutes a highly suitable preparation for study of the presence of receptors for specific neurotransmitters. Biochemical assays have shown the presence of high concentrations of dopamine (DA) in the Aplysia gill. We have studied the effects of DA and other putative transmitters on spontaneous and induced contractions in the isolated gill pinnule of Aplysia californica in an effort to determine which of these act on the gill muscle and which may be the neuromuscular transmitters for identified gill motorneurons.

A pinnule was removed from the gill and suspended by a ligature through the efferent vessel and attached to a Grass tension transducer. The afferent vessel was tied to a fixed anchor in the bath. Contractions were amplified and recorded on a Brush recorder. Drugs were applied by bath perfusion in either normal seawater, high Mg^{++} (150mM) seawater, or 30mM $CoCl_2$ seawater to depress synaptic activity. Reproducible contractions were elicited by a speaker-driven tactile stimulator.

Our studies focused on three types of contractions: spontaneous pinnule movements, contractions induced by tactile stimulation, and those induced by the perfusion of DA at 10^{-4}M. High Mg^{++} seawater blocked spontaneous and stimulus-induced contractions, but had only a slight reducing effect on DA-induced contractions. Seawater containing $CoCl_2$ blocked spontaneous and stimulus-induced contractions and had little or no effect on DA-induced contractions. Contrary to expectations, neither acetylcholine nor glutamate caused contractions in this preparation. These substances induce contractions when perfused through the gill in an intact preparation including the PVG and the gill ganglion. GABA, aspartate, histamine, epinephrine and norepinephrine had neither excitatory nor inhibitory effects. Carbachol and DA were inhibitory on specific muscles in stimulus-induced contractions. Octopamine and phenylethanolamine were also inhibitory to spontaneous and stimulus-induced contractions. Serotonin, which is present in peripheral gill neurons (Peretz and Estes, J. Neurobiol. 5:3, 1974), was inhibitory on spontaneous and stimulus-induced contractions as well as on DA-induced contractions.

Our results suggest that there are excitatory DA receptors on some smooth muscle cells in the gill of Aplysia. In addition, these experiments confirm the functional role of a peripheral nerve net, which mediates spontaneous and stimulus-induced contractions. The dominant effect of several putative neurotransmitters on the peripheral nerve net is inhibitory.

591 THE EFFECT OF INTERNAL Ca^{++} CONCENTRATION IN PARAMECIUM. Youko Satow. Lab. of Molecular Biology, Univ. Wis., Madison, Wisconsin 53706.

The internal Ca^{++} concentration in Paramecium aurelia is changed with the ionophoretic injection of Ca^{++} or $EGTA^{--}$, bathed in a K solution (KCl 4 mM, $Ca(OH)_2$ 1 mM, citric acid 1 mM, Tris 1.3 mM, pH 7.2). Fifteen sec, 10^{-9} A injection of Ca^{++} through an electrode filled with 100 mM $CaCl_2$ reduces membrane resistance by 30%, hyperpolarizes the membrane. The cell recovers from these effects within a minute. Additional injection of Ca^{++} has little effect. The membrane resistance becomes 200 to 250% of initial value with over 60 sec, 10^{-9} A injection of $EGTA^{--}$ through an electrode filled with 100 mM K_2EGTA. The effect of $EGTA^{--}$ injection depolarizes the membrane for some minutes. $EGTA^{--}$ injection following TEA^{+} injection has little effect on the resting membrane resistance or the resting membrane potential. The current-voltage relation at hyperpolarizing half after $EGTA^{--}$ injection is similar to that after TEA^{+} injection. These results show that the internal Ca^{++} controls a K permeability in P. aurelia.

A prolonged depolarization after the action potential, which is known as a Ca spike, appears by $EGTA^{--}$ injection. The slope of the plateau potentials in various Ca^{++} concentrations in a TEA solution where TEA^{+} replaces the K^{+} in the K solution is close to the theoretical slope (29 mV for ten-fold change in $[Ca^{++}]_o$) and is parallel to the slope of the peak potential. Therefore, the prolonged depolarization is due primarily to a Ca current and appears after the inhibition of K permeability and the reduction of internal Ca^{++} concentration.

An effect on the maximal rate of rise of action potential is seen by the change of internal Ca^{++} concentration; i.e., the maximal rate of rise is smaller by Ca^{++} injection and larger by $EGTA^{--}$ injection in the K solution. The change of Ca current appears on the I-V curve at depolarizing half. One possible interpretation will be discussed in comparison with the I-V curve by TEA^{+} injection.

Membrane potentials are recorded with intracellular microelectrodes filled with 500 mM KCl and the relative change of the internal Ca^{++} concentration with the injected Ca^{++} or $EGTA^{--}$ is estimated by the change of the peak potential before and after injection of ions.

The work was supported by NSF BMS 75-10433 to C. Kung.

592 L9-INDUCED GILL CONTRACTIONS IN APLYSIA ANTAGONIZED BY THE DOPAMINE RECEPTOR BLOCKERS FLUPHENAZINE AND ERGOMETRINE. John W. Swann*, C. Nelson Sinback* and David O. Carpenter (SPON: M. L. Wiederhold). Armed Forces Rad. Res. Inst., Bethesda, Md. 20014.

The gill of Aplysia californica contains 3 µg dopamine (DA) per gram of tissue--a very high concentration. Our aim is to determine the physiological role of DA in the gill. Experiments were performed on the semi-intact gill preparation of Aplysia. The preparation consists of the abdominal ganglion and the gill. The ganglion was isolated from the rest of the preparation in a vaseline-sealed chamber. The gill was cannulated and perfused. As we have previously reported, perfusion of the gill with DA at threshold concentrations of 10^{-7} to 10^{-6} M results in highly reproducible contractions of efferent vessel trunklets, pinnule longitudinal muscles, and afferent vessel. These contractions in part mimic gill contractions due to the motor neuron L7. DA perfusion also dramatically modulates (i.e., enhances) the gill contractions of L7 and at least one other motor neuron, LDGl. Biochemical assay of the soma of L7 found very little DA (1 µM). This finding suggests that L7 may not be dopaminergic.

More recently, we have found that induced spiking of L9 neurons causes the same contractions as DA and L7. As many as 3 of these L9 cells and L7 have been recorded from in the same preparation. The largest of the L9 cells causes contractions of the whole gill (i.e., all efferent vessel trunklets, pinnule longitudinal muscles as well as the afferent vessel). Other L9 cells control the movement of these same muscle groups but in a more restricted area of the gill. For instance, in five preparations we have recorded from two smaller L9 cells, one of which induced contractions of the anterior half of the gill, while the other cell controlled the posterior half. Unlike L7, the L9 cells show pacemaker activity, do not produce measurable EJPs in the gill (as recorded by an extracellular suction electrode), and send their axons to the gill via the siphon nerve. In addition, L9 cells are much less effective than L7 in producing gill movements.

Perfusion of the gill with the DA antagonist ergometrine maleate ($1\text{-}3 \times 10^{-4}$ M) produces at least partial and usually complete abolishment of L9-induced contractions. L7 and LDGl contractions are not affected. Fluphenazine HCl ($3\text{-}4 \times 10^{-5}$) appears to act as a mixed agonist-antagonist. That is, fluphenazine alone produces DA-like contractions, and it enhances L7-induced contractions. But fluphenazine blocks L9-induced contractions. LDGl contractions are not blocked by fluphenazine.

These results have led us to conclude that L7 is not dopaminergic and to develop the working hypothesis that the L9 cells are dopaminergic motor neurons. Biochemical assay of the L9 cells for DA will further test this hypothesis.

593 PHYSIOLOGY OF THE JUMP RESPONSE IN DROSOPHILA MELANOGASTER. Mark A. Tanouye* (SPON: J. Rosenbaum). Biol. Dept., Yale Univ., New Haven, Conn. 06520.

When a fly is startled, it initially jumps before opening its wings and flying away. The jump response is thought to be mediated via a giant fiber pathway from the brain to the thoracic ganglion[1]. The giant fiber system has been described anatomically from light and electron microscope serial sections[2]. The giant fiber synapses with a large motoneuron which innervates the tergotrochanter muscle of the ipsilateral mesothoracic leg, and an interneuron which innervates the motoneurons of the contralateral dorsal longitudinal flight muscles (wing depressors). In the present study, a physiological analysis of the jump response is described.

The mesothoracic leg provides the major thrust for the jump response. The tergotrochanter is a large, non-fibrillar muscle which originates on the dorsal surface of the thorax and inserts on the trochanter of the mesothoracic leg. The tergotrochanter may be selectively stimulated by an electrode located at its dorsal origin. In response to such stimulation, an all-or-nothing muscle potential is initiated, and the leg undergoes a fast and powerful extension. In addition, tergotrochanter activation causes an elevation of the wings.

The tergotrochanter muscle may also be activated by brain stimulation or cervical connective stimulation. In response to such stimulation, potentials may be recorded from the tergotrochanter muscle and the dorsal longitudinal muscles. These potentials have identical thresholds and characteristic latency relationships. In a dissected preparation, intracellular potentials were recorded from the giant fiber axon during brain stimulation. The results of these experiments show that tergotrochanter and dorsal longitudinal muscle activation due to brain stimulation occur via the giant fiber pathway.

Activity in the tergotrochanter muscle, the dorsal longitudinal muscles and the dorsal ventral muscles (wing elevators) was recorded at the start of normal tethered flight. Potentials occurred in the different muscles with latency relationships which were indistinguishable from those seen in response to brain or cervical connective stimulation. The present study therefore demonstrates that giant fiber activation alone is sufficient to explain the jump response of Drosophila melanogaster.

594 CALCIUM CURRENTS AND K-INACTIVATION MODULATE MOLLUSCAN SOMA SPIKES. S. H. Thompson* and P. A. Getting* (SPON: W. Craelius). Dept. Biol. Sci., Stanford Univ., Stanford, CA 94305.

The duration of somatic action potentials in some identified molluscan neurons increases markedly in a use-dependent fashion during low frequency repetitive firing. Spikes in these cells are characterized by a distinct bump on the falling phase which broadens into a plateau during repetitive activity and results in up to a 2.3 times increase in spike width at a frequency of 1 Hz. Spike broadening and the bump on the falling phase of spikes are blocked in Ca-free-Co saline, suggesting that a Ca^{++}-dependent process is involved.

Under voltage clamp inward current was studied in 100 mM TEA saline and was separated into a transient Na-current and a delayed Ca-current by ion substitution methods. Those cells which show spike broadening have much larger delayed Ca-currents than other cells. Repetitive depolarization at 1 Hz results in a small, progressive decrease in both Na- and Ca-currents.

The net outward current decreases during repetitive depolarizations or maintained clamps. Outward currents decrease to a similar degree both in cells that do and in those that do not show spike broadening. The decrease in net outward current does not result from an increase in inward current, nor from extracellular potassium accumulation, but rather from cumulative inactivation of the voltage-dependent component of delayed outward current, termed K-current. K-current inactivation does not proceed according to the formalism used by Hodgkin and Huxley to describe Na-current inactivation in squid axon. Instead, K-current inactivation accumulates during repetitive pulses and does not recover significantly during the interpulse interval at a stimulus frequency of 1 Hz. The Ca-dependent component of delayed outward current, termed C-current, does not inactivate at low frequency.

Both delayed Ca-current and cumulative K-current inactivation are required for spike broadening. The summation of maintained inward Ca-current with a progressively decreasing outward current results in spike broadening during repetitive firing.

595 MORPHOLOGY OF IDENTIFIED NEUROMUSCULAR JUNCTIONS IN LOCUST JUMPING MUSCLE. M.J. Titmus* and G. Hoyle, Department of Biology,. University of Oregon, Eugene, OR 97403

The extensor tibiae of the jumping leg of the locust is innervated by four physiologically different neurons; fast excitor (FETi), slow excitor (SETi), common inhibitor (CI), and a neurosecretory neuron. Neuromuscular junctions (NMJ's) were identified and examined electron microscopically. FETi terminals were found by examining fibers known to be innervated only by FETi. CI and SETi endings were distinguished in fibers innervated only by them after stimulating one axon or the other in presence of horseradish peroxidase (HRP)-saline. After gluteraldehyde fix, 3-3'-diaminobenzidine-HCl-H_2O_2 incubation, and osmium tetroxide post-fix, terminals could be identified as CI or SETi by presence or absence of HRP-labeled vesicles.

Excitatory and CI terminals are morphologically different; the former having junctional contacts on granular material on the muscle fiber surface and the latter almost always having no granular material. Pre- and post-synaptic membrane thickenings, pre-synaptic dense bodies and bars occur at all three kinds of NMJ's. The synaptic gaps at excitatory junctions usually contain dense material whereas CI gaps contain little or none.

Morphologies of vesicles in the three types of NMJ's differ qualitatively and quantitatively. Maximum and minimum diameters and their ratios were determined by computer from data fed in directly from a graphics terminal. Vesicles in excitatory endings are nearly round (max. diameter (d.)/min. d. ratios: FETi = $1.16 \pm .14$, n=1408, 12 terminals; SETi = $1.15 \pm .14$, n = 1408, 14 terminals). FETi vesicles are significantly ($P<<.001$) larger (mean max = 59.9 ± 8.4 nm, mean min = 51.8 ± 7.3 nm, mean x-sec area = 2450 ± 592 nm^2) than SETi (mean max = 49.8 ± 6.0 nm, mean min = 42.8 ± 5.2 nm, mean x-sec area = 1684 ± 341 nm^2). CI vesicles are irregular (max. d./min. d. = $1.27 \pm .18$, n=1050, 11 terminals with HRP and $1.38 \pm .24$, n=896, 9 terminals without HRP) but have similar areas to those of FETi (2561 ± 501 nm^2).

These studies show that physiologically different NMJ's display different ultrastructures and also that fast and slow axon terminals, although they may use the same transmitter, contain vesicles of different size. Investigations are in progress to determine whether this size difference is reflected physiologically in size of single quanta. (This research was supported by NSF BMS75-00463 and PHS 5 T GM 00336)

596 A MODIFICATION OF THE PARAFORMALDEHYDE HISTOFLUORESCENCE TECHNIQUE FOR APLYSIA CENTRAL GANGLIA AND MUSCLE. Thomas K. Tomosky-Sykes. Div. Neurobiology & Behavior, Dept. of Physiol., College of P & S, Columbia Univ., New York, N.Y. 10032.

There has been difficulty in using the paraformaldehyde (PF) histofluorescence technique, which allows visualization of 5-HT and catecholamine neurons, in the central nervous system (CNS) of marine organisms. I have developed modifications of the technique which permit the localization of 5-HT and dopamine in Aplysia CNS and muscle and may be applicable to other marine animals. The pinned-out tissue is exposed to a 10% formalin/20% sucrose solution in artificial seawater for 5 minutes (Azmitia and Henriksen; J. Histochem. Cytochem., 24:1286-1288, 1976), then desiccator dried over phosphorous pentoxide for 4 days. Thereafter the tissue is sequentially exposed to 70% relative humidity PF for 1 hour and 90% relative humidity PF for another hour at 80° C. The tissue is examined as a whole mount in oil using incident UV illumination. Fluorescence specificity was checked using the sodium borohydride technique. Ganglia were sometimes pretreated with 6-hydroxydopamine to reduce dopamine fiber fluorescence.

In contrast to a previous method which was not optimal for visualizing cell bodies, 5-HT and dopamine cell bodies were found in all ganglia (except genital) which were examined. The serotonergic nature of the RB cells in the abdominal ganglion and of the metacerebral cells in the cerebral ganglion has been confirmed. Furthermore, 5-HT nerve fibers were found in the heart, and dopamine fibers were found in the penis and gill. This method is currently being used to test the hypothesis that facilitator cells of the gill-withdrawal reflex are serotonergic (Brunelli et al.; Science, 194:1178-1181, 1976).

597 IDENTIFIED NEURONS MAKE IDENTICAL SYNAPSES IN MUSCA AND DROSOPHILA. Karen L. Valentino* (SPON: R. J. Wyman). Yale University, New Haven, CT 06520.

An interneuron has been found in Drosophila which synapses within the posterior dorsal mesothoracic nerve (PDM nerve) onto the dorsal longitudinal muscle (DLM) motor axons (King, Neuroscience Abstracts 3). It is thought that these synapses may mediate rapid conduction from the giant fibers to the flight muscles. If this is indeed the case, the physiological significance of the synapses in flight might be better studied in a larger fly. In fact, an interneuron similar to the one observed in Drosophila has also been found in Musca domestica.

The arrangement of the flight muscles and ganglion in the Musca thorax is virtually identical to that in Drosophila, although in Musca the anterior dorso-ventral fibrillar muscle is composed of four fibers rather than the three that are usually found in Drosophila. The major nerves are easily located in thick sections of the thorax. The proximal portion of the PDM nerve contains a synaptic region anatomically similar to that described in Drosophila. Although none of the nine large axons have been rigorously identified by serial section tracing to muscle motor end plates, each of the nine axons can be matched with axons appearing in corresponding sections in Drosophila. Three of these axons (the very large axon to the tergal depressor of the trochanter and the two accessory axons which also innervate this muscle) separate from the PDM nerve distal to the ganglion. The six other large axons represent the five DLM motor neurons which surround the peripheral interneuron. Synapses between the motor neurons and the peripheral interneuron appear to be formed by direct contact between the axons. The interneuron ends distal to these synapses, while the motor neuron axons increase in diameter as they continue toward the muscles.

The Muscidae are calypterate flies, while the Drosophilidae are acalypterates. The smallest taxonomic group that the two flies have in common is the suborder Cyclorrhapha. It is of interest, then, that such a specialized synaptic contact can be found in two such distantly related flies. This raises the possibility that this synapse may exist more widely within the order Diptera.

598 ELECTROPHYSIOLOGY AND ANATOMY OF IDENTIFIED NEURONS OF ASCARIS. J.P. Walrond,* I.S. Kass,* J.E. Donmoyer,* J.E.R. Moses* and A.O.W. Stretton Dept. of Zool., Univ. Wisconsin, Madison, WI 53706

The motor nervous system of Ascaris consists of five repeating sets of segmental neurons each containing eleven cells that make synapses onto muscle. In addition there are six ventral intersegmental neurons that make synapses onto motorneurons but not onto muscle. The motorneurons can be divided into seven classes on the basis of their shape and projections to muscle. 5 of the classes (R,G,B,VO and PB) send processes to the dorsal cord. The function of these five classes of motorneurons has been determined physiologically by stimulating single neurons and recording the evoked responses in the musculature. Of the five classes, 2 (B and PB) are inhibitory and three (R,G, and VO) are excitatory. The inhibitory neurons (one of which projects to the dorsal cord, the other to the ventral) receive their synaptic input from motorneurons, not from interneurons. This provides a pathway for reciprocal inhibition between the dorsal and ventral musculature. The excitatory neurons receive their synaptic input from the interneurons. 599 DURATIONS OF UNITARY SYNAPTIC POTENTIALS ARE MATCHED TO DIFFERENT DURATIONS OF INHIBITION REQUIRED BY A BEHAVIOR PATTERN. Jeffrey J. Wine and Grace Hagiwara*. Dept of Psych., Stanford U., Stanford, CA 94305.

Attempts to establish the neural bases of behavior invaribly rely on properties that emerge when neurons interact in large networks. In such accounts, the detailed cellular properties of neurons, such as membrane time constants, synaptic delays etc. are often obscured. Nevertheless, it is sometimes possible to relate basic cellular properties to behavior in a surprisingly direct way. We recently found that the durations of unitary synaptic potentials produced by different neurons are directly reflected in the temporal pattern of behavior.

Crayfish escape by rapid flexion and extension of the abdomen (a 'tailflip'). Flexion lasts for roughly 45 msec and is immediately followed by extension, which lasts another 60 msec, making the entire response just over 100 msec in duration. A tailflip can be triggered by a single impulse in one of four giant command neurons. The command neurons excite the flexor motoneurons directly, and thereby cause the flexion phase. In addition to their direct motor effect, the command neurons trigger widespread inhibition. Inhibitory postsynaptic potentials (IPSPs) have been recorded in eight classes of cells involved in tailflips. Five classes of cells in the flexion circuit (receptors, interneurons, command cell, giant flexor motoneuron, and flexor muscle cells) are inhibited within 10 msec after the initial flexion command, and remain inhibited during the entire cycle of flexion and extension. This ensures that flexion is brief and prevents its interference with reextension. Three classes of cells in the extension circuit (receptors, motoneurons and extensor muscle cells) are also inhibited following the flexion command, but they are then activated at the conclusion of flexion. Therefore, inhibition in the extension elements must be brief.

The requirement for long duration inhibition in flexor elements and short duration inhibition in extensor elements is met, in part, by synaptic specializations. Unitary IPSPs in flexor elements cause conductance increases lasting 70 msec or longer, while IPSPs in extensor elements are less than half that long. No exceptions were observed; long duration IPSPs (50 to > 100 msec) are seen in all five classes of flexor elements, short duration IPSPs (15-40 msec) are seen in all three classes of extensor elements.

A promising feature of this system is that four of the inhibitory neurons are identified. The transmitter in all cases is probably GABA, and all of the inhibitory synapses are accessible.

600 MODULATION OF LOCOMOTOR ACTIVITY BY ADJACENT CAMPANIFORM SENSILLA VARIES WITH SENSILLUM ORIENTATION. Sasha N. Zill*, Francisco J. Varela* and David T. Moran*. (SPON. A.R.Martin). Dept. Anat., Univ. Colo. Med. Center, Denver, Co. 80262.

Campaniform sensilla are mechanoreceptors that respond to cuticular strain. In the cockroach, Periplaneta americana, leg campaniform sensilla reflexively modulate postural and locomotor activities. These sensilla are also directionally sensitive: they respond to compression perpendicular to the long axis of their ovoid cuticular caps. The tibial segment of the leg is unique in possessing two adjacent subgroups of sensilla of mutually perpendicular orientation. The sensilla of the proximal subgroup, oriented transverse to the axis of the leg, respond to passive tibial extension. Those of the distal subgroup, oriented parallel to the leg axis, respond to tibial flexion (Spinola and Chapman, J. Comp. Physiol. 96, 257-272, 1975).

To determine if their reflex effects are also orientation dependent, individual campaniform sensilla were stimulated with a fine tungsten wire probe. Reflex effects were monitored by extracellular recording of motoneuron activity in nerves to the extensor and flexor muscles of the trochanter; these muscles lower and raise the leg respectively. Single sensilla exhibited potent, selective reflex effects that strictly depended upon their orientation. Sensilla of the proximal subgroup increased activity of the slow excitatory axon to the extensor muscle (axon D_S) and decreased activity of excitatory axons in the flexor nerve. In contrast, the distal subgroup decreased activity of the extensor axon and increased activity of flexor axons. Simultaneous recording of another nerve containing a branch of the common inhibitory axon confirmed that its activity was not affected by stimulation of sensilla in either subgroup.

We are presently testing the hypothesis that these sensilla are selectively excited in different postural positions assumed by the animal and modulate centrally generated locomotor patterns accordingly. (Supported by NIH-BRSG RR-05337, NIH Training Grant GM-01981-07, and NSF Grant BMS-73-06766).

LIMBIC SYSTEM

601 A GOLGI STUDY OF CELL TYPES IN THE HILAR REGION OF THE RAT HIPPOCAMPUS. David G. Amaral. Dept. of Psychology and Center for Brain Research, Univ. Rochester, Rochester, N.Y.

In view of the long-standing debate about the identity of the cells in the hilar region of the dentate gyrus, namely whether they are to be regarded as a special subfield of the Ammon's horn (as Lorente de Nó believed) or as a component of the dentate itself (Cajal's *stratum polymorphe*) an analysis of the cells in this zone in the rat has been undertaken, using several variants of the rapid Golgi method. No fewer than twenty different neuronal cell types have been identified on the basis of their somal size and shape, the number and orientation of their dendrites, the presence and types of dendritic spines, and the distribution of their axons. The association of dentate granule cells with the cells in the hilar region was found to be more extensive than has previously been reported. Dentate granule cell axons appear to terminate on dendrites of non-pyramidal cells, which are devoid of "thorny excresences", by means of filiform extensions which originate from mossy fiber terminal expansions and by means of thin collaterals of mossy fibers. The cells throughout the hilar region show an impressive number and variety of complex dendritic appendages. It is concluded that this region is an area of mergence of polymorphic zones of the *cornu ammonis* and the *fascia dentata*. Moreover, the present analysis does not provide support for the contention of Lorente de Nó that the deep hilar region is an extension of the *stratum pyramidale*. Rather, it is in agreement with Blackstad's suggestion that the "CA_4 area" is in fact the polymorphic zone of an *area dentata*. In support of this position are the following (1) pyramidal-like cells above the CA_{3c} region lie nearly parallel to the *stratum pyramidale*, apparently these cells have become "reflected" off the CA_4 region; (2) the "modified pyramidal cells" of the CA_4 region are so qualitatively and quantitatively different in thorny excresence density and dendritic orientation and thickness as to clearly distinguish them from typical pyramidal cells.

602 CYTOGENESIS AND MORPHOGENESIS IN THE RAT SEPTAL REGION. Shirley A. Bayer. Dept. Biol. Sci., Purdue Univ., W. Lafayette, IN 47906

Cytogenesis in selected nuclear groups of the rat septal region (diagonal band of Broca, medial, lateral, triangular, and septofimbrial) was analyzed autoradiographically after 3H-thymidine injections on two consecutive days during the prenatal period (5 μCi/gram body weight, day of sperm positivity is day 1). The percentage of cells labelled by each series of injections was determined in the offspring at 60 days of age in anatomically matched sections. By means of the progressively delayed comprehensive labelling method, the formation times of each cell population were determined.

Most of the neurons in the septal region form between days E15 and E17. There is a mediolateral gradient of cytogenesis within the major portion of the septum. The neurons in both medial septal and triangular septal nuclei form early (medial septal, 58% on E14-15; triangular septal, 56% on E15), and cytogenesis is essentially completed on E16. Neuron formation in both the lateral and septofimbrial nuclei occurs later, mainly on days E15-17 (lateral septal, 80%; septofimbrial, 74%). Formation is completed in the septofimbrial nucleus on E17, while it continues in the juxtaventricular zone of the lateral septal nucleus until E19. The neurons of the diagonal band also form on days E15-17 (69%); here, there is a caudorostral gradient of growth with anterior levels forming later than posterior levels.

The two gradients of growth seen in cytogenesis are also found in morphogenesis. The septal region develops from a ventromedial ridge of neuroepithelium along the lateral ventricle which continues across the midline to form the anterior boundary of the foramen of Monro. A zone of differentiating cells lies medial to the neuroepithelium on E14. In the region of the presumptive medial and lateral septal nuclei, this zone expands as new cells are added laterally. Concurrently, the neuroepithelium becomes progressively thinner, and mitotic activity drops off rapidly after E18. In the region of the presumptive diagonal band, there is a medial zone of differentiating cells from E15 on which lengthens caudorostrally. The germinal zone at this level contains both a neuroepithelium and a subependymal layer. Both remain active up to the time of birth and probably provide neurons for the olfactory tubercle, islands of Calleja, and nucleus accumbens.

603 PRESURGICAL HANDLING AND EXPLORATORY BEHAVIOR OF RATS WITH SEPTAL LESIONS. Wail A. Bengelloun[1], Jerry Finklestein*, Richard G. Burright* and Peter J. Donovick. Dept. Psychology, SUNY-Binghamton, Binghamton, New York 13901

The effects of septal lesions on behavior are greatly altered by the presurgical history of the experimental animal. Previous research from our laboratory indicates that environmental/social enrichment, dietary enrichment/deletion, and genotype-by-environment interactions all alter the classic septal syndrome. One form of early stimulation employed by many laboratories is handling. Such manipulations alter subsequent reactivity of the intact animal to novel stimuli in an open field and decrease adrenal corticosteroid levels. Using young adult rats, the present research examined the interactions between presurgical handling and subsequent septal lesions on postsurgical exploratory behavior in an open field.

One group of sixty-day old rats were handled twice daily for 20 days prior to surgery. The other group was left undisturbed during this period. Half of each presurgical treatment group received septal lesions, the others underwent surgical control procedures. On the 10th and 11th day after surgery all rats were tested in a dimly illuminated openfield for 5 minutes. The number of squares crossed and the number of times each animal stood up was recorded for each animal.

Control rats stood up more frequently than those with septal lesions and handled animals stood up more than their nonhandled counterparts. Numbers of squares crossed revealed a somewhat different picture. On both days control animals were more active than their brain damaged counterparts. However, on the test, presurgically handled rats with septal lesions were more active than nonhandled septals, whereas the handled controls were slightly less active than nonhandled controls. By the second day of testing, handled rats in both the lesion and control groups were more active than their nonhandled counterparts. These data further indicate that the apparent effects of septal lesions on behavior are differentially influenced by the specifics of the presurgical manipulations and the test situation.

604 CORTICAL PROJECTIONS OF THE THALAMIC MEDIODORSAL NUCLEUS IN THE RABBIT. Robert M. Benjamin, Jan C. Jackson* and Gregory T. Golden*. Dept. of Neurophysiology, University of Wisconsin Medical School, Madison, Wisconsin 53706.

The cortical projection of the thalamic mediodorsal nuclear complex (MD) in the rabbit was mapped with retrograde horseradish-peroxidase and anterograde tritiated proline techniques. The projection field occupied the entire medial wall rostral to a mid-corpus callosal level, wrapped around the frontal pole onto the lateral convexity and tailed off caudally on the dorsal bank of the rhinal sulcus. The projection of the lateral approximately one half of MD, the half which does not receive olfactory input, was confined to medial cortex supplying all but its most rostral region. This projection field of lateral MD was precisely organized in two dimensions with the most lateral part projecting most caudally on cortex and the most dorsal part projecting most ventrally. A representation for the third, anterior-posterior (A-P), dimension was not evident since any cortical point within the field was supplied by a cylinder of cells extending the entire A-P extent of lateral MD. The medial half of MD, which does receive olfactory input, projected to the remaining rostral medial cortex, the lateral convexity and rhinal sulcal region. The inverse dorsoventral relationship was partially preserved and an overlapping A-P gradient was present with sulcal projections originating more caudally in medial MD and the rostral medial projection originating more rostrally.

The MD field on medial cortex was shared with projections from other thalamic nuclei. PT (parataenialis) projected to the medial MD field on the rostral medial wall. AM (anterior medialis) projections were essentially coextensive with the lateral MD field and, within this field, VA (ventralis anterior) supplied the region of the supplementary motor area.

605 AXO-AXONIC SYNAPSES ON INITIAL SEGMENTS OF HIPPOCAMPAL PYRAMIDAL CELLS. R.B. Chronister*, Dept. Anat., R.W. Sikes and L.E. White, Jr.*, Neuroscience Research, Col. of Med., Univ. of South Alabama, Mobile, AL 36688.

The existence of synapses onto initial segments of axons within the central nervous system has been documented in the prepiriform cortex. These synapses occur on spinelike processes of the axons of prepiriform cortex neurons. These spinelike processes are visible in both light and electron microscopy. Golgi impregnations of the hippocampal formation reveal similarly appearing spinous processes. For this reason, the hippocampal formation was examined with transmission electron microscopy to ascertain the presence of initial segment axo-axonic synapses.

Adult rats were perfused with Peters' modification of Karnovsky's fixative. Following fixation, small blocks were cut from precisely localized regions of the hippocampus and postfixed in 1% osmium tetroxide. The blocks were then stained en bloc in uranyl acetate and embedded in epon. One micron thick sections were cut and examined to further substantiate localization. Silvergray sections were mounted on grids, stained per usual with lead citrate, and examined on a Phillips 301 transmission electron microscope. Initial segments were recognized by the thickening of the membrane and the bundling of the microtubules.

The spinous processes were of two basic types. The most common spine was sessile although pedunculated spines were also encountered. The pedunculated spines had vacuolated structures similar to those of dendritic spines while the sessile spines appeared to be devoid of these structures. In addition to the vacuolated structure, the pedunculated spines also contained fine filaments.

Both types of spines were postsynaptic. Presynaptic boutons often contained flattened vesicles and made type II synapses upon the spines. Similar type II synapses also were found on the shafts of the axons. On the dendrites of these neurons, type I synapses were present on the dendritic spines. The significance of these findings will be discussed.

606 Effects of transecting septal and subicular afferents to the anterior thalamic nuclei on straight-alley performance. Robert E. Davis, Janice Hendricks, and Ernest W. Kent. Dept. of Psych., University of Ill. at Chicago Circle, Chicago, Ill. 60680

Previous research suggests that the anterior thalamic nuclei receive direct input from the septum (primarily the lateral septum nucleus) and the dorsal subiculum (Meibach and Siegel, 1976). These fibers are susceptible to destruction by knife-cuts in the coronal plane, posterior to the columns of the fornix, ventral to the stria medullares, dorsal to the ventral fornix, and extending 1.5 mm on either side of the midline (Davis and Kent, 1976). This damage results in behavioral changes similar to those seen following total destruction of the hippocampus, septum or dorsal fornix (i.e., hyperactivity and enhanced acquisition of bidirectional shuttlebox avoidance). In an extension of this work, we have investigated the effects of this transection on the performance of rats in the straight alley.

Preoperatively, animals were trained to stable baselines. Following this, animals received either knife-cuts (AP-6.6, H-0.0, L-1.5; de Groot) or sham operations. After running speeds stabilized, the response to change in the amount of reward (shifting from 3-8-1-3 pellets; 3 days at each level), in the tactile cues of the alley and in the olfactory cues of the goal box were examined in these animals. Sham operated control and transected groups were similarly disrupted by both tactile and olfactory cue manipulations. Running speeds for both groups were initially elevated, returning to normal levels after several trials. Only sham operated animals were affected by changes in the amount of reward (downshifts from 8 to 1 pellet produced maximal disruption). Knife-cut animals were totally unresponsive to either downshifts or upshifts in the amount of reward. Running speeds for this group did not deviate from previously established baselines across all levels of reward.

Additionally knife-cut animals required significantly more trials than controls to reach an extinction criterion following removal of appetitive reward from the goal box.

607 DIFFERENTIAL EFFECTS OF AMYGDALA AND HIPPOCAMPUS STIMULATION ON OPERANT BEHAVIOR. Russell Denea*, Henry Lesse and Jeremiah Collins*. Department of Psychiatry and Brain Research Institute, School of Medicine, University of California, Los Angeles, Calif. 90024.

The effects of disruption of amygdala and hippocampal function by focal stimulations were studied in cats trained to bar press (BP) for milk. Since both structures have very low thresholds for epileptiform afterdischarges (AD), the relationship between electrographic and behavioral responses to repeated stimulations was investigated. During low frequency stimulation, continuous bilateral recordings from amygdala, hippocampus, neocortex and other sites were used to monitor brain activity; BP rate was recorded simultaneously. The threshold for eliciting afterdischarges (ADT) in the structure stimulated was determined by gradually increasing current while other parameters were held constant. Then ADT tests were continued at 48-hr intervals until threshold values stabilized.

Stimulation of the amygdala at intensities subthreshold for local afterdischarges and for elicited motor responses resulted in marked suppression of operant behavior which progressed as current was increased. In contrast, hippocampal stimulation proved significantly ($p < .001$) less disruptive of task performance at all intensities. The contrast was even more striking when ADs were induced. During 50 amygdala stimulation sessions (7 cats) there were no instances of bar pressing when ADs were evoked. However, in about half of the hippocampal ADT tests, subjects continued to BP during ADs. Although there was a mean decrease in BP rate during these sessions, the performance of some subjects was unchanged during induced ADs. In both structures, repeated focal stimulations resulted in an initial rapid decline in ADT with stabilization by the 7th session. A concomitant reduction in the currents required to disrupt behavior occurred indicating a parallel increased sensitivity to the effects of subthreshold stimulation on learned behavior. After subsequent repeated stimulations generalized motor seizures, rather than local ADs, were elicited eventually. The differential behavioral effects of subthreshold stimulation of the amygdala and hippocampus persisted after these "kindled" seizures developed.

(Supported in part by NIDA Grant DA-1351).

608 A HORSERADISH PEROXIDASE STUDY OF SUBCORTICAL PROJECTIONS TO THE HIPPOCAMPAL FORMATION IN SQUIRREL MONKEY (SAIMIRI SCIUREUS). J. L. DeVito. Reg. Primate Res. Ctr., Univ. of Wash., Seattle, WA 98195

Large amounts of horseradish peroxidase (0.7-1.4 µl; 33%) were injected into rostral and caudal regions of the hippocampal formation involving the hippocampus, entorhinal cortex and amygdala rostrally and hippocampus, entorhinal cortex and retrosplenial cortex caudally. More discrete amounts (0.2 µl; 33% HRP) were injected into the middle part of the hippocampus, subiculum and presubiculum. A control needle track descending as far as the lateral geniculate nucleus was injected with 0.2 µl HRP.

Sites of retrograde transport common to all hippocampal injections were as follows: the perifornical region in the dorsal hypothalamus, the supramamillary nucleus, the lateral hypothalamic area at the level of the mamillary bodies, the medial septal area including dorsal and ventral components of the diagonal band nucleus and the anterdorsal (AD) and laterodorsal (LD) thalamic nuclei. The large caudal hippocampal injection resulted in a large number of labeled cells in LD and AD and a smaller number in the anteroventral (AV) thalamic nucleus. Large rostral injections resulted in labeled cells in the anteromedial (AM) and anteroventral thalamic nuclei and fewer labeled cells in AD and LD. With the exception of one case limited largely to an injection of the dentate gyrus, subiculum and presubiculum, labeled cells were present in the midline tegmentum inferior to the decussation of the brachium conjunctivum. The dorsal raphe nucleus was labeled in all cases but also exhibited a few labeled cells in the control animal. Midline thalamic nuclei were labeled after large rostral and caudal injections but not after more restricted injections.

These results reveal tegmental and hypothalamic sources of afferent fibers to the hippocampal formation. The generally accepted medial septal and diagonal band nuclei projections were readily apparent. However, a projection from the lateral septal area which has been suggested recently (Siegel and Tassoni, Brain Behav. Evol., 4:185, 1971) was not observed. Finally, the anterior thalamic nuclei and the laterodorsal thalamic nucleus appear to project to the hippocampal formation, possibly via the cingulum bundle (Domesick, Brain Res., 20:19, 1970).

609 HABITUATION OF AROUSAL IN RATS WITH SELECTIVELY REDUCED HIPPOCAMPAL CONNECTIONS. Mary W. Dickie* and Phillip J. Best. Dept. of Psychology, Univ. Virginia, Charlottesville, VA 22901

The hippocampus is important in a wide variety of behaviors including habituation of the arousal reaction. Hippocampal unit activity is drastically reduced when the animal is awakened from slow wave sleep (SWS) (Mays and Best, Exptl. Neurol. 1975, 47, 268-279). This arousal habituates over time. Lesions of the fimbria-fornix (FF) or of the entorhinal cortex (EC) enhance duration of arousal from SWS and delay habituation (Wacker and Best, NSC 1976 #530). The current study asks how habituation of the arousal response is affected by simultaneous bilateral lesions of both EC and FF.

On a related issue, Steward, Cotman and Lynch (Exptl. Brain Res. 1974, 20, 45-66) report that unilateral lesions of the entorhinal cortex cause new fibers to sprout from the contralateral dentate gyrus within 8-12 days. The current study asks what effect a unilateral EC lesion will have on habituation of the arousal response. Furthermore, will the nature and magnitude of such an effect change over time with the appearance of newly sprouted fiber projections.

Fifty four male Sprague-Dawley rats were grouped as controls (C) and as rats sustaining electrolytic lesions as follows: bilateral entorhinal cortex (EC), fimbria-fornix (FF), bilateral entorhinal cortex and fimbria-fornix (BF), and unilateral entorhinal cortex subdivided into immediately-tested (UI) and delay-tested (UD) groups.

EEG activity was recorded from neocortex and hippocampus. All groups were tested following 3-day recovery except UD group which was delayed 21 days to allow for sprouting. A series of 25 tones (2.9 KHz, 89 dB, 1 sec) was presented during SWS. The arousal response was assessed on behavior and on neocortical EEG activation following each tone.

Both FF and EC groups showed an initial arousal response higher than C group, both showed significant resistance to habituation ($p<.05$), and EC's showed persistently higher levels of arousal than FF or C. The BF group showed the highest level of arousal throughout. The UI group had a higher initial arousal response than C or UD but did not differ from them during later tones. Groups C and UD did not differ.

Thus, partial interruption of hippocampal connections by either FF or EC lesions enhance arousability, and attenuate habituation of the arousal response. Compound lesions result in even greater arousal which is strongly resistant to habituation. Unilateral EC lesions do not produce a measurable deficit. Thus, minor damage of hippocampal connections does not cause appreciable loss of habituation of the arousal response.

610 SELECTIVE ATTENTION FOLLOWING SEPTAL LESIONS. Peter J. Donovick, Richard G. Burright*, William W. MacLaughlin* and Melinda K. Hull*. Dept. Psychology, SUNY, Binghamton, N.Y. 13901.

The discrimination behavior of rats with septal lesions is affected by their altered reactivity to stimulus conditions surrounding the learning situation. Compared to control animals, rats with septal lesions are differentially affected by experience with cues relevant to the task itself. Using original discrimination problems with relevant redundant cues, and then selectively making certain cues irrelevant, we recently showed that rats with septal lesions, relative to intact controls, use one cue-dimension at the expense of others. Such results imply an attentional rigidity on the part of septal damaged rats -- an interference with the mechanism's underlying the organisms' abilities to "take a multiple look" at its environment.

In the present experiment we examine the effects of septal lesions on how the rat responds to, and subsequently utilizes, cue information which was made relevant after they had achieved criterion performance in a discrimination task. Our results suggest that septal lesions result in a disruption of attention. That is, relative to control animals, rats with septal lesions apparently failed to attend to the newly relevant cues provided and clearly, were deficient when later called upon to utilize such information. These findings are consistant with our notion that septal lesions alter the relative weighting of important sensory information which the CNS must process, and that changes in learning performance frequently reflect a function of altered attentional mechanisms.

611 RELEASE OF ACETYLCHOLINE FROM CEREBRAL CORTEX AND HIPPOCAMPUS OF FREELY MOVING RATS. J.D. Dudar*, J.C. Szerb, Dept. of Physiology and Biophysics, Dalhousie University, Halifax, N.S., I.Q. Wishaw*, Dept. of Psychology, University of Lethbridge, Lethbridge, Alta.

Electrical recordings from the hippocampus show that rhmthmical slow activity (RSA or theta) is generated during voluntary movement (freq. 6-12 Hz) and in response to sensory stimulation (freq. 4-7 Hz). The former is resistant to atropine but blocked by urethane anesthesia, while the latter is preserved during urethane anesthesia and is blocked by atropine. In the neocortex low voltage, fast activity (LVFA) accompanies voluntary movement and this LVFA is sensitive to urethane but resistant to atropine, while the LVFA during sensory stimulation is preserved during urethane anesthesia but blocked by atropine. There appear to be two ascending systems: one activated by sensory stimulation and atropine sensitive, the other closely related to voluntary movement and atropine resistant (Vanderwolf, J. Comp. Physiol. Psychol. 88, 300, 1975).

In order to test whether these differences in EEG patterns reflect differences in the activation of cholinergic neurons, acetylcholine (ACh) was collected from the hippocampus (HC) and neocortex (CTX) of freely moving male rats during motor behavior (treadmill running), sensory stimulation and resting conditions. ACh was collected by a constant perfusion technique (0.02 ml/min) after acetylcholinesterase inhibition and using local atropine SO_4 (1 µg/ml) to maximize ACh release which was estimated by radioenzymatic assay.

Sensory stimulation and motor behavior induced similar increases in ACh release (2x resting levels) from the HC and the release was not changed by atropine sulfate injection (7 mg/kg i.p.). ACh release from CTX did not show significant changes. In the HC, sensory stimulation, under urethane anesthesia, induced a similar increase to that seen without anesthesia whereas drinking behavior did not alter ACh release above resting levels.

These results suggest that activation of cholinergic neurons in the HC does not correlate with the susceptibility of RSA to antimuscarinic agents. (Supported by M.R.C.).

612 THE ISLANDS OF CALLEJA. James H. Fallon, Joseph N. Riley, Jack C. Sipe and Robert Y. Moore. Dept. Neur., UCSD, La Jolla, CA 92093.

The islands of Calleja are a prominent and consistent feature of the mammalian brain, yet very little is known about their anatomy, connections or functions. The anatomy and connections of the islands were analyzed in the rat using Nissl, Golgi-Kopsch, and EM methods, the glyoxylic acid (GA) histochemical method, autoradiography and the horseradish peroxidase (HRP) technique for anterograde and retrograde tracing.

The islands of Calleja, as defined here, are composed of tight clusters of granule cells with an approximate diameter of 7µm and a nucleus which fills about 75% of the cell. The islands include the insula magna, located at the border between the septum and nucleus accumbens, and granule cell clusters in the polymorph layer of the olfactory tubercle (OT). The islands are surrounded by rich fiber plexi and frequently surround a central "core" of neuropil in which there may be a large neuron. In Golgi material, the granule cell axons are fine with small varicosities. The dendrites and axons ramify predominantly within the island cluster and adjacent neuropil and have not been seen to project out of the surrounding neuropil. The dendrites of medium and large cells in the surrounding polymorph layer of the OT, as well as cells of the septum and nucleus accumbens, penetrate into the islands, those of some nearby, larger cells appear preferentially to project into the islands.

Some afferents to the islands have been identified. These are topographically organized in a medial-lateral fashion. The afferents are from the dopamine (DA)-containing cells of the substantia nigra-ventral tegmental area (SN-VTA), the septum, nucleus accumbens, amygdala and piriform cortex. The dopamine innervation of the islands, as determined with GA technique, is moderately dense. The DA fibers can be found mainly in the neuropil surrounding the islands and in the "core" of the islands. Following injections of ^{3}H-proline/leucine into the SN or VTA, autoradiography demonstrated that the medial SN projects to the lateral islands, while the VTA projects to the medial islands. Injections of HRP into the septum, nucleus accumbens, dorsal amygdala or piriform cortex result in anterograde and retrograde labeling in the islands. Preliminary ultrastructural analysis of HRP material suggests, in accord with the light microscopic observations, a reciprocal projection between the granule cells and other basal forebrain structures. It is concluded that the granule cells and surrounding large cells may form additional loops in the basal forebrain, with the appropriate connections present to allow for significant integrative functions. 613 HIPPOCAMPAL COMPLEX-SPIKE AND THETA CELL ACTIVITY EVOKED BY STIMULATION OF LIMBIC STRUCTURES IN UNRESTRAINED RATS. S.E. Fox and J.B. Ranck, Jr. Neuroscience Prog., Univ. of Mich., Ann Arbor, MI. 48109 and Dept. of Physiology, Downstate Med. Ctr., SUNY, Brooklyn, N.Y. 11203

Three independently moveable recording microelectrodes were implanted stereotaxically in hippocampal formation of rats to hit the cell layers of CA1, CA3 and fascia dentata in a single lamella. Stimulating electrodes (fixed or moveable) were implanted in medial septal nucleus, in ventral hippocampal commissure (1 mm from the midline contralaterally) and in ipsilateral entorhinal cortex. These were positioned under electrophysiological control for maximal field potentials (FPs) in hippocampus at low thresholds. In addition, neocortical electrodes, neck muscle EMG electrodes and 1 to 3 fixed hippocampal reference electrodes were implanted and cemented in with acrylic. After a week, responses were recorded to single and paired stimuli to the various sites, taking care to keep behavior constant (i.e. in a relatively steady state). With this preparation most of classical hippocampal extracellular electrophysiology can be done in a behaving animal, allowing study of: 1) effects of different behaviors on electrophysiological characteristics of a given cell or FP, or 2) differences in electrophysiological characteristics of cells of different behaviorally identified types.

In most cases FPs in the freely moving animals were similar to those described by others in acute preparations. The behaviors used most extensively were slow wave sleep, paradoxical sleep, drinking and walking on a treadmill. Quantitative differences in both evoked unit activity and FPs were seen in several sites during the different behaviors, demonstrating the necessity for "steady state" behavior. We have previously reported that complex-spike (CS) cells and theta (T) cells differ in pattern and frequency of firing, duration, behavioral correlates and localization. Our present data showed: 1) at all locations, the latency of evoked CS cell activity was almost entirely predicted by the latency of the population spikes (presumably summed extracellular action potentials of projection cells--i.e. pyramidal and granule cells), while T cells had multiple action potentials before, during and/or (most frequently) after the population spikes; 2) CS cells were occasionally antidromically activated, T cells were not; 3) many T cells had additional electrophysiological properties of the "inhibitory interneurons" of Andersen, et al. (J. Neurophysiol. 27: 608, 1964). The present data, along with earlier data from this laboratory support the hypothesis that most CS cells are projection cells and that T cells are interneurons mediating recurrent inhibition.

614 HIPPOCAMPAL RHYTHMICAL SLOW ACTIVITY (RSA) DURING OVERTRAINED LOCOMOTION AND JUMPING IN THE CAT. Christopher J. Frederickson, Kay L. Hall*, Charlotte S. Smylie* and John P. Drobnica*. Program in Psych., Univ. of Texas at Dallas, Box 688, Richardson, Tx. 75080.

From 9 cats chronically implanted with either fixed or roving macroelectrodes aimed at dorsal hippocampus, 4 cats which showed high-amplitude (350 to 600 μv; monopolar derivation) RSA in the hippocampal EEG were selected as subjects. The animals were trained to wait immobile till a door opened, then walk 3.2 M through an enclosed square alley to food presented on a continuous reinforcement (CRF) schedule. Hippocampal RSA accompanied locomotion in the alley (walking and trotting) through all phases of the study, during initial training, and after prolonged overtraining as well. On the last recorded session, after 4 to 21 wks of overtraining with 1037 to 3810 practice trials, RSA was present during locomotion in 86%, 98%, 100% and 100% of the seconds of record scored for the 4 animals; median amplitudes of the 100 RSA waves measured were 320, 440, 520 and 520 μv for the same 4 animals, respectively, and modal RSA frequencies were 6, 6, 7 and 6 Hz. Comparison of the data from the last recorded session with that obtained after only 1 wk of training showed no tendency for either frequency or amplitude of RSA to decrease with continued practice at the task. However, in 2 cats, RSA amplitude was slightly larger on the first training day than after 1 wk of training.

RSA of a slightly (1 Hz) lower modal frequency than that recorded during locomotion was also usually present during immobile waiting prior to walking trials; typically, the RSA during waiting was 5 to 15% larger in amplitude than that recorded during locomotion.

In a second experiment the same 4 cats were trained to jump .9 M to a platform for food (CRF). Examination of videotapes, and force-sensor records showed that the jumps were quite stereotyped after 5 to 10 trials. Hippocampal RSA was prominant during the last 1 to 3 sec prior to lift-off during initial training on the jump and remained prominant on virtually every trial even after lengthy (up to 2 wks with 500 jumps) overtraining.

The results suggest that hippocampal RSA activity accompanies the behaviors of walking, trotting, and jumping in the cat even after the behaviors have been thoroughly practiced and have become stereotyped in performance.

615 DIFFERENTIAL NOREPINEPHRINE AND SEROTONIN CONCENTRATIONS IN THE HIPPOCAMPUS OF NORMAL RATS AND IN RATS FOLLOWING SEPTAL LESIONS. Fred H. Gage, Roy G. Thompson* and James J. Valdes.* Chemistry of Behavior Program, TCU, Fort Worth, Texas 76129.

Fluorometric analysis of serotonin (5-HT) and norepinephrine (NE) content of the hippocampal formation revealed that both biogenic amines are distributed heterogeneously in the dorsoventral axis, and that NE also exhibits a heterogeneous distribution in the medial-lateral direction while 5-HT does not. Dissection of the hippocampus into its dorsal and ventral halves shows that both NE and 5-HT exhibit higher concentrations in the ventral hippocampus in comparison to its dorsal counterpart. A dissection which separated the cell fields CA 1&2 from CA 3&4 and the dentate gyrus showed NE to be highest in the latter region, while 5-HT was uniformly distributed between the two regions. Taken together, these data indicate that NE is more highly concentrated in the CA 3&4 and dentate area of the ventral hippocampus while 5-HT concentration differences are apparent only in a dorsal-ventral dissection.

Concentrations of NE and 5-HT in the dorsal and ventral hippocampus were also determined at 1, 3, 6, 11, 16, 24, and 30 days following a lesion to the septal nuclei. The results demonstrate that biogenic amine levels in the dorsal hippocampus achieve maximal depletion earlier than do their ventral counterparts, and that percent depletion is greater for 5-HT than NE in both dorsal and ventral areas.

On the first day following septal lesions, dorsal 5-HT is increased above normal levels. Sixteen days after a septal lesion, 5-HT is substantially depleted below normal levels. In addition, by 30 days, 5-HT shows recovery from its earlier depleted state. Behavioral changes related to sensory reactivity correlate with the relative decreases and recoveries of NE and 5-HT following septal lesions.

616 COMPARATIVE STUDY OF FOREBRAIN AFFERENTS TO THE HABENULA IN THE CAT AND THE RAT AS REVEALED BY HRP NEURONOGRAPHY. S. Gravel*, R. Boucher*, J.M. Scarabin* and A. Parent, Lab. Neurobiol., Fac. Med., Laval Univ., Quebec, Canada

Injections of HRP (30% sol'n, 0,05-0,4 μl) were made in the habenular complex of 11 cats and 13 rats. Retrogradelly labelled cells were visualized after a survival period of 24 to 48 hrs by means of the method of LaVail et al., ('72, '73). In rats, most injections were confined to the lateral habenular nucleus (LH). In such cases a very large number of labelled cells were found within the rostral two-thirds of the entopeduncular nucleus (EN) (see also Herkenham, Neurosc. Abstr., '75). Numerous positive neurons also occurred in the lateral preoptico-hypothalamic region (LPHR) and in the perifornical area rostrally to the level of the injection site. In addition a few labelled cells were found in the substantia innominata (SI), in the vertical limb of the diagonal band of Broca (DBB), beneath the ventromedial hypothalamic nucleus and at the basis of the claustrum. In cats most of the HRP injections were also confined to the LH. In such cases, numerous labelled cells were found in the posterior septal nucleus, in the bed nucleus of the stria terminalis and in the LPHR rostral to the injection site. In addition a few labelled cells occurred in the LPHR contralateral to the injection site. A significant number of positive cells were also present in the SI and/or the horizontal limb of the DBB and in the perifornical area. A few positive neurons were visualized in the vertical limb of the DBB, in the medial hypothalamus and in the ventral thalamus immediately above the third ventricle. The EN of the cat, however, contains very few labelled neurons although some positive cells of the LPHR closely surround the ventromedial edge of the EN. In a few cases where the injection site slightly invades the mediodorsal thalamic nucleus, numerous labelled neurons occurred in the olfactory tubercle and less abundantly in the accumbens septi nucleus. These findings suggest significant species differences regarding the habenular afferents in cats and rats. One of the most striking differences is that the EN of the cat contains very few HRP labelled cells after LH injection in comparison to the EN of the rat which can be shown to be the major source of afferents to the HL with the same method. The pallido-habenular projection in the cat, therefore, could be a much more discrete and/or a more highly collateralized system than it is in the rat.

(Supported by grant MT-5781 of the Medical Research Council of Canada).

617 LOCALIZATION OF HIPPOCAMPAL SLOW ACTIVITY IN THE URETHANE-ANESTHETIZED RAT. Kenneth F. Green, J.N.P. Rawlins, and Per Andersen. Dept. Psych., Cal. State Univ., Long Beach, CA 90840, Dept. Exp. Psych., Oxford Univ., Oxford OX1 3UD, England, and Inst. Neurophysiology, Univ. of Oslo, Karl Johans Gt. 47, Oslo, Norway.

The purposes of the work were to map areas within the hippocampus where theta activity was generated and to examine phase relations between systematically selected sites.

Urethane-anesthetized rats were prepared by removing the skull and tissue overlying the left dorsal hippocampus and bathing the exposed brain in warm mineral oil. Theta was activated by stimulating the brain stem with tungsten microelectrodes. Recordings were made with silver ball electrodes on the surface or with tungsten microelectrodes during vertical or horizontal penetrations: one electrode remained stationary for gauging the momentary state of the animal; the other moved from the fimbria posteriorly or from the septum laterally in 0.5-mm steps.

Theta was found only in CA1, with amplitude maxima in stratum oriens (usually within the first 0.1 mm of penetration) and in stratum lacunosum-moleculare (at the fissure) separated by a null-theta region high in stratum radiatum. On occasion, each generator appeared capable of operating without the other. Below the fissure, a high-frequency activity masked theta, while in CA3 no theta was recorded unless cerebrospinal fluid was in contact with the conducting portion of the electrode.

Phase changes were found with vertical, lateral, and posterior movements of the electrodes. Vertical penetration revealed a shift of approximately 180° from surface to deep generators -- from + to - 0.1 mm of the null, a shift of about 140° was found in the direction of deep leading. Lateral movement showed no shift in the surface generator, but in the deep one medial sites led lateral sites by 20° to 30°. Movement anteriorly from the subiculum revealed a complex pattern in both generators: generally, more anterior sites followed more posterior sites; however, within 1.0 mm of center, an inversion occurred which persisted for about 1.0 mm in each generator. The inversion was more anterior in the deep generator.

618 COMPARISON OF SPONTANEOUS AND STIMULATED HIPPOCAMPAL THETA ACTIVITY IN RATS. Nobuyoshi Hagino and Hideo Saito. Dept. of Anatomy. U.T.H.S.C.S.A., San Antonio, Texas 78284.

Concentric bipolar electrodes were inserted stereotaxically into the frontal cortex, dorsal hippocampus (D-HPC), midbrain reticular formation (mdRF) and ventral region of periaquaductal gray matter behind the trochlear nucleus (PGM). Surgical preparation was performed under urethane anesthesia(900mg/kg body weight). Four hours after initial anesthesia sleep and arousal patterns were assessed in adult male rats by EEG recording from the frontal cortex and D-HPC. Stimulation of mdRF or PGM produced cortical arousal and hippocampal theta activity: arousal threshold was 0.25 volt 0.5 msec 100Hz for 10 sec. In these rats posterior thalamic deafferentation was performed using an L shaped knife; the middle and posterior thalamic nuclei were isolated posteriorly from the midbrain, and laterally from the internal capsule, and ventrally from the dorsal margin of the hypothalamus. In this preparation, the anterior region of thalamus and reticular hypothalamic pathways(Anchel,Lindsley 1972) were intact. Posterior thalamic deafferentation prevented spontaneous cortical arousal and hippocampal theta activity. Stimulation of mdRF or PGM was capable of inducing cortical arousal and hippocampal theta activity, however, the arousal threshold was elevated (1.0 volt).

An attempt was then made to determine functional pathways for inducing hippocampal theta activity. In intact rats stimulation of mdRF or PGM produced fast and slow components of evoked potential in D-HPC (fast component was determined within 10 msec after stimulation). After posterior thalamic deafferentation the fast component was suppressed and the pattern of slow component was altered upon mdRF stimulation. However, deafferentation did not alter the pattern of fast component upon PGM stimulation. Further extracellular unit recordings were made under urethane anesthesia in order to examine the fast component of evoked potential previously observed in D-HPC. Stimulation of PGM produced evoked unit responses which were superimposed on the fast component of evoked potential. However, mdRF stimulation did not produce such evoked unit response within 10 msec. The evidence indicates that PGM has a direct neural connection with D-HPC. However, mdRF may not have such a direct neural connection with the D-HPC.

These results and facts support the interpretation that diffused reticular thalamic pathways (Moruzzi, Magoun 1949) are responsible for spontaneous hippocampal theta activity. However, stimulation of the reticular hypothalamic pathway or periaquaductal septohippocampal pathway is capable of inducing hippocampal theta activity. Neither of these pathways are capable of inducing spontaneous hippocampal theta activity without involvement of the thalamus. (Supported by NIH HD 10071).

619 REINFORCEMENT VALUE AND SOCIAL BEHAVIORAL INFLUENCE OF ELECTRICAL STIMULATION OF THE HYPOTHALAMUS OF RHESUS MONKEYS. James G. Herndon, Jr.*, Adrian A. Perachio and Michael McCoy*. Yerkes Primate Center, Emory Univ., Atl. GA 30322 (SPON: W. Bouris).

Social aggressive behavior of rhesus monkeys can be elicited by electrical stimulation of the hypothalamus (Perachio and Alexander, In: Neuropsychology of Aggression, 1974). It has been argued that brain stimulation produces aggression only if the stimulation is aversive (Plotnik et al., In: The Physiology of Aggression and Defeat, 1971). While operant responding for stimulation of an attack-producing site was reported (Robinson et al., Physiol. Behav., 4, 1969), it has been pointed out that the duration of the stimulation trains which produced rewarding effects was considerably shorter than the duration used to produce attack (Valenstein, Nebr. Symp. on Mot., 1974). The present study assesses the social effects of short trains of stimulation of demonstrated reinforcement value.

Two male monkeys in whom social aggression was produced by 4-10 sec trains of stimulation applied to hypothalamic sites, were trained to press a lever for stimulation of other sites. Except for duration, the parameters of stimulation used as an operant reinforcer were identical to those used in the social setting (1.0 msec pulses at 50/sec, .3-.4 mA). Mean response rates for stimulation were: for animal #1, 15.8 resp/min, and for animal #2, 72.9 resp/min. When an attack-producing site was stimulated in the operant setting, animal #1 consistently maintained low-to-moderate rates of responding (5.62, range 3 to 20 resp/min). Animal #2, however, would not respond for stimulation of attack-producing sites. The following conclusions are drawn: (1) Moderate levels of operant responding can be maintained by stimulation of hypothalamic sites which produce attack. (2) Maintenance of responding for stimulation of attack-producing sites does not occur in all animals. Therefore, the reinforcement properties and social consequences of stimulation can be dissociated.

To determine the social consequences of short duration electrical stimulations, widely spaced .4 sec trains of stimulation were presented to animal #1 in a social setting. The animal alerted, oriented toward and initiated movement in the direction of the target animal. Thus, components of attack were apparent. Second, the rate of self-stimulation was tape-recorded to be reproduced in the social setting. While this experiment has not been completed, it seems likely that attack will occur since some clusters of recorded operant responses were dense enough to produce virtually uninterrupted stimulation, lasting several seconds longer than this animal's usual attack latency.

620 FORNIX FIBERS, CONTEXTUAL RETRIEVAL, AND MOTIVATIONAL STATES AS CONTROLLERS OF BEHAVIOR. Richard Hirsh, Brian Leber*, and Kelvin Gilman*. Dept. of Psychology, McGill University, Montreal, P.Q., Canada.

It is known that motivational states guide, as opposed to drive behavior in a manner that is different from external stimuli. It has been postulated that motivational states serve as retrieval cues and that this process is mediated by the hippocampus. As a test animals with total fornix transections or medial septal lesions were trained to obtain food and water in the same T-maze by making opposing responses. At the outset of learning both lesioned groups showed greater response consistency than sham-operated controls in terms of frequency of occurrence and alternation. This tendency increased and then decreased as a function of experience. The animals with transected fornices showed strong negative correlations between performance levels in obtaining food and water and slower in reaching criterion. Animals with septal lesions reached criterion more quickly than controls.

In another experiment the same type of animals were run in an experiment which was similar except that food and water were obtained in different mazes. The lesioned animals again showed response consistency during the early stages of learning, but reached criterion in a normal number of trials. The first experiment was repeated with animals in which the dentate granule cells had been destroyed by neonatal irradiation, with results similar to those of fornix transection.

The results support the proposed involvement of the hippocampus in the process by which motivational states prompt retrieval.

621 SUBCORTICAL CONNECTIONS FROM AREA 9 WITHIN THE PRINCIPAL SULCUS OF THE RHESUS MONKEY CEREBRUM. Stanley Jacobson, Nelson Butters* and Nisa Tovsky*. Department of Anatomy, Tufts University School of Medicine and Psychology Service, V.A. Hospital, Boston, Mass., 02111.

In the rhesus monkey removal of the midportion of the cortex around the principal sulcus produces impaired ability to perform delayed alternation tasks. In order to more completely define the anatomical connections of this region, the retrograde and anterograde axoplasmically transported tracers (Horseradish peroxidase and tritiated proline, lysine and leucine) were injected into the cortex surrounding the principal sulcus. In three adult rhesus monkeys the tracers were injected into the dorsal and ventral portions of the cortex bordering the principal sulcus with animal one receiving injections into the anterior one-third, animal two receiving injections into the middle third and animal three receiving injections into the posterior one-third.

The thalamic input to this region showed a heterogeneous input to this zone from nuclei in anterior (AM,AV), intralaminar and midline (PCN. Reuniens, CLC, CDC, PF), medial (MDmc,MDpc), ventral (VAmc), lateral (lateral dorsal, lateral posterior and Pulvinar medial) and posterior (Li). The heaviest number of labeled cells were seen in MD, PCN, PUl M and VAmc. With the autoradiographic method, reciprocal connections were noted to the thalamic nuclei with the heaviest numbers of labeled cells.

HRP-positive cells were also seen in the hypothalamus from injections in all three portions of the cortex surrounding the principal sulcus. Cells were seen in the lateral hypothalamic nucleus in all three cases. Cells were only seen in the dorsal medial nucleus, medial mammillary nucleus and tubermammillary nucleus following injections into the midportion.

Projections were also seen throughout the caudate with anterogradely transported proline, lysine and leucine. The fibers were heaviest in the head of the caudate in the dorsomedial portion. Fibers were also seen in the body and tail of the caudate but they were in lower concentration than in the head of the caudate.

The results of this study demonstrate that there are common features to the thalamic and striatal connections to the cortex bordering the principal sulcus. However, only the midportion of this region receives a strong afferent input from the hypothalamus.

622 SELECTIVE HIPPOCAMPAL LESIONS: DIFFERENTIAL EFFECTS ON SPATIAL ACQUISITION AND RETENTION IN RATS. Leonard E. Jarrard. Dept. Psychol., Washington & Lee Univ., Lexington, VA 24450.

Recent research demonstrating different behavioral effects resulting from selective damage to either hippocampal cell fields or hippocampal projections (Jarrard, J. Comp. Physiol. Psychol., 90:1035-1050, 1976), in conjunction with studies implicating the hippocampus in spatial memory (Olton, Walker, and Gage, Brain Res., In Press), prompted the present investigation of the effects of selective hippocampal lesions on acquisition and retention of a complex spatial maze. Rats were divided into two control groups (operated and unoperated) and 5 groups that received bilateral lesions to either the fimbria, dorsal CA1 cell field, alveus, dorsal fornix, or hippocampus (including damage to all cell fields and fimbria). The animals were trained on an eight-arm radial maze. Subjects either underwent training on the spatial maze postoperatively or were trained preoperatively and tested for retention after the operations.

Impaired acquisition and normal retention were found following damage to dorsal CA1 cells and the alveus; both acquisition and retention were impaired in rats with damage limited to fimbria and those with extensive hippocampal lesions. It is suggested that hippocampal projections from the dorsal CA1 cell field to the subiculum play an important role in the acquisition and storage of new spatial information but these connections do not appear necessary for the retrieval of spatial information learned preoperatively. (Supported by NSF Grant BNS 75-18160.)

623 EFFECTS OF COMBINED HIPPOCAMPAL-ENTORHINAL LESIONS ON SPONTANEOUS ALTERNATION, OPEN FIELD ACTIVITY AND SPATIAL MAZE LEARNING IN RATS. Daniel P. Kimble, Dept. of Psychology, U of Oregon, Eugene, OR 97403.

Steward, Cotman, and Lynch (Exp. Brain Res., 1974, 20, 45-66) have shown that following unilateral entorhinal lesions, the normally sparse contralateral entorhinal-hippocampal pathway sprouts and produces a substantial reinnervation of the dentate gyrus on the lesioned side. The present experiment was designed to evaluate the behavioral consequences of severe damage to the ipsilateral entorhinal-hippocampal connections, and the sequence of behavioral changes which might accompany the reinnervation process.

Rats were given unilateral entorhinal lesions combined with contralateral dorsal hippocampal lesions involving the dentate gyrus (HIPP-ENTO, N=11). Control rats were given unilateral lesions of either the entorhinal cortex or the dorsal hippocampus or were unoperated (N=12). Open field activity was measured for 5 min each day on postoperative days 2,4,9 and 14. Spontaneous alternation in an unbaited T-maze was examined on postoperative days 3,5,9,15 and 53. Three different batteries of Rabinovitch-Rosvold maze patterns were used in the Hebb-Williams apparatus. Battery I (mazes 1,5,11) was administered on postoperative days 6,7, and 8. Battery II (mazes 2,6 and 10) was administered on postoperative days 11,12 and 13. Battery III (mazes 4,7,12) was administered on postoperative days 49,50 and 51. Postoperative testing times were chosen to correspond to before, during and after the peak period of reinnervation as reported by Steward, et al.

Spontaneous alternation was reduced to chance levels in the HIPP-ENTO rats on days 3,5 and 10. Partial recovery was seen on day 15 and complete recovery (77% alternation) on day 53. Lesion induced hyperactivity in the open field was seen in the HIPP-ENTO rats on days 2,4 and 9 but was not significantly different from controls on day 14. In contrast to these results, a significant and persistent maze learning deficit was observed. HIPP-ENTO rats made significantly more errors on Battery I (173 vs 82), Battery II (79 vs 48) and Battery III (69 vs 35). Statistical significance was evaluated using a Mann-Whitney U-test ($p = .002$ for each battery). Thus, while there is behavioral recovery of normal levels of spontaneous alternation and open field activity, whatever contralateral reinnervation is taking place in these rats is apparently not capable of supporting recovery of the lesion induced maze learning deficit during the postoperative period under study.

624 RADIO-TELEMETERED ELECTRICAL ACTIVITY FROM AMYGDALA DURING SOCIAL BEHAVIOR IN MONKEY. Arthur Kling, Sid Deutsch* and Horst D. Steklis*. Dept. of Psychiatry and Bioengineering, CMDNJ-Rutgers Medical School, Piscataway, N.J. 08854.

Electrical activity from the amygdala was recorded in 6 monkeys (C. aethiops) during social interactions via a totally subcutaneous radio-telemetry unit with an external turn on-off device.

Relatively artifact-free recordings were obtained from all subjects from a single electrode chronically implanted in the left baso-lateral amygdala. Each subject was studied for 2-3 weeks with varying numbers of conspecifics in a large lexan enclosure with a loop antennae. The electrical activity was recorded on a polygraph and data tape recorder, and later subjected to spectral analysis.

Fourteen behavioral interactions were associated with consistant patterns of amygdala activity. Highest power outputs, especially at the faster frequencies, were associated with active and passive "genital inspection" and "being threatened", followed by "running" and "being chased". Lowest outputs, (except during sleep) were associated with tension reducing behaviors of active and passive grooming.

Additional recordings from multiple brain sites using a multichannel transmitter indicates differential responses during discrete behavioral interactions from other brain sites. Amygdala activity from the latter device support the findings from single channel recordings.

These results suggest that electrical activity from amygdala during social behavior is related to the "affective context" of the interaction rather than the overt behavior.

625 TWO-RSA CONCEPT SUPPORTED: EFFECTS OF ATROPINE, URETHANE AND SEPTAL STIMULATION. R.C. Kramis* and C.H. Vanderwolf. Dept. Psychology, Univ. Western Ontario, London, Canada.

Electrical stimulation of the diagonal band of Broca (DBB) in 8 chronically implanted rats elicited synchronous slow wave electrical patterns bilaterally in hippocampus during movement and immobility. These elicited patterns 1) appeared similar to spontaneously generated hippocampal rhythmical slow activity (RSA), i.e. theta, but were driven at stimulus train frequencies, and 2) were affected by atropine sulfate and ethyl urethane in the same way as spontaneously generated movement- and immobility-related hippocampal RSA patterns. The data support the contention (Kramis, Vanderwolf, & Bland, Exp. Neurol., 1975, 88, 300-323) that hippocampal RSA is not a unitary phenomenon, but rather is generated by two pharmacologically and behaviorally distinct systems.

In each rat: 1) Appropriate stimulation (e.g. 0.2 msec pulse duration, 4.0 msec inter-pulse interval, 40 msec train duration, 5-12 trains/sec, 1-6 V., 5-60 μa) elicited frequency-specific hippocampal slow waves during movement and immobility. 2) After atropine sulfate injection (50 mg/kg) DBB stimulation was ineffective unless the animal moved, whereupon frequency-specific waves were immediately elicited. Thus the neural system mediating hippocampal slow waves during immobility had apparently been blocked by atropine. 3) Ethyl urethane (0.5 - 1.5 g/kg) produced immobility and prevented elicitation of the movement-associated hippocampal slow waves which remained after atropine injection alone. 4) Ethyl urethane alone allowed DBB elicitation of frequency-specific hippocampal slow waves during the urethane-induced immobility. This indicated that urethane blockade of the hippocampal waves associated with movement after atropine was specific to a movement-related neural system and was not due to a general CNS depression. 5) The hippocampal slow waves elicited during the immobility induced by urethane alone were abolished by atropine sulfate just as were the waves elicited during spontaneous immobility in the undrugged animal.

Similar stimulation of lateral septum (8 rats) produced hippocampal frequency-specific slow waves which were not, however, abolished by the above drug treatments. Perhaps the lateral septal but not the DBB stimulation effects were antidromic. Caudate and globus pallidus stimulation produced no frequency-specific hippocampal patterns although hippocampal RSA occurred when movement was elicited.

626 AUTORADIOGRAPHIC DEMONSTRATION OF HABENULOPEDUNCULAR AFFERENTS TO RAT INTERPEDUNCULAR NUCLEUS. Nicholas J. Lenn and Viviana Wong*. Dept. Neurol.,Pediat.,Carnegie Lab.Embryol.,Sch.Med., Univ. of California, Davis, CA 95616.

In order to further clarify the distribution and electron microscopic identification of interpeduncular nucleus (IPN) afferents from habenula (Lenn, J.Comp.Neur.166:73-100,1976), ^{3}H-leucine was injected into the habenular region. Light and electron microscopic autoradiography was performed after one day's survival.

Following injections which labelled predominantly medial habenula neurons, the habenulopeduncular tract (HPT) was massively positive. After an asymmetrical injection with predominant labelling of one HPT, the ipsolateral half of IPN was more heavily labelled than the contralateral half. There was a horizontal, linear pattern to the silver grain distribution, representing the horizontal axon plexus. HPT was recognized as a distinct tract lateral to IPN at all levels of the nucleus. HPT decreased in size and intensity of label from rostral to caudal as fibers left it to cross IPN.

Electron microscopic autoradiographs were analyzed by determining relative grain densities (RGD: % label over a tissue component divided by % area occupied by that component) in random micrographs of IPN. For 1100 silver grains, the preterminal and terminal axonal RGD was 2.6, and the dendritic RGD, 0.14. The axonal labelling predominated over the horizontal axon plexus, in agreement with previous data and the light microscopic observations. The synaptic labelling was mostly in relation to S synapses, confirming previous degeneration experiments. The crest synapses, also considered habenulopeduncular afferents on the basis of degeneration experiments, were labelled in 95% of the 21 cases observed. The degeneration study had suggested that crest synapses were formed by one axon from each habenula. In the autoradiographs after markedly asymmetrical labelling of medial habenula, 75% of the labelled crest synapses showed labelling of only one of the axonal endings. This again supported a bilateral origin of crest synapses in the normal IPN. The identification and distribution of habenulopeduncular afferents has been detailed, confirming and elaborating results obtained by other methods. (Supported by NIH grants #NS12265, #HD08658. 627 VENTRAL GLAND MARKING AND OPEN-FIELD ACTIVITY CHANGES FOLLOWING DISRUPTION OF ACCESSORY, MAIN, OR BOTH OLFACTORY SYSTEMS. Georgia l'Hommedieu-Vitale*. (SPON: E. M. Hull). Dept. Psych., SUNY Buffalo, Buffalo, N. Y. 14226.

Lesions of central and peripheral olfactory structures differentially affect various behaviors, e.g., activity, aggression, and sexual behavior. Central lesions disrupt both the main and accessory olfactory systems. Peripheral lesions are most commonly produced by necrocoagulation following washing the main olfactory epitheleum with a $ZnSO_4$ solution, which does not disrupt the vomeronasal organ (Singh, Tucker, & Hofer, 1976). Thus the effects of central vs. peripheral lesions, which is based on the level of the olfactory system being disrupted, may be reinterpretted as a main vs. accessory olfactory system distinction, based on the disruption of these parallel systems.

Twenty-eight young adult male gerbils were isolated and assigned to four groups of equal size. Four surgical techniques were employed: 1. ablation of the olfactory bulbs:BA, 2. sectioning of the vomeronasal nerves on the medial surface of the olfactory bulbs: VND (after Winans & Powers, 1970), 3. transverse sectioning of the main olfactory bulbs anterior to the accessory olfactory bulbs, without damaging the vomeronasal nerves: BS, and 4. sham control: SH. Open-field activity and social interaction behaviors were assessed on day 14 after surgery. Disruption of either the main or the accessory olfactory system (BS, VND, and BA animals) results in significantly increased activity compared to sham control animals ($p<.01$).

When paired with a standard animal, ventral gland marking of the experimental animal is severely depressed ($p<.01$) only when the accessory olfactory system is disrupted (VND and BA animals). This may reflect the significance of the sensory information that is lost with accessory system disruption, or the significance of the loss of input to those forebrain areas innervated by the accessory system.

628 INVESTIGATION OF THE CHOLINERGIC PATHWAY IN THE NUCLEUS ACCUMBENS. J.E. Marchand*, J.C. Stanley, and J.F. DeFrance. Dept. of Neurobiology and Anatomy, Univ. Tex. Med. Sch. at Houston, Houston, Tex. 77025.

The nucleus accumbens septi (nAcS) might well be considered as a bridge between the limbic and extrapyramidal systems. One of the remarkable features of the nAcS is its intensive staining for acetylcholinesterase (Jacobowitz and Palkovits, 1974; Lewis and Shute, 1967; Srebro, Mellgren and Harkmark, 1976). A study was, therefore, undertaken to investigate the effects of acetylcholine (ACh) and atropine (Atp) in the nAcS.

Microstimulation electrodes were placed in the fimbria-fornix (fi-fo) system and lateral pre-optic (IPO) or anterior medial forebrain bundle (MFB) of acutely prepared rabbits. Field potentials and extracellular unitary potentials were recorded following stimulation.

Field potentials evoked via fimbria-fornix stimulation appeared as complex responses in the nAcS. An early negativity (of monosynaptic origin) was followed by a shallow positivity and there upon by a second negativity. This second negativity was often of low-amplitude and prolonged, but could also become potentiated at certain stimulus frequencies to the point that population action potentials appeared. Unitary recordings confirmed that both negativities represented the action of the same population of cells. ACh and Atp were administered iontophoretically (Atp was also given intravenously in certain experiments). While ACh has a facilitatory effect upon both the monosynaptic and polysynaptically activated field potentials, Atp appeared effective only against the polysynaptic component, blocking it. Stimulation of the IPO or MFB also evoked atropine-sensitive monosynaptic excitatory responses in the nAcS. Therefore, it is possible that fi-fo stimulation activates a IPO acetylcholine pathway to the nAcS that is monosynaptically excitatory. Supported by NSF Grant #S01 RR-05745-03 to JDF.

629 A SENSORY MAPPING OF THE SEPTAL AREA OF THE RAT. L. F. Mercer*and N. R. Remley. Dept. Psych., Texas Christian Univ., Ft. Worth, TX 76129.

Responsiveness of single units in the septal area of male Sprague Dawley rats to sensory stimulation was investigated to determine the distribution and degree of convergence onto the individual units. Unit activity was sampled in six planes transecting the septal area at 0.5mm intervals extending from 0.5mm posterior to 2.0mm anterior to bregma. Test stimuli consisted of light flashes, bursts of white noise, flank and vibrissa contact, quinine and saccharine solutions dropped onto the tongue, and odors of estrous female urine and coffee passed into the nostrils.

Units responding to visual, auditory and olfactory stimulations were found throughout the longitudinal extent of the septal area with relatively uniform distribution between the lateral and medial nuclei and the diagonal band region. Somatosensory responsiveness was found in a somewhat more localized field having medial and ventral prominence and becoming wider in the posterior planes. Gustatory representation was similar to somatosensory distribution with a slightly wider field.

Convergence of inputs was assessed by examining the number of modalities to which each cell responded. There was a tendency for cells in the dorsal aspects of the septal area to show a greater degree of convergence than found in ventral regions.

630 SUBSTANTIA INNOMINATA, SEPTAL AREA AND NUCLEI OF THE DIAGONAL BAND IN THE RHESUS MONKEY: ORGANIZATION OF EFFERENTS AND THEIR ACETYCHOLINESTERASE HISTOCHEMISTRY. Marek-Marsel Mesulam, Gary W. Van Hoesen and Douglas L. Rosene*. Harvard Neurological Unit, Beth Israel Hospital, Boston, Massachusetts 02215.

In 29 rhesus monkeys the hippocampus, the olfactory bulb and diverse neocortical areas were injected with horseradish peroxidase (HRP). The tissue was processed by four distinct histochemical methods: 1) A procedure which yields a blue reaction-product at sites of HRP activity (Mesulam, JHistochemCytochem, '76); 2) A Koelle procedure for acetylcholinesterase (AChE); 3) A Kasa procedure for the indirect visualization of choline acetyltransferase (ChAc) activity; 4) A combined procedure for the simultaneous demonstration of HRP(blue) and AChE(reddish-brown)(Mesulam, ibid.). The focus in this study was limited to the substantia innominata, the septal area and the nuclei of the diagonal band.

Our results show that the traditional subdivisions of the basal forebrain have an orderly organization of efferents such that: 1) Olfactory bulb injections of HRP result in the labeling of neurons predominantly in the nucleus of the horizontal limb of the diagonal band; 2) Hippocampal injections result in the labeling of neurons predominantly in the medial septal area and nucleus of the vertical limb of the diagonal band; 3) Neocortical injections result in labeling of neurons located predominantly in the nucleus basalis of the substantia innominata; 4) Within the nucleus basalis, medially located neurons project predominantly to frontal, cingulate and parietal cortex while the majority of efferents to temporal neocortex originates from neurons located more laterally. None of these topographical arrangements are rigid and various degrees of overlap exist.

We have also shown that the basal forebrain areas under study contain a population of perikarya which are rich in AChE and ChAc content. In fact, the combined AChE-HRP procedure showed that:1) Almost all of the nucleus basalis perikarya which are labeled with HRP after neocortical injections are also AChE-rich; 2) Only a very small proportion of the perikarya which are HRP-labeled after olfactory bulb injections are AChE rich; 3) After hippocampal injections, an intermediate proportion of the HRP-labeled perikarya are also AChE-rich. Hence, the basal forebrain of the rhesus monkey contains a core of AChE-rich perikarya which sends topographically organized efferents to the olfactory bulb, to hippocampus and to widespread neocortical areas. This may constitute a telencephalic extension of the brain-stem reticular formation; it may employ acetylcholine as its transmitter; and it may modulate motivational aspects of behavior. (Supported by NIH grants NS 05403, 09211, 06209 and the Benevolent Foundation of Scottish Rite Freemasonry, Northern Jurisdiction,U.S.A.)

631 FIRING PATTERNS AND BEHAVIORAL CORRELATES OF NEURONS IN ENTORHINAL CORTEX OF FREELY-MOVING RATS. Susan J. Mitchell* and James B. Ranck, Jr. Dept. of Physiol., Downstate Medical Center, SUNY, Brooklyn, N.Y. 11203.

The purpose of this study was to describe the firing of neurons in medial entorhinal cortex (MEC) and the relation of firing rate and pattern to the behavior of the rat. These data allow inferences to be made about the electrophysiology of the system and about information flow in the entorhino-hippocampal segment of the limbic system. Rats studied had bilateral stereotaxically implanted movable microelectrodes aimed at MEC. Additional fixed electrodes were placed to record slow waves in hippocampus and neocortex, and EMG of neck muscles.

One group of neurons was identical to all theta cells of hippocampus and some theta cells of medial septal nucleus (Ranck, J. Exp. Neurol. 41: 461, 1973). These are found in a band (or bands) in layers II or III of MEC, amidst the cells which project to hippocampus. A regular theta rhythm can be recorded in MEC. As the microelectrode moves through MEC the theta rhythm changes its phase 180° with respect to the hippocampal theta rhythm. This phase shift occurs in the outermost layers of MEC suggesting that there is a theta generator there.

Two other groups of neurons with distinct behavioral correlates have been found. One, firing single and complex-spikes (discharges of 2-7 action potentials usually decreasing in amplitude with interspike interval of 1.5-6.0 msec) fired only when a novel object was placed on or near the table. These neurons fired a few times when the object was presented then were off for several minutes. The second group of neurons, firing only single spikes, had distinct spatial characteristics. They fired at their maximum rates (approx. 30/sec) when the rat was at a particular location in the room or when he approached this location.

Another group of MEC neurons fired in bursts of action potentials (intraburst rate 30-50/sec) during SWS. This bursting pattern occurred only when big slow waves were present. Neurons with this pattern are seen in all layers of MEC. Similar patterns of firing have been seen in hippocampus and neocortex by us and others. Some of these neurons fired continuously during awake behaviors at rates either greater than or less than their rates during SWS; others had increased rates of firing during certain other behaviors.

632 SELECTIVITY IN THE DESTRUCTION OF HIPPOCAMPAL NEURONS BY KAINIC ACID. J. Victor Nadler, Bruce W. Perry* and Carl W. Cotman. (SPON: N.M. Weinberger). Dept. Psychobiol., Univ. Calif., Irvine, CA 92717.

Kainic acid, a potent excitatory analogue of glutamic acid, has previously been shown to destroy neurons in the arcuate nucleus and striatum, while sparing afferent fibers. Presumably, the susceptible neurons are depolarized for a prolonged period, leading to an irreversible ionic imbalance. We have now investigated the excitotoxic action of kainic acid on rat hippocampal neurons.

Adult rats were injected with doses of kainic acid ranging from 0.1 to 3μg, either intraventricularly or directly into the hippocampal formation. Although all hippocampal neurons could be killed by kainic acid, these experiments demonstrated a clear-cut hierarchy of sensitivity to the drug. The most sensitive neurons were those regio inferior pyramidal cells which receive mossy fiber projections (area CA3-4). They were killed within three days by injection of as little as 0.3μg and were replaced by a proliferation of glial cells. At the same time the Fink-Heimer stain revealed, as expected, degenerating fibers and boutons in the commissural, associational and Schaffer collateral terminal zones. Administration of somewhat higher doses was required to destroy the CA1-2 pyramidal cells. Detectable cell loss was seen in this area only when all CA3-4 pyramidal cells had apparently been killed. Hippocampal interneurons were less sensitive than pyramidal cells to kainic acid, and dentate granule cells and subicular cortical cells were killed only when large doses were injected into their immediate vicinity.

Acetylcholinesterase histochemistry was employed to detect any destruction of the cholinergic septohippocampal tract (whose cell bodies were unaffected). In contrast to the massive and rapid hippocampal cell loss, these fibers appeared undamaged, even at the highest doses used. Thus kainic acid evidently affected postsynaptic elements preferentially, in agreement with its actions in other regions. The highly selective toxicity of this drug indicates its utility in studies of hippocampal anatomy and function. (Supported by NSF grant BNS 76-09973 and NIH grant NS 08597).

633 PERIAQUEDUCTAL GRAY LESIONS IN THE RAT: EFFECTS ON PAIN SENSITIVITY, MORPHINE ANALGESIA, VOCALIZATION AND EMOTIONALITY. Gene C. Olson* and John C. Liebeskind. Dept. Psych., UCLA, Los Angeles, CA 90024.

The midbrain periaqueductal gray matter (PAG) has been implicated in a wide variety of specific behaviors. The present study sought to understand the diverse effects of PAG lesions by examining a number of different behaviors in the same animals. Adult male rats underwent electrolytic lesions at various levels of PAG and adjacent tegmentum. Lesions were approximately 1.0 to 2.5 mm in diameter. Animals with PAG lesions at the level of the oculomotor nucleus (rostral lesions) were more active than sham operated animals in the first two minutes in the open field. They also showed an increased baseline latency to paw lick on the hot plate (51.5°C), but only 20% of normal morphine analgesia (10 mg/kg I.P.). Normal vocalization to handling was totally absent in these animals, but they were not mute. Brief squeaks could be elicited by tail shock (1.5 msec pulses at 125 Hz, for 1 second) at 6 times normal threshold. In these animals we were unable to elicit either ultrasonic vocalization or squeaking that outlasted stimulation.

Animals with more caudal PAG lesions at the level of the Dorsal Raphe nucleus did not differ from shams in the open field. They showed a decreased baseline paw lick latency on the hot plate and a slight increase in vocalization. The degree of morphine analgesia was also attenuated in this group, but to a lesser extent than in rostral lesioned animals. Neither group showed long term differences in tail flick latency or body weight, although there were transient feeding deficits accompanying some of the larger rostral lesions. These results support the view that the PAG is importantly involved in emotional expression, and indicate as well that rostral and caudal portions of this structure are functionally distinct.

634 OLFACTORY AND SEPTAL EVOKED POTENTIALS IN THE DORSAL HIPPOCAMPUS OF AWAKE AND ANESTHETIZED RATS. S. Overmann, R. Bornschein*, D. Woolley* and K. Swanson*. Animal Physiology, University of California, Davis, CA 95616.

Hippocampal (HIP) potentials evoked by stimulation of olfactory cortex (OC), diagonal band of Broca (DB), and lateral septum (LS) were studied in anesthetized rats. Distribution of HIP responses to OC and DB stimulation were surprisingly similar: a low amplitude initially negative response in CA1 and CA2 reversed more ventrally to a high amplitude initially positive response in the dentate gyrus. For both inputs the transition from negative to positive potentials occurred at or slightly below the HIP sulcus. Positive peak latencies were 22 msec for OC stimulation and 41 msec for DB stimulation, with peak negative responses occurring 2-4 msec earlier in each case. The olfactory input to the HIP is via the perforant path. Strong similarities in the distribution of DB-evoked HIP potentials suggest that this input may also use the perforant path. Distribution of HIP potentials to LS stimulation was quite different: an initially negative response in the cortex and superficial HIP lamina was replaced more ventrally in the HIP and dentate gyrus by an initially positive response. The transition from negative to positive potentials was midway between stratum pyramidale and the HIP sulcus. Peak latencies were 16 msec for the positive wave and 22 msec for the negative wave. The HIP response to LS stimulation was believed to be antidromic because of its relatively short latency, stability, and resistance to drug effects, and because the only pathway connecting LS and HIP is efferent to the HIP. In awake chronically implanted rats the single positive wave to OC stimulation observed under anesthesia was replaced by a double positive wave with peak latencies of 20 and 40 msec. The second wave was either abolished or reduced in amplitude and its latency increased by anesthetics, natural sleep, and drugs acting on cholinergic or monoaminergic receptors. Amplitude of the first wave to OC stimulation was doubled by anesthesia, sleep, and drugs acting on noradrenergic receptors. In awake rats the HIP response to DB stimulation was reduced in amplitude and its latency was increased by apomorphine and tremorine, whereas the amplitude was increased by scopolamine, ketamine and sleep. The results indicate that cholinergic and monoaminergic systems are involved in some of the HIP responses to septal and OC stimulation. Furthermore, the second HIP wave to OC stimulation and the DB input to the HIP are reciprocally altered by sleep, some anesthetics, scopolamine, clonidine and phentolamine. This may indicate that septal and olfactory inputs play a reciprocal role in HIP function. (SO supported by NIH Postdoctoral Award # ES05057.)

635 LOSS OF EPISODIC MEMORY IN RATS WITH FORNIX LESIONS: A STUDY ON SINGLE ALTERNATION PERFORMANCE. Michele Pisa* (SPON:D. Bindra). Dept. Psychol. McGill Univ., Montreal, Quebec, Canada H3A 1B1.

Several investigators have suggested an impairment in the mechanisms of extinction to account for the behavioral effects of hippocampus lesions. According to this interpretation earlier reinforced responses compete excessively with conditioning of alternative responses in the presence of the same stimuli.The preempting effect of earlier learning would be ultimately responsible for the amnesic syndrome on account of an abnormal interference between conditioned responses at retrieval. The present experiments tested the alternative possibility that the response disinhibition is secondary to an impairment in recall of episodes or discrete events.

Rats with a sham operation or with a lesion in the fornical connections of the hippocampus were sequentially tested in different versions of a lever-press single alternation task, whose correct performance requires inhibition of the more recent choice. The experimental rats were initially found impaired in acquisition of alternation between closely spaced bars. After increasing the distinctiveness of the alternatives, by placing the levers at the ends of a long alley with the food well midway between them, the lesioned animals immediately learned to alternate as efficiently as the controls. Their performance remained similar to that of the controls when they were subsequently tested for alternation in a T-maze, with the levers in the horizontal arms and the food well in the vertical arm. However, the rats with lesions were again impaired when retested in the original condition with adjacent bars. Also, the interpolation either of baffles or of a 10 sec delay in the vertical arm, both of which resulted in multiple turning responses between choices, severely disrupted the alternation performance of the rats with lesions in the T-maze. Both in the latter cases and in the condition with adjacent bars the experimental rats did not choose randomly,rather they adopted position "hypotheses", alternately perseverating on one or the other choice.

The results indicate that response perseveration, far from being a necessary consequence of hippocampal damage, depends on an inability to recall a discrete event after similar intervening events degrade, through interference,short-term memory of the episode. Being unable to recall the cueing event after distraction, the fornix-lesioned animals attempted to cope with the task by relying on a different source of information, that is the difference between the alternatives in associative strength.

The findings conform to the hypothesis that subjects with hippocampal damage can adequately learn and recall habits, that is reinforced associations, but are severely impaired in retrieval of episodes.

(Supported by the Medical Research Council of Canada).

636 EVIDENCE FOR A SECOND HIPPOCAMPAL-DIENCEPHALIC PHYSIOLOGICAL PATHWAY COMPARABLE TO THE FORNIX SYSTEM--A UNIT STUDY IN THE AWAKE MONKEY. Charles E. Poletti* and Manit Sujatanond* (SPON: Wm. H. Sweet). Massachusetts General Hospital, Boston, MA 02114

In a preceding study in the intact monkey, neuronal firing in response to hippocampal volleys and after-discharges was studied in the hypothalamus, preoptic region, and basal forebrain using extracellular microelectrode techniques. Changes in firing patterns were observed in 22% of 666 units studied. In basal forebrain structures 34% (60) of 177 units responded; in the preoptic region 30% (30) of 99; and in the hypothalamus 14% (56) of 390 units. Response latencies in all three regions were found as short as 10 msecs. This preceding study raised the probability of a hippocampal efferent influence on basal diencephalic structures mediated independent of the fornix system.

The current study tested for a hippocampal influence on basal diencephalic neuronal firing in three chronic awake monkeys with complete bilateral lesions of the fornix system. Single or multiple shock stimulation to chronic bipolar electrodes implanted in the anterior hippocampus significantly altered the firing pattern of 13% (80) of 619 units studied. Changes in firing patterns were observed in 18% (32/174) of units in basal forebrain structures (septal nuclei, gyrus rectus and olfactory tubercle); 5% (3/63) in preoptic areas; and 12% (45/382) in the hypothalamus. The three structures with the highest percentage of responses were the bed nucleus of the stria terminalis (22%), ventromedial nucleus of the hypothalamus (19%) and nucleus accumbens (18%). Minimum initial latencies were 22 msecs. in basal forebrain areas, 25 msecs. in preoptic areas and 20 msecs. in the hypothalamus. Of 80 responding units, 61 (76%) were initially excited, 19 (24%) inhibited. The unit responses were characteristically excitatory with small initial latency variability, and a high firing index to low threshold single shock stimulation.

These combined results establish a second major efferent pathway from the anterior hippocampus to hypothalamic, preoptic and basal forebrain structures comparable in physiological influence to the fornix system. There is evidence that the non-fornix and fornix hippocampal efferent pathways exert a contrasting influence on neurons in the ventromedial nucleus of the hypothalamus.

637 DRUG SENSITIZATION AND ELECTRICAL KINDLING. Robert M. Post, Kathleen M. Squillace,* Willard Sass,* and Agu Pert. Sections on Psychobiology and Biochemistry, Adult Psychiatry Branch, NIMH, Bethesda, Md., 20014. (SPON. R. Wyatt)

A series of studies were performed to examine the interaction of electrical and "pharmacological" kindling paradigms. In Study I, 35 rats were implanted with unilateral amygdala electrodes and pretreated with 10 days of no handling (n=11), daily saline (n=12), or daily cocaine injections (40 mg/kg, i.p., n=12). Electrode placements were verified to be in the amygdala histologically except in one animal whose electrode was in the internal capsule and still showed a normal pattern of kindling. Daily cocaine, which produces increases in sensitivity to motor-activating and stereotypic effects, did not alter the rate of electrical kindling although the saline injected (stressed) animals had a significantly longer onset to first kindled seizure than the nonhandled controls. The effect of lidocaine (40 mg/kg i.p.) pretreatment for 21 days on the rate of subsequent amygdala kindling will be reported. In experiment II, 38 animals were implanted with unilateral amygdala electrodes; 20 were sham stimulated, while 18 were stimulated at 200 μA, 50 Hz, for 500 milliseconds once daily. Following 21 days of stimulation, experimental and control animals were challenged following 3 day intervals with cocaine (10 mg/kg), apomorphine (0.2 mg/kg), cocaine (40 mg/kg), apomorphine (4 mg/kg) and lidocaine (60 mg/kg). At the higher doses of cocaine and apomorphine, the kindled animals had significantly decreased cocaine-induced vertical activity and increased apomorphine vertical activity ($p < .01$). 14 of 16 kindled animals had lidocaine-induced convulsions compared to only 4 of 17 controls (χ^2, $p < .001$). In study III, 19 animals were treated with oral lithium (0.6 meq/15 gms of lab chow) beginning 7 days prior to amygdala kindling and continuing during 21 days of electrical stimulations. Regardless of pretreatment in Studies I-III, approximately 40% of kindled animals showed marked oscillations in after-discharge durations; these animals displayed cycle lengths varying from 2 to 5 days. Lithium did not alter the rate of kindling or the emergence of marked oscillations in after-discharge durations. The results of Study IV examining the effect of naloxone and morphine on electrical kindling of the amygdala will also be presented.

These data indicate that there are important and complex interactions between "pharmacological" and electrical kindling paradigms. Kindling may represent a tool for producing long-lasting alterations in responsivity of selective neural substrates valuable in dissecting biobehavioral relationships.

638 ELECTROPHYSIOLOGICAL ANALYSIS OF EVOKED ACTIVITY IN THE MAMMILLARY COMPLEX OF THE CAT. Harvey Reisine*. (SPON: A. Rudell) Dept. of Physiol., SUNY, Downstate Medical Center, Brooklyn, N.Y. 11203.

Cats were anesthetized with sodium pentobarbital and, in some, the fornix was exposed ipsilateral to the recording site. Bipolar stimulating electrodes were placed according to stereotaxic coordinates in the mammillothalamic tract (MTT) and were placed visually in the dorsal fornix (DFX). Stimuli were square wave pulses, 0.02 to 0.05 msec in duration and 0.1 to 4.0 mA in intensity. Spontaneous and evoked activity was recorded with glass insulated tungsten microelectrodes (10 to 30 μ tip protrusion).

Antidromic labelling of projection neurons in the mammillary complex assisted in identifying the recording site during an experiment. Lesions made at the bottom of a penetration were observed in histological sections and verified electrode positions. Properties of 57 mammillary units, evoked by MTT stimulation, included: 1) all or nothing response at a critical stimulus intensity, 2) unit responses varied in latency less than 0.3 msec, 3) each unit response followed a stimulus train of 200 Hz, 4) the absolute refractory periods of these unit responses, determined by paired pulse stimulation, was 0.5 to 2.6 msec and 5) collision was observed when the spontaneous activity of the unit triggered a stimulus with an appropriate delay. The latencies of unit responses ($\leq$ 4 msec) correspond to the earliest prominent (0.5-2.3 msec) negative component (1-3 msec latency) of the field potential recorded in the mammillary complex following stimulation of the MTT.

Stimulation of the DFX at 1 Hz results in a multi-component field potential recorded in the mammillary complex, including an early negative component (4-6 msec latency) which follows a 100 Hz stimulus train. A negative component is observed following stimulation of the post-commissural fornix with a shorter latency (2.5-3.5 msec) which occludes the negative component evoked by DFX stimulation, implying that a common set of afferents is being stimulated. Conduction velocity of the fornix fibers is estimated at 3.5 m/sec. Unit responses following stimulation of the DFX have latencies of 9 to 20 msec and follow a stimulus train no greater than 20 Hz implying that they are postsynaptic. When the stimulating electrodes are moved deeper into the DFX, the amplitude of the negative component is diminished and a different, positive-negative, wave is recorded, the positive peak having a latency ranging from 30 to 35 msec. This wave does not follow a stimulus train greater than 5 Hz implying a postsynaptic origin. Both evoked potentials from DFX stimulation were unaffected by destruction of the rostral pole of the hippocampus, i.e., posterior to the stimulating electrodes. (Aided by NS0577303).

639 INFLUENCE OF LATERAL SEPTUM (LS) STIMULATION ON THE EXCITABILITY OF MEDIOBASAL HYPOTHALAMIC (MBH) NEURONS IN THE RAT. Leo P. Renaud, H.W. Blume*, Q.J. Pittman, R.E. Kearney* and B.W. MacKenzie*. Div. of Neurology, Montreal General Hospital, Montreal H3G 1A4, Canada

Previous electrophysiological studies on MBH neurons of the rat have demonstrated that many of these cells, in particular the neurons in the ventromedial nucleus, have afferent and efferent connections with extrahypothalamic areas, e.g. the amygdala, periaqueductal gray (PAG), midline thalamic nuclei and medial preoptic area (Brain Res. 93: 145-151, 1975; J. Physiol. 260: 237-252, 1976; J.Physiol. 264: 541-564, 1977).

In pentobarbital anaesthetized male Sprague Dawley rats, further studies were conducted on 267 MBH neurons to examine their excitability during single 1 Hz LS stimulation. A PDP 11/40 computer was used to analyze spike discharge probability patterns after LS stimulation, to compare these responses to those elicited by stimulation in the amygdala and PAG, and to examine the topography of the tested neurons. 46% of neurons (n = 124) tested with LS stimulation were unresponsive. Of the remainder, only 3 cells displayed antidromic invasion (mean latency 6.7 msec $\pm$ 4.5 S.D.) indicating that very few MBH neurons project to LS, in contrast with more than 18% of MBH cells that project to the medial preoptic-anterior hypothalamic area. 40% of neurons (n = 109) displayed orthodromic excitation (latency range 4-52 msec; mean 16.7 $\pm$ 8.4 S.D.) while 12% of neurons (n = 31) displayed a depression of activity (latency range 4-40 msec; mean 19.0 $\pm$ 11.2 S.D.) after LS stimulation. Most of the responsive neurons were localized in the ventromedial and paraventricular nuclei, and the anterior periventricular region. Approximately 50% of responsive cells in the ventromedial nucleus also displayed orthodromic activation or depression after amygdala stimulation, indicating a significant convergence of afferent pathways. In contrast, few LS responsive neurons were influenced by PAG stimuli. These studies indicate that both LS and amygdala are important afferent sources of information for neurons in the ventromedial nucleus.

640 EFFECTS OF MORPHINE AND DIAZEPAM ON SPONTANEOUS NEURON ACTIVITY IN THE LIMBIC SYSTEM OF THE CAT. J.H. Robinson* and S.C. Wang* (SPON: Martin C. Wallenstein). Dept. of Pharmacology, College of Physicians and Surgeons, Columbia University, New York, N.Y. 10032.

The effects of morphine and diazepam (Valium) were studied on spontaneous unit activity in locally anesthetized, immobilized cats which had been surgically prepared under halothane anesthesia. Glass-coated, platinum-iridium microelectrodes were used to record single neurons in the cingulate gyrus, septum and the lateral hypothalamic area. Morphine sulfate (1.0-2.0 mg/kg i.v.) augmented the spontaneous discharge rates of the majority (64%) of the neurons tested (n=33). This morphine induced increase was as much as 500% in some cases. In contrast, diazepam (0.1-0.2 mg/kg i.v.) reduced the spontaneous discharge rates as well as the augmented firing rates induced by morphine injection in 85% of the neurons tested (n=26). At times, administration of diazepam attenuated the morphine augmented firing rates below pre-morphine control levels. These data are qualitatively similar to that reported on the amygdala and hippocampal formation (Chou and Wang, Fed. Proc., Vol. 35, 3, 269, 1976). Finally, administration of two neuroleptic agents, haloperidol (0.5-0.1 mg/kg i.v.) and perphenazine (0.1-0.3 mg/kg i.v.) had no significant or consistent effect on morphine induced firing rates. These findings, along with data reported on the amygdala and hippocampus, suggest that, in cats, the entire limbic system may play an important role in morphine-induced behavioral responses and may also represent the site of action for the tranquilizer diazepam. (Supported by NIH Grants #HL 12738, #NS 05173 and #NS 00031.)

641 EFFECTS OF ACETYLCHOLINE, SUBSTANCE P AND STIMULATION OF HABENULAR NUCLEI ON RAT INTERPEDUNCULAR NEURONAL ACTIVITY. B.R. Sastry* (SPON: J.W. Phillis). Department of Physiology, College of Medicine, University of Saskatchewan, Saskatoon, Saskatchewan, Canada S7N OWO.

The high levels of choline acetyltransferase and acetylcholinesterase activities in the interpeduncular nucleus (IPN) as well as the reportedly reduced activity of the former enzyme following the destruction of the rat brain habenula suggest that the habenulo-interpeduncular pathway (HIP) may be cholinergic. The levels of substance P (SP) in the IPN also decrease after a lesion in the habenular nuclei. Therefore, both acetylcholine (ACh) and SP may be involved in the HIP-induced effects on IPN cells. In male Sprague Dawley rats anaesthetized with a mixture of methoxyflurane, nitrous oxide and oxygen, the activity of single IPN cells was recorded through the central barrel (2 M NaCl) of 7-barrel micropipettes. The outer barrels contained drugs that were iontophoretically applied and 2 M NaCl for current controls. Many neurones in the dorsolateral IPN exhibited rhythmic activity. These cells fired at 15-100 Hz for 10-30 sec duration and this activity was interrupted by silent periods of 20-35 sec. Other neurones in the dorsal and ventral IPN discharged single spikes or small bursts of spikes at irregular intervals. Stimulation in the habenular nuclei (1 Hz) produced the following effects on the IPN neurones: 1) a short latency (< 5 msec) depression of brief duration (< 100 msec) occasionally followed by a weak facilitation; 2) a short latency excitation (about 5 msec) followed by a prolonged weak depression; 3) a long latency (> 20 msec) excitation of prolonged duration (200-500 msec); or 4) a long latency depression (> 20 msec). The IPN cells that were excited by the habenular stimulation were also activated by ACh and SP. In the majority of the cases atropine antagonized the facilitatory effect (long latency facilitation) of habenular stimulation and the excitation by ACh. The effects of SP were not substantially altered by atropine. Lioresal antagonized the long latency excitation produced by the activation of HIP and SP excitation but it also antagonized ACh. γ-Aminobutyric acid (GABA) depressed the IPN cells and bicuculline antagonized this depression. The inhibition of the IPN neurones by activation of HIP was unaffected by bicuculline. The rhythmicity of the dorsolateral IPN cell firing was unaltered by stimulation of the habenula, or by the application of ACh, SP, atropine and Lioresal (see also Lake, Exp. Neurol. 41, 1973). The results of this investigation indicate that 1) ACh and SP in the HIP may be involved in mediating the long latency excitation of IPN cells and 2) GABA is not involved in the inhibition of IPN cells produced by stimulation of the habenular nuclei.

642 PARALLELISM BETWEEN THE EFFECT OF LESIONS OF THE CORTICO-MEDIAL OR BASO-LATERAL AMYGDALA ON BEHAVIORAL AND PLASMA CORTICOSTERONE RESPONSE TO STRESS. Jo A. Seggie and John Chambers*. Neuroendocrine Research Section, Clarke Institute of Psychiatry, 250 College St., Toronto, Ontario M5T 1R8.

It has been suggested that the amygdala may be involved in regulation of adrenal corticosteroid secretion. The present study was undertaken to determine the effect of lesions of the cortico-medial or baso-lateral amygdala on the adrenal corticosteroid response to stress. Data presented elsewhere have indicated that neither of these lesions has any effect on normal resting levels or on 24-hour variations in plasma corticosterone. The baso-lateral amygdala lesion used in the present study produced an increase in behavioral reactivity as measured by resistance to capture, freezing and startle response while the cortico-medial amygdala lesion had no effect on these behaviors.

Adult male rats were housed in individual cages under a light cycle of 12 hours light/12 hours dark. Separate groups of normal, sham-operated or amygdala-lesioned rats were subjected to one of two stressors at the same time of day and sacrificed by decapitation 0, 5, 10 or 15 minutes after the end of stress. Trunk blood was collected for hormone assay. A low level of stress was imposed by picking the animal up for 5 seconds while a higher level of stress was imposed by placing the animal into a novel environment for 3 minutes. In the first study, lesions were placed bilaterally in the baso-lateral amygdala while in the second study the lesion group sustained cortico-medial amygdala lesions.

Cortico-medial amygdala lesions had no effect on the pattern of plasma corticosterone responses to either of the stressors. The baso-lateral amygdala groups, however, exhibited a corticosterone response to stress that was of shorter latency and greater magnitude than the non-lesioned controls. Thus, the 2 types of amygdala lesions had parallel effects on behavior and adrenal stress response without affecting resting corticosterone levels. Baso-lateral amygdala lesions potentiated both the behavioral and adrenal responses to stress while cortico-medial amygdala lesions had no effect on either of these variables. The former finding is reminiscent of the effects of septal lesions which potentiate both behavioral and hormonal indices in response to stress in rats without affecting resting hormone levels (Biological Psychiatry 11(5): 583-597, 1976).

643 EFFERENT CONNECTIONS OF THE SUBSTANTIA INNOMINATA IN THE CAT. Allan Siegel and Raymond Troiano*. Dept. of Neuroscience, New Jersey Medical School, Newark, New Jersey, 07103.

The efferent connections of the substantia innominata in the cat were studied utilizing the technique of ^{3}H-amino acid radioautography. Injections of ^{3}H-leucine (0.2-0.3 μL., 20 μCi/μL) were systematically placed throughout all levels of the substantia innominata and adjacent structures. Survival times varied from 1-2 days. Our results indicate that cells situated in the most lateral portions of the substantia innominata project heavily to the medial and central amygdaloid nuclei via two routes -- a direct ventral pathway and the more circuitous stria terminalis. These neurons also project caudally to the bed nucleus of the inferior thalamic peduncle, lateral hypothalamus, and ventral tegmental area. Rostral projections of this region were traced to the olfactory tubercle, nucleus accumbens and bed nucleus of the stria terminalis. The efferent connections of more medial and caudal portions of the substantia innominata resemble the projections of the lateral hypothalamus and include such targets as the lateral hypothalamus, ventral tegmental area, lateral habenular nucleus and septal area. Therefore, this component of the substantia innominata may be viewed as a rostral extention of the preoptico-hypothalamic continuum. Whenever the large, angular, multipolar cells of the basal nucleus of Meynert were labeled, axons were observed projecting towards cortical areas. When the labeled cells within this group were situated medially, axons projected around the genu of the corpus callosum into the prefrontal cortex and anterior limbic area. When the labeled cells were situated laterally, axons projected to the pyriform and prepyriform cortices. Additionally, other fibers also appeared to extend into temporal and parietal neocortical regions from this site.

644 REFRACTORY PERIOD ESTIMATES OF NEURONS MEDIATING THE APPETATIVE AND AVERSIVE EFFECTS OF ELECTRICAL STIMULATION OF THE LATERAL HYPOTHALAMUS IN THE RAT. Ronald W. Skelton* and Peter Shizgal, Dept. of Psych., Concordia Univ., Montréal, Québec Canada.

Does escape from rewarding Lateral Hypothalamic stimulation (LHS) reflect the direct excitation of neural elements other than those mediating the rewarding effect? Deutsch and Albertson (Behav. Biol. 11, 1974) addressed this question by behaviourally estimating refractory periods (RP's) of the neural elements subserving escape responses and self-stimulation. Yeomans (Physiol. Behav. 15, 1974) criticized their scaling methods suggesting an alternate procedure used in our partial replication of their work.

Rats were trained to press one lever to turn on and another to turn off trains of single or paired pulses. The frequency thresholds for on- and off-responding were determined for 9 intrapulse intervals (IPI) and compared to frequency thresholds for single pulses. If the ratios of frequency thresholds thus derived estimate the relative effectiveness of the second pulse of each pair (E_2), then changes in E_2 with IPI should reflect the RP of directly stimulated neural elements.

The increases in E_2 over IPI of .6-1.2 msec were similar for on- and off-responses and so indicated similar refractory periods for the neural elements mediating the two behaviours. However, in some rats, E_2's for the different behaviours were different at IPI = .2 msec. Yeomans (ibid.) has argued that E_2 at this IPI reflects local potential summation in elements too distant from the electrode to be fired by the first pulse of each pair. This implication of differing spatial distributions of neural elements involved in on- and off-responses is consistent with previous reports of different current thresholds as well as our own findings of differing frequency-intensity functions. These results are best explained by assuming that the electrode directly stimulates two functionally distinct neural populations. Thus, although our results are similar to those of Deutsch and Albertson, we disagree with their RP values and their conclusion that a single population of neural elements is responsible for both responses.

645 EFFECTS OF SCOPOLAMINE AND ATROPINE ON HIPPOCAMPAL EEG IN THE CAT. Charlotte S. Smylie*, Richard B. Lenig* and Christopher J. Frederickson (Spon: R. D. Stillman). Program in Psych., Univ. of Texas at Dallas, Box 688, Richardson, TX 75080

Four cats with chronic EEG electrodes yielding high-amplitude (350-750 uv) Rhythmical Slow Activity (RSA) from the dorsal hippocampus were trained to wait immobile till a door opened, then walk through an alley to food. All animals showed the following EEG patterns during performance: waiting was generally accompanied by RSA (4-7 Hz; 350-700 μv) with intermittant episodes of Small Irregular Activity (SIA) (5-30 Hz; 200-400 μv) and occasional rare bursts of Large Irregular Activity (2-30 Hz; 350-600 μv); walking was accompanied by continuous RSA (5-8 Hz; 350-650 μv); lapping the food was accompanied by mixtures of slow, small RSA (3-7 Hz; 200-400 μv) and SIA.

Comparatively small doses of scopolamine hydrobromide (.05 mg/kg) or atropine sulfate (1.0 mg/kg) (i.p.) virtually abolished the RSA during immobile waiting and food lapping. After injection, waiting was accompanied by LIA (up to 900 μv) with occasional periods of SIA, and lapping was accompanied by roughly equal amounts of LIA and SIA. The same drug doses did not, however, entirely block the RSA which accompanied walking. RSA was present at least sometimes during walking in all drug tests, and in most cases RSA was the predominant pattern during walking. Still, some episodes of walking without RSA did occur in every drug test.

Large doses of scopolamine (0.5 & 1.0 mg/kg) and atropine (10 and 20 mg/kg) severely depressed spontaneous walking and all but eliminated food lapping. During immobility, LIA was essentially continuous except for occasional episodes of SIA. During walking, LIA and SIA were the predominant patterns, SIA often marking the initiation of movement and LIA accompanying continued walking. However, in all cases, RSA was also occasionally recorded during walking. No consistent behavioral differences between the walking accompanied by RSA and that accompanied by SIA or LIA were apparent, although RSA was generally more likely when walking was provoked by handling than when walking began spontaneously.

The results suggest (1) that the RSA which accompanies immobility or food lapping in the cat is more sensitive to anticholinergic blockade than that which accompanies walking, and, (2) that high doses of antocholinergics can block some, but not all, of the RSA which accompanies walking in the cat.

646 EVIDENCE FOR CHANGES IN CNS RESPONSIVENESS FOLLOWING HYPOTHALAMIC STIMULATION DURING HIBERNATION IN GROUND SQUIRRELS (CITELLUS LATERALIS). T. L. Stanton* and A. L. Beckman. Dept. Physiol., Sch. Med., Univ. of Pa., Philadelphia, Pa. 19104.

Previous work has demonstrated that a given dose of acetylcholine (ACh) microinjected into the midbrain reticular formation (MRF) produced transient increases in body temperature (T_b) that progressively increased in magnitude as time in the bout elapsed. The present study examined whether a similar progressive change in CNS responsiveness occurs following ACh stimulation of the preoptic/anterior hypothalamus (PO/AH), which produces arousal from hibernation. A bilateral microinjection of ACh (20, 50, or 100μg) was given during different portions of the hibernation bout via chronically implanted cannulae. Metabolic rate and T_b were continuously recorded during the tests. The results showed a rapid change in responsiveness occurring in the early portions of the bout. No change in T_b was evident in the 1st quarter, although a small increase in oxygen consumption was observed following 100μg of ACh. In the 2nd quarter, increases of 0.10°C to 5.2°C were observed. After 50% of the bout, it was rare to observe any increase in T_b that did not culminate in full arousal from hibernation. The results indicate that whereas a change in CNS responsiveness during hibernation is evident following stimulation of the PO/AH, it differs in character from the more progressive change in responsiveness observed throughout the bout following MRF stimulation. (Supported by USPHS grant NS10597.)

647 BASKET AXON PROJECTIONS IN THE DENTATE GYRUS. R. G. Struble*, N. L. Desmond*, W. B. Levy and A. H. Riesen (SPON: P. D. Wilson). Dept. of Psych, UC-Riverside, Riverside, CA 92521.

The detailed descriptions of the hippocampus by Ramon y Cajal, Lorente de Nó, and others have been of significant aid in directing and interpreting neurophysiological investigations of this structure. As a prime example, Andersen and colleagues (In The Hippocampus, vol. I, 1975) have pinpointed the hippocampal basket cell as the source of the powerful, local recurrent inhibition associated with granule and pyramidal cell activation. However, the report by Andersen and Lømo (In Basic Mechanisms of the Epilepsies, 1969) describing an inhibition in the dentate gyrus oriented along the longitudinal, i.e., septo-temporal, axis of the hippocampus is unexpected if not incompatible with the reported projections of basket cells.

Using the rapid-Golgi method on the dissected, linearized rat hippocampus, this study extends the classical findings of Ramon y Cajal and Lorente de Nó. In particular, this report provides new data regarding the vector of basket cell projections relative to the hippocampal lamellar structure.

Two classes of basket cells were observed in the dentate gyrus. Basket nerve endings were found which were traced back to axons originating in the hilar region of the hippocampus. Such projections were limited to 2-3 transverse sections. As such, these basket cells are similar to those described by Lorente de Nó.

Distinctive from the basket cells with hilar-localized somata are those located in the dorsal leaf of the dentate gyrus. These pyramidal-shaped cells are located within and just subjacent to the granule cell layer. From serial section observations, it is apparent that these cells project some distance in the longitudinal axis. The mean (±SEM) septo-temporal trajectory length was 1045 (±67) μm, while the trajectory within a section, i.e., transverse to the septo-temporal axis, was 387 (±34) μm (n=11).

Although Cajal did describe these basket cells, he apparently did not appreciate the extent of the axonal projections, possibly due to the difficulty in visualizing this longitudinal projection in the normal, unstraightened hippocampus and because of the lack of emphasis on the lamellar organization of the hippocampus until Lorente de Nó. Closer analysis of the terminal ramifications of the basket axons showed that not all areas within the projection field of one basket cell axon were contacted by terminal ramifications of the observed basket axon. Rather, there was a checkerboard-like distribution of the axon plexus with large areas within the projection field free of the endings of a single basket axon. Thus, these basket cells would quite likely be the origin of the longitudinal inhibition previously described in the dentate gyrus. (Supported by PHS grant HD 10401-13A1 to A. H. Riesen and NSF grant BNS 75-18089 to W. B. Levy)

648 THE TOPOGRAPHIC DISTRIBUTION OF SOME INTRINSIC HIPPOCAMPAL CONNECTIONS IN THE RAT. L.W. Swanson, J.M. Wyss and W.M. Cowan. Dept. of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, Missouri 63110.

The organization of the intra-hippocampal connections of the dentate gyrus and Ammon's horn (fields CA1-4) have been examined with the autoradiographic, HRP, and Timm's methods, the results being plotted on an unfolded map of the hippocampal formation prepared from a large scale model (1:82). Mossy fibers from cells in the inner blade, from the crest region, and from the outer blade of the dentate gyrus, all project for approximately the same distance and in the same general direction through both the infra- and supra-pyramidal bundles. These fibers end adjacent to a narrow, mossy fiber-free, transition zone of the regio inferior, near the CA2/CA3 boundary. The distribution of the mossy fiber pathways depends, however, on its septo-temporal origin. Thus in the septal one-third of field CA3, the mossy fibers follow an "L-shaped" path, crossing transversely and then longitudinally in a temporal direction parallel to the transition zone. At more temporal levels the mossy fibers are essentially transversely disposed.

Field CA4 appears to project bilaterally to the dentate gyrus, to fields CA1, CA3 and CA4 of Ammon's horn, and to the subiculum. Following small ^{3}H-proline injections involving cells in the septal two-thirds of field CA4, without involvement of field CA3c, transported label can be found over a wide area involving the septal one-half to two-thirds of the terminal field. Neurons in the temporal part of field CA4 have a more restricted bilateral projection to the temporal one-fourth of the dentate gyrus, Ammon's horn and subiculum. Similarly, small ^{3}H-proline injections into the septal one-half of field CA3 label extensive bilateral parts of the septal two-thirds of fields CA1 and CA3, and a limited part of the subiculum adjacent to CA1. More temporal injections also label a septally-directed pathway which seems to correspond to Lorente de Nó's "longitudinal association" bundle. The overall extent of the labeled terminal field following injections of either field CA3 or CA4 was quite similar on the two sides of the brain, but that on the ipsilateral side was invariably slightly larger. Field CA1 has been found to project to adjacent parts of the ipsilateral subiculum, with a septo-temporal organization similar to that of the mossy fibers. The results emphasize the highly organized interrelationship between Ammon's horn and the subiculum and also indicate that a small region of the dentate gyrus can widely influence other parts of the dentate gyrus, Ammon's horn, and the subiculum, of both sides.

649 AN EFFECT OF THE LATERAL SEPTUM ON LATENT INHIBITION. A.W.Toga,* H.Burton,* D.G. Davenport,* and S. Horenstein. Depts. of Psychology and Neurology, Saint Louis University, Saint Louis, MO 63104.

Latent inhibition was attenuated in a series of rats which underwent bilateral destruction of the lateral nucleus of the septum. The phenomenon of latent inhibition refers to a lower rate of responding in the presence of a conditioned stimulus that was previously presented without reinforcement. Prior to surgery all animals were trained by appetitive conditioning to press a bar upon illumination of a cue (S^+) but not to the house light. Neither was lit during the intertrial intervals (ITI). The criterion for entering the second phase of the experiment was 80% response to S^+. Upon reaching this level subjects were divided into 4 groups matched for response rates. Two of the groups were assigned to the brain lesion and two to the sham condition. Bilateral ablation of the lateral septum was accomplished stereotactically. The sham controls underwent similar surgery except that the electrodes were lowered to just above the septum. Half each of the operated and control groups were assigned to a preexposure phase in which they received 180 presentations of a 1000 Hz tone within 60 minutes. The other animals sat in an identical training box without tone for 1 hour. Immediately following preexposure all animals were subjected to the first of 4 daily successive discrimination training sessions. S^+ now consisted of a simultaneous 5 sec exposure to the tone, house and cue lights, and S^- the latter two alone. After testing the animals were killed by formolsaline infusion and the brains removed for verification. Latent inhibition or a delay in the initial learning following preexposure was less pronounced in the lesioned animals. Additionally, the septal (lesioned) animals responded more often in the presence of S^-. Finally, these animals had lower learning rates. The perseveration resulting from these lesions resembles that following more extensive septal ablation. A response-perseveration model to explain these results seems appropriate since the septal animals responded in the presence of S^- and had a lower learning rate. One may conclude that destruction of the lateral septum releases behavior from those mechanisms which normally link it to appropriate stimuli.

650 SPECTRAL STUDIES ON 40 Hz, RHINENCEPHALIC RHYTHM, IN THE ELECTROENCEPHALOGRAM (EEG). C. C. Turbes, J. M. Simard* and G. T. Schneider*. Creighton University School of Medicine, Omaha, NE 68178 U.S.A.

These studies were on eight cats with chronic implanted electrodes in the amygdala, nucleus accumbens septi, left and right frontal, parietal, temporal and occipital cerebral cortical areas. Recordings were made with Grass Model #8-10 electroencephalograph. Three channels were recorded on an F.M. tape recorder for further analysis of data. The data was processed with a Varian V-72 minicomputer. Channels were sampled alternately at 2.5 ms and 120 data segments for each channel of 2.56 seconds duration each. This 2.56 seconds of data was transformed using a Fast Fourier Transform algorithm to give a power spectral estimate.

The 40 Hz rhythm, in the amygdala, was most apparent in the alert, hungry, oriented and searching cat. All neocortical areas showed 40 Hz activity during these behavior states. Amphetamine enhanced the 40 Hz activity in the amygdala and neocortical areas. There was also a shift to 48 Hz to 50 Hz in the amygdala during the action of d-amphetamine. Depressants, barbiturates, decreased and eliminated 40 Hz activity at amygdala and cerebral cortex.

651 A POSSIBLE PROJECTION TO THE INFERIOR COLLICULUS FROM THE VENTRAL MESENCEPHALIC TEGMENTUM. S. R. Vincent*, T. Hattori and E. G. McGeer (SPON: A. Jakubovic). Div. of Neurol. Sci., Dept. of Psych., Fac. of Med., Univ. of British Columbia, Vancouver, B. C. V6T 1W5, Canada.

Using light and electron microscopic techniques, evidence for a projection from the ventral mesencephalic tegmentum to the inferior colliculus has been obtained. Rats were given unilateral stereotaxic injections of 0.1 µl of 60% horseradish peroxidase (HRP) into the lateral portion of the inferior colliculus. One day later they were perfused and processed for light microscopic examination. HRP-labelled cells of about 20 micron diameter were observed in the medial geniculate and in the A-10 region of the ventral mesencephalic tegmentum ipsilateral to the injection site.

Following the unilateral injection of 0.25 µl of tritiated leucine (10 µCi/µl) into the A-10 area, transport of label to the ventro-medial portion of the inferior colliculus was observed by light microscope autoradiography. The synaptic morphology of the terminals of this projection was explored further by electron microscopy following lesions of the A-10 region. Rats received unilateral stereotaxic electrolytic lesions (1 mA for 40 sec) of the A-10 area and two to three days later were perfused and prepared for electron microscopic examination. Degenerating boutons of about one micron diameter were observed in the ipsilateral inferior colliculus. Both symmetric and asymmetric axodendritic synapses were observed to degenerate. Some myelinated fibres were also seen to be degenerating in this region.

Although the A-10 area is known to contain dopaminergic cell bodies which project to nucleus accumbens, the transmitter in the A-10-inferior colliculus projection is not known. It is interesting to note that the substantia nigra, which contains dopaminergic cells projecting to the deeper layers of the superior colliculus (Rinvik et. al., 1976, Brain Res. 112: 388; Hopkins & Niessen, 1976, Neurosci. Letters 2: 253). Thus the existence of a projection from the A-10 area to the inferior colliculus provides support for the idea of a parallelism in the projections of the substantia nigra and the A-10. This projection to the inferior colliculus, an area intimately concerned with auditory function, could play an important role in the affective dissorders in which the A-10 to nucleus accumbens has already been implicated.

652 EFFECTS OF HIPPOCAMPAL X-IRRADIATION ON A DOMINANCE ORDER IN THE RAT. Robert B. Wallace, Gary Freeman*, Jack Werboff*, Robert Graziadei*, and Walter Weiss*. U.of Htfd., Ct. 06117

The technique of focal X-irradiation of the rat hippocampus provides a selective lesion of the granular cells of the dendate gyrus. Anatomically it is possible to limit destruction to hippocampal granule cells since only they are in a proliferative state during radiation with surrounding regions essentially nonproliferative. Behaviorally the advantage of a neonatal lesion is that it allows a developmental approach as to the role of the hippocampus throughout the animal's life.

A number of studies have dealt with possible consequences of hippocampal lesions by assessing behaviors such as two-way avoidance, passive avoidance, and open field behavior. Little work has been done, however, with situations more closely related to behaviors that might normally be required in development. From Altman's hypothesis, we might view the juvenile animal under the protection of its mother as developing exploratory and other skills necessary for independence. Once this state is reached, such uninhibited "play" might well be maladaptive in securing food, protection, and rearing young, thus the development of inhibitory mechanisms would be essential. A study by Kim et al., (1971) supports this notion by showing that hippocampetomized adult rats have little fear in the presence of a live cat and tend to be less aggressive spontaneously or when provoked by shock as evidenced by fear attacks in dyadic pairing. Lorenz (1966) has suggested that aggression may be important in ontogenetic development as a means of self-preservation.

In an effort to pursue some of the issues addressed above, the following dominance study was carried out. Five experimental animals (male Long-Evans hooded rats - random bred in our laboratories) were exposed to focal hippocampal X-irradiation - 150r per day from 2 - 15 post partum; examination of hippocampal anatomy initiated a 70 - 80% reduction in the number of granule cells in the hippocampal dentate gyrus. Five additional males served as non-irradiated sham animals and five served as control animals. Dominance was measured in a plexiglass enclosure with a grid floor across which a 0.5 m.a. scrambled shock was pulsed. Animals were remotely observed and were run in a round robin procedure. Recordings were made of the amount of time each animal spent on the dominance enclosure platform in a trial.

Results indicated that the irradiated animals were submissive to the control animals as reflected in significantly lower total times on platform. Aggressive behavior, even when adaptive in the situation, would appear to be suppressed in the irradiated animals. Some support for the model proposed by Altman was noted.

653 BASAL FOREBRAIN CONTROL OF SWALLOWING. Ananda Weerasuriya*, Detlef Bieger and Charles H. Hockman. Sch. Basic Med. Sci., and Dept. Physiology and Biophysics, Univ. Illinois, Urbana, IL .

In adult cats anesthetized with urethane, electrical stimulation of the basal forebrain facilitated swallowing elicited by electrical stimulation of the superior laryngeal nerve. A stereotaxic mapping study revealed that the facilitatory sites were distributed along the course of the ventral amygdalofugal pathway, specifically its rostral forebrain and hypothalamic components projecting to the anterior amygdalar area, substantia innominata, lateral preoptic area, anterior hypothalamus and nucleus accumbens. The descending pathways mediating facilitatory influences from the nucleus accumbens and amygdala to the brainstem were delineated by placing acute discrete radio-frequency lesions in known target areas of efferents from the two structures. Our results suggest that the amygdala and nucleus accumbens influence swallowing via descending efferents that travel through the lateral hypothalamus.

Reflexly-induced swallowing was also facilitated by microinjections of dopamine (100 µg) at the same amygdalar and accumbens sites which enhanced the reflex response when electrically stimulated. In addition, the reflex response was augmented by close-arterial injections into the forebrain of dopamine agonists L-DOPA (0.2-2.0 mg/kg) and apomorphine (0.04-0.14 mg/kg), an effect that could be blocked by pimozide (0.4 mg/kg, i.v.).

The results from these experiments along with those from an earlier study (Bieger and Hockman: Exp. Neurol., 52: 311-324, 1976) draw attention to the role of the basal forebrain in suprabulbar control of swallowing, and suggest that the observed modulatory influences are mediated by structures known to receive dopamine neuron projections.

Basal forebrain control of swallowing draws attention to the role played by this part of the brain in the integration of olfacto-gustatory information required for the enactment of somato-visceral motor synergies. 654 ORIGIN OF THE HIPPOCAMPAL COMMISSURAL PROJECTION IN THE MOUSE USING THE RETROGRADE HORSERADISH PEROXIDASE METHOD. James R. West*, Howard O. Nornes, and Clifford L. Barnes*. Dept. Anat., Sch. Med., University of Iowa, Iowa City, IA 52242, and Sch. Vet. Med. Biomed. Sci., Colorado State University, Fort Collins, CO 80523.

Following small injections of concentrated horseradish peroxidase (HRP) into various regions of the hippocampal formation of C57BL/6J mice, we found retrogradely labeled neurons in regions relatively specific for the injection sites. That is, a mediolateral localization was observed in which labeled cells were found in regions of the regio inferior roughly corresponding to homotopic injection sites in the contralateral hypocampus. Lateral injections labeled cells in CA3a,b regions while more medial injections labeled cells in CA3c-CA4 regions. The most surprising finding was labeled cells in the hilus of the dentate gyrus. Labeled cells in this region were found exclusively following injections that included, or were restricted to, the contralateral dentate gyrus. The HRP procedure also confirms earlier work by several investigators of a moderate spread of the commissural projection along the sepetotemporal axis. 655 DENTATE GRANULE CELL ACTIVATION BY LATERAL OLFACTORY TRACT STIMLATION. R. Wilson* and O. Steward. Depts of Neurosurgery and Physiology. University of Virginia School of Medicine, Charlottesville, VA 22901.

Historically, the hippocampal formation has been believed to be closely associated with olfactory structures, yet until recently the route from the olfactory bulb to the hippocampal region was unknown. Recent studies, however, have shown that the projections of the lateral olfactory tract (LOT) terminate in layer I of the ventrolateral entorhinal cortex (EC)(Heimer, J. Anat. 103, 1968). Since the EC is the major source of extrinsic afferent input to the hippocampal formation, it has been assumed that this represents the pathway through which olfactory impulses reach the hippocampus. Because the entorhinal projections originate from two cell populations within the EC, one projecting to the dentate gyrus (DG) and the other to regio superior of the hippocampus proper (Steward & Scoville, J. Comp. Neurol. 169, 1976), the question arose whether either or both of these pathways could be activated by olfactory bulb afferents. The hippocampus has a laminated organization making it possible to determine electrophysiologically the synaptic zone activated by a particular afferent. For example, the lateral and medial components of the EC projection to the DG distribute to the outer and middle portions of the granule cell dendrites respectively. These differences are reflected following EC stimulation by a difference in the laminar profile analysis of evoked potential amplitude. In addition, since the laminar profile of evoked potentials in regio superior is easily distinguishable from that in the DG, it is possible to define which of these areas is activated. To investigate the pathways carrying olfactory information, stimulating electrodes were situated in lateral and medial EC and in the LOT. An extracellular recording electrode was advanced in 50 µm steps through hippocampus and the DG, recording the evoked potential following stimulation at each site. Stimulation of the LOT evoked a 14 msec latency potential in the DG. The laminar profile of this potential was virtually indistinguishable from that produced by lateral EC activation but different from the profile evoked by stimulation of medial EC in both dorsal and ventral leaves of the DG. This result suggests the presence of a major polysynaptic pathway from the LOT which travels via the lateral EC to the dentate gyrus. (Supported by USPHS RESEARCH GRANT NO. 1 RO1 NS12333 to O. Steward)

656 EFFECT OF MEDIAN RAPHE STIMULATION ON NEURONAL TRANSMISSION THROUGH THE DENTATE GYRUS IN THE FREELY MOVING AND THE ANESTHETIZED RAT. Jonathan Winson. Rockefeller University, New York, NY 10021.

Previous work in this laboratory in the rat (Winson and Abzug, Science in press) has shown that the efficacy of neuronal transmission through the dentate gyrus following perforant path (pp) stimulation is dependent on behavior. The present investigation was undertaken to ascertain whether serotonergic mechanisms might play a role in producing this effect.

To study the problem, movable electrode devices for stimulating pp and recording from the dentate gyrus were implanted in rats. In addition, a bipolar stimulating electrode was positioned in the median raphe nucleus (MR) to activate the 5-HT pathway originating in MR and innervating the hippocampus. To aid in localization, field potentials in the dentate gyrus elicited by MR stimulation were monitored during implantation. After recovery, animals were tested in the freely moving state. Stimuli were applied to the pp, and evoked action potentials were recorded extracellularly from populations of granule cells during two behaviors, slow wave sleep (SWS) and the still, alert state (Alert). In each behavior, the pp stimulus was either presented alone or was preceded by a stimulus applied to MR, thus resulting in four test conditions at any given value of pp stimulus current, MR stimulus current, and delay time between MR and pp stimuli. Tests were run at a series of pp and MR stimulating currents and at a series of delay times.

As reported previously, granule cell response to pp stimulation alone was greater during SWS than during Alert. Prestimulation applied to MR resulted in a marked augmentation of the already elevated response during SWS, while prestimulation had no effect in the alert state. The augmentation during SWS was dependent on delay time, being prominent at delays of 20 to 65 msec. After tests, animals were anesthetized and retested. Augmentation of the granule cell response following MR prestimulation was also present in the anesthetized condition with a similar dependence on delay time. The results suggest a behaviorally specific serotonergic influence on neuronal transmission through the dentate gyrus.

657 HYPOTHALAMIC AND BRAINSTEM AFFERENTS TO THE HIPPOCAMPAL FORMATION IN THE RAT. J. M. Wyss, Dept. Anat. and Neurobiol., Sch. Med., Washington Univ., St. Louis, MO 63110.

Following moderately large injections of horseradish peroxidase (HRP) into the hippocampal formation (including Ammon's horn, the subiculum and presubiculum) and using benzidine dihydrochloride as the substrate, retrogradely labeled cells have been identified in several regions of the hypothalamus and brainstem, many of which have not previously been recognized as projecting directly to the hippocampal formation. Among the regions showing labeled neurons are: (1) the lateral and posterior hypothalamic areas; (2) the periventricular nucleus; (3) the supramamillary nuclei; (4) the rostral part of the ventral tegmental area; (5) the interpeduncular complex; (6) the superior central nucleus; (7) the dorsal raphe nucleus; (8) the dorsal tegmental nucleus; and (9) the locus coeruleus. In many of these regions the cells were labeled bilaterally, but in nearly every case a significantly greater number of cells was labeled on the side of the injection. The precise site of termination of these hippocampal inputs remains to be determined, but it is evident from these observations that there is a substantial direct input into the hippocampal region from the hypothalamus and rostral brainstem, in addition to the better known indirect input which is relayed in the medial septal/diagonal band complex.

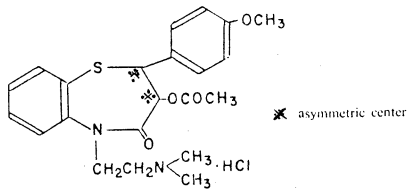
MEMBRANE STRUCTURE AND FUNCTION

658 DIRECT ACTION OF THE CALCIUM BLOCKER DILTIAZEM ON THE CALCIUM CURRENT OF SNAIL NEURON. Norio Akaike*, Kai S. Lee* and Arthur M. Brown. Dept. Physiol. & Biophys., Univ. Tex. Med. Branch, Galveston, TX 77550.

We compared the actions of two drugs, Diltiazem and Verapamil, which block Ca^{2+} currents in excitable membrane. Ca^{2+} currents in single Helix aspersa neurons were examined using our suction pipette method (Nature, 265, 751, 1977) which allows us to combine intracellular perfusion with voltage and current clamp. Ca^{2+} currents are separated by blocking K^+ currents with Cs^+ and Na^+ currents with $Tris^+$ or TTX (10^{-5} g/ml). The action potential in isolated neurons has a threshold but is also voltage-dependent. Diltiazem (10^{-6} to 10^{-4} M) and Verapamil (10^{-5} M) decreased the amplitude of the isolated soma spike markedly, reduced upstroke velocity, prolonged duration and increased threshold potential. Diltiazem and Verapamil blocked Ca^{2+} channels in a voltage dependent manner, their actions being greater at lower voltages. τ_m of Hodgkin-Huxley model was slightly increased while τ_h was greatly increased. The effects of Diltiazem on Ca^{2+} conductance were facilitated in the presence of 10^{-4} M Ni^{2+} and partly reversed by increasing perfusate Ca^{2+} concentrations.

Diltiazem: d-3-acetoxy-cis-2, 3-dihydro-5-[(dimethylamino)-ethyl]-2-(p-methoxyphenyl)-1, 5-benzothiazepin-4(5H)-one hydrochloride.



Diltiazem

659 EFFECT OF LOW-SODIUM SOLUTIONS ON CONDUCTANCE IN THE GIANT ABDOMINAL NEURON (R_2) OF APLYSIA. James P. Apland and David R. Livengood. Department of Neurobiology, Armed Forces Radiobiology Research Institute, Bethesda, MD 20014.

Low-sodium external solutions have been reported by various authors to cause an increase, a decrease, or no change in conductance of molluscan neurons (Marmor, Prog. Neurobiol. 5(2):169, 1975). A careful investigation was undertaken to establish whether a conductance change could be demonstrated consistently in the R_2 cell and, if so, to establish the ionic mechanism involved. Numerous sodium substitutes, including Tris, mannitol, magnesium-mannitol, glucosamine, tetraethanolammonium, tetramethylammonium, bis(2-hydroxyethyl)dimethylammonium, choline and arginine were used. Ramp-generated current-voltage plots were used to establish slope conductances. A conductance increase was consistently observed with most of the substitutes. This change could be blocked by extracellular application of 30 mM cobalt chloride. These results imply that calcium is involved in the phenomenon. In some experiments no conductance change was observed in low-sodium solutions. In these experiments a conductance decrease could be demonstrated following application of cobalt. This suggests that a conductance increase, which could be blocked by cobalt, was masked by a decreased sodium conductance brought about by removal of external sodium. It is not yet clear whether the conductance increase in low-sodium solutions is due to a direct increase in calcium conductance or to a calcium-mediated increase in potassium conductance. It was also observed that application of cobalt abolished anomalous rectification in these cells. This suggests that anomalous rectification, which is dependent on external potassium, may involve a calcium-mediated increase in potassium conductance.

660 MECHANICAL ACTIVATION AND ELECTROPHYSIOLOGICAL PROPERTIES OF INTERCOSTAL MUSCLE FIBERS FROM MALIGNANT-HYPERTHERMIA-SUSCEPTIBLE (MHS) PIGS. S. H. Bryant and I. L. Anderson*. Dept. Pharmacol. & Cell Biophys., Univ. Cincinnati Col. Med., Cincinnati, OH 45267, and Col. Vet. Med., Oklahoma State Univ., Stillwater, OK 74074.

The triggering of hyperthermia and the abnormal contraction of muscle from MHS pigs are believed to be due to some defect in the excitation-contraction coupling that leads to elevated calcium levels in the myoplasm. In an effort to quantify the abnormality in the untriggered state we examined the kinetics of mechanical activation of intercostal muscle fibers, controlling the membrane potential with a 2-electrode voltage-clamp and blocking action potentials with tetrodotoxin as described by Adrian et al. (J. Physiol.240:207,1969). External intercostal biopsies were removed from MHS Poland-China and control pigs under anesthesia provided by ketamine, thiopental and nitrous oxide. Small bundles of intact fibers were dissected from the biopsy and studied with microelectrodes in vitro at 38° C. Fibers were depolarized in steps from a holding potential of -90 mV and the membrane potential necessary to produce a microscopically visible threshold contraction was recorded for a series of pulse durations. The membrane potential versus pulse duration produced a "strength-duration" curve for mechanical activation. The mean rheobase for control fibers was -54 mV with the curve leveling off between 100 and 500 msec., whereas the mean curve for MHS fibers was markedly shifted in an approximately parallel manner to a rheobase of only -86 mV close to the holding potential. Dantrolene sodium (2.5 mg/L) added to the bath shifted the strength-duration curve of the MHS fibers toward control values with a rheobase of -54 mV, and the control curve was shifted to a rheobase of -31 mV. The MHS curve in dantrolene was steeper than control fibers in dantrolene at short durations. Cable parameters were also measured in both types of fibers. Membrane resistance was higher and membrane capacitance was lower in MHS fibers compared with control (1218±80 and 582±54 ohm·cm^2; 5.6±0.5 and 10.4±0.9 uF/cm^2, respectively). The strength-duration curves for mechanical activation can be fit reasonably well by a model that assumes that the rate of calcium release from the SR is proportional to the amount of voltage-dependent charge movement in the T-system, the uptake of calcium is first order or saturable, and the threshold calcium concentration is constant and similar in both types of fibers. The lowered mechanical threshold that we found in MHS fibers is best fitted in the simulation by a defect that leads to altered release of calcium. (Supported by USPHS, NIH Grant NS-03178).

661 DOES THE ENDOLYMPHATIC POTASSIUM DEPOLARIZE THE HAIR CELL MEMBRANE? Ruben Budelli* and Humberto Bracho*. (SPON: Douglas Junge). Dept. Head & Neck Surg., Sch. Med., UCLA, Los Angeles, CA 90024.

The hair cells in the vertebrate inner ear, face two different ionic environments. On the innervated side, these cells are in contact with perilymph (a low potassium fluid) and on the ciliated side with endolymph (a high potassium fluid). If the hair cells in the inner ear have membrane potentials dependent on the external potassium concentration, they would be depolarized by the high endolymphatic potassium. To test this possibility we used the macula sacculi in Necturus maculosus to measure the membrane potentials at different potassium concentrations in vitro and in vivo. In the in vitro experiments the saccular wall which contains the macula was excised and placed in a double chamber, in such a way, that the hair cells ciliated side was facing upwards and the solutions on each side of the neuroepithelium could be exchanged independently for solutions with different potassium concentrations. The results show that the neuroepithelial cells in the macula sacculi are depolarized when the potassium concentration is raised on either side of the neuroepithelium. To find out if these cells are depolarized in the normal animal, we recorded the membrane potentials in the neuroepithelial cells in vivo, with the labyrinth intact and after removal of the otolith and replacement of the endolymph by perilymph. The neuroepithelial cells have a larger membrane potentials when the endolymph was substituted by perilymph. An equivalent circuit which explains some of the experimental results is the following:

$Vm = V_1 + Rm.i$

$i = (-V_1 + V_2)/(Rm + R'm + Re)$

if:

$R'm = Rm$ and $Re \quad Rm$:

$Vm = \frac{1}{2}V_1 + \frac{1}{2}V_2$.

Where:

V_1, V_2= Potassium dependent batteries

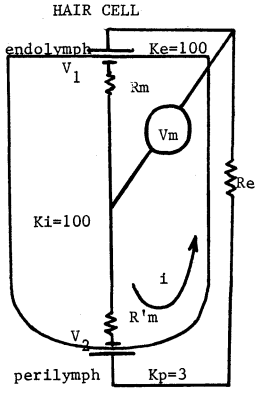
Rm, R'm= Potassium dependent membrane resistance.

Re= Epithelial resistance other than Rm.

Ke= Potassium(endolymphatic)

Kp= Potassium (perilymphatic)

Ki= Potassium (intracellular)



662 FATTY ALDEHYDE AND FATTY ACID COMPOSITION OF NORMAL HUMAN CNS AXOLEMMA-ENRICHED FRACTIONS. V.P. Calabrese, G.H. De Vries and W.J. Zetusky*. Depts. of Neurology and Biochemistry, Med. Coll. of Va. and McGuire VA Hospital, Richmond, VA 23298

Axolemma-enriched fractions from normal human white matter were prepared by osmotically shocking myelinated axons and separating them from myelin on a discontinuous density gradient of 0.8 M, 1.0 M and 1.2 M sucrose. The lipid of the 1.0 M/1.2 M axolemma-enriched fraction was extracted using chloroform-methanol 2:1 v/v and the GPE and GPC fractions were separated by thin layer chromatography. The GPE plasmalogen aldehydes of the 1.0/1.2 fraction and myelin were quantitatively hydrolyzed and isolated by thin layer chromatography using benzene as the solvent. The distribution of plasmalogen aldehydes was determined by GLC of both the free aldehydes and dioxalene derivatives on a DEGS column. Methyl esters of the GPE and GPC fractions were prepared with sodium methoxide, extracted into hexane and analyzed by GLC on a DEGS column.

The myelin aldehydes were comprised of 25% C16:0, 3% C17:0 (?), 18% C18:0 and 54% C18:1. The 1.0/1.2 fraction consisted of 23% C16:0, 5% C17:0(?), 23% C18:0 and 49% C18:1. By contrast CNS "grey matter" GPE aldehydes consisted of 3% C14:0, 1.8% C16:0, 2% C17:0(?), 60% C18:0 and 17% C18:1. For grey matter the weight ratio of C18:1/C18:0 was 0.30 while for myelin it was 3.02 and the 1.0/1.2 fraction had a ratio of 2.14.

Analysis of the GPE and GPC fatty acids showed they were made up primarily of the C16 and C18 family of fatty acids with lesser amounts of what is tentatively indentified as C20:1, C20:2, C20:4 and C24:0. In addition the GPE (1.0/1.2 fraction) contained significant amounts of C22:6 which was virtually absent in the myelin fraction. There were quantitative variations in the distribution of fatty acids from preparation to preparation. In one preparation myelin GPE had a 20:1/20:2 ratio of 2.4 which is similar to what others have found while the analogous lipid in the 1.0/1.2 fraction had a 20:1/20:2 ratio of 0.32.

The results indicate that the axolemma-enriched fraction showed a fatty aldehyde pattern very similar to myelin rather than the cell bodies from which they originate. The difference in the GPE fatty acid profile of the myelin and 1.0/1.2 fraction suggests that there is little contamination of the 1.0/1.2 fraction with myelin lipid. The data suggest that the 1.0/1.2 fraction aldehyde is an intrinsic axolemmal component. The similarity in the GPE aldehyde patterns may indicate a close metabolic relationship between myelin and axolemma.
(Supported by NIH grant NS 10821-04 and a grant from the Multiple Sclerosis Society RG1117-A-1).

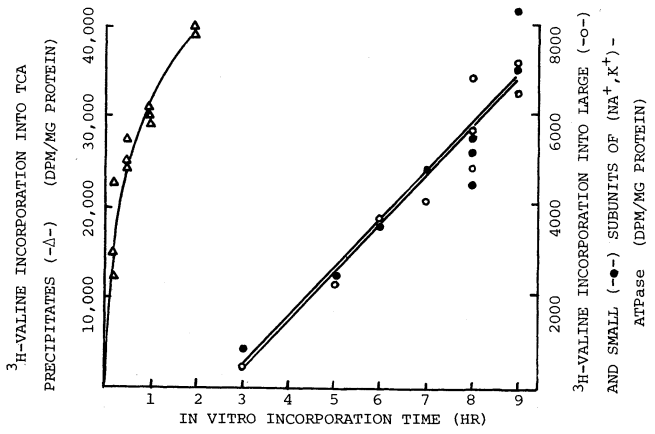
663 SYNAPTIC VESICLES: QUANTITATION OF PURITY AND CHARACTERIZATION. Steven S. Carlson*, John A. Wagner* and Regis B. Kelly (SPON: Walter M. St. John). Dept. Biochem. & Biophys., U. Cal., San Francisco, CA 94143.

Prior to biochemical and biophysical characterization of synaptic vesicles, it is essential to determine their degree of contamination by other membranes. To this end we have developed biophysical techniques for estimating vesicle purity in addition to techniques for vesicle purification. Synaptic vesicles of approximately identical properties have been purified from the electric organs of both Torpedo californica and Narcine brasiliensis, by differential centrifugation of homogenates, followed by flotation on equilibrium sucrose density gradients and molecular seive chromatography on a Controlled Pore Glass column (3,000 A pore size). If necessary, final purification can be achieved on equilibrium glycerol density gradients (vesicle density = 1.10 $g.cm^{-3}$), since glycerol density gradients measure membrane density, unlike sucrose gradients where the density is largely determined by the internal volume of the vesicle (vesicle density = 1.05 $g.cm^{-3}$). At this state the vesicles are over 85% pure, using the criteria of size, charge, and density. The size distribution is best measured by boundary sedimentation in the analytical ultracentrifugation where U.V. absorbing material moves as a single boundary of 100S. Protein, lipid, and acetylcholine coincide on preparative velocity sedimentation in 5-25% glycerol gradients. Charge is measured by electrophoresis in Ficoll density gradients (2-10%). Again, acetylcholine, protein and lipid move as a single component migrating towards the anode at approximately 2.2 x 10^{-3} cm^2/volt-min. Finally, protein, lipid and acetylcholine coincide after equilibrium sedimentation in 20-50% glycerol gradient.

The specific activity of the pure vesicles appears to be between 4 and 6 μmoles acetylcholine/mg protein. Characterization of phospholipid, protein and nucleotide composition of the vesicle has allowed us to estimate a molecular weight of approximately 10^8. From the $S_{20,w}$, and the diameter of the vesicle, the calculated molecular weight is 1.2 x 10^8. Stimulation of the electric organ to exhaustion leads to markedly reduced yield of acetylcholine vesicles, indicating that the purified vesicles are indeed those involved in release. Supported by NIH grant NS 09878. SC (NS01365) and JW (NS05092) are NIH Postdoctoral Fellows.

664 SYNTHESIS OF (Na^+,K^+)-ACTIVATED ADENOSINE TRIPHOSPHATASE. Lynn Churchill and Lowell E. Hokin*, Dept. Pharmacol., Univ. of WI Med. Sch., Madison, WI, 53706.

The synthesis of (Na^+,K^+)-activated adenosine triphosphatase ((Na^+,K^+)-ATPase) has been studied in the electric organ of the electric eel, Electrophorus electricus. In vivo injections of L-(3,4-(n)-^{3}H)-valine into the Main organ and incubations in vitro of this label into isolated groups of Sachs organ cells have been utilized to label the enzyme. Purification of the enzyme has been achieved utilizing modifications of previously published procedures (Dixon and Hokin, Arch. Biochem. Biophys. 163, (1974) 749). In vitro incorporation into the trichloroacetic acid (TCA) precipitate of homogenate (-Δ-) and the large (-o-) and small (-●-) subunits of (Na^+,K^+)-ATPase is illustrated in Fig. 1. The TCA precipitate shows immediate and rapid incorporation; whereas, the (Na^+,K^+)-ATPase subunits show a 2.5-3 hour lag period prior to incorporation. Similar results were observed with the in vivo injections, demonstrating that the lag time is not an artifact of Sachs organ cell isolation. Since our isolation procedure could select for (Na^+,K^+)-ATPase subunits that have already assembled into the plasma membrane enzyme, the lag period could represent the time required for transport and assembly of the subunits. Similarity in the lag period for the large and small subunits suggests that either the routes of transport are similar or assembly into the plasma membrane is the rate-limiting step.



665 MEMBRANE STRUCTURE OF DEVELOPING CHICK MUSCLE FIBERS IN REGIONS WITH HIGH AFFINITY FOR α-BUNGAROTOXIN. S. A. Cohen and D. W. Pumplin. BBB, NICHD, and LNNS, NINCDS, NIH, Bethesda, Md 20014.

A method employing polyvinyl alcohol for the freeze-fracture of monolayers of cells in tissue culture (Pauli et al, JCB 72,763) was modified for use with low-density cultures of chick muscle cells. The method allowed cells to be grown in normal fashion on collagen-coated glass cover slips, and fractured essentially all the muscle fibers along their entire lengths, yielding complementary replicas of nearly 50% of the membrane. Thus, we could observe variations in structural features over large areas of membrane, as well as study those features which occurred relatively rarely. Furthermore, we could reliably localize, in replicas, regions of fibers which were previously observed by high-resolution Nomarski and fluorescence microscopy. Structural features included openings in the membrane, represented by pits (25 nm diameter) in the cytoplasmic leaflet and by corresponding "volcanos" in the external leaflet. These were often found in groups of 2-7 having a nearest-neighbor spacing of about 85 nm. External leaflets had a relatively low density of randomly-dispersed particles in a range of sizes. Cytoplasmic leaflets had two distinctive types of larger particles and a background of randomly-distributed smaller particles. Round-topped particles (7 nm) were found in loose aggregates (1000/μm^2) associated with slightly curved ridges. Angular particles (10 nm) were most conspicuous in closely-packed clusters (2500/μm^2) in which these particles were arranged in rows. In fibers of control cultures, such clusters contained 20-50 particles, and were spaced at random intervals >1μm. Fibers grown in the presence of tetrodotoxin, an agent known to increase the number of cholinergic receptors, contained larger areas of membrane (2-5 μm diameter) in which angular particles were numerous. Such areas contained a number of clusters of 5-50 particles each. They were sharply defined by the edges of the outermost clusters rather than by a gradually decreasing density of individual particles. Membranes appeared relatively smooth, and other types of particles did not aggregate, indicating that the clusters were not an artifact of poor freezing. Furthermore, using the fluorescent label tetramethylrhodamine coupled to α-bungarotoxin, we have identified (in cultures treated with TTX) regions of muscle fibers having a high density of cholinergic receptors. When freeze-fracture replicas of these fibers were examined, groups of clusters of large angular particles were found in the specific locations previously identified by their fluorescence. The association of aggregates of large angular particles with binding of a ligand specific for cholinergic receptors suggests that these particles may be the ultrastructural correlate of these receptors.

666 UDP-GALACTOSE: CERAMIDE GALACTOSYLTRANSFERASE IN A RAT CNS AXOLEMMA-ENRICHED FRACTION. E. Costantino-Ceccarini, A. Cestelli* and G. H. De Vries. Dept. of Neurology, Albert Einstein Coll. Med., Bronx, N.Y. 10461 and Dept. Biochemistry, Med. Coll. Va., Richmond, Va. 23298.

A CNS axolemma-enriched fraction (AXL) was prepared from 25 day old rat brain by density gradient separation of an osmotically shocked preparation of purified myelinated axons. This fraction has been shown to be enriched in surface membrane marker enzymes and shows specific binding of tetrodotoxin (Trans. Am. Soc. Neurochem. 7:223, 1976). Since more than 20% of the lipid in the axolemmal fraction is galactolipid we were interested to know whether some of the galactolipid could be synthesized by the AXL itself. AXL consistently showed activities of galactosyl transferase which were similar to that of microsomes. Since the axolemma is derived from a different cellular type we investigated the possibility that the enzyme could be different from that found in the myelin and microsomes (Brain Res. 93, 358, 1975). No differences in the pH optimum have been found. However some differences were found in the divalent cation requirement for optimal activity. The effect of increasing temperature on the activity of the enzyme present in the different fractions was investigated. The rate of inactivation of the enzyme present in AXL was different from that of either myelin or microsomes. These data suggest that the UDP-galactose: ceramide galactosyltransferase in the axolemma-enriched fraction is different from that of the myelin or microsomes. (Supported by NIH grants NS 10821-04, NS 10885, NS 12807: NSF grant BNS 76 00925, and a grant from the Alfred P. Sloan Foundation.)

667 KINETICS OF LOCAL ANESTHETIC ACTION IN VOLTAGE-CLAMPED FROG MYELINATED NERVE. Kenneth R. Courtney, Joan J. Kendig* and Ellis N. Cohen*. Department of Anesthesia, Stanford University School of Medicine, Stanford, CA 94305.

Local anesthetic agents block nerve conduction by complexing with a receptor site associated with the sodium channel. Previous studies have shown that lipid insoluble, quaternary local anesthetic analogues can bind to and unbind from the receptor only when the channels are open. This requirement is reflected in the observation that the increment of sodium channel block produced by a channel-opening depolarization (frequency-dependent block) does not decrease over time. While local anesthetics of low lipid solubility such as QX-572 (quaternary) and GEA 968 (tertiary) also preferentially interact with open channels, they show in addition a slow interaction with closed channels. Frequency-dependent increments in channel block do diminish over time, relaxation time constants for these two agents ranging from 10 to 100 sec for doses which block about half the sodium conductance in the rested nerve. Lidocaine, a local anesthetic agent of intermediate lipid solubility, displays a faster interaction with closed channels, relaxation time constants measuring 0.1 to 1 sec at equi-effective doses. These observations suggest that the rapidity of interaction of local anesthetic agents with closed channels may be correlated with lipid solubility. This hypothesis has been tested by exposing voltage clamped frog nodes of Ranvier to bupivacaine, a local anesthetic agent of high lipid solubility at a dose (50μM) which blocked about half the sodium conductance in the rested nerve. However, this agent was found to have a slow rather than a fast interaction with closed channels, not unlike that observed for the low lipid soluble agents QX-572 and GEA 968, and much slower than that observed with lidocaine. The relaxation time constant associated with binding to and unbinding from closed channels was about 50 sec for nodes held at -80 mv and 10°C. We therefore propose that local anesthetics of intermediate lipid solubility show the greatest facility for fast interactions with closed channels, while agents at both the low and high extremes of lipid solubility react relatively slowly. This information should prove useful in determining the microscopic nature of the local anesthetic binding site in the sodium channel. These characteristics are of importance with respect to the frequency-dependent blocking capabilities of local anesthetics in nerve and cardiac tissues, and thus to the analgesic and antiarrhythmic properties of these agents. (Supported by NIH grants GM-22113 and NS-13108)

668 INTRAMEMBRANOUS PARTICLE CHANGES IN TRITON X-100 TREATED PNS MYELIN. M. J. Cullen, R. G. Peterson and H. deF. Webster. NIH, Bethesda, MD 20014 and Dept. Neurobiol. and Anat., Univ. Texas Med. Sch. at Houston, Houston, TX 77025.

Sciatic nerves from young mice were incubated for 4-8 hrs. in 0.5% Triton X-100 in 0.5M ammonium acetate, a solution known to solubilize P_1 and P_2 myelin basic proteins. As previously noted (Peterson, 1976), treated nerves showed extensive splitting and unraveling of the myelin sheath along the major dense line. Some small areas of compact myelin remained. In freeze-fracture replicas, areas of myelin with lamellar splitting were free of intramembranous particles while areas of particle-rich membrane were associated with the patches of compact myelin membrane. Short fixation of 15 mins. to 2 hrs. was sufficient to stabilize the myelin membrane and prevent the Triton X-100 effects even when incubation was extended to 20 hrs. Controls, both normal and 0.5M ammonium acetate treated nerves, had predominantly conpact myelin sheaths with intramembranous particle-rich membrane leaflets.

The data suggest that Triton X-100 alters the compact structure of myelin. In areas where lamellae are split and separated, there is a loss of intramembranous particles. Some of these intramembranous particles may be associated with the P_1 and P_2 proteins believed to be located in the major dense line region of compact myelin.

669 HYPEROXIA AND MEMBRANE POLARIZATION: COMPARED WITH ANOXIA. John Cullerton* and Jacob Zabara. Dept. Physiol./Biophysics, Temple University Hlth. Sci. Cntr., Philadelphia, PA 19140.

Although it has been demonstrated that the compound action potential is depressed in hyperoxia, the relationships to membrane polarization and similar effects in anoxia remain unknown. The compound action potential (A.P.) and the demarcation potential (D.P.) from frog (Grass and Bullfrog) sciatic nerves were amplified and displayed on a Tektronix RM 564 dual channel storage oscilloscope via a Tektronix RM 122 preamplifier. Stimuli and polarizing currents were generated by a dual channel Grass S 8 stimulator with two stimulus isolation units. Continuous recording was achieved by construction of leads in an epoxy seal in the wall of the pressurization tank (Bethlehem Corporation) ending in silver-silver chloride electrodes. Temperature was measured with a mercury bulb thermometer placed in the pressure tank and observed through a glass port. The pressure was in pounds per square inch gauge and controlled by adjusting the pressure-reducing valve at the oxygen cylinder. In order to develop reliably a stable D.P., isotonic KCl was applied to the tied end of the nerve while it was stored overnight with the rest of the nerve kept on Ringer's soaked gauze.

The effect of hyperoxia (9 ATA) to diminish the A.P. and D.P. could be reversed by continuous anodal polarization, which, over a period of minutes, restored the potentials to their control value. Discontinuance of the anodal polarization resulted in a resumption of the decline of these potentials. This effect of anodal polarization could be exhibited for a period of several hours. The threshold varied inversely with the change in the D.P. A steady and sizeable increase in threshold indicates the initiation of membrane deterioration. Polarizability, as tested by brief rectangular pulses producing catelectrotonus, decreases when the hyperoxic effect is unopposed by anodal polarization and corresponds directly to the change in the D.P. This anodal polarization can antagonize the hyperoxic caused decay of the A.P., but not restore it after conduction has ceased. The decrease in the D.P. indicates membrane depolarization as is observed in anoxia. Further, the action of anodal polarization to maintain membrane polarizability and the A.P. is similar in anoxia.

If reducing equivalent depletion is the cause of the depolarization, the anodal polarization may act to supply (unstably) reducing equivalents. Also, metabolic depletion appears to produce a faster time course of oxygen toxicity in this preparation. Depolarization may expose the membrane to an accelerated oxygen toxic effect. Thus, destructive damage of the plasmalemma is not primary in either hyperoxia or anoxia, but rather appears to arise from a deficiency in the metabolic supply to the membrane.

670 SCORPION NEUROTOXINS AS AFFINITY REAGENTS FOR SOLUBILIZED VOLTAGE DEPENDENT SODIUM CHANNEL ELEMENTS. W. J. Culp*, D. Welch*, D. Mayka* and J. Taylor*. (SPON: H. Borison). Dept. Biochem., Dartmouth Med. Sch.

The physiological actions of neurotoxins purified from the venoms of two species of scorpion have been defined by intracellular recording from a variety of excitable tissues and by voltage clamp studies on the frog Ranvier node. Purified Leiurus quinquestriatus neurotoxins selectively inhibit the onset of sodium inactivation. This inhibition of "h" gating is reversible. Centruroides sculpturatus neurotoxins specifically alter the voltage dependence of sodium activation, or "m" gating, as described for the whole venom of this species by Cahalan (J. Physiol. 244, 511 (1975)). Biochemical studies indicate that these physiologically distinct neurotoxins have a number of structural similarities including molecular weight, isoelectric pH values, spectral properties and sensitivity to oxidation.

Defined neurotoxins from both species of scorpion have been successfully radiolabeled. These toxins have been employed as affinity reagents in an attempt to identify "m" and "h" gating components solubilized from eel electroplaque membrane. Sucrose gradient studies demonstrate the presence of presumptive voltage dependent sodium channel gating elements in these extracts which exhibit high affinity neurotoxin binding. Related studies have provided evidence for a somewhat lower affinity interaction between Leiurus neurotoxins specific for "h" gating and the acetylcholine receptor, both in situ in clonal muscle cell lines and in detergent extracts of electroplaque membrane.

671 cAMP-DEPENDENT PHOSPHORYLATION OF ENDOGENOUS SUBSTRATES IN SYNAPTIC PLASMA MEMBRANES. A. de Blas, Y-J. Wang and H.R. Mahler. Indiana Univ., Bloomington, IN 47401.

cAMP (0.010 mM) stimulates the phosphorylation of six endogenous protein substrates in synaptic plasma membrans (SPM), using 0.01 mM (^{32}P)ATP as donor. These polypeptides have tentative Mol.wt. of 340,000, 80,000, 75,000, 66,000, 54,000 and 50,000 and are designated proteins (or bands) 1, 2, 3, 4, 5 and 6, respectively. We have followed the presence of these endogenous substrates in different cortex subfractions and find Band 6 to be ubiquitous, while band 4 is restricted to SPM. Analogous phosphorylation of membrane proteins is not seen in purified mitochondria from cortex or in crude mitochondrial fractions from cerebellum or liver. In SPM a peak of phosphorylation is reached for all substrates within 5-10 s. Dephosphorylation of Band 6 is faster (within 30-60 s) than the rest, which remain fully phosphorylated for at least 2 min. When the concentration of ATP is raised to 0.5 mM the phosphorylation of Band 6 decreases sharply with no effect on the other bands. Deoxycholate in concentrations $\geq$ 0.5% inhibits both phosphorylation and dephosphorylation of the cAMP-responsive bands over the cAMP-independent polypeptides. Phosphorylation of Bands 2 and 3 appear most susceptible to this inhibition. Triton X-100 at concentrations $\geq$ 0.5% stimulates phosphorylation of all protein substrates in SPM, except for that in Bands 2 and 3, which appears specifically inhibited. Treatment with this detergent does not lead to the selective solubilization of any of the phosphate acceptors. Phosphorylation stimulated by cAMP of proteins in the SPM is not modified by extraction of the latter with either chloroform-methanol or treatment with phospholipases A and C. However, preincubation of the membrane with either of these enzymes results in stimulation of the phosphorylation of all bands susceptible to this modification, either in the absence or presence of cAMP. All these phosphoproteins appear to be degraded by trypsin. The stimulation of phosphorylation of Bands 1 - 6 exhibits a pH optimum around 6, with bands 5 and 6 the most sensitive to variations in pH. Potassium or phosphate ions stimulate phosphorylation in a non-selective fashion, except for that of Band 6, which is inhibited by phosphate. Different transmitter-related agonists and antagonists for muscarinic and nicotinic cholinergic, and for beta-adrenergic receptors do not affect phosphorylation in the presence, or absence, of cAMP. It is also unaffected by Na and/or K ions.

672 LIPID COMPOSITION OF NORMAL HUMAN CNS AXOLEMMA-ENRICHED FRACTIONS. G.H. De Vries, C.J. Zmachinski*, W.J. Zetusky*, and V.P. Calabrese Depts. of Biochemistry and Neurology, Med. Coll. of Va. and McGuire VA Hospital, Richmond, VA 23298

Axolemma-enriched fractions were isolated from human white matter via a purified preparation of myelinated axons which were osmotically shocked and fractionated on a discontinuous density gradient to yield myelin, and two membrane fractions at the 0.8 M/1.0 M and 1.0 M/1.2 M sucrose interfaces (axolemma-enriched fractions). The myelin lipid is comprised of 25% cholesterol, 45% phospholipid and 30% galactolipid. The 0.8/1.0 axolemma-enriched fraction lipid is comprised to 30% cholesterol, 28% galactolipid plus 42% phospholipid. The 1.0/1.2 axolemma-enriched fraction lipid is comprised of 23% cholesterol, 30% galactolipid and 47% phospholipid. The myelin ethanolamine phosphatides comprised 17% of the total lipid weight with 75% of the total ethanolamine phosphatides in the plasmalogen form; choline phosphatides comprised 11% of the total myelin lipid with 7% of the total choline phosphatides in the plasmalogen form. Sphingomyelin comprised 7% of the myelin lipid with lesser amounts of phosphatidyl serine and phosphatidyl inositol. The 0.8/1.0 fraction has about the same amount of choline phosphatides, phosphatidyl serine and phosphatidyl inositol as myelin but the fraction contains only 14% ethanolamine phosphatides. The 1.0/1.2 fraction is distinctly different in its phospholipid composition from myelin and the other axolemma-enriched fraction. Choline phosphatides comprise 16% of the total lipid with about 15% in the plasmalogen form; ethanolamine phosphatides comprise about 16% of the total lipid with over 50% of the total ethanolamine phosphatides in the plasmalogen form. Sphingomyelin comprises 4% of the total 1.0/1.2 lipid and the levels of phosphatidyl inositol and phosphatidyl serine are similar to myelin and the 0.8/1.0 fraction. Expressed on a weight basis the ratio of choline to ethanolamine phosphatides is 0.64 in myelin, 0.83 in the 0.8/1.0 fraction and 1.06 in the 1.0/1.2 fraction. Gangliosides comprise 0.5% of the total lipid in the 0.8/1.0 fraction and 1% of the total lipid in the 1.0/1.2 fraction. We conclude that the lipid composition of the axolemma-enriched fractions resembles myelin in the galactolipid and plasmalogen content, however, the composition is distinctly different in having a higher lecithin and ganglioside content and somewhat lower ethanolamine phosphatide content. The lipid composition and the low levels of both 2'3' cyclic nucleotide 3' phosphohydrolase and myelin basic protein lead us to believe that not all the galactolipid in these fractions is due to myelin contamination but that it is an intrinsic component of the mammalian axolemma.

673 REGIONAL DISTRIBUTION OF IONIC MECHANISMS IN THE BARNACLE PHOTORECEPTOR MEMBRANE. Duane R. Edgington* and Ann E. Stuart. Dept. Neurobiology, Harvard Med. School, Boston, MA 02115

Properties of the somatic, axonal and presynaptic membranes of photoreceptors of the giant barnacle (B. nublius) were compared by recording intracellularly from each region. Each of these regions could be superfused separately or surgically isolated from one another. Previous work has shown that these cm-long neurons have a high resistivity membrane that allows voltage changes generated by light in the somata to spread decrementally along the axons to the presynaptic terminals. In the terminals, a voltage-sensitive Ca current apparently associated with transmitter release is normally opposed by a tetraethylammonium (TEA)-sensitive K current but can become regenerative in mM TEA (Ross and Stuart, Biol. Bull. 151, 427 (Abs) 1976 and in prep.). We show here that the Ca current and the TEA-sensitive K current, and in addition, a TEA-insensitive K current, are present in the soma and axon as well as in the terminals.

Although the axons conduct decrementally in normal saline, a Ca action potential (AP) can be elicited in the axon in the presence of TEA. The axonal AP has a slower rate of rise and higher threshold than the terminal AP. The axonal AP is blocked by 5 mM Co while 15-20 mM Co is required to block the terminal AP; the dose-response relations suggest that Co is competing with Ca in both regions. Thus a given depolarization appears to generate a smaller Ca current in the axon than in the terminals. The soma also displays a Ca AP when bathed in TEA, with properties similar to the axonal AP. We conclude (1) that Ca channels are not localized exclusively in the synaptic membrane but (2) that they are present in lower density in the soma and axon than in the terminals.

The effects of TEA on Ca APs indicate that TEA-sensitive K channels must also be present in all regions of the membrane. In the terminal, the AP is followed by an undershoot of long duration (seconds) that is present even in 400 mM TEA. This undershoot is due to a conductance increase whose reversal potential varies with extracellular K concentration. Ca APs elicited in somata and axons with TEA are also followed by long-lasting undershoots. Thus the TEA-insensitive K channels like the TEA-sensitive channels and Ca channels are present throughout the photoreceptor membrane.

674 SODIUM-POTASSIUM ATPASE IN BRAIN CAPILLARIES. Howard M. Eisenberg and Robert L. Suddith*. The Division of Neurosurgery and The Marine Biomedical Institute, The University of Texas Medical Branch, Galveston, Texas 77550.

In these studies we examined the capacity of brain capillaries to actively transport Na^+ and K^+. In other tissues it has been clearly shown that active transport of these ions is intimately related to Na-K ATPase and in fact that the magnitude of this transport may be related only to the amount of the enzyme that is present. Brain capillaries were isolated from mouse cerebral hemisphere by a process of homogenization, serial filtration and differential centrifugation. Subcellular fractions were incubated with ATP in the presence or absence of ouabain (1mM). The activity of Na-K ATPase, expressed as uM of inorganic phosphorous released per mg. of protein per hour was taken to be the difference in activity found in the absence and in the presence of ouabain. Na-K ATPase activity was similarly determined in subcellular fractions made from human umbilical endothelial cells and from C_6 astrocytoma cells. Na-K ATPase activity in the brain capillary preparation was 9.07 ± 1.98. This activity was considerably greater than that measured in preparations made from umbilical vein endothelium, 0.024 and slightly greater than that determined in preparations of C_6 astrocytoma cells, 1.16. The amount of phosphorous liberated by the brain capillary preparation increased with time and increased with substrate concentration following Michaelis-Menton kinetics. Radiographs made following incubation of unlysed brain capillaries with tritiated ouabain showed ouabain binding along the capillary segments.

There are reasons to suggest that similar active processes are involved in the formation and initial regulation of K^+ concentration in cerebrospinal fluid (CSF) and brain extracellular fluid (ECF). The fluids are similar, if not identical. Brain ECF has been shown to be a significant source of CSF, a flow demonstrated even when osmotic conditions favored a flow in the opposite direction. An active ouabain sensitive Na^+ transport is the driving force for CSF formation by the choroid plexus ependyma and that although regulation of CSF K^+ concentration is complex, there is evidence for regulation of the nascent fluid at the choroid plexus. Although brain ECF and CSF are similar, it is unlikely that the CSF has a total influence on K^+ concentration of the brain ECF. The finding of significant levels of Na-K ATPase in brain capillaries supports this idea of similar active processes and suggests that brain capillary endothelium may be in some ways functionally similar to choroid plexus ependyma.

Supported by PHS Grants NS07377 and NS11255

675 STUDIES ON GANGLIOSIDE PATTERNS AND CHOLERA TOXIN-PEROXIDASE LABELING OF AGGREGATING CELLS FROM THE CHICK OPTIC TECTUM. Edgar L. Engel, John G. Wood, and Frances I. Byrd*. Dept. Anat., Univ. of Tenn. Ctr. for the Hlth. Sci., Memphis, TN. 38163.

The changes in ganglioside patterns in aggregating cells from the chick optic tectum have been examined, and these changes correlated with the cytochemical localization of cholera toxin-peroxidase binding sites on these cells and in the developing rat cerebellum. Tectal cells from 6- and 8-day embryos were studied in reaggregating cultures (Seeds, Proc. Natl. Acad. Sci., USA. 68: 1858, 1971), since changes in tectal cell surface properties have been shown to occur during these embryonic stages (Gottlieb, et al., Proc. Natl. Acad. Sci., USA. 71: 1800, 1974). Thin layer chromatograms (TLC) of gangliosides from cultures 1, 7 and 14 days in vitro (DIV) were compared with patterns from optic tecta of corresponding embryonic ages. Aggregates and dissociated cells were also fixed and treated with cholera toxin-peroxidase to localize its presumed binding site, G_{M1} (Manuelidis, et al., Science 193: 588, 1976). These in vitro cytochemical studies were compared to labeling of fixed tissue slices from developing rat cerebellum.

Cultures from both 6- and 8-day tectal cells showed increases in the amount of ganglioside-sialic acid, but these increases lagged behind those occurring in vivo. Densitometric scans of TLC patterns of gangliosides from dissociated cells, aggregates and optic tecta revealed changes in the relative proportions of the various gangliosides as development proceeds both in vitro and in vivo. Early stages in the formation of aggregates have G_{D3} as the predominant ganglioside. After 1 week in culture, G_{D3} has decreased proportionately, and G_{D1a} has become the major ganglioside. G_{M1} and G_{T1} increase from initially low levels over the time periods studied. Parallel changes in ganglioside profiles occur in vivo.

Cholera toxin-peroxidase bound uniformly to the processes and soma of aggregating, 8-day tectal cells throughout the culture times studied. Labeling of dissociated cells and aggregates (1 DIV) from 6-day tecta appeared diminished in comparison to the older stages. In vivo studies on the developing rat cerebellum demonstrated labeling of plasma membranes of all cell types. This localization includes plasma membranes of developing processes, growth cones, synaptic membranes and the synaptic cleft.

The cytochemical observations indicate a rather uniform distribution of cholera toxin-peroxidase receptors on developing neuronal membranes. Other changes in gangliosides observed may be related to such events as the formation of synaptic junctions in tectal cell aggregates and the optic tectum. Supported by USPHS Grants 5T01-GM00202 and NS-12590; Sloan Fellowship (JGW).

676 IMPLICATIONS OF A CURRENT-CONDUCTANCE CORRELATION ON THE OPERATION OF THE K-CHANNEL OF THE SQUID GIANT AXON Jurgen F. Fohlmeister* (SPON: R.E. Poppele). Lab. of Neurophysiology, Department of Physiology, University of Minnesota, Minneapolis, MN 55455 and Marine Biol. Lab., Woods Hole, Mass. 02543.

Voltage clamp studies were performed on internally perfused giant axons of the squid Loligo pealei, bathed in artificial sea water solutions containing sufficient TTX to completely block the sodium channel. Potassium current was measured as a function of time with the internal and external K^+ concentrations varied isotonically in the ratios c_K^i/c_K^o = 150/50, 300/50, 300/10 and 450/5 (milliequivalents top and bottom) providing a wide range of E_K. At selected times following the test clamp step and covering the range 0.5 to 30.0 ms, membrane potential was stepped an additional ΔE = 10mV, and instantaneous conductance $g_K \equiv \Delta I/\Delta E$ was derived. In this way we obtained families of curves g(t), I(t) for test potentials E_T = -20, +5, +30, +55mV (inside relative to outside). Plotting g_K versus I_K for each given E_T, we found that all early time (t<4ms) points fell on the same straight line, independent of the c_K^i/c_K^o ratio. This result is in contrast to an I_K dependence of $g_K(E-E_K)$ with g_K explicitly dependent only on E and t. Long time (t>6ms) points fell on curvilinear lines consistent with periaxonal K^+ accumulation.

According to transport theory g_K^{-1} is proportional to $\int_{\text{ai}}^{\text{o}} \frac{dx}{c_K(x)\,u_K(x)}$ when the membrane is near thermodynamic steady state, $u_K \equiv K^+$ mobility. Under constant field and constant u_K assumptions, the "independence principle" equation of Hodgkin-Katz does predict nearly the correct ΔI's and the accompanying required changes in $c_K(x)$. These assumptions however lead to incorrect slopes of early time g_K vs I_K curves. Modifying the constant field to include an "image force" induced energy barrier (heights in the range 0 to 10 kT) results in no improvement of the g_K vs I_K slopes. A sizeable barrier may in fact lead to unrealistically large diffusion constants or intramembrane concentrations needed to support the required current I_K. The correct g_K-I_K slope results from a non-uniform mobility, $u_K(x)$, such that the mobility is reduced near the axoplasmic side, relative to the periaxonal side.

677 CONDUCTION VELOCITY AFTEREFFECTS OF SPIKE ACTIVITY: QUANTITATIVE STUDIES. Stephen A. George and Peter T. Silberstein*. Amherst College, Amherst MA 01002.

The aftereffects of a given impulse can cause a subsequent one to travel at a different velocity, resulting in changes in interval between the spikes during propagation. The theoretical work described here was designed to provide insight into the mechanisms responsible for the conduction velocity (CV) changes, and to study the effects of the resulting changes in interspike interval on the statistical description of spike trains.

The Hodgkin-Huxley equations for propagated action potentials in the squid axon, and the similar set of equations developed by Dodge and Hille for frog sciatic nerve fibers, were solved on a computer using ordinary iterative methods without approximations. Results were as follows: (i) Conduction velocity of second spike. The squid axon equations predicted substantial refractory slowing of a 2nd impulse initiated within 15 msec after the 1st one, and slightly supernormal CV for a 2nd spike initiated between 15.5 and 24 msec after the 1st one. The maximal effect was a 1.5% CV increase at 19 msec, which is much less than the effect observed in many types of fiber. The effect was even smaller in computations using the Adelman-Palti model for K^+ accumulation around the fiber. The equations for sciatic nerve predicted refractory slowing but no supernormal CV, although that phenomenon has been found experimentally in sciatic nerve fibers. (ii) Excitability and conduction velocity. The magnitude and time course of post-spike CV changes closely paralleled the changes in excitability as determined by threshold computations. (iii) Displacement of initial voltage. In squid, the CV of a single spike decreases monotonically with increasing levels of maintained depolarization of the membrane before the stimulus pulse. In contrast, depolarizations of up to 9 mV caused an increase in the CV of sciatic nerve spikes; for larger depolarizations, the effect was reversed. In summary, the increases in CV during the supernormal period observed in many fibers cannot be accounted for by the membrane mechanisms incorporated in the Hodgkin-Huxley model for impulse propagation, as elaborated for the frog and squid axons.

In a separate study, CV aftereffect data was applied to two types of simulated spike train with known initial statistical characteristics (Poisson trains, and trains generated by a clock with added random delays). The interval histograms and serial correlation coefficients for both types of train showed substantial changes after propagation, in cases with certain initial interval distributions. The changes in spike train parameters were large enough to affect the transmission of information in fibers that use an interval code.

678 RECONSTITUTION OF ACTIVE ION TRANSPORT BY PURIFIED SODIUM AND POTASSIUM ION-ACTIVATED ADENOSINE TRIPHOSPHATASE. Stanley M. Goldin* (SPON: E. Henneman). Harvard Medical School, Boston, MA 02115.

Purified sodium and potassium ion-activated adenosine triphosphatase (NaK ATPase) was reconstituted into phospholipid vesicles. The resulting in vitro transport system consisted of NaK ATPase associated with single bilayer vesicles, primarily 400A-600A in diameter, as determined by Sepharose gel-filtration. An average of only 5% of the total NaK ATPase activity in this system was unreconstituted. About half of the reconstituted NaK ATPase was oriented "inside out" with respect to its in vivo orientation: externally added ATP generated active uptake of Na^+ ions into the vesicles, inhibitable by internally incorporated but not externally added ouabain. The vesicle Cl^- permeability was more than tenfold higher than the Na^+ and K^+ permeabilities; the Na^+ and K^+ permeabilities were equal. Scans and amino acid analysis of SDS gels of the reconstituted NaK ATPase preparation showed that the two polypeptides of the NaK ATPase preparation showed that the two polypeptides of the NaK ATPase constituted ~95% of the vesicle protein; no other protein component was more than 2% of the vesicle protein.

This in vitro transport system was sufficiently characterized to prove that the reconstituted NaK ATPase catalyzes active countercurrent K^+ transport coupled to active Na^+ transport; the stoichiometry of Na^+/K^+ pumped/ATP hydrolyzed is ~3/2/1, as observed in red cell and nerve. The purity and high reconstitution efficiency of the NaK ATPase enable one to unambiguously demonstrate that no protein of molecular weight >12,000 besides the NaK ATPase can be involved in this transport.

679 MORPHOLOGIC INTERRELATIONSHIPS BETWEEN MITOCHONDRIA AND THE ENDOPLASMIC RETICULUM OF NEURONS. Maryanna Henkart. Behavioral Biology Branch, NICHD, NIH, Bethesda, Maryland 20014.

Mitochondria have been thought to be the primary cellular organelle responsible for Ca sequestration in neurons, while results from this and other laboratories have implicated the endoplasmic reticulum (ER) in that function. Thus, it was of interest to study the morphologic interrelationships of these two organelles. Using a stain selective for membranes, the mitochondria and ER have been studied in serial thin sections of mouse spinal cord and dorsal root ganglion cells in culture, in ganglion cells of Aplysia and snail, and in the squid giant axon. Mitochondria are often enwrapped by ER, and there are often images of apparent continuities between the ER and mitochondrial outer membranes. Although these images in thin sectioned material are frequent and suggestive, they are ambiguous because the continuities between the lumens of ER and outer mitochondrial space are smaller than the thickness of a section. In addition to the images of apparent continuities the following observations suggest that the continuities are real: a) Mitochondrial outer membranes sometimes appear to be continuous with the nuclear envelope. b) Mitochondrial outer membranes sometimes form subsurface cistern-like junctions with the surface membrane adjacent to or apparently continuous with subsurface cisterns of ER. c) In swollen or lysed cells membrane continuities can easily be traced between the mitochondrial outer membrane and rough ER. d) In neurons prepared for histochemical demonstration of peroxidase, reaction of product is sometimes found in the space between the inner and outer mitochondrial membranes. This is due to endogenous oxidases associated with mitochondria. In the vicinity of these stained mitochondria, reaction product is sometimes also seen in the nearby ER lumen. Thus, either the endogenous oxidase enzymes are localized both in mitchondria and that small area of adjacent ER, or there is a pathway for diffusion of reaction product from the mitochondria into nearby ER. Freeze fracture images are being studied to clarify the nature of these continuities. These observations demonstrate a morphologic pathway for the direct exchange of materials between the lumen of the ER and the space between the inner and outer mitochondrial membranes. Such continuities may be transient and may not involve all mitochondria.

This interaction between the ER and mitochondria could be important in the control of intracellular Ca, but could be involved in many other cellular processes as well.

680 CALCIUM ACTIVATED AFTERHYPERPOLARIZATION IN HIPPOCAMPAL SLICES MAINTAINED IN VITRO. John R. Hotson*, Philip A. Schwartzkroin, and David A. Prince (SPON: T.A. Pedley). Dept. Neurol., Stanford Univ. Sch. Med., Stanford CA 94305.

In CA1 cells of guinea pig hippocampal slices a 125msec intracellular depolarization pulse elicits repetitive action potentials followed by a prolonged afterhyperpolarization (AHP). The AHP has an amplitude of 2-8 millivolts and a duration of 250-1000 msec. A 15-25% membrane conductance increase occurs during the peak amplitude of the AHP. This conductance change then decreases in parallel with the return of the AHP toward the resting membrane potential.

In contrast, direct stimulation of CA3 recurrent Schaffer collaterals evokes a short duration hyperpolarizing potential in CA1 cells which has previously been identified in vivo as an inhibitory postsynaptic potential (IPSP) (Kandel et al., J NEUROPHYSIOL 24:225, 1961). The hyperpolarization associated with the IPSP, but not the AHP, can be attenuated by intracellular injection of chloride. Combining intracellular chloride injection with extracellular ammonium acetate (2mM) perfusion produces further IPSP attenuation. Ammonium acetate is presumed to cause intracellular chloride accumulation by blocking its active extrusion (Lux, SCIENCE 173:555, 1971). This dissociation of the IPSP from the AHP indicates the latter is independent of chloride and, by exclusion, appears to reflect an increased membrane conductance to potassium ions.

Manganese (2mM), a calcium antagonist, reversibly inhibits the AHP and its associated conductance increase. The preceding depolarization-induced repetitive action potentials are unchanged. Synaptic field potentials and postsynaptic potentials are also blocked by manganese. These data indicate that the prolonged AHP is the result of an increase in membrane conductance to potassium which is activated by a preceding calcium influx. Similar hyperpolarizing potentials have been found in various invertebrate and vertebrate preparations (Barret & Barrett, J PHYSIOL 255:737, 1976). This report is the first description of such an AHP in mammalian cortex. It may have functional significance in limiting high frequency neuronal firing and burst generation in epileptogenesis. 681 GLYCOSYLTRANSFERASE ACTIVITIES IN NORMAL AND DENERVATED MUSCLE PLASMA MEMBRANES. Peter L. Jeffrey* and Stanley H. Appel. Jerry Lewis Muscular Dystrophy Center and the Dept. of Neurology, Baylor College of Medicine, Houston, Tx. 77030

Surface carbohydrates have been implicated in cell-cell interaction and cellular adhesion. Following denervation the muscle cell reacquires its capacity for muscle-muscle as well as nerve-muscle interactions. If carbohydrates play a role in the process of intercellular recognition and adhesion, the surface membranes of denervated muscle would be expected to undergo significant changes with respect to carbohydrate content and glycosyl transferase activity.

Plasma membranes were isolated from extensor digitorum longus, soleus, and gastrocnemius skeletal muscles of normal rats and rats denervated for 7 days. Sialic acid content of sarcolemmal membranes increased from 16 to 40 nanomoles per mg after denervation. Hexose content was found to increase from 280 to 980 nanomoles per mg while total hexosamine increased from 30 to 46 nanomoles per mg.

Sialyltransferase activity was measured by the transfer of radioactively labeled sialic acid from CMP-sialic acid to endogenous acceptor present in the membranes or an exogenous acceptor asialofetuin. Galactosyl transferase was measured by transfer of radioactively labeled galactose from UDP-galactose to endogenous or an exogenous acceptor, asialo-agalacto-fetuin. Both enzymes showed maximal activity at pH 6.8, the galactosyl transferase showed a broader optimal activity from 6.3 to 7.4. Enzymes were linear with respect to both time and enzyme concentration under the conditions employed. Endogenous activities of the transferases were less than 10% of those in the presence of exogenously added acceptors in normal muscle membranes and changed minimally on denervation. Sialyl transferase and galactosyl transferase activities towards the fetuin derivatives were increased two-fold after 7 days' denervation in sarcolemmal membranes.

These increases in carbohydrate content of membrane macromolecules are not paralleled by similar increases in membrane polypeptides or lipids. Since in most membrane systems carbohydrates are asymmetrically located and appear to project to the extracellular environment, it appears reasonable to suggest that the increased carbohydrate content of denervated plasma membranes may participate in the process of cell-cell interaction.

682 IN VIVO INHIBITION OF SKELETAL MUSCLE SODIUM PUMP BY OUABAIN IN RATS. George Karpati, Andrew A. Eisen* Stirling Carpenter* and Hanna Pappius* Montreal Neurological Institute, Montreal, Canada.

Ouabain administered to Sprague Dawley rats (15mg/kg body weight) intraperitoneally produced marked weakness of most skeletal muscles, while respiration remained adequate. The paresis started at 10 minutes, reached the maximum at 30 minutes and disappeared by 90 minutes. During maximal weakness, femoral arterial blood pressure was normal, and the ECG showed only S-T segment depression. At this time, ouabain concentration in sera was 5.7×10^{-5} M(N=5) and in plantaris muscles 3.2×10^{-6} M(N=12). Sera removed at the height of the paresis showed a marked rise of K^+ (10.85 mM, N=7) and a modest increase of Ca^{++} (11.31 mg%, N=8) while Na^+concentration declined (137 mM, N=7).

In vivo isometric twitch tension was initially (between 5-15 minutes) potentiated to 137% of the control values; then it progressively declined to 0 at 30 minutes and subsequently recovered exponentially to normal values by about 100 minutes post-injection. The amplitude of the compound action potential followed a similar time course of decline and recovery, but there was no initial potentiation. The action potential amplitude and conduction velocity in the mixed ventral caudal nerve remained normal throughout. The muscle fibres showed no abnormality by histochemistry and EM at the height of paresis.

It is concluded that in rats, ouabain induces paralysis by specific inhibition of the sarcolemmal Na^+ K^+ ATPase,in doses which do not appear to significantly impair cardiac rythm or contractility. Lower concentration of ouabain produces positive inotropic effect of skeletal muscle. These effects of ouabain can be utilized as an in vivo assessment of available functional ouabain binding sites in rat skeletal muscles.

683 MOLECULAR ARCHITECTURE OF CNS SYNAPSES: CHARACTERIZATION AND POSSIBLE FUNCTIONS OF CONSTITUENT PROTEINS. Paul T. Kelly and Carl W. Cotman. Dept. Psychobiol., Univ. Calif., Irvine, CA 92717.

The major polypeptides in isolated synaptic junctions(SJ) and postsynaptic densities (PSD) have been analyzed by two-dimensional polyacrylamide gels. Peptide maps of these major synaptic proteins have been compared to muscle actin, cytoplasmic tubulin and the major neurofilament protein. These results show: (1) α- and β-tubulin present in SJ and PSD fractions are indistinguishable to the subunits of cytoplasmic tubulin, (2) the actin in these subsynaptic fractions is the β- and γ-actin isoproteins found in non-muscle cells and α-actin, characteristic of skeletal muscle, is not detectable, (3) the major PSD polypeptide is distinct from all other known fibrous proteins. Because of its biochemical distinctness we have named the major PSD protein "synapsin". It is proposed that synapsin may be the basic structural backbone of the PSD and may serve as the molecular interface between the dendrite's cytoskeletal network and postsynaptic membrane. Intermolecular disulfide bonds appear to play a critical role in this union.

The presence of actin and tubulin suggests that the synaptic junction may have heretofore undiscovered chemo-mechanical properties. However, in order for this to be the case it is necessary to have the enzymes to catalyze such structural changes. It appears that isolated SJ fractions contain a significant amount of Ca^{++}-stimulated and ouabain insensitive ATPase activity. Although the functional role of this ATPase activity is yet unclear it may represent a myosin-like ATPase system which in conjunction with actin and other constitutents could comprise a synaptic mechano-contractile system. Thus, besides serving a static structural role it is likely that the synapse's cytoskeltal network of fibrous proteins can regulate membrane shape and spine configuration at asymmetric synapses. Ca^{++}-stimulated ATPase could also regulate the amount of tubulin associated with synaptic junctional membranes as it appears a similar enzyme does in regulating tubulin polymerization at the mitotic spindle. The activation of the ATPase may originate from changes in intracellular Ca^{++} caused by presynaptic activity. In this way presynaptic activity may alter postsynaptic structure. 684 PHOSPHOLIPID LABELING IN THE NOCTUID MOTH EAR: A MODEL FOR BIOCHEMICAL STUDIES OF TRANSDUCTION. Patricia L. Kilian* and Jochen Schacht, Kresge Hearing Research Institute, University of Michigan, Ann Arbor, MI 48109.

The mechanism of transduction of vibratory energy into nerve impulses is the basic question in a molecular theory of hearing. In the mammalian inner ear, sound stimulation induces the receptor potential and numerous other bioelectric phenomena in the organ of Corti: afferent and efferent synaptic transmission, generator and action potentials. Biochemical processes possibly associated with these secondary events would obscure those underlying transduction. In contrast, hearing organs in insects are functionally simple and easily accessible. The tympanic organ of the Noctuid moth seems especially suited for such investigations. There are two independent auditory receptor cells in each ear. These are primary sensory cells with no intervening synapses. While pulsed tones trigger receptor and action potentials, continuous tones lead to rapid adaptation of spike activity leaving the receptor potential as the only bioelectric event (Adams and Belcher, J. Acoust. Soc. Am. 56:S40, 1974). This behavior presents an ideal system for biochemical studies of transduction, i.e., sound-induced generation of receptor potential. Results obtained from our species, Agrotis ypsilon, confirm previous electrophysiological findings from other Noctuids. The hearing organ is sensitive to ultrasonic frequencies (highest sensitivity at 40 to 60 kHz) and shows the above adaptation pattern. Biochemical studies demonstrate that this organ is amenable to radiotracer studies. Typically, 5 µl of carrier-free ^{32}P-orthophosphate are injected into the moth's thorax. Moths are sacrificed by injection of glutaraldehyde followed by microwave irradiation. Labeled ATP, phosphoproteins, and phospholipids are measured in the nodular sclerite, a thick strip of cuticle adjacent to the tympanic membrane, and in the scoloparium where the two sensory cells are located. The time course of phospholipid labeling is very similar to that of mammalian inner ear tissues: polyphosphoinositides (phosphatidyl inositol phosphate and diphosphate) are the most highly labeled lipids reaching maximal labeling in 30 min. Phosphatidic acid incorporates less ^{32}P but shows a similar time course while phosphatidyl inositol and ethanolamine have a much slower rate of ^{32}P-incorporation. The polyphosphoinositides are of special interest for an investigation of transduction because their rapid metabolism has been implicated in the control of membrane permeability possibly via binding and release of calcium. Also, their turnover has been shown to be affected by ototoxic drugs. (Supported by grants from The Deafness Research Foundation, the Michigan Memorial-Phoenix Project, and by Program Project Grant NS 05785).

685 MONOSACCHARIDE TRANSPORT IN CAPILLARIES ISOLATED FROM RAT BRAIN. Alan R. Kolber* and Pierre Morell. Biol. Sci. Res. Ctr., Dept. Biochem., Univ. North Carolina Med. Sch., Chapel Hill, N.C. 27514

We have developed a rapid method for the isolation of rat brain microvessels in high yield, and have initiated a kinetic study of monosaccharide uptake by these capillaries.

Pooled whole brains of 25-day old Sprague-Dawley rats were minced and then homogenized in a phosphate-buffered Krebs-Ringer medium containing 0.5% polyvinyl pyrollidine (PVP-Ringer). Material passing through a 351 µ nylon screen, but retained on a 44 µ screen, was suspended in 1.8 M sucrose in PVP-Ringer; and these capillaries were further purified by floatation ultracentrifugation in a 1.8 M-1.2 M-sucrose discontinuous gradient in PVP-Ringer. The capillary fraction contained about 0.5% of the total brain homogenate protein.

Monosaccharide uptake experiments were performed in a 30 µl total incubation volume containing 75 µg protein and 1 µCi of [^{3}H]sugar in PVP-Ringer. The reaction mixtures were incubated for various lengths of time at 30°C and the reactions were terminated by addition of 3 ml ice-cold PVP-Ringer and collection of the capillaries on a Millipore filter. The filters were washed, dried, and the radioactivity determined by liquid scintillation counting.

The kinetic parameters examined to date suggest that monosaccharide uptake by isolated rat brain capillaries fulfills the following criteria for "carrier-mediated" diffusion: (1), 3-O-methylglucose (3-OMG) uptake into isolated capillaries exhibits saturation kinetics — the half-times of uptake for several concentrations of this sugar vary more than predicted on the basis of simple diffusion; (2), kinetic analysis of stereospecific inhibition of 3-OMG uptake by 2-deoxy-D-glucose indicates that this sugar has a higher affinity for transport than 3-OMG; (3), 3-OMG uptake is inhibited by the glucoside, phloridzen, a specific inhibitor of carrier-mediated monosaccharide transport; (4), isotope distribution data suggests that 3-OMG distributes in the available capillary (cell) water space to a concentration not exceeding that in the external medium — the uptake is non-concentrative.

686 CHOLESTEROL CONTENT MODULATES THIOPENTAL'S MEMBRANE/BUFFER PARTITION COEFFICIENT. K. Korten* and K.W. Miller*. (SPON: E.T. Hedley-Whyte). Harvard Medical School, Depts. Anaes. & Pharm., Peter Bent Brigham and Massachusetts General Hospitals, Boston, Massachusetts.

General anesthetics have long been thought to act by a mechanism involving non-specific dissolution into the hydrophobic regions of membranes, yet the role that membrane composition plays in modulating the amount of anesthetic adsorbed, and the possible relation of this to the specificity of anesthetic action, has not been systematically explored. We report here membrane/buffer partition coefficients (λ) of thiopental in a number of biological membranes and in artificial membranes of defined lipid composition.

λ was determined at 25°C and pH 6.6 using ^{35}S-thiopental. After equilibration suspensions of human erythrocyte ghosts, rat liver mitochondria or microsomes were sedimented by centrifugation and samples were taken from both the supernatant and pellet for scintillation counting. Red blood cell membranes were also depleted of cholesterol during a preincubation with sonicated phosphatidylcholine vesicles, from which they were subsequently separated by centrifugation. After washing and resuspension they were equilibrated with ^{35}S-thiopental and λ determined as above. The protein, phospholipid and cholesterol contents of all biomembranes were determined spectrophotometrically. The λ of thiopental in sonicated phospholipid bilayers, which are not readily sedimented, was determined by ultrafiltration and scintillation counting of the lipid suspension and of the filtrate.

In erythrocyte ghosts λ was found to be 25, but rose to 40 after partial cholesterol depletion. In mitochondria and microsomes λ was found to be 47 and 77 respectively.

The intact biomembranes present a heterogeneous hydrophobic medium. Our data allow some conclusions to be drawn about the distribution of the anesthetic in the membrane. No simple correlation was observed between λ and the proportion of protein in the membrane, so that a relatively small fraction of the anesthetic is probably associated with protein. On the other hand λ increased as the cholesterol/phospholipid ratio decreased in both the biomembranes and the lipid bilayers of defined compositions, suggesting that most of the anesthetic is dissolved in the lipid region. Compared on this basis only λ for the microsomal membranes deviated somewhat from that expected from its cholesterol content. Thus the cholesterol content of biomembranes appears to be the most important, but not the only, factor determining thiopental's partition coefficient. (Supported by USPH Grant GM-14904).

687 POTASSIUM AND CALCIUM ION CONDUCTANCE NOISE IN HELIX NEURONS. K.S. Lee*, N. Akaike*, A.M. Brown, H.M. Fishman and L.E. Moore. Dept. Physiology & Biophysics, University of Texas Medical Branch, Galveston, Texas 77550.

Voltage-dependent unit channel conductances, presumed to be the basic units of membrane excitability, have been measured by fluctuation analysis of membrane noise observed in squid axon, node of Ranvier and frog neuromuscular junction. The unit conductances have values of 10^{-11} to 10^{-12} mhos. Similar measurements have not been made in nerve cell bodies and would be of interest since somas have larger specific membrane resistances and more numerous ionic conductances than axons. We made these measurements on isolated Helix aspersa nerve somas using a method which combines voltage clamp with internal perfusion. Membrane noise increased by 2-4 orders when membrane potential was stepped from -60 to -10 mV. Specific K^+ ion conductance noise was determined by computing difference power spectral densities from individual neurons before and after substituting Cs^+ for K^+ intra- and extracellularly. Under these conditions Cs^+ suppresses K^+ currents. Power density spectra of current noise measured during a 15 sec voltage clamp step to -10 mV were calculated using a Fast Fourier Transform algorithm. At these long times outward K^+ current is steady and the transient K^+ current is inactivated. Potassium difference spectra were fitted to a single Lorentzian function by a Marquardt least squares method. A unit channel conductance, $\gamma_K \cong 10^{-14}$ mhos, was calculated using the relationship $\gamma = \sigma^2/\bar{G}(1-a)$ where σ^2 is the area under the fitted Lorentzian curve, $\bar{G}$ is the mean conductance and a is the ratio of the conductance at a given potential to its maximum value. Similar procedures were employed for the calcium conductance (G_{Ca}) using nickel ions to suppress G_{Ca}. The unit Ca^{++}conductance was $\gamma_{Ca} = 10^{-15}$ mhos. The $K^+$and Ca^{++} noise spectra had corner frequencies of ~20 Hz consistent with voltage clamp relaxation times measured at these potentials. The small unit conductance values found in these experiments, as compared to those found in other neural preparations, suggest that some process other than free diffusion in aqueous pores is responsible for ion movements in the soma membrane.

688 EFFECT OF EXTRACELLULAR POTASSIUM ON THE STEADY-STATE ELECTROGENIC Na-K TRANSPORT SYSTEM OF THE CRAYFISH GIANT AXON. Edward M. Lieberman. Dept. Physiol., Sch. Med., East Carolina Univ., Greenville, North Carolina 27834.

A previous investigation from this laboratory (Lieberman & Nosek. Pflugers Archiv. Europ. J. Physiol. 366:195, 1976) demonstrated that the crayfish axon electrogenic transport system contributes approx. -7mV to the total steady-state membrane potential of -85mV. Electrogenic current is approx. 3.5μA/cm^2. The Na to K transport ratio was calculated from a modification of the conductance equation for non-equilibrium potential and ionic steady-state using electrical parameters measured with space and current clamp techniques. The Na/K transport ratio ranged between 1.7/1 and 2.1/1 for control steady-state conditions.

The investigation has been extended to the effects of extracellular K on the electrogenic potential, current and transport ratio. The axial wire space and constant current clamp methodology has been previously described (Lieberman and Lane. Pflugers Archiv. Europ. J. Physiol. 366:189, 1976). All axons were equilibrated in Cl-free solutions using Isethionate as the anion substitute. Ouabain (5×10^{-4} to 10^{-3}M) was used to determine the electrogenic transport contribution to the membrane potential. Ouabain poisoning caused no change in membrane resistance except that directly attributed to the change in membrane potential.

$[K]_o$ between 0 and 21mM did not appear to effect $[K]_i$ for periods of up to 3 hours. $[Na]_i$ is minimally affected as indicated by little change in the AP overshoot and direct measurements of $[Na]_i$ (Wallin, Acta physiol. scand. 70:431, 1967). At each $[K]_o$, new potential steady-states were reached in 5-10 min. and remained stable for up to 3 hours. Net transport current was least at $0[K]_o$ (3μA/cm^2) and greatest at $21.6[K]_o$ (7μA/cm^2). The contribution of the electrogenic transport system to membrane potential was greatest at $0[K]_o$ (14 mV) and least at $21.6[K]_o$ (6 mV) as a result of membrane resistance changes which occur with external K. Evidence suggests that the crayfish axon transport system is able to adjust to changes in $[K]_o$ to maintain intracellular ionic constancy for periods of up to 3 hours. Under these circumstances the assumption that a steady-state exists seems valid and the modified steady-state conductance equation may be used to calculate ionic currents, conductances and the Na/K transport ratio. The findings of this study indicate that the transport ratio is variable and ranges from 1.25/1 at nominally $0[K]_o$ to extremely high values (28/1) at 16.2 $[K]_o$. Project supported by NIH grants NS08773 and NS13531.

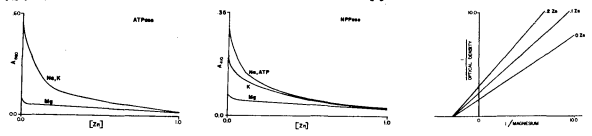
689 ACTIONS AND INTERACTIONS OF ZINC ON RAT BRAIN NA,K-ATPASE AND A PARTIAL REACTION. G.L. Longenecker, H.E. Longenecker, Jr. and L.J. Kopaciewicz*. Depts. Pharmacol./Physiol., U. So. AL Med. Coll., Mobile, AL 36688

We have shown effects of Zn at low concentration (>10uM) on frog neuromuscular junction (NMJ) which resemble effects of Na,K-ATPase inhibitors (e.g., ouabain). Attempts to correlate symptoms of Zn poisoning with effects on Na,K-ATPase are variable: some show Zn can substitute for magnesium (Mg) and support Na,K activation, others that it inhibits by competition with ATP. We have examined the effects of Zn on a heavy microsomal Na,K-ATPase, and on a partial reaction.

Na,K-ATPase was prepared from homogenates of stripped rat brains in .25M sucrose buffered with histidine, containing disodium EDTA in all but the final solution. Assay mixtures contained 40 mM tris (pH 7.4), 2mM ATP, 3mM Mg, 100mM Na and 10mM K. Reactions were started by addition of ATP, and followed by Pi determination. The enzyme hydrolyzed ATP minimally in the presence of Mg alone, with a ouabain-sensitive 5-6x increase on addition of Na/K. The K-sensitive dephosphorylation step was examined by use of p-nitrophenylphosphate (NPP). Assay conditions were 40mM tris (pH 7.4), 4mM Mg, mM K, 10mM Na and mM ATP. Reactions were started with NPP. Yellow color of p-nitrophenol was read at 410nm. NPPase activity was minimal with Mg, increased with K, and increased further with Na and ATP. Zn as the acetate was preincubated with the enzyme in both assays.

Zn inhibited both the Na,K- and Mg- components of the ATPase; the I-50 (concentration for 50% inhibition) of the Na,K component was c 100uM graphically (fig 1). All components of NPPase were inhibited with I-50s for the K- and Na,ATP- components also c 100uM (fig 2). We have shown non-competitive inhibition between Zn and Mg (fig 3).

Zn inhibition of Na,K-ATPase is consistent with effects of Zn at the NMJ. The concentrations necessary to inhibit Na,K-ATPase correlate with those affecting the NMJ: the lower the Zn, the longer the time for NMJ effects to develop. Zn affects Na,K-ATPase and NPPase by non-competitive inhibition between Zn and Mg. Additional effects of Zn at the NMJ include a Mg-like inhibition of stimulated transmitter release, i.e., calcium antagonism: this may also occur via a binding of Zn to ATPase or other Mg sites. (U.S.A. Intramural/NIH 1R01ES01321-01 support)



690 **TOPOGRAPHICAL STUDIES OF GLYCOPROTEINS AND GANGLIOSIDES IN SYNAPTOSOMES.** S.P. Mahadik*, B. Hungund*, and M. M. Rapport, (SPON: H. Tamir). N.Y.State Psychiatric Inst., New York 10032.

We have studied synaptosomes by the method of Steck (1972): i.e. oxidation with galactose oxidase followed by reduction with [^{3}H]-Na borohydride, which labels exposed terminal galactose and galactosamine residues of glycoproteins and glycolipids. Purified synaptosomes were labeled and disrupted by osmotic shock; the membranes were then fractionated on a step gradient of diatrizoate (Tamir et al., Anal. Biochem., 1976) to give 4 membrane fractions (A to D) and a mitochondrial pellet (E). Specific incorporations (ratio of label found with enzyme to that without enzyme) were: A, 4.5; B, 2.4; C,D,E, $\leq$ 1.6. When membrane fractions were first isolated and then labeled, specific incorporation was 5 to 6 fold greater but showed little discrimination among fractions. Membrane fractions A and B obtained from labeled synaptosomes contained 1/3 of the label in protein and 2/3 in lipid. After labeling isolated membranes, the label was $<$ 1/5 in protein and $>$ 4/5 in lipid. Since the highest degree of specific labeling after treatment of intact synaptosomes was found in fractions A and B, and since this and other evidence indicate that these are the purest synaptic plasma membrane fractions, their protein and ganglioside components were analyzed. Protein from these delipidated membranes showed 6 labeled bands in 10% polyacrylamide tube gels with M_r of 96K, 72K, 53K, 33K, 25K, and $<$ 17K daltons. After labeling the isolated membranes, the labeled bands were M_r 130K, 96K, 80K, a broad region from 70K to 50K, 34K, 27K, and $<$17K. Labeled bands were PAS positive. The highest degree of staining and label incorporation were in the 70K to 50K region. Polypeptides in gradient slab gels showed large incorporation of label in three regions: 160K to 96K, 70K to 40K, and 7.8K to 3.2K. These results show that most of the polypeptides in the ranges 160K to 96K and 70K to 40K were not labeled in intact synaptosomes but became accessible to the enzyme in isolated membranes. The polypeptides that predominate on the external synaptosome surface are the 70K band and the smaller polypeptides in the range of 7.8K to 3.2K. Most of the specific label in the lipid fraction after labeling intact synaptosomes was present in G_{M1} ganglioside; its presence in the galactose residue was confirmed. After labeling isolated membranes, the label was found in zones corresponding to G_{M2}(45%), G_{M1}(26%), G_{D2}(15%), G_{D1b}(14%). Since the carbohydrate-containing molecules in the membrane are considered to be associated with the outer surface and since only a small portion of these molecules have their saccharide chains exposed in the intact synaptosome, the molecular organization in the membrane must be very close-knit. After disruption, this tight organization appears to fall apart with consequent exposure of most of the constituent saccharide chains.

691 ASSOCIATION OF ^{3}H-ALPRENOLOL WITH MEMBRANES: LOCAL ANAESTHETIC AND β-ADRENERGIC EFFECTS. Carl Mendel* and Richard R. Almon. School of Med., Univ. of Calif, San Diego and Division of Cell and Mol. Biology, State University of New York at Buffalo, Buffalo New York 14214.

The conceptual relationship between displaceable ligand associations and "specific binding" to receptors is an integral part of the current approach to studying populations of receptor sites. The present report examines this relationship with respect to the study of putative β-ADRENERGIC receptor sites. The antagonists alprenolol, propranolol (Pro) and pindolol all have considerable local anaesthetic effects which are related to the partitioning of these compounds into cell membranes. As an approach to distinguishing partitioning from binding, a comparative analysis was made of the association of (-) ^{3}H-dihydroalprenolol (^{3}H-Alp) with human erythrocyte (RBC) membranes and with membranes derived from brain. The assumption was that the human RBC membranes would exhibit only displaced partitioning, whereas the membranes from brain would exhibit both displaced PARTITIONING and BINDING. The data show that the ^{3}H-Alp partitions into biological membranes. The addition of other agents such as Pro which also partition into the membranes, alters the membrane to a sufficient degree such that the ^{3}H-Alp partition coefficient changes. If the partition coefficient is lowered as is the case when Pro is added, the ^{3}H-Alp is displaced from the membrane. The ability of "competing agents" to change the ^{3}H-Alp partition coefficient is related to that compound's n-octanol-water partition coefficient and its ability to act as a local ANAESTHETIC. In addition to its ability to mimic displaceable surface binding, the partitioning also can influence adenylate cyclase activity. Membranes from brain tissue do contain another class of associations not present in human RBC membranes. Unlike the partitioning (present in both) this class of association has all the characteristics expected of the association of ^{3}H-Alp interacting with a single set of identical independent sites with a Ka of 2.04 x $10^8 M^{-1}$. It is concluded that the use of ligand displacement to define putative β-adrenergic receptor population is NOT ENTIRELY VALID because 1) it assumes all displaceable ligand is bound to unique surface structural sites; 2) it does not consider the possible equilibrium distribution of the radioactive ligand among several different environments; 3) it does not consider the possibility that the displacing agent may also distribute among the same several micro-environments and consequently change their properties and 4) that this change in the properties of particular micro-environments may alter not only the labeled ligand partition coefficient, but also the activity of secondary transduction systems such as adenylate cyclase.

692 SURFACE PROTEINS OF DIFFERENTIATING RAT CEREBELLAR CELLS MAINTAINED IN DISPERSED CELL CULTURE. Lee N. Minier* and Robert S. Lasher. Dept. Anatomy, Univ. Colo. Med. Center, Denver, Colorado 80262.

Several lines of evidence suggest that developmental processes may be partially mediated through varying arrays of cell surface components (proteins, glycoproteins) during growth and differentiation of given cell types. Using enzymic radioiodination as a cell surface probe, neuronal and non-neuronal cells of rat cerebellum maintained in dispersed cell culture were evaluated for their complement of cell surface proteins during differentiation in vitro. Particular attention was given to the appearance and distribution of the large, external, transformation-sensitive (LETS) protein. Neuronal and non-neuronal cell types were freed from the culture surface with the aid of an electrolytically sharpened tungsten needle and collected in a micropipette attached to a micromanipulator. Initial solubilization of the surface proteins was done in a lysing buffer containing urea, 2-mercaptoethanol, the non-ionic detergent Nonidet P 40 and water. Use of this buffer facilitated removal of DNA from the sample by subsequent centrifugation at a force of 10,000 x g. Final solubilization of membrane-associated proteins was accomplished by addition of the sample to an electrophoretic buffer containing sodium dodecyl sulfate as a primary chaotropic agent. These surface proteins were resolved by microelectrophoretic, radioautographic and fluorographic methods. Neuronal cells from various postnatal age rat cerebellums maintained for different periods of time in vitro were found to have very little or no iodinatable LETS protein on their surfaces. Conversely, non-neuronal cells associated with cerebellum were found to have significant amounts of LETS on their surface at all times of growth in vitro investigated. This protein apparently is the major iodinated surface component of non-neuronal cells, and co-migrates with purified LETS protein from chinese hamster ovary cells. In addition, non-neuronal cerebellar cells transformed by SV40 virus appeared to have reduced levels of LETS protein on their surfaces.

Other variations in the surface protein electrophoretic patterns of neuronal and non-neuronal cell types are presented and discussed with reference to potential age-dependent alterations of cell surface organization. Such alterations appear to be generally restricted to the low molecular weight classes of peptides. Research support: NIH Training Grant GM 01981 (LNM) and NIH Grant NS13133 (RSL).

693 ELECTROPHYSIOLOGICAL AND GENETIC DISSECTION OF THE MEMBRANE OF PARAMECIUM. Donata Oertel, Stanley J. Schein* and Ching Kung*. Lab. Mol. Biol. and Dept. of Genetics, Univ. Wisc., Madison, WI 53706.

In order to understand better the molecular biology of electrical excitability in biological membranes, mutants have been isolated with genetically altered membranes. Voltage clamp studies show that Paramecium tetraurelia has at least 3 voltage dependent conductances which presumably correspond to 3 kinds of membrane channels: 1) a calcium conductance sensitive to depolarization, 2) a rectifying conductance sensitive to depolarization, and 3) a potassium conductance sensitive to hyperpolarization. Step depolarizations of the Paramecium membrane result in a transient inward current and then a steady state outward current. The calcium inward current and rectifying outward current were separated by ion substitution and by using a mutant which lacks functional Ca^{++} channels. This showed that Ca^{++} channels inactivate. The difference in voltage sensitivity enables us to distinguish the hyperpolarization-sensitive K^+ channels from depolarization-sensitive channels. Reversal potentials of "tail" currents in ionic environments with various K^+ concentrations obey the Nernst relation showing that these channels are specific for K^+.

694 VOLTAGE CLAMP STUDIES OF INTERACTIONS BETWEEN HALOTHANE AND HIGH HYDROSTATIC PRESSURE ON APLYSIA BURSTING NEURONS. J. Farmentier, P.B. Bennett* and B.B. Shrivastav*. Dept. of Anesthesiology, Duke University Medical Center, Durham, North Carolina, 27710

Exposure to halogenated hydrocarbon anesthetics initially increases the firing rate of autoactive neurons in the Aplysia CNS but after longer contact blocks this activity. Bursting neurons show an initial increase in the frequency of membrane oscillations, with more impulses per burst, followed by gradual membrane hyperpolarization and loss of activity. During early stages of narcosis depolarizing current can trigger action potentials of waveform and duration similar to normal impulses, which implies that mechanisms controlling these events are not seriously disrupted while currents controlling the slow waves are altered.

Identified bursting neurons (L3, L6, R15) were voltage clamped inside a pressure chamber with a single microelectrode clamp system (Wilson and Goldner, 1975, J. Neurobiol. 6:411-422) and complete current-voltage (I-V) curves were recorded using 5 second long voltage steps to identify the negative resistance region (-50 mV to -30 mV) which is responsible for slow wave activity. The pressure chamber was then filled with mineral oil, for the compression experiments, or mineral oil in which a sufficient amount of halothane had been dissolved to equilibrate the bathing medium of the ganglion to a calculated percentage of saturation.

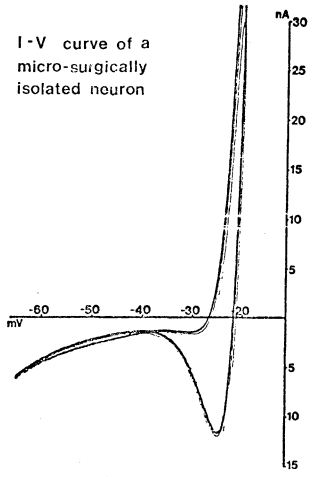
Exposure to halothane at 3-5% of saturation results in gradual (15-45 minutes) loss of the negative resistance characteristic (NRC) of the membrane until the I-V plot becomes linear. The long time delay we attribute to the large size of the Aplysia neurons. A plot of current at the peak voltage of the NRC against exposure time is a monitor of the developing anesthetic effect. Exposure to higher than 6% saturation results in a sudden reduction of current required to clamp the cell throughout its voltage range, followed by the above mentioned shift to near ohmic characteristics of the negative resistance region.

Hydraulic compression to 4000 p.s.i. results in a reduction of the holding current in the negative resistance region but the NRC is not eliminated. Compression to 4000 p.s.i. after sufficient exposure of halothane to result in linearization of the curve does not restore the NRC, and compression immediately following exposure to halothane does not prevent the anesthetic effect from developing. These results suggest that pressure reversal may be a multi-neuronal phenomenon and thus of a different nature than the direct effects of either pressure or anesthetics on active membrane processes. This work was supported by a Departmental Sponsored Award from the Dept. of Anesthesiology, Duke University Medical Center.

695 SEMI-STATIONARY CURRENT VOLTAGE CHARACTERISTIC OF REPETITIVELY FIRING NEURONS. L. Donald Partridge, Stuart H. Thompson*, Steven J. Smith*, and John A. Connor*. Friday Harbor Labs., U. of Wash., Friday Harbor, Wash., 98250.

The I-V curves of repetitively firing (non-bursting) neurons show non-linearities in the sub-threshold region. Micro-surgically isolated molluscan neurons were studied under voltage clamp during slow ramp voltage changes and were found to exhibit a region of negative slope conductance and a current hysteresis between the depolarizing and hyperpolarizing directed ramps. These I-V characteristics are especially important in their relationship to repetitive firing as they occur in the voltage region near spike threshold.

Ion substitution experiments suggest that the negative slope characteristic results from a non-inactivating or slowly inactivating Na^+ current with some further contribution of Ca^{++} ions. The hysteresis is a semi-stationary characteristic that becomes less pronounced as the rate of change of voltage is decreased. Injection of EGTA into the cell or replacement of Ca^{++} with Ba^{++} in the bathing solution reduces or abolishes the hysteresis suggesting a role of Ca^{++} in the phenomenon. It is thought that the hysteresis results from a Ca^{++} activated K^+ current.

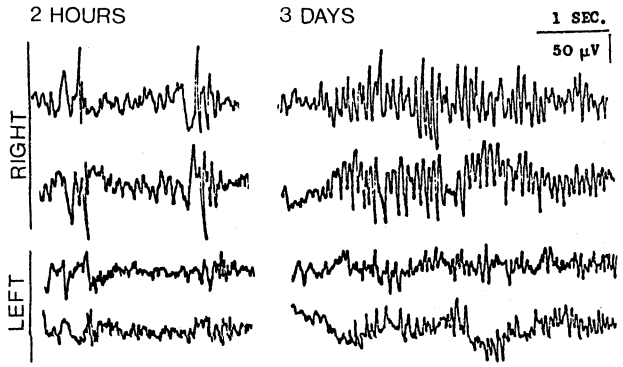


696 VOLTAGE-DEPENDENT CALCIUM CONDUCTANCE IN RODS. F. N. Quandt*, G.L. Fain*, and H.L. Gerschenfeld* (SPON: L.Kruger). UCLA Sch. Med., Los Angeles CA 90024, and Ecole Normale Superieure, Paris, France.

The membrane of rods is usually assumed not to have voltage-dependent conductances. The effects of compounds, known to block specific voltage-dependent conductances in other membranes, were determined in rods in order to examine more carefully the possible presence of these conductances. In the superfused, isolated retina of Bufo marinus, 6-12 mM tetraethylammonium (TEA) added to normal ringer produces a 5 mV depolarization of the rod membrane. Receptor potentials in TEA show a faster decay and are followed by a 3-4 Hz oscillation of the membrane potential. The peak-to-peak amplitude of these oscillations is initially as large as 35 mV but decays to zero within 5 sec. Similar oscillations are obtained with the addition of 4-aminopyridine to ringer, or by replacing Ca^{2+} with Sr^{2+} or Ba^{2+}. Ca^{2+} appears to be the major current carrier involved in the production of regenerative potentials during exposure to TEA. The amplitude of the TEA-induced oscillations decreases with decreasing external Ca^{2+}. Increasing external Ca^{2+} produces regenerative potentials which resemble action potentials and are spontaneous in the dark. The depolarization phase of the action potentials is up to 45 mV in amplitude, and 60-80 msec in duration. A subsequent 5 mV hyperpolarization phase decays in .5-1 sec. Sr^{2+} substitutes for Ca^{2+} in producing these action potentials as the peak amplitude increases with increasing Sr^{2+}. Action potentials can be recorded in a zero Na^+ringer with 28 mM Sr^{2+} and TEA. The TEA-induced oscillations in normal Ca^{2+} medium are reversibly blocked by the addition of .1 mM Co^{2+}, 5 mM Mg^{2+}, or .1 mM D-600; but not by $2 \cdot 10^{-6}$ M TTX. The oscillations are not due to an interaction between rods and horizontal cells since 2-5 mM Na^+ aspartate, which blocks the responses of horizontal cells, has no effect even though the simultaneously recorded b-wave of the e.r.g. is eliminated. The rod membrane must contain a voltage-dependent Ca^{2+} conductance which can generate regenerative potentials in the presence of TEA. TEA may act by partially blocking a voltage-dependent K^+ conductance. This potassium conductance could normally prevent the Ca^{2+} conductance from generating these regenerative potentials.

697 CHOLERA TOXIN INDUCES EPILEPTIFORM ACTIVITY. Rapport, M.M. and Karpiak, S.E. Div. Neurosci. NY State Psychiatric Inst. & Dept. Biochem., Columbia U., Coll. P & S, New York, N.Y., 10032.

The action of cholera toxin involves the combining of its B subunits with a specific G_{M1} ganglioside receptor on the cell membrane followed by penetration of its A subunit into the cell causing activation of adenylate cyclase (Sahyoun & Cuatrecasas, PNAS, 1975; Fishman & Brady, Science, 1976). Since G_{M1} ganglioside receptors are involved in the induction of recurrent epileptiform activity by antibodies (Karpiak, Graf & Rapport, Science, 1976), it was of interest to determine whether cholera toxin would, under similar conditions, also induce seizure activity. Rats were injected intracortically (∠2mm into the right sensorimotor cortex with 1 µg of purified cholera toxin in 10 µl Tris buffer (pH 7.5). The animals were then implanted with 6 cortical screw electrodes into the calvarium. The electrodes were attached to a microamphenol plug and affixed to the skull with acrylic cement. EEG recordings were a) taken from alert animals 15 min after surgery b) monitored for several hours c) then taken daily. The cholera toxin caused all rats to develop spiking activity ipsilaterally in 1 to 3 hrs (Fig). This activity increased in frequency on subsequent days, with some contralateral spread, and lasted for more than two weeks. This effect of cholera toxin provides additional evidence for the involvement of G_{M1} ganglioside receptors in the induction of seizure activity.



EEG 3 hrs and 3 days after injection (RIGHT) of cholera toxin.

698 CHANGES IN CONDUCTION VELOCITY ACCOMPANY ACTIVITY-DEPENDENT SHIFTS IN THRESHOLD OF FROG SCIATIC AXONS. Stephen A. Raymond. Research Laboratory of Electronics, MIT, Cambridge, MA 02139.

Conduction velocity in an axon is related to its threshold level. This study has investigated the extent of this correlation throughout each of the phases of threshold oscillation now known to follow conditioning impulse patterns in frog nerve fibers. Conduction velocity can be influenced over the entire course of an axon by changes in ionic milieu, currents generated in nearby structures, and shifts of local metabolism. Therefore, to assay conduction velocity changes arising solely from impulses traveling in the axon itself, extracted sciatic nerve fibers bathed in recirculated Bolye-Conway Ringer's at constant temperature, and pH were used.

The nerve trunk was stimulated with monopolar current pulses varying from 50-300μsec in duration. Threshold was hunted by adjusting the stimulus duration so that a dissected single fiber recorded by suction electrode at the end of the nerve responded to 50% of the stimuli. Conduction velocity was measured using a counter gated by the leading edge of the stimulus and closed by the arrival of the response at the recording electrode.

During the relatively refractory period conduction velocity showed a steep speed up corresponding to recovery of threshold. Throughout this period impulses are slower than those in the rested fiber. Threshold crossed the resting level entering the supernormal phase just as the velocity curve crossed its resting value. Delays to crossover match within 50μsec. Peak supernormality coincides with peak conduction velocity and the slow increase of threshold after the peak is matched by a diminishing velocity. The crossover from supernormality to depression also matches even as the crossover is made to occur earlier after conduction pulses by increasing depression. Velocity is slowed throughout depression by an amount proportional to the threshold level. Changes of up to 20% in conduction velocity often parallel a 50% increase in threshold. Slow fibers showed greater changes of conduction velocity during all phases than faster ones.

During intermittent conduction the velocity slowed progressively during the conduction periods. It reached a minimal level just before conduction failed. When conduction resumed, the initial impulses traveled as fast as in rested nerve. Then velocity slowed as depression built up. These observations are consistent with an explanation of intermittent conduction in terms of threshold changes.

The strict correlation between threshold and conduction velocity changes observed in controlled conditions on excised nerve fibers suggests that the same membrane processes and mechanisms underlie both phenomena. Both can be used to measure activity dependence of membrane processes on impulse conduction.

699 INWARD Ca CURRENT IN FROG SKELETAL MUSCLE FIBERS. J. A. Sánchez, L. Nicola Siri* and E. Stefani. Depto. de Fisiología y Biofísica, Centro de Investigación del I.P.N., Apdo. Postal 14-740, México 14, D.F.

It was recently described in frog skeletal muscle fibers a calcium dependent slow spike which was found by removing chloride and blocking potassium currents. In the present experiments we studied the membrane current underlying the slow calcium spike with voltage clamp using the three microelectrode technique. The saline contained: 40 mM Tetraethylamonium (TEA), 40 mM Na, 2.5 mM K, 10 mM Ca, 113 mM sucrose, sulfate as the anion and was buffered at pH 7.3. Mechanical artifacts were avoided by rolling and stretching the frog sartorius muscle around a 2 mm diameter perspex rod. On occasions, 350 mM sucrose was added to the saline. The experiments were performed at room temperature (19-23°C). Using long depolarizing voltage pulses (500 msec), there was an initial outward current due to the leak current and a remaining potassium current which was followed by a transient inward current. The latency and amplitude of the inward current depended upon the voltage pulse amplitude and it had a threshold of -25 mV. The latency measured at the maximum negative dI/dt was 400 mseg for threshold pulses decreasing up to 50 msec for large pulses. When increasing pulse amplitude, the potassium outward current increased in spite of TEA, and the inward current could not be accurately measured. This was partially overcome by extrapolating the potassium current which was substracted from the total current. The inward current was 114 + 24 $\mu A/cm^2$ (14, mean + SE) at ca 0 mV and the range of the extrapolated equilibrium potential was between +60 and +100 mV. The inward current was blocked by Co (10 mM), but not by tetrodotoxine (10^{-6}M). Furthermore, it was not sodium-dependent and it was suppressed by removing external calcium. These results indicate that calcium is the major ion contributing to this current. This calcium current inactivates. With prepulses of 500 msec the inactivation curve follows the expression: $h = 1/(1 + \exp((V - Vh)/k))$ with V_h of -23mV and k 6mV. This calcium channel resembles the slow calcium channel of the squid axon membrane. Its probable role related to the excitation contraction coupling mechanism will be discussed.

700 CALCIUM SPIKES IN HIPPOCAMPAL PYRAMIDAL CELLS. Philip A. Schwartzkroin and Mara Slawsky*. Dept. Neurol., Stanford Univ. Sch. Med., Stanford, CA 94305.

Using an in vitro hippocampal slice preparation, we have shown that CA1 pyramidal cells can generate a calcium spike. Slices 350-400 μ thick were cut from guinea pig hippocampus and incubated as previously described. Intracellular recordings were obtained by introducing potassium acetate micropipettes into CA1 cell body layer, stratum pyramidale. The cell body layer was visible as a light band on the trans-illuminated slice and clearly differentiable from the dendritic regions. Monopolar stimulation in stratum radiatum (Schaffer collaterals) evoked synaptic potentials and spikes; stimulation in the alveus elicited antidromic spikes. Intracellular depolarizing current pulses elicited trains of action potentials, with current threshold for spike firing about 0.25 nA. During an intracellular penetration, tetrodotoxin (TTX) (10^{-4} M) could be applied to localized regions of the slice by pressure ejection from a broken micropipette. Small droplets of TTX deposited at the cell body-basal dendrite region abolished antidromic spikes and spiking evoked by the usual depolarizing current pulses, but left intact synaptically elicited slow potentials; application of TTX to the apical dendritic region blocked synaptic potentials. When sufficient TTX had been applied to abolish all normal spiking activity in a cell, intense (1.5-4.0 nA) intracellular depolarizing pulses evoked long duration (50-60msec), slowly rising and falling, all-or-none "spikes". Application of droplets of calcium chloride (20mM) to the CA1 region (particularly in the apical dendrites) potentiated the amplitude of the TTX-resistant potential and made it much sharper (more spike-like). Manganese ion effects were then tested, since Mn^{++} is known to block Ca^{++} currents. Droplets of manganous chloride (20mM) deposited at the same sites as the Ca^{++} completely blocked elicitation of the TTX-resistant spike, or significantly raised the current threshold for spike initiation. Barium, an ion which can carry calcium currents as well as decrease some component of the potassium conductance, had complex effects when applied to the TTX-treated slice. Initially 20mM Ba^{++} caused a cell depolarization and spontaneous firing of long-duration spikes which were similar in appearance to cardiac action potentials. Low intensity depolarizing pulses (<1.0 nA) were sufficient to trigger all-or-none long lasting potentials. All drug effects were reversible, with normal cellular potentials returning within an hour of drug application. Drug effects were also localized, so that regions of a given slice adjacent to that receiving drug droplets displayed normal spiking activity. (Supported by grant NS 12151 from the NINCDS, NIH.)

701 MODULATION OF ELECTRICAL ACTIVITY IN APLYSIA NEURONS BY CHOLESTEROL. Cathy L. Stephens and Meir Shinitzky*.

Electrical activity of a single neuron from Aplysia californica was recorded while perfusing an isolated ganglion with lipids to modulate the membrane microviscosity. Sonicated liposomes of either egg lecithin (16 mg/ml) or egg lecithin (16 mg/ml) plus cholesterol (10 mg/ml) were diluted 1:4 (V/V) in sea water. The liposome-sea water mixtures were then applied to the ganglion during continuous electrical recording for up to 3 hrs. Perfusion of pacemaker and burster type neurons with lecithin-cholesterol liposomes, which increased the cholesterol level of the cell membrane, progressively diminished spontaneous activity and increased the threshold to elicit an action potential following intracellular stimulation. After 30-60 mins. incubation, the action potential was completely blocked, but the resting membrane conductance was unaltered. The spontaneous electrical activity of the cholesterol enriched neurons could be completely restored upon consecutive perfusion with lecithin liposomes for less than 30 minutes. This treatment, which presumably depletes the membrane cholesterol, demonstrated that the observed effect of cholesterol is reversible and passive. Furthermore, perfusion with lecithin liposomes of Aplysia neurons which were initially silent, generated continuous action potentials similar to pacemaker activity. These results strongly suggest that the activity of membrane sites which are involved in spontaneous electrical activity and generation of action potential is dependent on the membrane fluidity. Since the microviscosity of neural membranes may vary under various physiological conditions, such changes could induce significant alternation of neural activity in vivo.

702 IMMUNOCYTOCHEMISTRY OF BASIC PROTEIN IN CNS AND PNS MYELIN. N. Sternberger*, T. Tabira*, H. deF. Webster and M. W. Kies*. NINCDS, NIH, Bethesda, MD 20014.

Aldehyde fixed tissues from rat or Xenopus tadpole CNS and PNS were immunocytochemically stained with antibody to bovine myelin basic protein (BP) using the peroxidase-antiperoxidase method. Dense reaction product was observed on cut edges of myelin sheaths in tissue sections stained before embedding for electron microscopy. In isolated compact myelin, stained in suspension, reaction product was found only on outer lamellae or in centrally located areas where the lamellar structure was disrupted. Alcohol pretreatment of isolated myelin reduced the reaction with antibody to BP but enhanced the reaction with cerebroside antibody. The reaction of antibody to BP with thin sections of tissue stained after embedding was restricted mainly to the axonal and extracellular margins of intact myelin sheaths. No staining was observed after incubation with preimmune or BP absorbed sera.

703 DIFFUSION THROUGH THE SQUID AXON SCHWANN CELL LAYER. Robert E. Taylor, Francisco Bezanilla* and Eduardo Rojas* NINCDS,NIH, Bethesda,MD 20014; Dept. Physiology UCLA, Los Angeles, CA: Dept. Physiology, Univ.of East Anglia, Norwich, England.

We have investigated a number of models for diffusion through and resistance of the Schwann cell layer, taking the membranes of the Schwann cells to be impermeable. They are: 1) the anatomical model with the Frankenhaeuser-Hodgkin (F-H) space between the Schwann cells and the nerve membrane, the clefts between the Schwann cells, and the unstirred layer consisting of basement membrane, connective tissue and external solution; 2) anatomical model neglecting the convergence from the unstirred layer into the clefts but including specific and unspecific binding of saxitoxin (STX) and tetrodotoxin (TTX); 3) anatomical model without unstirred layer; and 4) thin membrane with unstirred layer.

These models were used to determine the conductance of a single sodium channel and the density of sites and kinetics of binding of TTX and STX (Keynes, et al. J.Gen.Physiol.61,267(1973); Bezanilla, et al. J. Gen. Physiol.61,268(1973); Keynes,et al. Phil.Trans.R.Soc. Lond.B.270,365-375(1975)).

We have considered the time course of F-H space concentration of: 1) potassium following initial loading; and 2) sodium, TTX or STX following sudden external concentration changes.

The effects of convergence into the clefts can be neglected both for diffusion and resistance. The clefts may be replaced by a thin membrane with small errors at short times. For sudden external changes in concentration the unstirred layer is always important. If the F-H space is initially loaded the unstirred layer may be neglected.

The thin membrane plus unstirred layer is the simplest adequate model which we have found for our studies of diffusion through the Schwann cell layer.

704 AXON LESIONS IN CHICK EMBRYO TIBIAL NERVES AFTER VINBLASTINE SULFATE (VBS). Betty Geren Uzman, Gloria M. Villegas* and Jeanne M. Curnutt*. VA Hospital and LSU Medical Center-Shreveport, LA 71130, and I.V.I.C., Caracas, Venezuela.

VBS injected into the chorio-allantoic (C-A) sac of 11 day incubated (dinc) chick embryos (C.E.) at a dose of 0.5μg VBS/g C.E. differentially affects bundle (B), segregated (S), isolated (I), and myelinating (M) fibers. As previously reported, 50% B fibers disappear 24-36 hours after VBS injection. Forty-eight hours after exposure to VBS, the axons of S, I, and M fibers exhibit a bull's eye appearance, with an electron-lucent (empty) zone between the axolemma and a central aggregate of neurofilaments, microtubules and granular material. Since S, I, and M fibers are generally affected when viewed in sizeable numbers in low-mag electron micrographs, and since their numbers are not significantly reduced after VBS injection, it is concluded that the "doughnut dissolution" and bull's eye aggregation of axoplasmic contents is consistent with fiber viability. In contrast, B fibers disappear in large numbers (≈ 20,-25,000) after VBS. Since the major difference between B fibers and S, I, or M fibers is the partial or complete envelopment of S, I, or M fibers by the Schwann cell, it is proposed that the apposition of axolemma to Schwann cell membrane is an unique junction stabilizing axolemmal (and axon) integrity against peripheral cytoplasmic (axoplasmic) disturbances of the cytoskeleton.

705 ALTERED ACTIVITY AND TEMPERATURE RESPONSE OF MEMBRANE-BOUND PROTEIN KINASES IN ERYTHROCYTES OF PATIENTS WITH MYOTONIC MUSCULAR DYSTROPHY. J.D. Vickers, M.P. Rathbone, and A.J. McComas, MRC Group in Developmental Neurobiology, Depts. of Neuroscience and Medicine, McMaster University Med. Centre, Hamilton, Ontario, Canada, L8S 4J9

Recently it has been demonstrated in erythrocytes from patients with myotonic dystrophy (MyD) that the phosphorylation of band 3 protein is reduced. We have examined the phosphorylation of spectrin, band 3 protein and phospholipids in erythrocyte membranes from MyD patients and healthy age- and sex-matched controls. We have also examined the temperature-dependence of these reactions. Using erythrocyte ghosts the incorporation of ^{32}P from [$\gamma^{32}P$] ATP into membrane proteins was determined at pH 7.4 at both 30°C and 37°C using the methods of Avrunch and Fairbanks (Biochem. (1974) 13:5507-5513). In 10 MyD patients incorporation of ^{32}P into band 3 protein was reduced at 37°C ($p<0.01$) was not different at 30°C from controls. Spectrin phosphorylation was reduced at both 30°C and 37°C compared to controls ($p<0.01$). Although phosphorylation of these membrane components was greater at 37°C than at 30°C in both controls and MyD patients the increase observed with patients was less than with controls (spectrin $p<0.025$, band 3 $p<0.001$). In two other patients (sisters) who had characteristic clinical manifestations of MyD, phosphorylation of both spectrin and band 3 protein was increased (> 2 standard deviations greater than values determined for other patients with MyD). Control values were comparable to controls for the other patients. In 5 out of 10 MyD patients the degree of phospholipid phosphorylation at both 30°C and 37°C was less than in controls ($p<0.001$). In the remaining 5 patients, phosphorylation was increased ($p<0.001$). Control values were similar for each group. Thus, altered phosphorylation of erythrocyte membrane components is not limited in MyD to a specific substrate. Although a primary genetic lesion in a single substrate protein has not been excluded, it is more likely that the altered phosphorylation and temperature responses are a result of an abnormal lipid environment of either the enzymes or their substrates.

706 ULTRASTRUCTURAL STUDIES OF MEMBRANE CHANGES DURING NEURONAL AGGREGATION. John G. Wood, Barbara J. McLaughlin, and Frances I. Byrd*. Dept. Anat., Univ. Tenn. Center for the Health Sciences, Memphis, TN 38163.

The use of reaggregating nervous system cultures provides a useful model for the study of many aspects of cellular associations during development of the nervous system but as yet there has been little use of electron microscopy to study this problem. Our approach is to utilize immunocytochemical methods to study the changes in membrane associated components on aggregating cells and, in order to obtain baseline information on changes in normal membrane morphology during reaggregation, cell or aggregate suspensions taken between 0 hr. to 14 days after dissociation are prepared for either standard thin section or freeze fracture analysis. The cells are rounded and dispersed freely at 0 hr. after dissociation. Between 2 and 6 hr. the cells become closely apposed on all sides by other cells and form small aggregates. At this time puncta adhaerentia junctions and focal gap and tight junctions are present between apposed cell bodies and processes. Between 1 and 5 days, more growth cones and neurites are present and fewer gap and tight junctions are seen. Synapses form between 5 and 7 days and continue to increase in number up to the fourteenth day. By 9 days, the peripheral border of each aggregate is composed of cells having numerous microvilli on their free surfaces and which are joined by zonula adhaerens junctions. Freeze fracture analysis of the early reaggregating cells (2-4 hr.) reveals a sparse intramembrane particle distribution on the cytoplasmic and external membrane leaflets of apposed cells. By 2 days intramembrane particles on the cytoplasmic leaflet of apposed cells are more numerous and small clusters of loosely packed particles are seen, which may represent junctional contacts between reaggregating cells. These particle clusters increase in number and size as reaggregation proceeds. By 7 days other particle arrays which correspond to intramembrane specializations characteristic of excitatory synaptic junctions are seen on cell bodies and neurites with increasing frequency. These observations suggest that correlated cell surface and intramembrane changes are occurring during the initial stages of neuronal reaggregation, which may reflect a basic morphological reorganization of cell membranes during neuronal recognition and synaptic junction formation. Such changes may be studied by cytochemical analysis utilizing ligand specific probes or antibodies to membrane components together with labeling techniques for electron microscopic localization.

707 CALCIUM TRANSPORT ACROSS BLACK LIPID MEMBRANES (BLM) AS DETERMINED WITH AEQUORIN. Miko Yoshida*, Arthur F. Clark*, W. L. Stahl* and P. D. Swanson. Dept. of Med. (Neurology), Biophy. and Ped., Univ. of Wa. Sch. of Med., Seattle, Wa. 98195.

Transport of calcium across an oxidized cholesterol bilayer membrane was monitored by following the change in the rate of light emission due to the reaction of the transported calcium with aequorin, a calcium sensitive protein. We used a semispherical bilayer bubble with aequorin present within the bubble, and a buffered external calcium solution. The semispherical membranes were formed using an apparatus similar to that described by Toyoshima and Thompson (Bioch. 14, 1518, 1975) and were suspended in a spectrophotometric cell. Electrodes, Ag/AgCl, were used to measure transmembrane potential and membrane conductance. The design of the apparatus allowed for exchange of both the internal and external solutions. A photomultiplier tube was positioned close to the spectrophotometric cell and the output was monitored on an oscilloscope and recorded. When the external solution contained 100mM KCl, 8mM Tris and 1mM CaCl and the internal solution contained the same solution but without calcium and containing aequorin, the membrane conductance was 5.5×10^5 ohm x cm^2 and the rate of light emission low. Upon addition of the calcium ionophore X-537A the membrane conductance increased in a time dependent manner and there was a concomitant increase in the rate of light emission. Quantification of the light changes were complicated by an increase in both the size and frequency of the pulses. In a second series of experiments we prepared two concentric bubbles with aequorin present only within the innermost bubble. This was done in order to isolate the aequorin so that it could not interact with the external membrane of interest. Thus electrical and physiochemical changes due to the addition of possible calcium transport protein or ionophores would not be affected by the presence of aequorin. Using the conditions above with KCl, Tris and CaCl in the external solution and the aequorin isolated within the inner bubble the conductance of the external membrane was 5.5×10^7 ohm x cm^2. As in the first system X-537A caused both an increase in the membrane conductance and the rate of light emission.

708 INTERNAL PERFUSION TECHNIQUE IN THE TUNICATE EGG AND EFFECTS OF INTERNAL IONIZED Ca UPON EGG Na and Ca CHANNELS. Mitsunobu Yoshii* and Kunitaro Takahashi* (SPON: M. Maeda). Inst. Brain Research, Univ. Tokyo Med. Sch., Tokyo, Japan.

Previous studies on the development of the excitability in the embryonic membrane of the tunicate have shown that the unfertilized egg membrane is excitable, having Na, Ca, delayed K, and anomalous K channels. In the differentiated tadpole larva, Ca channels were segregated in the muscle membrane, while Na channels were accumulated in ectodermal cells. During the development the assembly of ionic channels on the embryonic membrane must be modified by factors inside the egg cell. In the present study the internal perfusion technique was developed to analyse the effect of internal Ca ions upon Na and Ca channels in the tunicate egg membrane.

The perfusion apparatus consisted of the upper and lower compartments which were connected by a small funnel made from a piece of Pyrex capillary. The egg cell without follicular envelope was dropped in the funnel and brought into contact with the glass wall. The completion of the contact was checked by an increased resistance of more than 1000 Mohms between the compartments. Then,the lower part of the free membrane was ruptured by slight negative pressure or injection of high frequency current. Internal solution which contained 400 mM Na, F or Cl as anions, and 100 mM EGTA to regulate ionized Ca, was perfused in the lower compartment. The upper compartment was filled by external solution containing 400 mM NaCl and 100 mM $CaCl_2$ or $SrCl_2$. After the rupture the upper membrane was voltage-clamped and the holding potential was set at -90 mV at the internal side. Step potential changes revealed the same Na current as observed in the intact egg. The efficiency of the perfusion of the internal solution was confirmed by the negative shift of the reversal potential of Na channel current. The reversal potential became less than 5 mV with 400 mM internal Na 20 min after the rupture and increased beyond 85 mV after the replacement of 400 mM Na with 400 mM Cs. Therefore the efficiency of the exchange was more than 95% in 30 min with the present method. By using F ions as internal anions the preparation was kept stable more than two hours and large Na but no Ca currents were observed. By using Cl ions, however, both Na and Ca currents were observed as in the intact egg, although the stable condition could not be kept more than 30 min. An increase in ionized Ca from 10^{-7} to 8×10^{-4}M in the external solution containing Cl ions caused a reduction of Ca current by one fifth and enhanced Na channel conductance about twice. The reciprocal effects of internal Ca ions upon the egg Na and Ca channels suggested that the internal Ca ions have an important role in changing channel density of the embryonic membrane during development and differentiation.

709 ISOLATION AND CHARACTERIZATION OF NORMAL HUMAN CNS AXOLEMMA-ENRICHED FRACTIONS. W.J. Zetusky*, V.P. Calabrese, G. Anderson*, and G.H. De Vries. Depts. of Biochemistry and Neurology, Med. Coll. of Va. and McGuire VA Hospital, Richmond, VA 23298

A 3% homogenate of corpus collosum from frozen human brain was prepared in 0.85 M sucrose, .15 M NaCl, 0.01 M TES, pH 7.5 (Medium A) using 10 strokes of a Dounce homogenizer. Centrifugation of this homogenate (82,500 xg for 15 min) yielded a floating layer of myelinated axons plus free myelin and a pellet of debris, myelin-free axons and capillaries. The myelinated axon pad was further purified by rehomogenization and reflotation two times in Medium A. The myelinated axons were osmotically shocked in 10 mM TES, pH 7.5 and centrifuged at 82,500 xg for 30 min to form a pellet. The pellet derived from 1 gm of starting white matter was resuspended in 0.65 M sucrose containing 1 mM EDTA and 1 mM TES, pH 7.5 and was layered on a 3 step discontinuous gradient of 1.2 M, 1.0 M and 0.8 M sucrose. All sucrose gradient solutions contained 1 mM EGTA and 1 mM TES, pH 7.5. After centrifugation at 82,500 xg for 1 hour, 4 fractions were obtained: myelin floating in the 0.65 M sucrose layer, two axolemma-enriched fractions sedimenting to the 0.8 M/1.0 M and 1.0 M/1.2 M sucrose interfaces, and a pellet of myelin-free axons. The yield of 0.8/1.0 and 1.0/1.2 was 0.13 mg and 0.40 mg protein respectively per gram wet weight of starting white matter. The enrichment in specific activity over the starting whole white matter homogenate was two to four fold for 5' nucleotidase, approximately two fold for acetylcholinesterase and 6 to 16 fold for (Na^+-K^+) activated ATPase. The specific activity of 2'3' cyclic nucleotide 3' phosphohydrolase was slightly lower than whole homogenate in the 1.0/1.2 fraction but slightly higher in the 0.8/1.0 fraction. The specific activity of cytochrome c oxidase, antimycin resistant NADH oxidase, and antimycin sensitive NADH oxidase showed that the fractions were not significantly contaminated with mitochondrial inner membrane, microsomes or mitochondrial outer membrane. Specific radioimmunometric assays showed that less than 4% myelin basic protein was present in the 1.0/1.2 fraction and that less than 0.2% glial fibrillary acidic protein was present in either axolemma-enriched fraction. The 0.8/1.0 fraction contained predominantly unilamellar membrane plus some typical multilamellar myelin fragment vesicles. The 1.0/1.2 fraction contained mostly unlamellar membrane vesicles with only occasional myelin fragments. The data suggests that the majority of the unilamellar membranes in the 0.8/1.0 and 1.0/1.2 fractions are derived from the axonal plasma membrane.

MEMORY AND LEARNING

710 THE EFFECTS OF IMMEDIATE POST-TRAINING LOCUS COERULEUS DAMAGE ON THE LONG TERM PERSISTENCE OF MEMORY. W.C. ABRAHAM,*Ge Ruigt* and S.F. Zornetzer. Dept. Neuroscience, Sch. Med. Univ. Fla. Gainesville, Fl., 32610.

One of the least studied and most poorly understood of these component processes is the long term persistence of memory. This study investigated the role of the norepinephrine (NE) containing locus coeruleus (LC) in the persistence of memory. Previous work from our laboratory (Zornetzer & Gold, 1976; Zornetzer & Appleton, 1977) indicates that electrolytic lesions of the LC made immediately after mice learn a single trial inhibitory avoidance response, results in a prolonged period (at least 196 hours) of memory susceptibility to retrograde disruption by ECS. This prolonged period of susceptibility suggests that "consolidation" into a long term stable state is delayed following LC damage. Is the duration of the long-term stable memory increased by a period of time equivalent to the extended duration of the labile state? Or, is the long-term stable trace initiated at the time of training and unaltered by persistence of the labile trace?

Nichrome wire electrodes were stereotaxically implanted in the region of the LC bilaterally in male Swiss mice. Seven days after surgery all mice were trained in a single trial inhibitory avoidance apparatus. Immediately following training mice were lightly etherized and electrolytic destruction of the LC was made (anodal current, 300ua for 10"). Mice were returned to their home cages and tested for retention of the inhibitory avoidance response either 4, 6, 7, or 8 weeks after training. Forgetting curves were obtained for all mice. LC lesioned mice showed long-term persistence of memory identical to operated controls and normal mice. Thus, all groups had excellent retention at 6 weeks with an intermediate level at 7 weeks and virtually complete forgetting by 8 weeks.

These data indicate that forebrain levels of NE, normally provided by LC neurons, are not necessary for the persistence of memory over long periods. Further, since LC lesions result in a prolonged labile memory state these data also indicate that the initiation of the long-term stable memory is unaltered by post-training LC destruction since its persistence is identical in lesioned and control mice. These data suggest that two parallel states of memory exist. The first, a labile trace, ordinarily called STM, has a duration normally delimited by forebrain NE. The second, a long lasting stabile trace, ordinarily called LTM, is independent of NE biosynthesis by the LC, and therefore unaltered by immediate post-training LC destruction. The interactions of these two memory states and the resulting implications for traditional consolidation theory will be discussed.

711 Escape Deficits Following Exposure To Inescapable Shock: Dopaminergic And Noradrenergic Involvement. Hymie Anisman* and Lawrence S. Sklar* (SPON: W. G. Webster). Department of Psychology, Carleton University, Ottawa, Ontario, Canada.

Following exposure to inescapable/unavoidable shock subsequent escape performance is severely retarded. The performance disruption appears to reflect deficits in response initiation and maintenance rather than cognitive changes (helplessness). Specifically, the performance deficits occur only when escape responding is briefly prevented during test. This treatment does not affect performance of mice not previously exposed to inescapable shock. Treatment with catecholaminergic agents mimicked the effects of inescapable shock. Treatment with alpha-methyl-para-tyrosine (AMPT) (125 & 250 mg/kg), Bis-(4-methyl-1-homopiperazinyl-thiocarbonyl) disulfide (FLA-63) (40 & 60 mg/kg), haloperidol (.075, .15, .30, .45, & .60 mg/kg) or pimozide (.40 & .80 mg/kg) produced dose dependent escape deficits. With increasing dosages the magnitude of the deficit was accentuated, and shorter escape delays successfully elicited the performance disruption. As in the case of inescapable shock, prior escape training immunized against the disruptive influence of the drug treatments. Finally, low dosages of DA or NE synthesis inhibitors or receptor blockers, together with small numbers of inescapable shocks produced performance deficits beyond that elicited by either treatment alone. Scopolamine (.5 & 2.0 mg/kg) antagonized the effects of both inescapable shock and haloperidol. Predictably L-3,4-Dihydroxyphenylalanine methyl ester (L-DOPA) antagonized the effects of inescapable shock. It is concluded that both DA and NE, as well as ACh, mediate the escape deficits via their influence on response initiation and maintenance.

712 ERGODICITY IN PROBABILISTIC NEURAL NETS. Photios Anninos, Silvio Zenone*, Max Papadopoulos*. Dept. of Phys. Concordia University and Phys. Dept. Dawson College, Montreal, P.Q.

In a series of articles, Harth et al (1) and Anninos et al (2) have developed the dynamics of probabilistic neural nets. Harth and Edgar (3) have also shown how a completely random net can become structured as a result of sensory inputs and can, as a result, be made to perform a variety of learned tasks.

The idea that use leads to structuring in the CNS is the fundamental to the work of many workers. Eccles, in a series of articles and papers makes the case that "learning behaviour signals changes that have occurred in neuronal connectivity within the CNS". Eccles's explanation is that the basic mechanism of this process is synaptic facilitation. (4)

Changes in the connectivity pattern of probabilistic neural nets can be studied with the Anninos model. In fact hysteresis effects have been observed in the study of netlet activity. These changes in netlet activity are the result of variation in the connectivity parameters of the system. (5)

The purpose of current work is to pursue the latter idea further and to investigate hysteresis behaviour in its correlation to various learning paradigms. Information Theory and Entropy concepts are utilized in this regard.

An Entropy model suitable for probabilistic neural nets has been developed by Bergstrom (6) and by Bergstrom and Nevanlinna. (7). The results of Bergstrom and Nevanlinna are being utilized for the purpose of associating a suitable function to the hysteresis graph.

713 THE EFFECTS OF DELAYED SCOPOLAMINE ADMINISTRATION UPON MEMORY FOLLOWING LOCUS COERULEUS LESIONS. Robert S. Appleton*, A.J. Dunn and S.F. Zornetzer. Dept. Neuroscience, Coll. Med., Univ. Fla., Gainesville, Fla., 32610.

In previous studies we reported that posttraining electrolytic lesions of the locus coeruleus (LC) complex results in a long-lasting period of memory susceptibility to ECS produced retrograde amnesia (Zornetzer & Appleton, 1977). Memory retrieval during this prolonged period of susceptibility is, however, normal. Since the LC-mediated norepinephrine (NE) neurotransmitter system is deficient in these mice, the question arises, to what extent are other neurotransmitter systems involved in the maintenance of this long-lasting labile trace? Based upon the suggestions of a number of previously published papers, we chose to investigate initially the possible role of the cholinergic system in the maintenance of this labile memory trace.

Male Swiss ICR mice were prepared with chronic twisted wire electrodes targeted for the LC bilaterally. Seven days after surgery mice were trained on the single-trial inhibitory avoidance step-through apparatus. Immediately following training mice were lightly etherized and anodal lesions were made bilaterally (300 ua, 10"). Mice were returned to their home cages for 24 hr, at which time they were given an injection of either scopolamine HBr (1.0 or 2.0 mg/kg) or saline I.P. Following injection micewere returned to their home cages. Twenty four hrs after injection all mice were tested for retention of the inhibitory avoidance response. Following testing histological analysis of electrode placements was performed.

The results suggest that LC lesioned mice injected with scopolamine 24 hrs after training are impaired in their subsequent avoidance behavior. The data are discussed in terms of multiple and redundant neurotransmitter systems and memory.

714 THE EFFECTS OF AGING ON PRIMATE SHORT-TERM MEMORY, SENSORY PROCESSING AND LEARNING. Raymond T. Bartus, Denise Fleming* and H. R. Johnson*. CNS Pharmacology, Warner-Lambert/Parke-Davis Pharmaceutical Res. Div., Ann Arbor, Mich. 48106

The performance of five aged rhesus monkeys (17 years and older) was compared to that of five young monkeys (three to five years old) in a series of experiments designed to define the cognitive impairments associated with aging. An automated test apparatus (specifically designed to control or eliminate potentially confounding variables involving general attention, motivation, psychomotor coordination, etc.) was used for all experiments.

In the first experiment, short-term memory (STM) was assessed using an indirect delayed response procedure. It was found that aged monkeys suffer a severe STM deficit, performing quite accurately under control conditions, where little or no STM was required, but exhibiting marked impairment of performance after retention intervals of 15 and 30 sec.

The second and third experiments evaluated the extent to which impairments in sensory processing might be responsible for the age-related STM impairment. Sensory processing ability was evaluated by manipulating either the number of times the stimulus was flashed, or the duration of a single stimulus flash before the delayed-response retention interval was initiated. The results demonstrated that, although performance generally suffered when the stimulus information was reduced in this manner, no differential age-related effects in sensory processing occurred.

In the final experiment, learning ability was assessed using a two-choice visual discrimination paradigm. Color, pattern and pattern reversal discrimination problems were administered. Acquisition rates revealed no consistent discrimination learning impairments in aged monkeys, even though some discrimination problems were clearly more difficult to learn for both age groups. However, a marked reversal learning impairment was observed in the aged group. Thus, although original learning may not be adversely affected by age, the ability to modify previously learned habits apparently becomes quite impaired.

These data not only share striking similarities to much of the human geriatric literature, but are also in excellent agreement with data from frontally ablated monkeys. It is therefore suggested that the aged monkey provides an excellent neurobehavioral model to study impairments and processes associated with aging, and that a major neurological cause of the impairments may involve a dysfunction in frontal cortical and related anatomical areas.

715 ENKEPHALIN- AND MORPHINE-INDUCED FACILITATION OF LONG-TERM MEMORY. James D. Belluzzi and Larry Stein. Wyeth Laboratories, Philadelphia, Pa. 19101.

A role for enkephalin in the mediation of behavioral reinforcement has been suggested by several lines of evidence: (1) central injections of enkephalin may serve as reinforcement for self-administration behavior, (2) electrical stimulation of many enkephalin-rich regions, such as midbrain central gray, may support high rates of self-stimulation, and (3) such brain stimulation reinforcement may be blocked by low doses (0.5-2.5 mg/kg, s.c.) of naloxone (Belluzzi and Stein, 1977). The important role of reinforcement in learning and long-term memory formation, although controversial at the level of theory, cannot be disputed at the practical level. Accordingly, enkephalin and morphine treatments were administered immediately following training in a single-trial learning task in an attempt to facilitate long-term retention of the learned response. Rats with permanently-indwelling intraventricular cannulae received a mildly painful foot shock after stepping down from a shelf to a grid floor. Different groups received intraventricular injections either immediately or 15 minutes after the shock, as indicated in the Table. Three days later, long-term memory of the shock (as reflected by long step-down times) was measured in a retention test. Significant facilitation of the learned response was observed in the groups given immediate post-shock treatments of methionine-enkephalin (200 µg) or morphine. Two further observations suggest that these effects of the opiates on retention were due to an enhanced memory of the shock. First, the morphine treatments were ineffective if the shock was withheld on the training day. Second, delaying the morphine injection for only 15 minutes after the shock completely abolished its memory-enhancing effect. These results suggest that post-trial activation of opiate (enkephalin) receptors may facilitate memory consolidation.

Treatment	Dose (µg)	No. of Rats	Step-Down Time (Sec.) Mean ± S.E.M.
Ringer's	-	17	36.23 ± 9.37
Morphine	20	19	78.24 ± 12.14*
Morphine (Shock withheld)	20	8	5.75 ± 0.94**
Morphine (15 min. delay)	20	7	39.50 ± 23.70
Leu-Enkephalin	100	10	49.18 ± 22.02
	200	8	47.04 ± 19.71
Met-Enkephalin	100	5	8.82 ± 1.81
	200	10	114.25 ± 27.74*

* $p<.02$ vs. Ringer's; ** $p<.001$ vs. Morphine

716 HIPPOCAMPAL EEG PREDICTORS OF LEARNING RATE IN RABBITS. Stephen D. Berry* and Richard F. Thompson. (SPON: S.R. Coates). Dept. Psychobiology, UCI, Irvine, CA. 92717.

Spontaneous EEG samples were recorded from the CA1 area of dorsal hippocampus in 17 New Zealand White rabbits (Oryctolagus cuniculus) prior to the beginning of classical conditioning of the nictitating membrane (NM) reflex. The conditioning paradigm consisted of a tone CS (350 msec, 85 db, 1 KHz) and corneal air puff US (3 psi, 100 msec, overlapping and coterminating with the CS). A conditioned response (CR) was defined as any NM movement greater than 0.5 mm occurring after CS onset but before US onset in paired trials or within 500 msec of CS onset in probe (CS alone) trials. Rabbits were conditioned until they reached a criterion of 8 out of 9 consecutive CRs or for a maximum of 468 trials (4 sessions).

The 2 min preconditioning EEG samples were analyzed on a PDP-12 computer by a zero crossing program which determined the period between consecutive baseline crossings in the EEG, and accumulated the number of waves occurring in frequency categories (0-14 Hz in 2 Hz increments; 14-22 Hz in 4 Hz increments). Pearson Product-Moment coefficients were computed between the number of trials needed to reach criterion and the amount of time (number of waves times the period of the mean frequency of that category) in each of the frequency categories. In general, time scores in the theta (2-8 Hz) range were negatively correlated with trials to criterion (slower learning), while the higher frequency categories (8-22 Hz) showed positive correlations. The strongest overall relationship was between learning trials and waves in the 8-10 Hz range ($r=+.72$, $df=15$, $p<.01$). It was concluded that preconditioning hippocampal EEG is a reliable predictor of subsequent rate of NM conditioning in rabbits.

717 SHORT TERM MEMORY IN THE RAT: EFFECTS OF ELECTRICAL STIMULATION OF MIDBRAIN RETICULAR FORMATION. A. Rex Bierley* and Raymond P. Kesner. Dept. Psychol., Univ. of Utah, Salt Lake City, UT 84112.

An attempt was made to delineate the role of the midbrain reticular formation (MRF) in the modulation of short term memory (STM) processes. Long-Evans rats with bipolar electrodes implanted in the MRF were trained on a discrete-trial delayed alternation task. The task required the rat, in a two bar choice situation, to press the bar opposite to the one he pressed in initiating the trial in order to obtain reinforcement. Time between initiation of a trial and presentation of the two bars was varied from zero to 60 seconds. Rats trained on this task show a retention function (as inferred from performance) that decays within 60 seconds, reflecting a time course interpreted as a STM gradient. Low intensity electrical stimulation (40-70µA, 100Hz., 0.1msec pulse width) of brief duration (5 seconds) delivered to the MRF contingent upon an animal initiating a trial produced chance responding at all retention intervals. In a second experiment, the locus of this effect was studied by measuring performance at a 15 second retention interval and by varying the temporal presentation of MRF stimulation. It was shown that MRF stimulation delivered immediately, 5, or 10 seconds after the start of the trial produced chance responding. The same stimulation delivered prior to the start of a trial had no effect. Furthermore, no within-sessions proactive interference effects were observed. In additional experiments, it was demonstrated that disruptive effects were not due to interference with a motor set or to rewarding or punishing consequences of the stimulation.

The data suggest that the MRF plays a critical role in processes associated with persistence of information within a STM system.

718 EFFECTS OF BILATERAL AUDITORY CORTEX ABLATION ON BEHAVIOR AND UNIT ACTIVITY IN RAT INFERIOR COLLICULUS DURING DIFFERENTIAL CONDITIONING. Dorwin Birt*, Robert Nienhuis*, and James Olds (SPON: Frank Atencio)
California Institute of Technology, Pasadena, Calif. 91125

The development of both behavioral responses and short latency responses of inferior colliculus neurons to tone pips was studied in normal rats and rats with bilateral ablation of auditory cortex during a differential conditioning experiment. Behavior measured was the development of a differential movement during the one second interval between the onset of the tone CS+ and the food pellet US. Some animals with small lesions learned this discrimination but no animal with large lesions did so. Unit responses during the period 5-11 msec after stimulus onset were measured before and during conditioning. No apparent relationship was found between changes in these short latency responses and the pairing of the CS+ with food pellets in normals or lesioned animals. There was, however, a large effect of the lesions on the variability of the background firing rates of neurons during conditioning but not during pseudoconditioning. In normal animals an approximately equal number of units showed background increases and decreases during conditioning. In the lesioned animals there were more background increases and almost no decreases during conditioning. This was interpreted as favoring the idea that during the learning of such a discrimination a non specific activation from non cortical structures is selectively antagonized by cortical efferents.

719 DOES REWARDING HIPPOCAMPAL STIMULATION DISRUPT FOOD-REINFORCED LEARNING IN RATS? Mauro Caudarella,* K. A. Campbell* and N.W. Milgram, Dept. Psychol., Scarborough Coll., Univ. Toronto, West Hill, Ont., Canada, M1C 1A4.

Electrical stimulation of the dorsolateral hippocampus (HPC) has been used, in separate experiments, both to produce retrograde amnesia for recently-learned behaviors, and to reinforce operant behavior in self-stimulation experiments. These apparently contradictory effects led us to determine whether HPC stimulation would disrupt appetitive learning when stimulation follows each lever-press as in self-stimulation experiments. 23 hooded rats, stereotaxically-implanted with single monopolar electrodes in the dorsolateral HPC (CA3), were maintained at 85% of their body weight and randomly divided into 3 groups tested in identical Skinner boxes: one group received both a food pellet and .5 sec of 30μA, 60 Hz, sine-wave current immediately following each lever-press ("contingently-stimulated" group); a second group received a food pellet for each lever-press as well as .5 sec of stimulation whenever a paired animal in the contingently-stimulated group depressed the lever ("yoked control" group); and a third group received only food pellets, without stimulation ("surgical control" group). After familiarization with the food dispenser, the rats were left unassisted to learn to press the lever. Lever-presses were recorded every 15 min during daily 30-min sessions. The 2 contingently-stimulated rats which had not learned in 7 days were "shaped" successfully by the method of successive approximations. After 750 lever-presses, the rats were screened for self-stimulation and the data from only those rats that self-stimulated within 9 daily sessions were analyzed. The Kruskal-Wallis test indicated significant differences in acquisition ($p<.05$). The contingently-stimulated group required more trials than either control group to reach both an initial acquisition criterion of 35 lever-presses in 15 min and a more conservative learning criterion of 550 cumulative lever-presses. Thus food-reinforced learning was disrupted by HPC stimulation contingent on each lever-press, in spite of the fact that all animals in this group eventually self-stimulated. HPC stimulation delivered in more random fashion (yoked control group), however, did not disrupt learning. Surprisingly, when transferred to an identical Skinner box without a food pellet dispenser, contingently-stimulated animals and yoked controls were both slow to self-stimulate, requiring a mean of 5 daily sessions to acquire lever-pressing for HPC stimulation. The lack of immediate transfer in the contingently-stimulated group may indicate that the effects of HPC stimulation vary over time and such variation may account for the reported differential amnestic and rewarding effects of HPC stimulation.

720 RECOVERY OF MEMORY AS A FUNCTION OF THE DEGREE OF AMNESIA DUE TO PROTEIN SYNTHESIS INHIBITION. Hasker P. Davis, Mark R. Rosenzweig, Edward L. Bennett and Anne E. Orme* Psychology Dept., and Lawrence Berkeley Lab, Berkeley, CA 94720, USA.

Retrograde amnesia following inhibition of cerebral protein synthesis has generally been explained as being due to either a failure of consolidation or impairment of a retrieval mechanism. Major evidence claimed to support the retrieval hypothesis is provided by studies which utilize a reminder (usually footshock) to attenuate the amnesic consequence of the protein inhibitor. To examine this question, male Swiss Webster CD-1 mice were injected subcutaneously with anisomycin (1 mg/animal, 7 mg/animal, or 1 mg/animal every 2 hr x 7) and given one training trial in a passive avoidance box. All 424 subjects received a single retention test on each of four consecutive days, starting either 1, 7, or 21 days after training. One-half of the mice in each group received a footshock reminder 1 hr after their initial test. The degree of amnesia was significantly greater at longer training-test intervals and in groups treated with a high (7mg/animal) or multiple (1 mg every 2 hr x 7) dosage of anisomycin. The footshock reminder did not attenuate the inhibitor-induced amnesia ($p< 0.25$). Multiple testing did produce partial recovery but only in those animals that demonstrated some memory of training as indicated by their initial step-through latencies (STL). Most importantly, a comparison of STLs of saline animals first tested at 21 days with the STLs of anisomycin treated animals (1mg/animal) first tested at 7 days showed that these groups were similar in their initial poor retention and pattern of recovery on test days 1-4 ($p>0.30$). Groups that demonstrated complete amnesia on their initial test showed no recovery on subsequent tests. A within-group analysis of performance, irrespective of drug or training test interval, demonstrated that the degree of retention, as indicated by the initial STL, was the primary indicator of whether or not an animal would show recovery. These results indicate that recovery is to be expected in partially amnesic animals but not in animals completely amnesic; thus they provide strong support for the consolidation hypothesis.

721 RETROGRADE AMNESIA IN CHICKS: INDUCTION BY L-BAIKIAIN IS NOT ACCOMPANIED BY EEG SEIZURES OR DEPRESSION. Joel L. Davis, Lauren K. Gerbrandt*, Arthur Cherkin, Psychobiology Research Laboratory, VA Hospital, Sepulveda, CA 91343 and Dept. Psychology, California State University, Northridge, CA 91324.

Intraventricular injection of L-proline (L-PRO) induces retrograde amnesia without causing brain seizure or isoelectric activity, whereas D-PRO is non-amnesic. We now report that the proline analog L-baikiain (L-BAI; 4,5-dehydro-L-pipecolic acid) has similar effects at a lower dose. We injected chicks intracerebrally with 5 μl/hemosphere of L-BAI, L-PRO or D-PRO (150 mM, pH 7.2 ± 0.2), 1 min after one-trial training to suppress the spontaneous peck response to a 3-mm stainless steel bead. Avoidance of the attractive bead was conditioned by coating it with an aversive liquid (methyl anthranilate) immediately prior to training. Retention of the avoidance response was tested 24 hr later using the uncoated bead; reduced avoidance scores and increased peck scores indicate impaired memory retention.

Compound	Dose/Chick (μmols)	N	Avoidance Score (%)	Peck Score ($\sqrt{p}$ ± S.D.)
L-Baikiain	1.5	59	30.5	1.51 ± 1.23
L-Proline	1.5	59	49.2	0.85 ± 1.05
D-Proline	1.5	60	61.7	0.78 ± 1.10
L-Proline	6.0	304	34.5	1.59 ± 1.49
D-Proline	6.0	296	56.1	0.77 ± 1.15

The results demonstrate that L-BAI is an effective retroactive amnesic agent compared to D-PRO controls; the avoidance scores ($p<0.002$; χ^2 test) and peck scores ($p<0.001$; t-test) are significantly different. The amnesic effect induced by 1.5 μmols of L-BAI is comparable to that found with 6.0 μmols of L-PRO in previous experiments (see table). Higher doses of L-BAI (3.0-6.0 μmols) had lethal effects ($LD_{50} \approx 4.5$ μmols) not seen with L-PRO ($LD_3 > 12$ μmols).

We also examined the electrophysiological effects produced by L-BAI. Chicks were chronically implanted with active bilateral recording electrodes in the ectostriatum, an indifferent electrode under the comb, and a ground electrode in dorsal neck muscle. The following day, after a 15-min adaptation and EEG baseline period, chicks (N=6/group) received intracerebral injections of 1.5 μmols of L-BAI or D-PRO. Multiple-unit activity and raw integrated EEG activity were recorded for 10 min after injection. No seizure spiking or isoelectric activity was observed in polygraph records. No reliable differences in EEG and MUA reaction were observed after L-BAI versus D-PRO injections.

We conclude that L-BAI is approximately 4x more potent an amnesic agent than L-PRO; both are effective at non-lethal doses which cause no marked electrophysiological changes.

722 DEVELOPMENT AND TOPOGRAPHY OF CLASSICALLY CONDITIONED FLEXION REFLEX FACILITATION IN SPINAL CAT. Russell G. Durkovic. Dept. Physiol., Upstate Med. Ctr., Syracuse, N.Y. 13210 USA.

In previous analyses of classically conditioned flexion reflex facilitation in spinal cat preparations only parts of the conditioned response data have been used to measure changes in reflex activity. For example, Patterson et al. (JCPP 84:88, 1973) measured only the response to the first pulse of the conditioned stimulus (CS); Durkovic (Physiol. and Behav. 14:297, 1975) measured only the maximum tension observed during each CS presentation. In the present study the data from 30 conditioning and 30 sensitization control animals were analyzed over the entire duration of the CS. Of primary interest was first to see how rapidly the conditioned facilitation developed, and second to examine the topography of the facilitation over the course of each CS presentation.

In unanesthetized, decerebrate cats the spinal cord was transected at T-10. The tendon of the tibialis anterior muscle of the rigidly fixed hind limb was attached to a force-displacement transducer. Electrical stimulation of the cutaneous saphenous nerve of this leg served as the CS (10 i.p.s. for 1.5 secs). This train of stimuli was repeated once each minute for both conditioning and sensitization control animals. Each pulse of the CS evoked a reflex response in the muscle. The peak tension of each response was measured during CS alone trials, in acquisition and in extinction procedures for each animal. On the 30 acquisition trials, conditioning animals received electrical stimulation of the cutaneous superficial peroneal nerve at 30 ips (the unconditioned stimulus (US)) during the last 0.5 seconds of each CS presentation. In sensitization control animals the CS and US presentations were alternated every 30 secs. On extinction trials all animals received CS-only presentations.

By acquisition trial 2, consistently significant differences between conditioning and sensitization animals developed for the 3rd and 4th CS peaks (200-300 msec after CS onset). By acquisition trials 5-7 a consistent difference developed between conditioning and sensitization animals for each of the 10 peaks in the first second of each CS presentation. Response topography for both conditioning and sensitization control animals on these trials was essentially flat. However, during extinction trials some conditioned animals appeared to exhibit behavior reminiscent of the POST-US-R response pattern observed in human GSR conditioning studies, e.g., Lockhart (Psychophysiology 10:112, 1973).

723 BLOCKADE AND ACTIVATION OF CAUDATE CHOLINERGIC ACTIVITY. EFFECTS ON PASSIVE AVOIDANCE. Maribel Fernández Samblancat*, Marcos Solodkin Horowitz* and Roberto A. Prado-Alcalá. (SPON: Juan A. Roig). Dept. Psychophysiol. Sch. Psychol. Anáhuac Univ. and Physiol. Dept. Med. Sch. Ntnl. Univ. of México, México City, México.

It has been shown that cholinergic blockade of the caudate nucleus (CN) interferes with performance of positively reinforced behaviors as well as with active avoidance. In this paper we present evidence that passive avoidance (PA) is also mediated by a caudate-cholinergic mechanism. PA was studied in rats (Ss) using a two-compartment box. Ten sec after being put into the safety compartment, Ss were allowed to step into the gridded compartment where all received a footshock. Their latency to step into the latter compartment was measured, again, 24 (Group I) or 48 (Group II) hr later (retention test).

Different subgroups within Group I were studied: unimplanted, implanted with cannulae in the CN, and implanted in the parietal cortex. Microinjections of saline or of 3 different doses of atropine were tested. Group II had 3 subgroups: unimplanted, microinjected in the CN, with saline, or microinjected with choline. There was one treatment per group and all microinjections were bilateral, performed 6 min after the first (footshock) session.

When retention of PA was tested 24 hr after session one (Group I) a dose-dependent deficit was found in the caudate subgroups treated with atropine, whereas a much smaller deficit was found in the cortical atropine-injected subgroup. In Group II retention scores, from least to most were obtained by the saline $<$ unimplanted $<$ choline subgroups, the latter showing an increase in retention latency of more than 300% as compared with the unimplanted subgroup.

These results suggest that PA is also dependent on a caudate-cholinergic mechanism.

724 ULTRASTRUCTURAL CHANGES IN THE DENTATE MOLECULAR LAYER DURING CONDITIONING. Eva Fifkova, Barbara J. Van der Wege* and A. Van Harreveld. Dept. Psych., Univ. Colo., Boulder, CO 80309 and Calif. Inst. Technol., Pasadena, CA 91125

A long-lasting increase in the area of dendritic spines was observed in the dentate molecular layer following a single tetanic stimulus to the perforant path (Fifkova, Van Harreveld: J. Neurocyt. 6:211,1977). Likewise tetanic stimulation of the perforant path yields long-lasting postactivation potentiation (Bliss, Lømo: J. Physiol. 232:331,1973; Douglass, Goddard: Brain Res. 86:205, 1975) which suggests a causal relation between the two phenomena. Since increased unit activity in the dentate was observed in classical conditioning paradigms (Segal: Thesis, 1972; Thompson: Amer. Psych. 31:209,1976), present experiments were aimed at a search for morphological changes in the dentate molecular layer during conditioning. Forty-four mice (20g) had twice a day 50 pellets (45mg) available for 2 consecutive days in cages where the conditioning was to take place. On the third day fifty trials of tone followed by a pellet were presented in a single 2-hr session. Controls spent comparable time in the training cage with 50 pellets available. Following 90 min mice were sacrificed and prepared for electron microscopy. The area of dendritic spines in the dentate molecular layer was significantly larger in the middle and distal third of conditioned mice as compared to controls. Since fewer pellets were consumed by the conditioned animals than by controls, the former were divided into 3 groups relative to the pellet consumption (>75%; 50-75%; <50%). An inverse relation between these values and the magnitude of spine enlargement (Table 1), in spite of similar starting weights and weight loss, could point to unspecific factors, like stress, to be partly involved in the observed spine change. The increment in pellet consumption between the last feeding and during conditioning in group <50% was significantly lower. Since spine change was here the largest one, it could indicate that the entire procedure was stressful. However these animals ate at a lower rate throughout, so that the magnitude of spine change might also indicate that this group performed at its maximum. The increment in groups >75% and 50-75% did not differ significantly from controls, so that stress seems less likely to participate in the spine enlargement observed.

725 EFFECTS OF SEPTAL AND HIPPOCAMPAL LESIONS ON PAVLOVIAN CONDITIONING OF CORNEORETINAL POTENTIAL AND HEART RATE AND BLOOD PRESSURE CHANGES. James Francis, Shirley Buchanan*, and D. A. Powell. Neuroscience Lab., VA Hospital, and Univ. of S. C., Columbia, S. C., 29201.

Rabbits received either septal, hippocampal or sham lesions and were subjected to Pavlovian conditioning training in which corneoretinal potential, electromyographic activity, heart rate, and blood pressure CRs were measured. General activity in a free field and cardiovascular and eyelid shock thresholds were also assessed in selected animals. It was found that septal as well as hippocampal lesions resulted in an enhancement of the magnitude of the conditioned heart rate response and in some animals effected a reversal of the direction of the blood pressure CR. However, heart rate discrimination was unimpaired in differential conditioning experiments. There were some indications that the acquisition of the corneoretinal potnetial CR was facilitated by hippocampal lesions, but this effect was shown to be due to the lack of latent inhibition in animals which had received prior exposure to the CS. Animals with septal lesions and hippocampal lesions also showed relatively severe impairment of the corneoretinal potential discrimination in differential Pavlovian conditioning and reversal experiments. This impairment in discrimination resulted from an increased frequency of response to the non-reinforced CS-. Extinction performance was also impaired in hippocampal lesioned animals. Assays of hippocampus and cortex in animals with septal lesions suggests that these impairments may be due to the interruption of 5HT and NE neurons in the septum in route to the hippocampus. It is suggested that 5HT and NE inputs to the hippocampus modulate hippocampal pyramidal cells and thus control the visceroautonomic response to significant stimulation (i.e., novel stimuli, or stimuli associated with a reinforcer). Such an effect on viscero-autonomic systems may result in the impairment of somato-motor systems as discussed above.

726 SPATIAL PATTERNS OF EEG ACTIVITY WITH ODORS AT SURFACE OF OLFACTORY BULB. Walter J. Freeman. Dept. Physiol.-Anat., Univ. Calif., Berkeley, CA 94720

The olfactory receptors form a surface array that projects onto the surface of the olfactory bulb through the primary nerve. There is topographic order in this projection with broad divergence, such that each local neighborhood in the bulb receives input from a subset of receptors. Adrian (1950) proposed for encoding of olfactory information that the spatially distributed receptor activity evoked by an odor might induce a spatial pattern of bulbar activity different from the pattern induced by any other discriminate odor.

The further hypothesis has been advanced (WJF, 1975) that the odor-specific information of each local neighborhood in the bulb might be reflected in the amplitude of the induced wave of EEG activity recorded at the bulbar surface above that neighborhood.

To test these hypotheses an 8x8 array of 64 electrodes was chronically implanted over the lateral surface of the olfactory bulb. The 64 signals were amplified, multiplexed, digitized at 1 msec intervals, and stored in blocks 900 msec in duration. For selected bursts of the induced wave before and during the delivery of selected odors the root mean square amplitudes $v(x,y)$ were calculated and displayed by contour plots. For each plot the values for v were normalized to zero mean and unit variance. Comparisons were made between the means of 10 plots with a certain odor A, $\bar{v}_a(x,y)$, and 10 plots without the odor, $\bar{v}_o(x,y)$, or with a different odor B, $\bar{v}_b(x,y)$.

Adaptation was overcome by pairing selected odors as CS with appetitive or aversive UCS. The means over the first conditioning session of 10 trials in each rabbit for odor A showed that $\bar{v}_a \neq \bar{v}_o$, but over the second session, $\bar{v}_a$ and $\bar{v}_o$ were not significantly different, that is, $\bar{v}_a = \bar{v}_o$. When a second odor B was given on randomly interspersed trials without the UCS, then $\bar{v}_b = \bar{v}_a = \bar{v}_o$. When thereafter A was replaced by B, then over the first session $\bar{v}_b \neq \bar{v}_a = \bar{v}_o$, but thereafter $\bar{v}_a$ disappeared and $\bar{v}_b = \bar{v}_o$. When trials with A were interspersed with trials for B, both with UCS, then over 2 or more sessions $\bar{v}_a \neq \bar{v}_b$ and either $\bar{v}_a = \bar{v}_o$ or $\bar{v}_b = \bar{v}_o$ depending on whether A or B respectively was given first on that day.

The differences between $\bar{v}_a$, $\bar{v}_b$ and $\bar{v}_o$, when they occurred, were clearly visible in contour plots. The results show that the spatial pattern of the induced EEG wave is related to the expectation of an odor rather than to the odor per se, although the odor is required to form a template for the expectation. Some implications for short-term memory mechanisms will be discussed. Supported by MH06686.

727 VISUAL MEDIATION OF ONE-TRIAL CONDITIONED AVERSION LEARNING IN CHICKS. Karen E. Gaston* (SPON: C. R. Hamilton). Division of Biology, California Institute of Technology, Pasadena, CA. 91125.

A series of experiments investigated the ability of 10-day-old domestic chicks to acquire in one trial an illness-induced aversion to the visual and/or taste properties of an unfamiliar liquid. Chicks were allowed access for one hour to a novel, distinctively colored and flavored solution (green sucrose). Several minutes after the end of this drinking session, the animals were injected intraperitoneally with an illness-inducing dose of LiCl (Experimental Group) or with isotonic saline (Control Group). In a two-choice preference test administered 24 hrs later (green sucrose solution versus plain water), the Experimental Group demonstrated a strong aversion to the green sucrose solution, whereas the Controls displayed no significant preference. Chicks trained and/or tested without the color cue (uncolored sucrose solution) failed to exhibit a conditioned taste aversion. Thus, the conditioned aversion to green sucrose was apparently mediated by the visual (color) cue.

To determine whether there is interhemispheric communication of this conditioned aversion learning, interocular transfer tests are being conducted in monocularly-trained chicks. Preliminary results suggest that when the pre-illness experience with green sucrose solution is restricted to one eye, a conditioned aversion is not demonstrated during testing with the untrained eye. This finding contrasts with the good interocular transfer observed in birds for other tasks involving color discrimination or passive avoidance, while it is similar to the lack of transfer reported for imprinting and for visual cliff habituation.

The demonstration that young chicks are able to learn in one trial an association between food color and delayed illness offers a useful new paradigm for the study of associative learning and memory processes in the avian brain, and provides new evidence which supports the view that conditioned food aversion learning is an adaptive evolutionary specialization and does not depend on the animal's "learning to learn".

728 EFFECTS OF 6-HYDROXYDOPAMINE ON CLASSICAL (PAVLOVIAN) CONDITIONING OF THE RABBIT NICTITATING MEMBRANE RESPONSE. M. P. Gimpl*, J. A. Harvey, and I. Gormezano*. Dept. Psychol., Univ. Iowa, Iowa City, Ia. 52242.

This study examined the role of the catecholamines in associative processes (learning). Rabbits (N=16) were injected with 400 µg of 6-hydroxydopamine (6-HDA) into the left and six days later into the right lateral ventricle. Control rabbits (N=16) received vehicle injections. Ten to 30 days later all animals received an adaptation session followed by 10 daily conditioning sessions. A tone or light CS (conditioned stimulus) was presented 800 msec prior to delivery of a 100 msec paraorbital shock UCS (unconditioned stimulus). There were 30 tone-shock and 30 light-shock trials each day. Extension of the membrane to the CS during the 800 msec prior to shock onset was recorded as a conditioned response (CR) and extension to UCS onset as an unconditioned response (UCR).

6-HDA produced an enhanced rate of CR acquisition. Thus, relative to controls, 6-HDA treated rabbits exhibited: a) a greater total number of CRs to both tone and light ($p<0.05$); b) fewer trials to a criterion of 10 consecutive CRs to tone (50 vs 123, $p<0.001$) and light (67 vs 132, $p<0.01$); and c) shorter latency of terminal CRs for both tone (173 vs 313 msec, $p<0.001$) and light (238 vs 367 msec, $p<0.001$).

In a separate experiment, rabbits treated with 6-HDA (N=6) or vehicle (N=6) were exposed to ten daily sessions consisting of 30 tone CS, 30 light CS and 60 shock UCS trials in an explicitly unpaired sequence to test for non-associative effects of 6-HDA. Responses of the membrane were recorded during the 800 msec of CS presentation and the 800 msec prior to UCS presentation. Although 6-HDA subjects exhibited a slightly higher rate of responding during these intervals (approximately 10%) there was no evidence for sensitization or pseudoconditioning. Thus 6-HDA appears to have a specific effect on associative processes leading to enhanced learning.

At the conclusion of behavioral testing all rabbits were decapitated and brains were assayed for content of norepinephrine (NE), dopamine (DA) and serotonin (5-HT). 6-HDA produced large and significant decreases in telencephalic content of NE (86%) and smaller though significant decreases in DA (38%) and 5-HT (28%). Brainstem content of NE and 5-HT were also significantly reduced by 37 and 19%, respectively. It is suggested that the enhanced CR acquisition produced by 6-HDA is due to the depletion of telencephalic NE. 729 PHENOXYBENZAMINE ATTENUATION OF RETROGRADE AMNESIA. Paul E. Gold Dept. Psychology, Univ. Virginia, Charlottesville, VA 22901

The neurobiological mechanisms by which amnestic treatments act on memory are not understood. Electroconvulsive shock and direct electrical stimulation of the cortex appear to require brain seizures. Diethyldithiocarbamate (DDC), a drug which inhibits dopamine-B-hydroxylase activity, may produce amnesia by blocking brain norepinephrine synthesis. These amnestic treatments, as well as others, have a common property of being either intense physiological stressors or being themselves a component of a stress response (e.g. epinephrine or ACTH). We previously found that amnesia produced by subcutaneous posttrial epinephrine injections does not occur in animals which received a pretrial injection of phenoxybenzamine (PBZ), an alpha-adrenergic blocking agent. An agent (PBZ) which blocks amnesia produced by epinephrine may therefore also block amnesia produced by other treatments. The present study examined the possibility that PBZ might attenuate the amnestic effectiveness of frontal cortex stimulation and DDC.

Male Sprague-Dawley rats (250-300 gms) were trained in a one-trial inhibitory (passive) avoidance task. Thirty minutes prior to training, rats received injections of saline or PBZ (2 mg/kg; a dose which blocks the amnesia produced by epinephrine). After training, two groups received immediate injections of saline or DDC (680 mg/kg). Other groups received no posttrial treatment or frontal cortex stimulation (5 ma, 60 Hz, 1 sec) administered 5 sec after the training footshock (Ns=10-15). Retention performance (latency to re-enter the shock compartment; maximum=180 sec) was tested 24 hr. later.

Those animals which received saline prior to training and either frontal cortex stimulation or DDC after training had retention latencies significantly lower than those of the animals which received saline or no treatment after training. The animals which received PBZ prior to training and either frontal cortex stimulation or DDC after training had retention latencies that were comparable to those of the animals which did not receive an amnestic treatment.

These results indicate that pretrial injections of PBZ block the amnesia produced either by frontal cortex stimulation or DDC. Thus, these findings are consistent with results previously obtained using epinephrine as the amnestic agent. Because a single drug (PBZ) can block the amnestic effectiveness of these quite different treatments, the findings suggest that a common neurobiological mechanism may underlie the effects of each on memory.

730 EFFECTS OF CHOLINESTERASE INHIBITORS ON ACQUISITION AND RETENTION OF AVOIDANCE BEHAVIOR. L. P. Gonzalez and H. L. Altshuler. Texas Research Institute of Mental Sciences and Baylor College of Medicine, Texas Medical Center, Houston, TX 77030.

Sprague-Dawley rats were trained to a criterion of 10 successive avoidances in a shuttle-box avoidance task following an injection of either saline, neostigmine methylsulphate (0.032, 0.08, or 0.32 mg/Kg), or physostigmine salicylate (0.04, 0.1, or 0.4 mg/Kg). Neostigmine impaired acquisition in a dose-related fashion. Subjects which received the lowest dose did not differ significantly from saline-injected animals, but the highest dose completely blocked acquisition. Physostigmine, in doses equimolar to those of neostigmine, impaired acquisition at all three doses. The impairment of avoidance acquisition at the lowest dose of physostigmine, but not with an equimolar dose of neostigmine, suggests the involvement of central cholinergic mechanisms in the acquisition of shuttle-box avoidance. To examine the effects of these drugs on retention of shuttle-box avoidance, animals were trained to criterion having received no drug injection and were then retrained to the same criterion following drug injection at various times after initial training (1, 7, or 14 days). Saline animals required fewer trials to reach criterion at any of the retention intervals than during original training. Neostigmine impaired performance, again in a dose-related fashion, at each of the retention intervals. The highest dose of physostigmine impaired avoidance performance at each of the retention tests. Lower doses of physostigmine, however, had a time-dependent effect upon retraining. When injected 1 day after original training 0.04 and 0.1 mg/Kg physostigmine significantly improved avoidance, but when injected 14 days after original training these doses impaired performance. The results suggest that the peripheral effects of high doses of physostigmine block avoidance performance. The effects of lower doses of physostigmine are probably due to their central actions and are dependent upon the stage of learning.

731 LOCALIZATION AND GENERALIZATION OF VISUAL MEMORY AFTER TECTAL LESIONS IN GOLDFISH Karen F. Greif* and Margaret Y. Scott* (SPON: R. W. Sperry) Division of Biology, California Institute of Technology, Pasadena, CA 91125.

Memory for visual discrimination learning following lesions of trained tectal regions was studied in adult goldfish. Differential suppression of respiration to red or green light was used as the conditioned behavioral measure of learning (Scott, Exp. Neurol. 54: 579, 1977). The method made possible the use of small visual stimuli subtending 1.5° to be directed to precise retinal loci and hence to specifically designated target zones in the tectum. After a learning criterion was attained, the half-tectum which included the visual projections involved in training was excised. Retention was tested one day after surgery with no reinforcement in either the left or the untrained right eye.

Following training with stimuli confined to the posterior quadrant, intraretinal transfer was indicated by good differential responses from remaining untrained portions of the retinotectal system anteriorly and along the horizontal meridian. After training in the superior visual field, transfer occurred to the inferior field along the vertical meridian. The habit also generalized interocularly to the entire visual field of the untrained eye, even when initial training was restricted to the posterior-most portion of the visual field, which lies outside the region of binocular overlap. Results from 18 fish demonstrate that engrams for this discrimination task are not localized within the region of the tectum that receives direct retinal input during training. Retention of discrimination through the untrained right eye after lesion of the remaining anterior half of the right tectum suggests that engrams for monocularly-acquired visual learning are laid down bilaterally during task acquisition. Alternatively, memory traces may be stored in centers outside the tectum which remain accessible to both eyes.

732 MEMORY LOAD AND CARDIAC INTER-BEAT-INTERVAL. Stanley W. Hall, Jr.* and J. Richard Jennings* (SPON: R. Curtis Graeber) Walter Reed Army Institute of Research, Washington, D.C. 20012

Recent work based on initial suggestions of Lacey and Lacey has supported the sensitivity of heart rate or its reciprocal, inter-beat-interval (IBI), to information processing requirements. Jennings (1975) presented evidence that cardiac acceleration might be more sensitive to a task's memory requirements than to requirements for cognitive manipulation.

The current experiment directly examined the relation between cardiac acceleration and memory by manipulating memory load between 6 and 10 items. Using a recognition memory paradigm with variable intertrial intervals, memory items were simultaneously presented for 5 sec. followed by a 5-sec unfilled retention interval terminated by a single item probe. The subject judged whether the probe was a member of the preceding set and rated confidence of judgment. A signal detection analysis of the recognition data showed the expected monotonic decrease in detection with increasing memory load.

Averaged sec.-by-sec. IBI during the memory task showed a) initial deceleration preceding presentation of the memory set, b) acceleration followed by deceleration during presentation of the memory set, and c) acceleration through most of the retention interval followed by deceleration just prior to presentation of the probe. Thus, cardiac deceleration seemed a consistent correlate of anticipating important intratrial events (ie. presentation or removal of memory set or probe) and was maintained during information input. Acceleration can be associated with times corresponding to initial storage and subsequent rehearsal of memory items. Cardiac results for correct recognitions, as compared to errors, showed less initial deceleration and less acceleration during memory set presentation, but greater acceleration during the retention interval. The exaggeration of acceleration and deceleration for error producing items during presentation of the memory set is difficult to interpret although it may represent a failure to coordinate the requirements for item input and storage.

Neither the pattern nor magnitude of IBI changes varied with memory size. Given the absence of memory load effects in the current study, cardiac acceleration cannot be interpreted in terms of memory operations. No relations between signal detection indices and cardiac change were observed, raising similar questions. Overall the results suggest that the sensitivity of IBI to information processing may arise from a general process such as the regulation of access to processing capacity rather than specific processes such as memory encoding or rehearsal.

733 OPERANT LEARNING IN THE PRECOLLICULAR HEMI-DECEREBRATE RAT: INTACT BRAINSTEM SELF-STIMULATION IPSILATERAL TO LESIONED SIDE. Joseph P. Huston and Kurt Ornstein*. Inst. Pharmacol., Univ. Zurich, Zurich, Switzerland.

Rats were imlanted with stimulating electrodes along the superior cerebellar penduncle, 1 mm lateral to the midline. The animals which self-stimulated were decerebrated unilaterally ipsilateral to the positive electrode. All brain tissue, including hypothalamus, anterior to the colliculi was removed by aspiration. Four of the animals self-stimulated by lever-pressing for stimulation delivered ipsilateral to the lesioned hemisphere. Intact self-stimulation was observed from 4 hours to 3 months after the decerebration. Extinction was comparable to intact animals. In conclusion ipsilateral ascending telencephalic and diencephalic fibers are not critical for brain-stem self-stimulation (which raises serious doubts about the significance of certain catecholamine systems that are often invoked in self-stimulation). It follows, that, if ascending projections are involved, they must be crossed fibers. It is also possible, however, that the hypothalamus and thalamus are not critical for self-stimulation (and operant learning), in addition to the rest of the forebrain, which has been shown to be dispensable in the thalamic rat preparation (Huston and Borbely, Brain Res. 1973,50:467-472).

734 CONDITIONING CAUSED BY IONTOPHORETIC APPLICATIONS OF L-GLUTAMATE ON CORTICAL NEURONES IN CONSCIOUS ANIMALS. S. Ioffe*, V. Havlicek, H. Friesen, V. Chernick (SPON: R. Jell). Depts. of Physiol. & Pediatrics, Univ. of Man., Wpg., Canada. R3E 0W3

The possibility of a role for L-glutamate as a transmitter has been widely discussed in the literature. It has been shown, for example, that L-glutamate is released from the surface of the cerebral cortex by electrical stimulation of the reticular formation as well as cortical slices (Jasper, H. et. al., 1969; Hammerstad, J.P. et. al., 1972). On the other hand, studies concerning cellular analogs of learning (Rabinovich, M.Y. et. al., 1971, Voronin, L.L. et. al., 1972) have shown that during rhythmic stimulation of the cerebral cortex if the stimulus is interrupted the neurons fire at the time a stimulus would normally have been applied. In the present experiment we tested the hypothesis that L-glutamate participates in such conditioning. Extracellular potential of 22 neurons were recorded in five rabbits. The experiments paradigm involved the application of L-glutamate (2-15 nA) for 15-20 seconds of a regularly repeating 75 sec cycle. This was repeated from 40-100 times before interruption. In 18 cells statistically significant conditioned responses ($p < 0.001$ n=18) were recorded and these sometimes equalled or even exceeded the normal response to the application of L-glutamate at the time a stimulus would normally have been applied. This data provides indirect support for a role of L-glutamate in the formation of memory traces. Supported by the Medical Research Council.

735 SHORT-TERM MEMORY: A NEUROPHARMACOLOGICALLY DISTINCT PROCESS. Stanley J. Jackson* and Herbert P. Alpern. Dept. Psych. and Inst. Behav. Gen., Univ. Colo., Boulder, CO 80309.

Since cholinergic modulation of short-term memory has been documented this investigation was undertaken to determine whether other putative neurohumoral systems are involved in the expression of short-term memory.

During the preliminary phase of the experiment subjects were initially trained to a particular position (left or right arm) of a t-maze to avoid punishing foot-shock. After mastering this problem the subjects were trained to the opposite position and then successively alternated until they could reliably reverse their behavior after a single presentation of the reversal cue (foot-shock in the previously correct maze arm). The subjects were then delayed-response tested for short-term memory. On any given day during delayed-response testing each subject was given a single trial during which the reversal cue was presented, then tested for subsequent reversal behavior 5 min. post-cue presentation. This delay interval was chosen because it invariably produces high levels of correct performance. Lastly each subject was trained to a daily 5/6 criterion. The drugs were administered to male C57BL/6 IBG mice prior to daily delayed-response testing. Subjects treated with the cholinergic blockers atropine or scopolamine demonstrated impaired performance; interestingly neither the noradrenergic blockers diethyldithiocarbamate, sotalol, propranalol, or phentolamine, or the dopaminergic blocker haloperidol, nor the serotonergic blocker p-chlorophenylalanine affected performance significantly.

The findings of this study strongly suggest that short-term memory modulation depends heavily on a cholinergic mechanism, and also suggest that short-term memory is morphologically distinct from other memory processes.

736 AMNESIA PRODUCED BY INTRAVENTRICULAR ADMINISTRATION OF DIETHYLDITHIOCARBAMATE. Robert A. Jensen, Joe L. Martinez, Jr., Beatriz J. Vasquez*, James L. McGaugh, Teresa McGuiness*, David Marrujo*, and Scott Herness*. Department of Psychobiology, School of Biological Sciences, University of California, Irvine, CA 92717, U.S.A.

Previous work has shown that the dopamine-β-hydroxylase inhibitor diethyldithiocarbamate (DDC) produces amnesia. In addition to causing a fall in brain norepinephrine levels, peripheral administration of DDC has a number of toxic side effects that may contribute to the observed amnesia. In these experiments, DDC was administered intraventricularly to restrict the site of action and its effects on memory storage processes studied. Adult male Sprague-Dawley rats (n=271) were each implanted with a 1 cm, 25 ga stainless steel guide cannula with the tip aimed dorsal to the left lateral ventricle. Intraventricular injections of DDC (400 mg/ml; pH 11.4), NaOH (pH 11.4) or Ringer's solution were given through a 30 ga inner cannula. These injections were given either 24 hrs or 15 min before inhibitory avoidance training, or immediately, 6 hrs, or 24 hrs after training. Control animals received 10 µl injections of Ringer's solution. Additional rats received 10 µl injections of NaOH as a pH control. DDC was administered in the following doses: 4.0 mg (10 µl), 2.0 mg (5.0 µl), 1.4 mg (3.5 µl), 1.0 mg (2.5 µl), and 0.4 mg (1.0 µl). A 2-compartment black-white apparatus with a 2 mA, 2 sec footshock given upon entry to the dark side was used for inhibitory avoidance training. Three days after training, the animals were tested for retention, sacrificed, and histological examination performed.

The retention latencies of the NaOH control rats were similar to those of the Ringer's control groups in all cases indicating that the infusion of a high pH substance did not in itself produce amnesia. Profound amnesia was observed with 3 of the doses of DDC given 15 minutes before training. The median entrance latency of the rats receiving 1.4 mg DDC was 10.6 sec, 2.0 mg DDC, 1.7 sec and 4.0 mg DDC, 3.8 sec. All of these entrance latencies were shown to be significantly different from those of control animals by Mann-Whitney U-tests ($p < .01$). Only 4.0 mg DDC administered immediately after training produced amnesia ($p < .05$). All saline control groups showed median latencies of 300 sec with the single exception of the immediate post-training group in which the median latency was 297.4 seconds.

These findings demonstrate that intraventricularly administered DDC produces both anterograde and retrograde amnesia. This suggests that the amnesia seen after peripherally administered DDC is not mediated by side effects occurring outside the central nervous system. Additionally, this amnesia is both time dependent and dose related indicating that the effect of DDC is on some aspect of the memory storage process. (Supported by USPH Grants MH 05358, MH 05249, MH 12526, and NSF Grant BNS 76-17370).

737 SPECIFICITY OF PRENATAL AND PERINATAL LEARNING IN TERMS OF LATER BEHAVIOR PATTERNS: A CLINICAL FOLLOW-UP, Virginia Johnson. 1416 Westwood Blvd., Los Angeles, California 90024.

The construct of "learning" derives from the observation of adaptations or changes in behavior following an experience; if no such change can be observed, it would ordinarily be assumed no learning had taken place. Thus in animal and human newborns, certain behaviors indicate that learning already has taken place; as well as the availability of memory process. Such perinatal learning (or conditioning) has been observed in the young of several species, and it may be assumed that memory processes are activated by input from the environment prenatally as well as during and after birth.

Since such input can be demonstrated or reasonably inferred from responsive behavior in human subjects, it also follows that engrams coded at or before birth may form an early matrix to which reference is made continuously thereafter in the intact human nervous system (e.g. biofeedback). Furthermore, the nature of the input itself can be inferred from the observed behavior, thus suggesting a model for assessing the perinatal environment in terms of its effect on later behavior.

In 1971, 1972, and 1973 the author reported on various aspects of natal learning based on state-dependent experimental recall obtained under clinical conditions. The present paper summarises an analysis of this and other data which reflects specificity of early influences on later behavior, including sensory and motor expression, neurophysiological responses, and in some cases even life style. Verbal echoisms appearing spontaneously in the language of adult subjects often appeared to derive from very early learning. It is therefore suggested as a neuropsychological hypothesis in learning and memory that input from prenatal, perinatal, and postnatal environments is significant for the coding of engrams which act as experiential referrents for the developmentally older organism; and that such conditional experiences are specific and identifiable with respect to these later behavior patterns.

This model is congruent with research on neural and behavioral continuity; with clinical neurological data which relates the pathological interruption of function to specific lesions in the brain; and with the dependency of learning and conditioning upon the integrity of response systems. Furthermore, it raises the question of ethics and responsibility for the prenatal/perinatal environment in a society in which individual members may be patterned to a significant degree by early learning.

738 EFFECTS OF AMYGDALA AND STRIA TERMINALIS LESIONS ON AVERSIVE CONDITIONING IN THE RABBIT. Bruce S. Kapp, Robert C. Frysinger,* Michela Gallagher, and Andrew J. Bretschneider.* Dept. Psychol., Univ. of Vermont, Burlington, VT 05401.

In an attempt to investigate the role of the amygdala complex in learning and memory processes, we have initiated a series of studies designed at determining the effects of discrete lesions of the amygdala and its main afferent and efferent pathways on the acquisition of the nictitating membrane conditioned response in New Zealand rabbits. Rabbits received small bilateral lesions within the amygdaloid complex extending from the anterior amygdala area through the basolateral and basomedial nuclear groups. Additional rabbits were assigned to unoperated and operated control groups. Two weeks following surgery, all animals were given 100 conditioning trials per day for four successive days. Each trial consisted of a 500 msec, 92 dB, 1000 Hz tone, the offset of which coincided with the onset of a 50 msec 1.0 ma eyelid shock. The results showed that rabbits with lesions of the amygdala, when compared with operated and unoperated control rabbits, demonstrated profound deficits in the acquisition of the conditioned response, this deficit being manifested in a prolonged initial phase of non-responding.

A second experiment was designed to determine the importance of the stria terminalis, one of the two main afferent-efferent pathways of the amygdala complex, in the acquisition of the conditioned response. Rabbits receiving total or near total transection of the stria terminalis as it projects dorsally just ventromedial to the caudate nucleus did not demonstrate deficits in acquisition of the conditioned response when compared to unoperated control rabbits. The results of these experiments suggest that the amygdala complex and/or the afferent-efferent fibers projecting via the ventral amygdalofugal pathways play an important role in the acquisition of the nictitating membrane conditioned response.

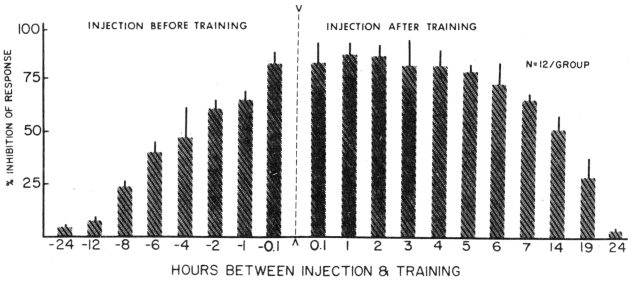
739 **ANTISERUM TO BRAIN GANGLIOSIDES INHIBITS CONSOLIDATION PHASES OF LEARNING.** **S. Karpiak, T. Sowin*, and M.M. Rapport, Div. Neuroscience, N.Y. State Psychiatric Inst., New York, N.Y. 10032.**

Intraventricular (i.ventric.) injection immediately after training (on a passive avoidance learning paradigm) of antiserum to brain gangliosides causes >90% inhibition of the learned response (Neurosci.Abstr. 2: 443). As a control, rats injected with antiserum after absorption with pure G_{M1} ganglioside show no inhibition. We have now examined the temporal parameters of the effects of i.ventric. injection of antiserum to brain gangliosides on learning. Mice (groups of 12) were injected with 8 µl of antiserum to total brain ganglioside at intervals before and after training on a step-through passive avoidance task. They were retested for the learned response 7 days after training. The results (Fig) show that with the shorter intervals between injection of antiserum and time of training, the inhibition of the learned response was greater. A high degree of inhibition (>75%) occurred with injection as long as 6 hrs after training. The control antiserum absorbed with G_{M1} ganglioside injected either at 4 hrs or 1 hr prior to training, or either 5 min, 1, 4 or 14 hrs after training caused no inhibition. Interferences with the learning process produced by antiserum injected before and after training were different since no inhibition was found with the 12 hr interval for injection preceding training (Fig). To determine whether the antiserum to ganglioside was affecting the acquisition or consolidation phases of learning, independent groups of mice were tested one hr (rather than 7 days) after injection, with intervals of 5 min, 1, 4 and 14 hrs between training and injection. These animals showed no inhibition. The results indicate that the antiserum inhibited the consolidation phases of learning and not the acquisition phase.



740 RELATIONS BETWEEN BEHAVIOR, SINGLE-UNIT ACTIVITY IN THE MIDBRAIN RETICULAR FORMATION, AND HIPPOCAMPAL THETA ACTIVITY IN THE ACTIVE RAT. John Kootz and Harry M. Sinnamon (Spon: D.B. Adams), Laboratory of Neuropsychology, Wesleyan University, Middletown, Ct. 06457.

Rats were prepared for recording of single-unit activity in the midbrain reticular formation (MRF) by means of movable microelectrodes and for recording of EEG activity in the hippocampus by means of fixed bipolar electrodes. Following recovery, tests for habituation, dishabituation and sensitization of orienting and movement elicited by click and flash stimuli were made. In preliminary tests for sensory responsiveness, the group of 24 units in the MRF were found to be particularly sensitive to tactile stimuli and to show more multimodal responses than non-MRF sites. Significant correlations, only one of which was negative, between behavior elicited by novel stimuli and unit activity were found for 13 of 24 units in the MRF. However, during tests for habituation and sensitization, unit activity in the MRF and behavior often failed to correlate. Only 4 of 13 MRF units recorded during behavioral havituation showed a parallel decrease in activity, and even in these cases, several instances of behavior-unit disassociation were found. Similar disassociations occurred during behavioral sensitization. Hippocampal theta activity, although moderately correlated with behavior in most animals was correlated with activity in only four MRF units. Activity in the MRF seems to bear no simple, close relationship with behavior elicited by novel stimuli.

741 GENETIC DIFFERENCES IN CYCLOHEXIMIDE INDUCED MEMORY IMPAIRMENT AND PROTEIN SYNTHESIS INHIBITION. Neal R. Kramarcy and Elton E. Quinton. Dept. Psych., Univ. of Louisville, Louisville, Kentucky 40208

Two strains of mice (C57BL/6J and DBA/2J) that have different memory and neurochemical characteristics were administered cycloheximide before training on a passive avoidance task. Retention was tested 72 hours later. Doses of cycloheximide as low as 7 mg/kg were effective in producing amnesia in the C57BL/6J when given 30 min. before training, and 150 mg/kg was amnesic up to 90 min. before training. The degree of memory impairment was both dose and time dependent in the C57BL/6J. In contrast, the DBA/2J exhibited memory impairment only after 150 mg/kg given 30 min. before training. Measurement of cerebral protein synthesis up to 6 hours after cycloheximide indicated a dose dependent relationship for the degree of inhibition and the rate of recovery in both strains. These data further suggest that memory-specific protein synthesis recovers more rapidly from cycloheximide than does general cerebral protein synthesis. Cerebral protein synthesis recovered more rapidly from cycloheximide in the DBA/2J than in the C57BL/6J. These results suggest that the difference in the effectiveness of cycloheximide on memory in the two strains may be due to the more rapid recovery of protein synthesis in the DBA/2J.

742 SODIUM NITRITE INDUCED AMNESIA IN RATS AND MICE. Joe L. Martinez, Jr., Robert A. Jensen, Beatriz J. Vasquez*, Joe S. Lacob*, and James L. McGaugh. Department of Psychobiology, School of Biological Sciences, University of California, Irvine, CA 92717, U.S.A.

We investigated the effects of sodium nitrite ($NaNO_2$) on acquisition and consolidation of an inhibitory avoidance task. $NaNO_2$ is a compound that has two distinct and specific actions. The first is to cause a relaxation of smooth muscle. Thus, one major site of action of $NaNO_2$ is vascular smooth muscle; $NaNO_2$ causes vasodilitation which may result in a hypotensive state. Secondly, the nitrite ion oxidizes hemoglobin to methemoglobin (MHb), and in high doses, may impair the oxygen carrying ability of red blood cells. These effects should produce hypoxia depending on dose. Most experimental studies induce hypoxic amnesia by administering gas mixtures. Surprisingly, little data are available on hypoxic amnesia induced through pharmacological treatment.

Male Swiss-Webster mice and Sprague-Dawley rats (50-60 day) were trained in a one-trial inhibitory avoidance step-through task. Animals were placed in a well-lit start compartment. Upon stepping through to the dark side, they received a footshock. Rats received a 2 mA, 2 sec inescapable footshock while mice received a 350 μA footshock terminated by escaping back to the start chamber. A retention test was given either 48 hrs (rats) or 72 hrs (mice) after training. The cutoff latencies were 300 sec (rats) and 600 sec (mice). The $NaNO_2$ was dissolved in distilled water and administered to the animals either 30 min (mice) or 15 min (rats) before training or immediately after training in the following doses: Mice (0.10, 1.0, 10.0, 100.0 mg/kg, i.p.); rats in the pretraining administration condition (5.0, 25.0, 50.0 mg/kg); rats in the posttraining condition (0.5, 5.0, 50.0 mg/kg). Significant differences resulted only when the animals were treated before training. Thus, for rats 5.0 and 25.0 mg/kg $NaNO_2$ produced amnesia (U=770.5, Z=5.915, $p<.0001$; U=733, Z=1.96, p=.05). For the mice only one dose (0.10 mg/kg) produced amnesia (U=859, Z=2.91, p=.0036). The effect was inversely dose related since in no case did the highest dose produce amnesia. MHb levels in $NaNO_2$-treated rats were determined by a cyanmethemoglobin assay. The following percentages of MHb were found following $NaNO_2$ administration: saline=0%; 0.5 mg/kg=0%; 5.0 mg/kg=2.0%; 25.0 mg/kg=19.49%; 50.0 mg/kg=33.25%. Additionally, in rats we found no gross EEG abnormalities such as epileptiform activity associated with a single dose of $NaNO_2$.

These findings indicate that $NaNO_2$ produces anterograde amnesia. However, the amnesia is not strictly dose-related, indicating that compensatory mechanisms were inititated by higher doses of $NaNO_2$. (Supported by UPHS grants MH 05249, MH 05358, MH 12526, AG 00469, and BNS 76-17370).

743 INSTRUMENTAL LEARNING IMPAIRMENT FOLLOWING LESIONS OF VENTRAL ANTERIOR THALAMUS IN RAT. Darryl B. Neill* and Michael D. Britt* (SPON: David Freides). Dept. Psychology, Emory Univ., Atlanta, GA 30322

Electrolytic lesions were bilaterally placed in the thalami of rats to include the ventral anterior and ventral medial nuclei. These animals were found to be impaired in the acquisition of a number of instrumentally-learned responses. They had difficulty learning to bar-press for food or water, and to run an alley for food reward. In addition, they could not learn to perform a 1-way avoidance response in an alley to avoid shock. A number of experiments were conducted to assess the nature of the impairment. First, if trained preoperatively on alley-running or bar-pressing for food or on alley shock avoidance, subsequent lesioning did not reliably affect performance on any of the tasks tested, indicating specificity for acquisition. Second, both spontaneous and amphetamine-induced locomotor activity were normal, indicating little or no impairment in gross motor function. Third, any lesioned-induced hypophagia or hypodipsia was limited to 2-3 days post-surgery, and the animals' food and water intakes appeared normal thereafter. When food or water-deprived, they immediately consumed food or water presented in the home cage. Fourth, the emotional reactions to handling and shock of the lesioned rats appeared normal. It was concluded that the learning impairments observed could not be readily explained on the basis of changes in gross motor ability, incentive value of reward, or emotionality.

This thalamic area is at the confluence of a number of cellular and axonal systems which have recently been linked to instrumental conditioning. The ventral medial nuclei of the rat are terminal sites of the nigrothalamic projection. The ventral anterior and medial nuclei receive a heavy projection from the globus pallidus. Silver impregnation studies of the forebrains of rats revealed major degeneration sites in dorsolateral anterior neocortex and neostriatum.

In summary, we feel that this thalamic region may contain axons and/or cell bodies involved in instrumental conditioning. Although our experiments tend to rule out some explanations, the exact nature of this involvement remains to be defined.

744 PONTINE RETICULAR FORMATION NEURON ACTIVITY DURING CLASSICAL CONDITIONING. Robert J. Norman and Jennifer S. Buchwald, Dept. of Physiology, Brain Res. Inst., Sch. Med., UCLA, Los Angeles CA, 90024.

We have previously reported conditioning of the blink response in chronic decerebrate cats implicating the pontine reticular formation as the site supporting such learning. In this study, single unit activity from the pontine reticular formation was recorded during classical conditioning with auditory discrimination in normal and bilaterally hemispherectomized cats. The cats were restrained in an atraumatic head holder allowing stereotaxic placement of metal microelectrodes into various location in the reticular formation and medial thalamic sites in the awake and behaving animal. Conditioning trials consisted of the presentation of a conditioned stimulus (500 msec., 65 db SPL) followed by a single shock to the outer canthus of the left eye (2 msec., 30 v). EMG was recorded bilaterally from orbicularis oculus. The discrimination procedure consisted of presenting tones differing in frequency from the conditioned stimulus but without the shock. Following several hundred trials the cats would respond with a characteristic conditioned response to the reinforced tone (CS+) but more infrequently or not at all to the unreinforced tone (CS-). Unit recordings were made only when the behavioral response had been well stabilized to avoid the more transient correlates of learning associated with the acquisition phase of conditioning. Unit activity was analyzed separately for four classes of trials depending on whether or not the animal responded and whether or not a response was appropriate on that trial (CS+, CS-). Correlations were also obtained for EMG reflex components which often occur during conditioning trials but which are not considered to be an essential part of the conditioning process. In contrast to the unconditioned state, a large percentage of neurons encountered showed reliable responses to the stimuli used in conditioning. Analysis of the patterns of activity suggested that the unit responses are more closely related to the motor response than to sensory input. Cross correlation of unit onset latency with EMG latency on conditioning trials suggests that the RF units are leading the conditioned response and represent a component of the central initiation of the response. (Supported by USPHS Grant NS-05437).

745 ASSOCIATIVE AND NON-ASSOCIATIVE CHANGES IN AUDITORY SYSTEM UNIT RESPONSES DURING CLASSICAL CONDITIONING IN THE RAT. J. Olds, R. Nienhuis* Div. of Biol., Calif. Inst. of Tech. Pasadena, CA 91125

Experiments were conducted to localize unit changes of short latency in the medial geniculate body and in the inferior colliculus of the rat during differential classical conditioning tests with tones as the stimuli and food as the reward. In an earlier study changes in responsiveness of an abrupt character appeared when the experimental paradigm shifted from the random presentation of signals to the paired conditioning trials. This observation indicated the possibility of arousal and orienting factors as the source of some of the changes. It seemed possible that the different average position of the CS+ in relation to the reward in conditioning trials as compared to the pseudoconditioning trials might be responsible for these changes. During the random series it was at a midpoint in the pellet-pellet interval; in the conditioning trials it was at the end of the pellet-pellet interval. In the first experiment to test for arousal effects, responses of 52 inferior colliculus and medial geniculate body units in 8 freely moving rats were studied at each of 8 randomly varied intervals (ranging from 20 sec to 180 sec following a food pellet). Large changes with a linear trend over the 8 intervals were observed in the initial onset component but not the later components of the unit responses. The changes consisted of two components, increases in the peak-response firing, and decreases in spontaneous background firing. It was therefore concluded that such changes could have been an artifact in earlier differential conditioning studies. Therefore, in the second experiment additional restrictive criteria for associative changes were instituted. 119 units in medial geniculate body and 135 units in inferior colliculus were studied during a differential classical conditioning task, in order to assess the associative nature of the later components of the auditory response. Restrictive criteria for associative changes were applied to individual cases and were aimed to eliminate previously uncontrolled-for, non-associative changes. Associative changes with latencies ranging between 25-57 msec were observed in 14 units in the medial part of the medial geniculate body and in the posterior nucleus. Changes with shorter latencies were observed but they did not meet the restrictive criteria. Responsiveness during conditioning was characteristic for different parts of the medial geniculate body. No clear associative changes were seen in the inferior colliculus.

746 MNEMONIC DISTURBANCE IN MACAQUES FROM STIMULATION OF ANTERIOR COMMISSURE VERSUS LIMBIC SYSTEM OR BASAL GANGLIA. William H. Overman, Jr.* and Robert W. Doty, Center for Brain Research, University of Rochester, Rochester, New York 14642.

Previous work (In: Lateralization in the Nervous System, Harnad, et al., Eds., Academic Press, 1977) had shown that electrical stimulation of the anterior commissure (AC) eliminated manual responses to conditional stimuli in 3 highly trained macaques. This effect was tentatively attributed to amnestic rather than to motoric or ictal causes since the animals displayed no disturbance of spontaneous movement and could respond promptly after cessation of tetanization of AC. In order to specify more precisely the nature of the disruption, 3 additional macaques were trained on a delayed match-to-sample task in which they selected (matched) from a pair of 100 visual stimuli, 50 trials per day, that stimulus (sample) which had been presented 5 sec earlier. Average accuracy was 94% correct. Tetanization with 0.2-msec pulses, 0.6 mA, 50 Hz, was then applied for 4 sec through electrodes implanted at one of 45 (histologically verified) loci during either the "sample", "delay", or "match" period for 25-35 trials each, interspersed among some 2000 control trials. Tetanization of AC produced no evidence of electrical after-discharge, but reduced accuracy of response to chance levels when applied during the "sample" or the "match" period ("match" responses made immediately after cessation of tetanization). Application during the "delay" was without effect. Tetanization of caudate nucleus, putamen or globus pallidus produced a similar failure to respond during the "sample" or "match" period, but generally did not interfere with accuracy of response, even in some instances in which intensities were used which could produce localized electrical after-discharge. On the other hand, stimulation at other loci in basal ganglia in some instances did reduce the accuracy of responding, and evidence of after-discharge was common. Tetanization in hippocampus or fusiform gyrus usually reduced accuracy of response to chance levels regardless of when the stimulation occurred, and whether or not localized after-discharges could be recorded using the currents employed in the behavioral situation. Stimulation at many loci, e.g. splenium of corpus callosum or superior temporal gyrus, was without effect on performance, although the animal often appeared to detect the stimulation. Stimulation of midline AC was ineffective in one case in which it was inadvertently transected by an hemorrhagic electrode track 5 mm lateral to the midline, and in another instance when the electrode barely contacted the posterior surface of AC. The primary conclusion is that tetanization of the intact AC effects a bilateral, transitory disruption of access to memory traces.

747 BRAIN-STIMULATION AS THE DISCRIMINATIVE STIMULUS IN A LITHIUM CHLORIDE CONDITIONED AVERSION PARADIGM. Anthony G. Phillips and F.G. LePiane*. Dept.Psychol., Univ. of British Columbia, Vancouver, Canada.

Electrical stimulation of basolateral amygdala during or immediately after consumption of a novel saccharin solution disrupts conditioning of taste aversion that normally occurs following subsequent poisoning with LiCl (0.2 mol. x 2% body weight). This effect appears to be locus specific as stimulation of neostriatum or substantia nigra failed to disrupt conditioned taste aversion although comparable stimulation will interfere with retention of a passive avoidance response. In an attempt to discover the nature of this disruptive effect on conditioned taste aversion, stimulation of basolateral amygdala or neostriatum was paired with drinking of H_2O prior to poisoning with LiCl. Pairing amygdaloid stimulation with H_2O in the 10 min drinking period. 48 h after LiCl treatment resulted in a 60% decrease in volume consumed. Caudate stimulation had no significant effect. Electrical stimulation of either nucleus had no significant effect on H_2O intake during the conditioning trial. Water intake 24 h after pairing LiCl with brain stimulation, was also unaffected. Injection of NaCl during the conditioning trial had no significant effect on subsequent H_2O intake in both groups of stimulated control animals. Similarly, injections of LiCl failed to disrupt H_2O intake, 24 and 48 h later, in unstimulated controls with electrodes implantated in basolateral amygdala or neostriatum. These results clearly show that stimulation of basolateral amygdala can serve as a discriminative stimulus in a LiCl aversion paradigm. Consequently, pairing amygdala stimulation with novel taste may serve as a complex conditioned stimulus in a conditioned taste aversion experiment. Therefore, apparent disruption of taste aversion during retention tests in which brain stimulation is omitted can best be attributed to failure to provide subjects with the original complex conditioned stimulus.

748 LINGUISTIC SPECIALIZATION OF THE LEFT HEMISPHERE. Francis J. Pirozzolo*, Harry A. Whitaker, Ola A. Selnes*, and Frederick Horner*. Department of Psychology, University of Rochester, Rochester, New York 14627.

Several recent attempts have been made to assess the auditory language capacity of children who have undergone left hemispherectomies early in life as neurosurgical treatment for Sturge-Weber-Dimitri Syndrome. Although the enforced development of speech and language in the right hemisphere seems to be normal by certain gross measures (e.g., verbal IQ), the right hemisphere does not appear to be a good substrate for the development of certain specific language skills such as syntactical competence. In relation to right hemispherectomized patients, these children exhibit deficiencies in repeating stylistically permuted sentences, integrating syntactic features to replace missing pronouns, and recognizing and correcting syntactically anamolous sentences. These results suggest that the two cerebral hemispheres may not be ontogenetically equal in their ability to serve as substrates for certain linguistic functions.

Using special tests designed to measure syntactic competence in a nine year-old boy with asymptomatic agenesis of the anterior two-thirds of the left temporal lobe (diagnosed by CT scan and confirmed at neurosurgery), we present further evidence of the role of the temporal lobe in language functions and the inferiority of the right hemisphere in performing at a level equal to the left in language acquisition. Although this patient had a WISC-R IQ of 121, he scored in the first percentile on a standardized test of receptive syntactical ability. Other auditory-linguistic defecits were revealed by our battery of language tests and they were incongruous with results of tests designed to measure spatial abilities. This case of agenesis of the left temporal lobe, along with other clinical and experimental observations, may provide compelling evidence to support the notion that the left hemisphere is genetically specialized or pre-programmed to perform language functions such as the auditory analysis of speech sounds.

749 CONCOMMITANT SOMATIC AND CARDIOVASCULAR CONDITIONING: EFFECTS OF CAUDATE LESIONS. D. A. Powell, Donald Mankowski*, and Shirley Buchanan*. Neuroscience Lab., VA Hospital, and Univ. of S. C., Columbia, S. C., 29201.

Different groups of rabbits received either unilateral or bilateral caudate lesions or were sham operated. Two weeks later all animals were subjected to simple or differential Pavlovian conditioning in which 500 millisec. tones of 80 db SPL intensity served as the CS and 200 millisec., 5Ma paraorbital shock served as the UCS. Corneoretinal potential (CRP), electromyographic activity (EMG) and heart rate (HR) CRs were assessed. In control experiments the unconditioned HR response as well as the CRP threshold to different intensities of shock was measured. Free field activity was also assessed. It was found that rabbits with bilateral caudate lesions, which destroyed 2/3 of the anterio-medial head of the caudate nucleus, severely impaired the acquisition of the Pavlovian conditioned corneoretinal potential response. Animals with smaller lesions (less than 1/3) or unilateral lesions showed normal acquisition of the CRP CR. However, large bilateral caudate lesions had no effect upon either the magnitude of the heart rate CR or the heart rate discrimination. Thus animals with relatively large lesions of the head of the caudate nucleus revealed a severe impairment in somatomotor learning but visceroautonomic conditioning was intact. Control experiments showed that generalized electromyographic activity was unaffected, as was general activity in a free field. Neither the CRP thresholds to shock or the unconditioned heart rate response was affected by caudate lesions. These data thus suggest that bilateral caudate lesions result in a specific impairment in the ability to generate a learned somatomotor response but do not impair visceroautonomic accompaniments of somatomotor learning.

750 ESCOPOLAMINE INJECTIONS INTO THE CAUDATE NUCLEUS. CORRELATION BETWEEN DEGREES OF TRAINING AND INSTRUMENTAL BEHAVIOR. Roberto A. Prado-Alcalá, Patricia Kaufmann Carbia* and Renee Moscona Alasraki*. Dept. Psychophysiol. Sch. Psychol. Anáhuac Univ. and Physiol. Dept. Med. Sch. Ntnl. Univ. of México, México City, México.

At last year's NS meeting (Prado-Alcalá and Cobos-Zapiaín, NS Abstracts, Vol. II) we showed that cholinergic blockade of the caudate nucleus (NC) of cats produced a significant impairment in the performance of recently acquired instrumental behaviors, whereas overtrained responses remain unaffected. In order to further study this effect we injected escopolamine into the CN of rats with different degrees of training.

Several groups of Wistar rats were trained under a CRF schedule to press a lever in order to be reinforced with water, during 5, 15 or 25 daily sessions. After training some were bilaterally implanted with cannulae in the CN. Two days after surgery they were retrained, and before the 4th session they were injected through the cannulae with a escopolamine bromide solution (30 ug/NC) or with saline solution. Unimplanted rats were trained for an equivalent number of sessions.

As compared with the unimplanted and the saline groups, it was found that escopolamine treatments induced: a) a highly significant impairment in instrumental performance in the 5-sessions groups; b) a mild effect in the 15-sessions group, and c) no deficits in the overtrained group.

These data confirm our earlier finding, and together with recent observations, support the hypothesis that as training progresses cholinergic mechanisms within the caudate nucleus become less involved in mediating instrumental responding, or that the CN, as a whole, plays a less significant role in such behaviors.

751 AGE DIFFERENCES IN ELECTRODERMAL AND DECISION RESPONSES DURING RECOGNITION MEMORY TESTING. Walter H. Riege, Howard F. Wallach* and Michael J. Cohen*. VA Hospital Sepulveda, CA 91343 and Dept. Psychiatry, Sch. Med., UCLA, Los Angeles, CA 90024.

Electrodermal responses (EDR) frequently are taken as an index of autonomic activity related to cognitive processing. Thompson and Marsh (1973, 1977) postulated a more restricted range in autonomic responsivity for the old in contrast with the young. To investigate correlation of EDR with decision and retrieval from semantic memory, we measured amplitude changes of skin potential (SP) and skin conductance (SC) time-locked with a person's decision responses (Yes/No) and decision time in a verbal recurrent recognition task. We predicted that the proverbial slower decision making of the old would produce lower EDR and more decision certainty.

Male volunteers (N = 12/group) from three age groups (Young, mean age $\bar{x}$ = 24.7 years; Middle-Aged, $\bar{x}$ = 44.4; Old, $\bar{x}$ = 65.9) were asked to selectively remember 16 words (8 emotionally charged, 8 neutral words selected from the Polarization Dimension, Heise, 1965) and to recognize these in lists of 50 words, equally balanced for emotional and neutral charge. Words were presented via tape recorder in fixed random order at a rate of one word every 20 sec while EDR and decision time (interval from repeating the presented word to its recognition decision) were recorded.

We found that the amplitude changes of EDR's were larger and the decision times shorter for emotionally charged than for neutral words. Correspondingly, more charged than neutral words were recognized by all persons. The old, on the other hand, made fewer correct and fewer false recognitions and had, unexpectedly, neither smaller SP nor smaller SC changes than younger persons. The old did also not take more but less time to decide; they adopted higher decision criteria (Signal Detection C_x), but these measures were neither correlated with EDR nor with decision time data. Only the middle-aged, not the old, had low EDR changes. In fact, EDR changes correlated with correct recognition only for neutral words in the young (4 = 0.44) and the middle-aged (r = 0.65) and did not differ for to-be-remembered or background words, so that we conclude electrodermal activity reflects general task effort rather than autonomic reactivity related to decision or memory processing.

752 THE ROLE OF ASSEMBLIES OF NEURONS IN A THEORY OF MEMORY. Kathleen J. Roney* and Gordon L. Shaw. Physics Department, University of California, Irvine, California 92717.

A study of the memory storage capacity of a network of N neurons having Hebb-type modifiable synapses (Shaw, "Space-Time Correlations of Neuronal Firing Related to Memory Storage Capacity," to be published) was made, based on an analysis of a model proposed by Little and Shaw (Behav. Biol. 14: 115-133, 1975). Although there are 2^N possible firing patterns for the N neurons in a given time step, it was found that only N linear combinations of these patterns dominate the firing behavior of the network. In response to a stimulus, a time sequence of these combinations will be excited. The sequence describes the average firing behavior as a function of time for each neuron in the network following stimulation and can be identified with the post stimulus histogram (PSH) for a given neuron. Using the definition of an assembly of neurons as hypothesized by John (Science 177: 850-864, 1972), the PSH of one neuron in an assembly (i.e., the response of a single neuron averaged over many presentations of the same stimulus) is equivalent to the average firing for all the neurons of an assembly in response to a single presentation of the stimulus. Thus, by applying John's hypothesis, we find that a highly interconnected network can be excited into many different sequences of (averaged) firing patterns of neuronal assemblies. This allows the response of a network to a single stimulus to be reproducible, as it must be in order to correlate with behavior. Thus the cell assembly concept is central to the analysis and appears physiologically reasonable in that an assembly of neurons permits the loss of some neurons without jeopardizing a particular firing pattern sequence, thereby preserving the memory associated with that particular sequence. To test these results, experiments involving the use of two or more extracellular microelectrodes must be done. In anticipation of the possible experimental confirmation of the existence of assemblies, we consider various possible physiological bases for the necessary "instantaneous" averaging over an assembly (e.g., electrotonic synapses). We will present results on the use of this physiological realization of John's hypothesis to explicitly incorporate assemblies into the theory.

753 HORMONAL INFLUENCES UPON SYNAPTIC PLASTICITY UNDERLYING THE KINDLING PROCESS. Robert P. Rose*, Frank Morrell and Thomas J. Hoeppner. Dept. of Neurological Sciences, Rush-Presbyterian-St. Luke's Med. Ctr., Chicago, Il. 60612 and Dept. of Neurosciences, Albert Einstein College of Medicine, Bronx, N.Y. 10461

"Kindling" is a progressively augmenting convulsive response to intermittent focal electrical stimulation of brain. A durable alteration of synaptic function is thought to underlie this process. Substantial evidence points to the importance of hormonal influences upon synaptic plasticity in learning situations. This study examines possible hormonal influences in kindling.

Untreated (control) and hypophysectomized male albino rats bearing implanted depth electrodes in basolateral amygdala of one side were subjected to daily electrical stimulation (150 uA, 60 Hz., 1 msec pulses, 2 sec. train duration). Polygraph recordings of cortical (via calvarium screws) and amygdala activity were made before and after stimulation. After-discharge durations and all behavioral manifestations of seizure activity were noted. Daily stimulation was continued until animals manifested tonic-clonic convulsions on three successive days. Animals were sacrificed after kindling was completed, and histology was performed (cresyl violet) to confirm electrode localization.

Hypophysectomy resulted in marked changes in the kindling process. If stimulation was initiated within two weeks of hypophysectomy the kindling rate was slowed. If stimulation was delayed more than three weeks kindling developed more rapidly than in controls. In both control and hypophysectomized animals the process was influenced by systemic steroid administration, suggesting that the effect of hypophysectomy was hormonally mediated. The findings suggest that hormonal mechanisms may play a role in the neural plasticity underlying kindling.

754 LOCAL LEARNING IN CORTICAL NEURONS. Stuart M. Rosenblum*, M. Byron Wilder*, and James H. O'Brien. Department of Medical Psychology, University of Oregon Health Sciences Center, Portland, Oregon 97201.

Attempts to understand the neural basis of learning have often involved a search for the sites within the brain at which learning occurs. In recent neurophysiological approaches, a demonstration of sites of local learning has amounted to differentiating between those neurons which actively participate in learning and those which are passively involved. Two experiments described in this presentation have shown that local learning changes occur in the sensory-motor cortex of the cat. All experiments were performed in acutely prepared, awake, immobilized cats.

Experiment One. Conditioned responses developed in pyramidal tract cells from pairing a sensory afferent stimulus (CS) with stimulation of the pyramidal tract which antidromically activated the cells (US). The results of a control experiment indicated that the conditioned changes in the response of the cortical neuron did not develop if the magnitude of the US was set just below the threshold to produce an antidromic spike in the recorded neuron. The learning changes were clearly not due to any orthodromic afferent systems activated by the US. Thus, it was concluded that the cortical conditioned response was not projected from some other locus within the brain but was mediated locally within the cortex.

Experiment Two. A reversible cryogenic blockade of the anterior midline thalamus was introduced during the middle one-third of a classical conditioning sequence. This blockade of nonspecific afferent input to the cortex resulted in disruption of cortical neuronal conditioning both during and following the cooling. The level of conditioned responses following termination of the cooling was significantly less than that found without cooling. This demonstrated that the conditioning which was found for neurons at the cortical level was not simply a reflection of changes which took place peripheral to the cryogenic blockade of the thalamus. These experiments provide evidence that the neurons of the cat sensory-motor cortex are capable of actively mediating the elaboration of a conditioned response, and so constitute a site of local learning within the brain.

755 RETICULAR STIMULATION FACILITATES RETRIEVAL OF MEMORY AFTER AN EXTENDED TRAINING TO TEST INTERVAL. Susan J. Sara, Bernard Deweer° and Bernard Hars°. CPEC, Univ. Louvain, 3041 Pellenberg Belgium, and Dept. Psychophysiologie, LPN, CNRS, GIF/Yvette,France

Stimulation of the mesencephalic reticular formation at a very low intensity has been used to facilitate treatment of information acquired immediately prior to the stimulation (Bloch and Deweer, 1968). The contiguity between the original presentation of information and the stimulation seems to be essential, as it is in most studies of hypermnestic and amnestic effects of physiological manipulations. However, Sara and Remacle have recently shown (BB, 1977) that increasing central activation by pretest injections of strychnine can facilitate retrieval. The present study investigated the effect of increasing arousal by reticular stimulation on retrieval.

Rats were given partial acquisition of a complex maze task and tested for retention 30 days after the first acquisition trial. Half of the rats were submitted to a reactivation (reminder) treatment immediately before retention testing and half were not reminded. These groups were subdivided into stimulated and non stimulated groups, in order to study the effect of the stimulation under different cognitive contexts. Results showed that the rats which were neither reminded nor stimulated showed a performance decrement compared to their last acquisition trial (forgetting). They took longer to run the maze and more errors than at acquisition. The reminder procedure alleviated forgetting when measured either by run time or errors. Reticular stimulation diminished the number of errors, but not run time, suggesting that memory retrieval is a multifaceted process and that these two treatments facilitate different aspects of this process.

A second test, twenty-four hours after the initial one using the same pretest manipulations , showed that there were no longer any differences among treatment groups. This was taken as further evidence that the forgetting seen in the non reminded, non-stimulated control group was a lapse, not a loss and that the forgetting is due to retrieval failure. Furthermore, retrieval is shown to be a labile process, subject to physiological interventions, thus establishing this aspect of memory as a potentially fruitful area of research, which has not, as yet been widely explored by psychobiologists.

756 EFFECT OF ANTISERA TO β AND γ GOLDFISH BRAIN PROTEINS ON THE RETENTION OF A NEWLY ACQUIRED BEHAVIOR. Victor E. Shashoua and Mary E. Moore*. McLean Hospital, Mailman Res. Ctr., Dept. of Biol. Chem., Harvard Medical School, Belmont, MA 02178.

In previous studies (PNAS 74, 1743-1747, 1977) three brain proteins were identified by double labeling methods as products which incorporated more labeled valine, after goldfish acquired a new pattern of behavior. Two of these proteins (β and γ) were subsequently isolated and used as antigens to prepare antisera in rabbits (Brain Res. 122, 113-124, 1977). The monospecificity of the antisera was established by several criteria including their capacity to precipitate the labeled antigens from total goldfish brain cytoplasmic proteins. The β and γ antisera were injected into the 4th ventricle of the brains of trained animals at various times after the initiation of training. Goldfish (98 animals) injected with antisera between 8 hours and as long as 48 hours after the initiation of training, could not recall the behavior when tested 3 days after training. Trained goldfish (97 animals) receiving nonimmunized rabbit serum were used as controls; they had complete recall of the behavior. Also no amnestic effects were obtained when goldfish were injected with an antiserum to a neuronal surface membrane protein NS-6 (obtained from Drs. J. Chaffee and M. Schachner of the Children's Hospital, Harvard Medical School). This suggests that not every antiserum to a brain specific protein can inhibit the recall of the training. In addition, the possibility that the antisera were toxic was controlled for by the observation that injections of β and γ antisera, prior to the training, produced no effects on the rate of acquisition or recall of the behavior. A study of the residence time of the antisera in the brain following an intraventricular injection was also carried out. The results are consistent with the hypothesis that β and γ might have some direct role in one of the biochemical steps leading to the formation of a long-term memory. (Supported by grants from NINCDS #09407 and The McKnight Foundation.)

757 PAVLOVIAN DEFENSIVE CONDITIONING IN 1 WEEK, 4 WEEK, 12 WEEK OLD KITTENS AND ADULT CATS. S. Stefan Soltysik* and George Wolfe* (SPON: N.A. Buchwald), MRRC, Sch. of Med., UCLA, Los Angeles, CA. 90024.

Hindleg flexion, running, vocalization, respiratory and heart rate changes were recorded during classical defensive conditioning in cats and kittens. The subjects were trained in a specially designed Pavlovian stand in which the treadmill floor enabled running with the animal's head immobilized. Most of the subjects had cranial implants for electrophysiological recording from the brain. EKG was taken with chest electrodes. Respiration was monitored with a small thermistor positioned in an external nare. Vertical and forward-backward movements of the left foot were recorded by means of jointed levers. The Conditioned Stimulus (CS) was a 5.25 sec steady stream of air from a 15 gauge tube directed at the sacral region. The shock Unconditioned Stimulus (US) from an AC stimulator lasted 300 msec and started 5 sec after the CS onset. Training consisted of 10 sessions of 10 trials each run twice a day for 5 consecutive days (100 trials of CS-US pairing). The training was preceded by a 5 trial session of CS alone and followed by two 20 trial extinction sessions.

Leg flexions to CS did not develop in 1 and 4 week old kittens, but were fairly evident at the age of 12 weeks (>60% in sessions 9 and 10) and even more frequent in adults (>80% in sessions 9 and 10). Conditioned vocalization was typical in adults and in some of the 12 week old kittens. Two types of vocal responses were observed. Conditioned distress calls were correlated with stable leg flexion responding to CS; angry growls were observed in cats with poorer performance of the conditioned leg flexion. Running was not strengthened or maintained by CS-US pairing and disappeared during training. Heart rate and respiratory changes to CS were present at all ages. Several types of cardiac responses were observed and their evolution during training seem to reflect both associative and non-associative processes. The results are interpreted as an evidence of differential rate of maturation of the CNS structures involved in associative processes underlying emotional (preparatory) and leg flexion (consummatory) responses elicited by noxious stimuli.

758 ELEVATION OF BRAIN TYROSINE CONCENTRATIONS BY CYCLOHEXIMIDE IS NOT RESPONSIBLE FOR ITS AMNESIC EFFECTS. Curt W. Spanis and Larry R. Squire. Psychology Service, V.A. Hospital, and Psychiatry Dept., UCSD, La Jolla, CA 92161.

Administration of cycloheximide, an inhibitor of protein synthesis, elevates brain tyrosine concentrations. This finding raised the possibility that the amnesic effect of this drug could be due to abnormal brain tyrosine concentrations. We have found that 1) amnesic doses of cycloheximide produced a 200-250% elevation in brain tyrosine concentrations that persisted for several hours after injection; 2) injection of L-tyrosine, in doses that elevated brain tyrosine more than cycloheximide, did not affect memory. Therefore, the effect of protein synthesis inhibitors on brain tyrosine is not sufficient to explain their amnesic effect.

759 ANTEROGRADE AMNESIA FOLLOWING ECT: AN ANALYSIS OF THE BENEFICIAL EFFECTS OF PARTIAL INFORMATION. Larry R. Squire, C. Douglas Wetzel*, and Pamela C. Slater*. Psychology Service, V.A. Hospital, and Psychiatry Dept., UCSD, La Jolla, CA 92161.

Patients receiving bilateral ECT learned a list of words and then were tested for retention by three different retention procedures -- partial information, yes-no recognition, and 2-choice recognition. A comparison of all three retention conditions indicated that the yes-no recognition condition was particularly difficult for amnesic patients. Moreover, at short learning-retention intervals, the partial information procedure was beneficial for amnesic patients but not for normal subjects. These results confirmed previous findings with the partial information procedure and suggested that the amnesic syndrome can exhibit qualitatively distinct features not apparent in normal memory. During the course of forgetting, however, normal subjects came to exhibit a nearly identical pattern of performance as amnesic patients. These findings indicated that apparently qualitative defects in performance can sometimes be characterized as a quantitative change along a normal continuum. It seems possible that there are important similarities between the poor memory of amnesic patients and the poor memory of normal subjects long after learning.

760 PHASE-SHIFTS OF CIRCADIAN RHYTHMS PRODUCE RETROGRADE AMNESIA. Walter N. Tapp* and Frank A. Holloway. Dept. Psychiatry and Behav. Sci., The University of Okla. Health Sci. Center, Okla. City, Ok. 73190.

Male albino rats were entrained to a 12:12 light-dark (LD) cycle. Rats were housed in photocell activity cages and activity was recorded throughout the experiment. Rats were trained in a one-trial passive avoidance task. Shortly after training, the LD cycle was phase-shifted 0, 6, or 12 h. Testing was 48 h or 7 days after training.

Training and testing did not affect the circadian activity rhythms of control rats which were not phase-shifted. These animals showed stable, high levels of retention performance at 48 h and 7 days. Following LD shifts, the circadian activity rhythms showed temporary disturbances characteristic of resynchronization to a new LD cycle. Disturbed circadian activity rhythms usually appeared within 24 h of the phase-shift and disappeared within 5 days. Retention performance of phase-shifted animals was impaired 48 h or 7 days after training. Since retention deficits were seen in phase-shifted animals trained and tested in the same light condition, explanations based on generalization decrements due to differences in light conditions can be excluded. Similarly, retention impairments 7 days after training suggest that the deficit is not due to impaired performance since the animals had resynchronized to the new LD schedule by then. Two more plausible explanations invoke storage or retrieval mechanisms. Disruption of the animal's internal rhythmic organization may be sufficient to disrupt memory storage. Phase-shifting internal rhythms may alter the animal's internal state leading to a state-dependent retrieval deficit.

761 FACILITATORY EFFECTS OF RESERPINE IN AN INHIBITORY AVOIDANCE TASK. Beatriz J. Vasquez*, Joe L. Martinez, Jr., Robert A. Jensen, and James L. McGaugh. Department of Psychobiology, School of Biological Sciences, University of California, Irvine, CA 92717 U.S.A.

Reserpine is a monoamine depletor that interferes with storage mechanisms. Some studies report that reserpine has no effect on memory while other research indicates that it can produce amnesia in both active and inhibitory avoidance tasks. Part of the contradictory findings may be related to different levels of footshock employed and to circadian differences arising from the use of variable treatment-test intervals. This study was designed to address itself to these problems. Two footshock levels (350 uA, 2 mA) and two doses of reserpine (0.3 and 3.0 mg/kg) given i.p. either 6 hr before training, immediately after or 6 hr after training, were used in this experiment. Circadian differences were assessed by comparing each treated group to a control that had the same training-treatment interval. Male Swiss-Webster mice were trained in an inhibitory avoidance task using a two-chamber straight alley apparatus. Animals were placed into a well-lit start compartment separated from a dark and larger shock chamber by a guillotine door. When the mouse entered the dark compartment it received a footshock that terminated when the animal escaped back to the start compartment. Retention tests were given 72 hr later; latencies to step-through were recorded to a maximum of 600 sec.

In the groups that received a 350 uA footshock 6 hr before training, 3.0 mg/kg reserpine resulted in impaired retention performance ($U=671$; $Z=2.57$; $p=.01$). However, when reserpine was given 6 hr after training (3.0 mg/kg; 350 uA) a significant facilitation of retention performance was observed ($U=346$; $Z=2.48$; $p=.0132$). In the 2 mA footshock condition, 3.0 mg/kg reserpine given 6 hr before training produced an impairment of retention ($U=513$; $Z=2.57$; $p=.01$). When the same treatment (3.0 mg/kg; 2 mA) was administered immediately after training it produced a significant facilitation of retention performance ($U=228$; $Z=1.89$; $p=.0588$).

The fact that reserpine facilitated retention performance when given after the training trial indicates that the drug was acting to enhance some aspect of the memory consolidation process and not influencing performance factors, although the latter cannot be completely ruled out. Impairment of retention was seen only with the high dose of reserpine injected 6 hr before training. Animals under this condition were behaviorally depressed at the time of training as evidenced by their longer initial entrance latencies. Therefore, with pre-training injections, the effects on retention might be due to interference with acquisition rather than or in addition to storage processes. 762 DOPAMINERGIC BASIS OF SELF-STIMULATION INDUCED IMPROVEMENT IN MEMORY. Norman White and Robert Major*. Dept. Psychol., McGill Univ., 1205 McGregor Ave., Montreal, Canada.

Naive, thirsty rats searched for a standard drinking tube which was located in one wall of an open field. For one group of rats the tube contained water, for another group the tube was dry. As each rat contacted the tube it was removed from the open field and placed into a self-stimulation cage. One half of the rats in the water group, and one half of the rats in the no-water group were allowed to bar press 1000 times for lateral hypothalamic stimulation. The remaining rats in each group were simply confined in the self-stimulation cage for 30 min. Twenty-four hours later each rat was put into the open field and the latency to contact the drinking tube (which was dry for all groups) was recorded. The rats which found water in the drinking tube on the training day and self-stimulated afterwards had significantly shorter latencies than the rats which found water but did not self-stimulate. The rats which found a dry drinking tube on the training day and self-stimulated afterward had significantly longer latencies to contact the tube (most did not approach it in 5 min) than the rats which found a dry tube and did not self-stimulate. We interpreted this finding as indicating that self-stimulation improved the rats' memory for prior events even though the stimulation was not a part of the contingent association that the rats learned to produce the observed performance. The data from three additional experiments using the same experimental paradigm suggest that the dopaminergic nigrostriatal bundle mediates the memory effect that we observed. 1) Electrode placements in the far lateral hypothalamus produced the memory effect, but electrode placements in the mid-lateral hypothalamus did not, even though both placements produced equal rates of bar pressing. 2) Electrode placements in area A9 produced the memory effect, but electrode placements in the pre-optic area did not, even though both placements produced equal rates of bar pressing. 3) A dose of 0.3 mg/Kg of the dopaminergic blocker Pimozide, given 4½ hrs before testing, eliminated the memory effect in rats with far-lateral placements without affecting rates of self-stimulation. The appropriate vehicle control injections had no effect on rates of self-stimulation or on the improvement of memory. As we did not observe any reduction in rate following our dose of Pimozide the data suggest that the effects of specific dopaminergic manipulations on self-stimulation may be interpretable in terms of an effect on memory similar to the one reported here: this effect could have occurred inadvertently in other experiments. The data also confirm recent suggestions that the nigro-striatal bundle is involved in the consolidation of memory for some kinds of learning, and demonstrates that memory can be improved by self-stimulation; that is, by stimulation that is clearly reinforcing.

MONOAMINERGIC SYSTEMS

763 LOCUS COERULEUS LESIONS: INCREASE IN NOCICEPTIVE THRESHOLDS. Robert F. Ackermann*, Richard J. Bodnar, Dennis D. Kelly, and Murray Glusman. New York State Psychiatric Institute and Albert Einstein College of Medicine, New York, N.Y.

Serotonin (5-HT) depletion or lesions of the dorsal raphé nuclei of the brainstem have been shown to attenuate morphine-produced and stimulation-produced analgesia. In contrast, norepinephrine (NE) depletion enhances morphine-produced and stimulation-produced analgesia. The present study examined the effects of destruction of the locus coeruleus (LC), a noradrenergic pontine nucleus, upon nociceptive flinch-jump thresholds. Thirteen rats were tested for four preoperative baseline flinch-jump sessions. Lesions were then placed in the locus coeruleus bilaterally and nociceptive thresholds were determined daily for 5 weeks post-operatively. The lesions were localized by catecholamine histofluorescence procedures as well as by conventional histological staining techniques. In 9 of the 13 animals, either bilateral or unilateral damage was found in the LC or in the ascending dorsal noradrenergic bundle, as evidenced by green fluorescent back-up caudal to the lesions. Eight of the nine animals in this group demonstrated significantly increased jump thresholds. In the remaining four animals, both lesions spared the LC but caused damage of serotonergic elements in the raphé region, as evidenced by yellow fluorescent back-up caudal to the lesions. These raphe-damaged animals demonstrated either unchanged or significantly decreased jump thresholds. The results suggest apparently contrasting roles of NE and 5-HT in nociception. (Supported by NIMH Grant #13579, New York State Health Research Council Grant #365 and by Grant #NS 09649.)

764 AN INVESTIGATION OF THE ROLE OF THE MEDIAL NUCLEUS OF THE RAPHE IN BEHAVIOR. Karen E. Asin, David Wirtshafter and Ernest W. Kent. Dept. Psych, Univ. Il. at Chicago Circle, Chicago, Il. 60680

Last year we reported that lesion of the medial but not the dorsal nucleus of the raphe impaired both the acquisition and extinction of a food rewarded runway task (Neurosci. Abst. II, #676). In an elaboration of our initial study, we have evaluated the effect of the intertrial interval on the acquisition of a straight alley task. Medial raphe lesioned (MRL) rats were deficient relative to controls in acquiring the response when the trials were spaced 15 minutes apart but not when the trials were immediately successive. This result may suggest that the acquisition deficit is due, in part, to distraction of MRL animals by stimuli encountered between trials. As a measure of reactivity to changes in stimuli within the alley, MRL and control subjects which had previously been trained were run for six trials during which the floor of the alley was covered with sandpaper. Control rats demonstrated a marked initial decline in running speeds, with a rapid recovery to baseline levels. MRL rats, however, showed a less pronounced diminution in speed, but were slower than controls to return to baseline.

Subsequently, spontaneous alternation was studied over two successive, non-rewarded trials in a T-maze. Compared to control animals, MRL rats displayed strong perseverative tendencies, confirming the findings of Geyer et al. (Br.Res.106,1976). We extended these findings to methysergide and p-chlorophenylalanine (PCPA) treated subjects, who also tended to repeat their initial choice. When the two arms of the maze were reversed between trials, behavior on the second trial was essentially random. Therefore, it appears that the nature of the repetitive responding cannot be described solely in terms of either stimulus or response perseveration. Additionally, we found that 5-HTP treatment of PCPA injected animals was able to restore spontaneous alternation to control levels. Perseverative responding was also investigated in a straight alley task in which alternate trials were food rewarded. Whereas control rats eventually ran faster on rewarded than non-rewarded trials, MRL rats failed to respond differentially.

The above results indicate that there are both similarities and differences in the behavioral consequences of medial raphe and hippocampal or septal lesions. The extent to which serotonin reduction in these limbic structures underlies the behavioral effects seen in MRL subjects remains to be determined.

765 ASCENDING SEROTONERGIC SYSTEMS CONTROLLING RHYTHMICAL ACTIVITY IN THE SEPTAL AREA OF THE RAT. S.Y. Assaf* and J.J. Miller, Dept. Physiology, Univ. British Columbia, Vancouver, B.C.

Stimulation of hypothalamic and brainstem regions have been shown to elicit contrasting patterns of hippocampal electrical activity (HEA). These responses, either rhythmical slow wave 'theta' or a desynchronized pattern are correlated with a bursting or irregular firing of neurones in the medial septal nucleus respectively. Recent neuroanatomical investigations have demonstrated that projection systems originating in the monoamine-containing nuclei of the brainstem may form the neural substrates through which these distinct patterns of activity in the hippocampus and septum are altered. The present study was undertaken to determine the effects of stimulation of the ascending serotonergic system on the extracellularly recorded unit activity in the septal area and to relate these responses to HEA. On the basis of their discharge patterns, two types of medial septal neurones were identified; (1) I-neurones, which characteristically fired in an irregular or random pattern and exhibited no temporal relationship with HEA and (2) B-neurones, which discharged either in rhythmical bursts (2-10 spikes) correlated with the 'theta' response or in an irregular manner during desynchronized HEA. Single pulse stimulation (10-15V) of the median raphe nucleus (MR) inhibited the discharge of I-neurones for periods of 30-200 msec but did not influence B-neurones. Repetitive stimulation of the MR at low intensities (2-3V, 100 Hz) prolonged the inhibition of I-neurones and resulted in the disruption of the bursting discharge of B-neurones as well as a shift of HEA from the 'theta' mode to a desynchronized pattern. Depletion of central serotonin levels (85-93%) following injections of p-CPA (400 mg/kg) 4 days prior to acute recordings resulted in a blockade of the MR elicited responses in both the septum and hippocampus. These data suggest that I-neurones are monosynaptically inhibited by a serotonergic projection from the MR and that these cells in turn mediate the disruption of the bursting discharge of B-neurones resulting in the desynchronization of HEA.

766 PLASMA AND BRAIN LEVELS OF HOMOVANILLIC ACID (HVA) AND 3,4,-DIHYDROXYPHENYLACETIC ACID (DOPAC): EFFECTS OF HALOPERIDOL AND NIGROSTRIATAL PATHWAY STIMULATION. N. G. Bacopoulos*, S. E. Hattox*, R. H. Roth and J. W. Maas. Departments of Pharmacology and Psychiatry, Yale Univ. Sch. Med., New Haven, CT 06510.

The concentrations of HVA and DOPAC were measured in rat caudate nucleus and plasma by GC-mass fragmentography. Blood (5-6 ml) was collected by cardiac puncture and centrifuged at 10,000 x g for 20 min. Deuterated HVA and/or DOPAC were added to plasma aliquots or supernates of caudate nucleus as internal standards. Catechol acids were extracted into ethyl acetate from acidified plasma aliquots or supernates of caudate nucleus homogenates. The ethyl acetate was evaporated and the pentafluoropropionyl derivatives of HVA or DOPAC were formed by reaction with pentafluoroproprionic acid anhydride and pentafluoropropanol. Quantitation was performed by the technique of selected ion monitoring using a Finnigan model 3200 quadrupole electron impact mass spectrometer. Ions at m/e 460 and 462, or 387 and 392 originating from endogenous and deuterated HVA and DOPAC respectively were monitored. Identification was verified by comparing ratios of two ions derived from each endogenous compound. The level of free HVA in rat plasma was 4.5 ± 0.321 ng/ml (N=8, x ± S.E.M.). The level of plasma HVA was increased 50 ± 5.6% two hours after administration of haloperidol (1.25 mg/kg s.c.). Further increases in the dose of haloperidol did not cause any additional elevations in plasma HVA. Stimulation of the nigrostriatal pathway for 30 minutes at a frequency of 15 Hz (Murrin, L.C. and Roth, R.H., Mol. Pharm. 12:463, 1976) resulted in a significant increase in the levels of HVA (73 ± 12%) and DOPAC (153 ± 38%) in the caudates ipsilateral to the stimulation. The HVA concentration in the plasma of stimulated animals was increased 22.5 ± 6.2% ($p < 0.05$) as compared to unstimulated controls. These experiments suggest that changes in the concentration of HVA in the plasma may reflect changes in the activity of central dopamine neurons. Experiments are in progress to determine the relative contribution of brain to plasma levels of dopamine metabolites.

Supported in part by USPHS grant numbers MH14092 and MH24642 and postdoctoral fellowship USPHS 1 F32-MH07146-01 given to NGB.

767 VERATRAMINE: EVIDENCE FOR CENTRAL SEROTONINERGIC AGONIST ACTION. Roger F. Butterworth, Kanji Izumi*, Michel Gonce* and André Barbeau. Dept. of Neurobiology, Clinical Research Institute of Montreal, Montreal, Quebec, Canada.

The secondary amine, Veratramine, was first isolated by Saito (Bull. Chem. Soc. Japan, 15, 22 (1940)) from the Japanese Veratrum Grandiflorum, followed later by others from the American Veratrum Viride. The most noteworthy action of Veratramine is its excitatory action on the central nervous system; doses in excess of 1.4 mg. per kg. administered i.p. to male Swiss albino mice produce tremor within a few minutes of administration. At a dose of 3 mg. per kg., the excitatory pattern consists of a more intense tremor followed by a characteristic "struggling", and in many cases, convulsive behaviour.

The behavioural excitation produced by Veratramine is accompanied by changes in serotonin (5HT) content of certain brain regions while brain dopamine (DA) and noradrenaline (NA) remain unchanged. The following drugs, in the doses indicated were found to be without effect on the excitatory behaviour produced by Veratramine (3 mg. per kg., ED_{99}): Haloperidol 5 mg. per kg.; Phentolamine 10 mg. per kg.; Propranolol 10 mg. per kg.; Atropine 10 mg. per kg.; α-methyl-p-tyrosine 250 mg. per kg.; p-chlorophenylalanine 300 mg. per kg. Previously Tanaka (J. Pharmacol. Exp. Ther. 113, 89 (1955)) showed that the anticonvulsants phenobarbital and diphenylhydantoin were only partially effective as inhibitors of Veratramine's action and this, only at toxic doses.

The central serotonin receptor antagonist, methysergide in doses of 5-15 mg. per kg. produced a dose-dependent inhibition of Veratramine's action, causing both a decreased intensity of excitation and a delay in onset of tremor. These results suggest a serotonin agonist role for the mechanism of excitatory action of Veratramine on the central nervous system.

(Supported by the Medical Research Council of Canada - Grant MT-4938)

768 EFFECTS OF UNILATERAL FOREBRAIN DEPLETIONS OF SEROTONIN, NOREPINEPHRINE AND DOPAMINE ON HYPOTHALAMIC SELF-STIMULATION. Robert J. Carey. VAH at Syracuse, Syracuse, NY 13210.

Rats with functional bilateral medial forebrain bundle electrodes were administered 2-3 unilateral 2 µl injections of 6-hydroxydopamine (2 µg/µl) into the substantia nigra over a two week period. The injections which produced 99% depletion of striatal-cortical dopamine either had no effect on self-stimulation rate intensity functions or produced equivalent bilateral decreases in self-stimulation. Instances of decreases in self-stimulation were always associated with marked decreases in motor activity as indicated by photobeam activity measurement. Thus, virtually complete unilateral forebrain dopamine depletions had no selective effect on hypothalamic self-stimulation. Additional rats, however, were given unilateral 6-hydroxydopamine injections into the dorsal and ventral norepinephrine pathways in combination with 6-hydroxydopamine injections into the substantia nigra. The threshold for self-stimulation in these rats was markedly lowered on the injected side. Thus, unilateral forebrain depletions of dopamine (99%) plus norepinephrine (90-95%) selectively enhanced hypothalamic self-stimulation. Finally, if a lesion of the midline raphe nuclei was made in combination with a unilateral 6-hydroxydopamine injection into the substantia nigra self-stimulation was attenuated on the injected side. These studies suggest that serotonin and norepinephrine but not dopamine are important modulators of hypothalamic self-stimulation.

769 ACTIVATION OF LOCUS COERULEUS NORADRENERGIC NEURONS BY PERIPHERAL NERVE STIMULATION. J.M. Cedarbaum* and G.K. Aghajanian (Spon: M. Davis), Depts. Psychiat. & Pharmacol., Yale Univ. Sch. Med., New Haven, CT 06508

Previous experiments have shown that, even in anesthetized animals, the noradrenergic neurons of the locus coeruleus (LC) respond to noxious stimuli with a brief increase in firing rate followed by a quiescent interval, after which the cells resume their normal pattern of activity. Experiments in which horseracish peroxidase was injected into the LC revealed that the LC receives direct, monosynaptic input from large, presumably nociceptive neurons located in the marginal zones (Rexed Lamina I) of the dorsal horns of the spinal cord. To further study the response of LC neurons to peripheral stimuli, we have stimulated peripheral nerves (saphenous, sural or sciatic) in the hind lege of chloral hydrate-anesthetized rats while recording single unit activity in the LC. The response of LC cells to nerve stimulation (single square-wave pulses, 0.05-5 mA, 1 msec duration, at a rate of 0.5 Hz) consisted of short and long latency components. At low stimulus intensities (0.05-1 mA), LC cells responded with a single spike/stimulus (latency 18-35 msec). Higher stimulus intensities (up to 5 mA) evoked bursts of several additional spikes/stimulus, beginning 50-100 msec following the initial spike. Stimuli delivered contralateral to the recording site in the LC were more effective than ipsilateral stimuli, the threshold for evoking a response in the LC being 5-10 fold higher for ipsilateral than for contralateral stimulation. The evoked activity of LC units was prevented by lesioning the anterolateral quadrant of the spinal cord contralateral to the stimulated nerve and ipsilateral to the recording site in the LC. Lesions of the dorsal columns were without effect. The evoked spike activity of LC cells was followed by a period of suppressed cell firing lasting in some cases up to a full second. Early during this period of suppressed activity the response to the second of a pair of stimuli was markedly diminished. The duration of this suppression was reduced by the α-adrenergic blocking drug piperoxane, administered either systemically or directly into the vicinity of LC cells by microiontophoresis. This suggests that the post-stimulus suppression of firing is adrenergically mediated, perhaps by collaterals of the LC cells themselves. Thus the LC appears to receive input from the spinal cord, most likely from branches of nociceptive spinoreticular and/or spinothalamic fibers traveling in the anterolateral white matter. The response of LC cells to peripheral stimuli is powerfully gated, presumably by α-adrenoreceptor-mediated collateral inhibition within the LC. Such a mechanism might allow the LC to function as a "novelty detector" responding acutely and transiently to external events. (USPHS Grant MH-17871 and the State of Connecticut).

770 THE EFFECTS OF ORTHODROMIC AND ANTIDROMIC STIMULATION ON TYROSINE HYDROXYLASE ACTIVITY IN THE RAT SUPERIOR CERVICAL GANGLION. A. Chalazonitis* and R.E. Zigmond (SPON: P.B. Dews). Department of Pharmacology, Harvard Medical School, Boston, MA 02115

Stimulation of the preganglionic cervical sympathetic trunk produces a delayed increase in tyrosine hydroxylase activity in the rat superior cervical ganglion (Ben-Ari and Zigmond, J. Physiol. 248: 48P, 1975). To determine whether stimulation of nicotinic receptors in the ganglion is involved in this effect, rats were pretreated with the ganglion blocking drug, chlorisondamine (15 mg/kg, s.c.). Sixty minutes later the animals were anesthetized with chloral hydrate (440 mg/kg) and the preganglionic trunks were exposed and cut bilaterally. The distal portion of the trunk on one side was then stimulated for 90 min with 40 Hz trains (current on for 250 msec, off for 500 msec). We have previously shown that these parameters of stimulation produce approximately a two-fold increase in tyrosine hydroxylase activity in the ganglion. Electrophysiological recordings throughout the period of stimulation demonstrated that the chlorisondamine treatment completely blocked the evoked potentials normally recorded from the surface of the ganglion. Subsequent measurement of tyrosine hydroxylase activity showed that the nicotinic antagonist significantly decreased the effect of preganglionic stimulation on this enzyme activity. Seventy-two hours after the stimulation, ganglionic tyrosine hydroxylase activity was 85% higher on the stimulated side than on the contralateral control side of uninjected animals but only 24% higher in chlorisondamine pretreated animals.

In order to determine whether increased neuronal firing of the post-ganglionic neurons per se (i.e., without release of the preganglionic transmitter) was sufficient to produce an elevation of tyrosine hydroxylase activity, the ganglion on one side was stimulated antidromically via the internal carotid nerve. The postganglionic trunks were not cut in this experiment. The antidromically evoked compound action potential was recorded and did not diminish significantly during the period of stimulation. Although several parameters of stimulation were tried, none produced an elevation in tyrosine hydroxylase activity compared to "sham stimulated" controls (i.e. animals treated identically except the current was not turned on). The results suggest that the elevation in tyrosine hydroxylase activity produced by synaptic stimulation is not simply due to an increase in the frequency of action potentials in sympathetic neurons.

We are currently trying to determine the minimum amount of preganglionic stimulation required to produce a significant increase in tyrosine hydroxylase activity and have found that a 10 min period of stimulation at 10 Hz is sufficient to produce a small (25%) but significant rise in enzyme activity.

771 DEMONSTRATION OF INDOLEAMINE NEURONS AND THEIR PROCESSES IN THE RAT BRAIN; SELECTIVE LOSS IN THIAMINE DEFICIENCY AND REGENERATIVE PLASTICITY WITH PYRITHIAMINE INDUCTION AND THIAMINE READMINISTRATION. Victoria Chan-Palay. Dept. Neurobiol., Harvard Med. Sch. Boston, MA 02115.

Indoleamine structures in normal, pair-fed control and thiamine-deficient brain of rats are selectively localized by autoradiography following serotonin oxidase inhibition and simultaneous administration of ^{3}H-5HT (10^{-5}M) and cold norepinephrine (10^{-4}M) by continuous intraventricular infusions of 3 hr duration. Locations of indoleamine neurons in the normal and control brains are comparable in the brain stem, diencephalon, epithalamus and circumventricular organs. These emit vast axonal plexuses throughout the brain, ventricular, and leptomeningeal surfaces. Thiamine deficiency causes a dramatic loss of almost all indoleamine neurons in midbrain and medulla, in which rare dystrophic cells and axons survive. In the diencephalon a few neurons survive with commensurately greater axon preservation. The periventricular grey of spinal cord, medulla, midbrain and diencephalon; mammillary nuclei, cerebellum and floor of IVth ventricle, normally richly served by indoleamine axons, are the areas most severely affected. However, the ventricular and leptomeningeal plexuses remain intact. It is postulated that thiamine deficiency may cause a change in the uptake of exogenous 5HT and destruction of certain indole-containing structures. Of these latter, the synaptic indoleamine systems such as the cerebellar 5HT mossy fibers which synapse within glomeruli disappear. The nonsynapsing indoleamine systems that utilize neurohumoral transmitter dispersion instead of localized synapses persist, e.g., the ventricular axons. Chronic (4-6 wks) diet-induced thiamine deficiency is not readily reversible. Acute treatment with pyrithiamine (thiamine antagonist, 20µgm/day for 4-6 days) causes rapid indoleamine loss. However, upon readministration of thiamine (20µgm/day for 2-14 days) indoleamine-containing structures rapidly regenerate. These experiments demonstrate the intimate dependence of the indoleamine systems of the brain upon thiamine, destruction of these structures in the vitamin deficient animals and their regenerative plasticity upon readministration of thiamine. The distribution of greatest indoleamine deficit in the thiamine deficient brain coincides with those regions showing pathologic changes in Wernicke-Korsakoff's syndrome in man: the mammillary bodies, medial thalamus and hypothalamus, periventricular grey, floor of IVth ventricle and cerebellum. This indoleamine loss constitutes a pathognomonic change of thiamine deficiency, though not necessarily the only one. These experiments are excellent models for study of mechanisms involved in the human disease. (Supported in part by PHS Grants NS 10536, NS 03659 and Training Grant NS 05591 from the NINCDS.)

772 EFFECTS OF LSD ON THE ACTIVITY OF DOPAMINE-CONTAINING NEURONS IN THE SUBSTANTIA NIGRA OF RATS. Greg R. Christoph*, Donald H. Kuhn and Barry L. Jacobs. Dept. Psychol., Princeton Univ., Princeton, N.J. 08540.

Behavioral and neurochemical evidence suggests that d-lysergic acid diethylamide (LSD) directly interacts with dopamine (DA) receptors in the CNS (Pieri, et al., Nature 252: 586, 1974; Creese, et al., Life Sci. 17: 1715, 1975). In order to more directly investigate the dopaminergic properties of LSD, its effects on the spontaneous firing rate of DA-containing neurons in the substantia nigra were studied. In chloral hydrate anesthetized rats, DA-containing neurons were identified on line by their firing rate (2-7 spikes/sec) and spike duration (> 2 msec) characteristics. DA agonists are known to reduce the firing rate of these neurons, and DA antagonists block or reverse this effect. Low doses of LSD (25-50 ug/kg, i.v.) significantly depressed the firing rate of 77% of the DA containing neurons in the zona compacta of the substantia nigra, whereas 23% of the cells were unaffected or slightly excited. Pretreatment with the DA antagonist haloperidol (0.1 mg/kg, i.v.) blocked the inhibitory effects of LSD, and haloperidol injected after LSD reversed its depressive effects. Suppression of firing rate was probably not due to the serotonergic properties of LSD, since 5-methoxy N,N dimethyltryptamine (25-100 ug/kg., i.v.), a drug that has serotonergic properties similar to those of LSD, exclusively produced excitation. Non-dopaminergic cells in the region of the substantia nigra were typically greatly excited by administration of LSD. These results indicate that LSD can act as a DA agonist in the CNS. Dopaminergic cells were also tested with LSD (50 ug/kg) after the firing rate was reduced 50% by pretreatment with d-amphetamine (AMPH, mean dose = 1.2 mg/kg, i.v.). LSD increased the firing rate of most of these cells to a level slightly below the pre-AMPH baseline. Dopaminergic cells that were tested with LSD (200 ug/kg) and allowed to recover, were then tested with AMPH. The 50% inhibition dose of AMPH (4.7 mg/kg) was significantly greater for these rats than for rats without prior LSD. The results of these AMPH/LSD interaction experiments may indicate that LSD also has DA antagonist properties. These electrophysiological data are consistent with neurochemical data which suggest that LSD is a mixed agonist/antagonist of DA in the CNS.

773 MAPPING OF BRAIN STIMULATION REWARD: PONTINE TEGMENTUM AND CAUDAL MIDBRAIN. Dale Corbett* and Roy A. Wise. (Spon: J. Stewart). Dept. Psychology, Concordia Univ., Montreal, Canada H3G 1M8.

Recent lesion studies cast doubt on the view that noradrenergic (NA) systems mediate pontine tegmental and caudal midbrain self-stimulation (SS). It is not apparent, however, what alternative systems might underlie SS in these areas. In order to uncover candidate systems, 411 stimulation sites were tested in 46 rats using chronic moveable electrodes (Wise, 1976). Both positive and negative SS electrode placements were examined in nissl-stained tissue as well as in glyoxylic acid treated tissue for the demonstration of catecholamines.

Self-stimulation was obtained from the following areas: dorsal raphe nucleus (RD); ventral periaqueductal gray; superior cerebellar peduncle (PCS); pontine tegmental gray; mesencephalic nucleus of the trigeminal (MesV); and motor nucleus of the trigeminal (MotV). Electrode placements on the lateral border of the locus coeruleus (LC) adjacent to MesV supported SS, while those on the medial edge of LC failed to support SS despite extensive behavioral shaping. This supports the view (Vanderkooy and Phillips, 1977) that MesV is the critical site for SS with electrodes in the area of LC. SS was closely correlated with the rostral (caudal midbrain) and caudal (posterior LC) cells of MesV. While NA cell bodies or fibers were evident in all regions that supported SS, the location of positive SS placements often did not coincide with the areas most densely innervated by NE elements. For example, SS was readily obtained from RD, where there were relatively few NE fibers, while SS was not obtained dorso-lateral to RD where abundant NA fibers were evident. A similar pattern was observed with placements in the PCS and the pontine tegmental gray.

These data suggest that NA systems in the pontine tegmentum and caudal midbrain do not support self-stimulation. Rather, it seems that the trigeminal system plays an important role in brain stimulation reward in these regions. This finding has important implications for current theories of motivated behavior.

774 LOCUS COERULEUS STIMULATION INCREASES PLASMA LEVELS OF 3-METHOXY-4-HYDROXYPHENYLETHYLENEGLYCOL (MHPG) IN RATS. J. N. Crawley, J. W. Maas, R. H. Roth and S. E. Hattox* Departments of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06510

3-Methoxy-4-hydroxyphenylethyleneglycol (MHPG) is a major metabolite of norepinephrine (NE) formed from both central and peripheral adrenergic neurons. To determine whether the functional activity of central noradrenergic neurons is reflected in plasma levels of MHPG, we have electrically stimulated a homogeneous group of central NE neurons, the locus coeruleus (LC) in rats.

The LC was stereotaxically and electrophysiologically located in urethane-anesthetized rats, with a tungsten bipolar electrode (external diameter 0.5 mm, internal fine wire diameter 0.1 mm). Stimulation through this electrode was bipolar, with a peak-to-peak amplitude of 400 µA, duration 2 msec, at 20 Hz, for 30 minutes. Control (sham operated) rats were identically prepared but stimulation current was not passed. Immediately thereafter, 4-6 ml blood was removed by cardiac puncture for enzymatic hydrolysis and ethyl acetate extraction of total MHPG, and quantification by gas chromatography-mass spectrometry. To verify effective LC stimulation, the cerebral cortex hemispheres ipsilateral and contralateral to LC stimulation were dissected and frozen at -70°C for gas chromatographic assay of MHPG. In LC stimulated rats, total MHPG increased 30-80% in the ipsilateral cortex as compared to contralateral, while the two sides were similar in sham controls. The rest of the brain was stored in formalin for histological sectioning and staining with cresyl violet to verify correct electrode placement in the locus coeruleus.

Plasma levels of total MHPG in sham controls averaged 10.6 ng MHPG/ml plasma (±1.41 SEM, N=4). Total plasma MHPG in locus coeruleus stimulated rats averaged 30.1 ng/ml (±3.16 SEM, N=6), $p<0.01$. Experiments with ganglionic blocking agents demonstrate that a significant portion of the plasma MHPG increase during LC stimulation is derived from the central nervous system. Further experiments are in progress to dissect out the central vs. peripheral contributions to plasma MHPG. The results herein indicate that plasma MHPG does reflect changes in functional activity of central NE neurons.

775 STUDIES ON THE POSSIBILITY OF AN EXTRAGANGLIONIC SOURCE OF ADRENERGIC TERMINALS TO THE SUPERIOR CERVICAL GANGLION. W.G. Dail and Joe Wood. Dept. Anat., Univ. New Mexico Sch. Med., Albuquerque, NM 87131, and Dept. Neurobiol. and Anat., Univ. Texas Med. Sch., Houston, TX 77025.

In the sympathetic ganglia of many mammals, adrenergic varicose fibers are found in close proximity to ganglion cells. In the superior cervical ganglion (SCG), it has been suggested that such fibers represent the source of catecholamines released by stimulation of the cervical sympathetic trunk. The varicose fibers are said to arise predominantly from small intensely fluorescent cells or from ganglion cells within the SCG. That a portion of these fibers may arise from adrenergic ganglion cells caudal to the SCG is a recent and alternate proposal. To test this latter hypothesis, we have performed histofluorescence and EM studies of the SCG of the rabbit. Ligatures placed on the cervical sympathetic trunk resulted in the accumulation of catecholamines in fibers proximal to the tie, indicating a flow of the neurotransmitter toward the SCG. Moreover, following section of the cervical sympathetic trunk, chromatolytic changes were observed in some of the ganglion cells caudal to the lesion. When the normal SCG was fixed with $KMnO_4$ it was revealed that approximately 25% of the synaptic profiles were of the adrenergic type. Two days following deafferentation of the SCG, cholinergic terminals could no longer be identified. However, adrenergic terminals were commonly seen. Counts of the adrenergic profiles and degenerating terminals indicated that the proportion of adrenergic terminals remained at 25% following section of the cervical sympathetic trunk.

These data indicate that the superior cervical ganglion is not a target organ for adrenergic fibers found in the cervical sympathetic trunk.

776 SENSITIZATION OF POSTSYNAPTIC SEROTONIN RECEPTORS BY CHRONIC PRETREATMENT WITH TRICYCLIC ANTIDEPRESSANTS: AN IONTOPHORETIC STUDY. C. de Montigny and G.K. Aghajanian, Depts. Psychiat. & Pharmacol. Yale Univ. Sch. Med., New Haven, CT 06508

The monoamine hypothesis of depression is partly based on the therapeutic efficacy of tricyclic compounds which block amine uptake. However there is a time discrepancy between the acute pharmacological and the delayed clinical effects. Furthermore, no clear difference has been demonstrated between the clinical efficacies of norepinephrine (NE) and serotonin (5HT) uptake blockers.

To approach these questions, we studied the acute and chronic effects on postsynaptic 5HT receptors of two antidepressants: chlorimipramine (CIMI), a 5HT uptake blocker, and desipramine (DMI), a NE uptake blocker. Male albino rats were pretreated for 1-17 days with a daily dose of 5 mg/kg, i.p., of CIMI or DMI, the last dose being given 24 h before testing. Recordings were also obtained 15-90 min following 5 mg/kg, i.p., of the same drugs. In a cerveau isole preparation unit recordings were obtained from the ventral lateral geniculate body (LGB), which receives a dense 5HT input. 5HT was pulsed iontophoretically for 60 sec onto these neurons in alternation with γ-aminobutyric acid (GABA). The efficacy of these compounds was evaluated by the IT_{50} values; i.e., the product of the current I by the time T_{50} required to obtain a 50% depression from the baseline firing rate.

Acute administration of CIMI and DMI did not modify the initial response (i.e., sensitivity) of LGB neurons to 5HT or GABA. CIMI, but not DMI, prolonged the recovery time from the depression induced by 5HT. Recordings obtained 24 h after a single dose of CIMI or DMI failed to disclose any significant change of the IT_{50} values for both 5HT and GABA. However, in animals pretreated chronically with CIMI, LGB neurons were found to be much more sensitive to 5HT but not GABA. Chronic DMI pretreatment also enhanced selectively the sensitivity to 5HT. IT_{50} measures revealed an increase sensitivity to 5HT of 2 to 4 fold.

These results suggest that chronic administration of both types of antidepressants sensitizes postsynaptic 5HT receptors. The enhanced response of LGB neurons to 5HT cannot be due to the block of 5HT uptake since acute CIMI failed to modify sensitivity. The progressive sensitization and its long duration contrasts with the immediate and short lasting presynaptic effects of these drugs on amine uptake. Moreover, despite dissimilarities in their amine uptake blocking properties, CIMI and DMI exert a very similar action on postsynaptic 5HT receptors. Thus the common action of these tricyclic drugs in producing a delayed sensitization of postsynaptic 5HT receptors correlates better than their presynaptic effects with therapeutic efficacy in depression. (Supported by NIMH Grants MH-17871 and MH-14459 and Can. Med. Res. Council).

777 THE STAGES OF BEHAVIOR PRODUCED BY CONTINUOUS AMPHETAMINE INTOXICATION ARE ALTERED BY LESIONS OF CATECHOLAMINE CELLS. Michael S. Eison, Gaylord Ellison, and Harris S. Huberman*. Dept. Psychology, UCLA, Los Angeles, CA 90024

Slow-release silicone pellets containing d-amphetamine base were implanted subcutaneously in normal rats housed in social colonies and the effects on behavior during the following seven days of constant amphetamine intoxication were observed. A reliable progression of behavioral changes was observed in 3 replications. Compared to control rats, amphetamine rats were hyperactive and exploratory on the first day after pellet implantation. This gradually evolved over 24 hours into motor stereotypies of an increasingly more circumscribed nature even though brain levels of amphetamine were equivalent to a 2mg/kg subcutaneous injection of d-amphetamine sulphate, a dose which does not produce intense stereotypy when given in acute injections. During days 2 and 3 after pellet implantation the amphetamine animals engaged in nearly constant stereotypies, self-grooming, sniffing surfaces, or manipulating straw. The stereotypies then decreased even though appreciable amphetamine was still present in the brain, and on the 4th day after implant the amphetamine animals transiently withdrew to the burrows area. Thereafter, on days 5-7, they showed heightened startle responses, increased fight or flight behavior, and stable aggressive pair-bonds formed among the amphetamine animals. This late stage of social disruptions produced by constant amphetamine intoxication can serve as an animal model of amphetamine psychosis in humans because the stages of behavior are similar to those shown by humans given frequent, low doses of amphetamine.

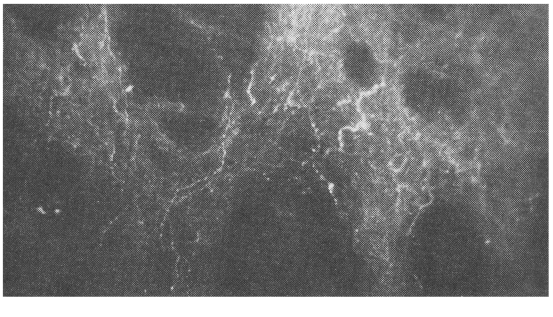
These stages of constant amphetamine intoxication are altered by radio-frequency lesions of Substantia Nigra (SN) or Locus Coeruleus (LC). Rats with SN lesions initially show enhanced locomotion but attenuated stereotypy and anorexia, while rats lesioned in LC exhibit a rapid onset of sniffing stereotypies. However, the later stages of constant amphetamine intoxication occur only in unlesioned controls, who show the most intense stereotypy on day 2, the greatest rebound depression (time in burrows), and maximally show the social disruptions which appear after 5 days of constant amphetamine. Thus, the integrity of both dopaminergic and noradrenergic systems was necessary for the full expression of this animal model of amphetamine psychosis.

778 A SLOW-RELEASE SILICONE PELLET FOR PRODUCING CONSTANT AMPHETAMINE STIMULATION: DELAYED EFFECTS ON BEHAVIOR, BIOCHEMISTRY, AND CAUDATE MORPHOLOGY. Gaylord Ellison, Harris Huberman* and Michael S. Eison. Dept. Psychology, UCLA, Los Angeles, CA 90024

The design and construction of slow-release silicone pellets containing 48mg of d-amphetamine (dA) will be described. These pellets release dA for at least 10 days, producing brain dA levels of 1.58ug/g and 0.88ug/g at 2 and 7 days after implantation in adult rats. Implanted rats become hyperactive in stabilimeters within a few hours and gradually enter continuous stereotypy for several days. After 3 days the stereotypies break and the rats become hyperirritible and startle easily. Tolerance can be shown by decreased stereotypy when fresh pellets are implanted.

Rats were perfused at various times after pellet implantation and glyoxylic acid, vibratome-sectioned slides prepared. At about the same time the stereotypies disappear there is a decrease in background fluorescence in the caudate and bright catecholamine axons with swollen varicosities appear. These effects increase with time: 17 days after implantation and 10 days after pellet removal there are long, thick fluorescing axons in the caudate and engorged, stump-like processes (see Figure below).

These alterations in caudate morphology are accompanied by distinctive regional changes in tyrosine hydroxylase activity and morphology of substantia nigra cells. These changes are similar to those reported in intact regions of the caudate after partial caudate lesions, implying that constant dA even at low doses leads to the destruction of dopamine terminals. At the same time these alterations appear the rats break out of stereotypy and begin to show paranoid-like behaviors, implying that structural alterations in the caudate are correlated with the appearance of an animal model of amphetamine psychosis.



779 MONOAMINE-CONTAINING DENDRITES: A GENERAL MAMMALIAN PHENOMENON. David L. Felten and John R. Sladek, Jr. Depts. of Anatomy, Indiana Univ. Sch. Med., Indianapolis, IND. 46202 and Univ. Rochester Sch. Med. and Dent., Rochester, N.Y. 14642.

Primate and non-primate monoamine systems were examined for the presence of monoamine-containing dendrites with the Falck-Hillarp and the glyoxylic acid methods. Monoamine-containing dendrites were found in all major monoamine groups in unpretreated rhesus, stump-tail, and squirrel monkeys, and were also abundant in monoamine groups in the rat, cat, and rabbit. These dendrites were both smooth and varicose in appearance. Some fluorescent dendrites formed bundles with close apposition of individual processes.

Norepinephrine-containing dendrites. Neurons of the medullary and pontine noradrenergic groups were multipolar with numerous fluorescent primary and secondary dendrites. Groups A1 and A5 demonstrated the most extensive dendritic profiles. Groups A6, A7 and central gray noradrenergic cells also displayed prominent dendritic fluorescence. Locus coeruleus dendrites bundled together transversely as they traversed the mesen. tract. V.

Dopamine-containing dendrites. Neurons of groups A8, A9 and A10 displayed prominent dendritic fluorescence despite major architectural variations in the appearance of these groups in the background of fluorescent processes superimposed on the cell bodies. Dendrites were frequently seen extending ventrally into pars reticulata of substantia nigra. A10 dendrites occasionally bundled among emerging fibers of the III nerve. Dopamine-containing dendrites were also present in the arcuate nucleus and other hypothalamic cell groups, but were best seen in neonates with the glyoxylic acid method.

Serotonin-containing dendrites. Serotonin dendrites of both smooth and varicose appearance were visible in all serotonergic groups, but were strikingly abundant in the dorsal raphe nucleus and central superior nucleus and in laterally adjacent reticular formation. Serotonergic dendrites formed prominent bundles within the medial longitudinal fasciculus.

This study confirms the finding of fluorescent dendrites reported in substantia nigra by Björklund and Lindval (BRAIN RES. 83:531, 1975) and in locus coeruleus by Sladek and Parnavelas (BRAIN RES. 110:657, 1975). It expands Felten's findings of the pervasive presence of monoamine dendrites in the squirrel monkey (BRAIN RES. 120:553, 1977) to other primates and non-primates. The presence of monoamines within dendrites may reflect nothing more than a storage compartment for parikaryal synthesis of these transmitters. Another possibility based upon recent evidence for release and post-synaptic activity of monoamines from dendritic areas is that dendritic neurotransmission, or simply dendritic release may be a generalized mammalian phenomenon.

780 SENSITIVITY CHANGES IN THE CENTRAL CARDIOVASCULAR ACTIONS OF SEROTONIN. E. Friedman*, E. Buchweitz* and G. Lambert* (SPON: D. Quartermain). New York Univ. School of Medicine, New York, NY 10016.

In previous studies from our laboratory, we have characterized the centrally-mediated cardiovascular responses to serotonin-receptor stimulation in the rat (Life Sci. 17, 915, 1975). These appear to be localized in an area perfused by the third ventricle. In the present communication, we report on experiments designed to explore possible alterations in receptor-sensitivity in this serotonin neuronal system. In the first set of experiments, serotonin-containing neurons were destroyed by intraventricular (ivc) injection of 75 ug of 5, 6-dihydroxytryptamine (DHT) and receptor sensitivity was monitored 3-4 weeks later. The extent of neuronal destruction was followed by measurements of ^{3}H-serotonin uptake into hypothalamic synaptosomes obtained from DHT-treated and control-vehicle-treated rats. The dose-response curve to ivc injection of serotonin in the lesioned rats showed a 1000 fold shift to the right when compared to sham animals. However, the responses to ivc injection of 2, 5 dimethoxy 4-methyl amphetamine (DOM), a direct serotonin receptor agonist, into lesioned animals did not differ from those in sham rats. In a second series of experiments, receptor sensitivity changes were monitored following repeated serotonin-receptor stimulations. Decrease in receptor sensitivity was noted during repeated injections of serotonin or DOM. The degree of sensitivity loss with serotonin developed slowly at low doses (50 ng-5 ug) and more rapidly at higher doses. The desensitization to ivc DOM was more noted. These results suggest that (1) the enhanced sensitivity to ivc serotonin observed following destruction of central serotonergic neurons is due to interference with the serotonin uptake process and not to alterations at the receptor level and (2) receptor desensitization develops to repeated serotonin receptor stimulation.

Supported by a Grant-in-Aid from the American Heart Association to E.F.

781 ELECTROPHYSIOLOGICAL RESPONSES OF MIDBRAIN DOPAMINERGIC NEURONS TO A NON-AMPHETAMINE CNS STIMULANT. D. C. German, H. Harden*, S. Browder*, F. Morrison*, R. S. Kiser, and P. A. Shore*. Depts. of Physiol., Psychiat., and Pharmacol., U. of Texas Health Sci. Ctr., Dallas, TX, 75235.

Amfonelic acid (AFA) is a potent CNS stimulant. Unlike d-amphetamine (d-AMP), AFA has little peripheral action, and AFA's central action in the rat is not blocked by inhibition of tyrosine hydroxylase, but is attenuated by reserpine. d-AMP is thought to act on the dopamine (DA) neuron by direct release of DA and blockade of reuptake, while AFA acts on the DA neuron to facilitate impulse-induced DA overflow (Shore, J. Pharm. Pharmac., 28(1976), 855-857). Because d-AMP is known to reduce the firing rate of midbrain DA neurons, an effect reversed by a subsequent injection of haloperidol (Hal) (Bunney et.al., J. Pharmacol. Exp. Ther., 185(1973), 560-571), it was of interest to determine whether AFA had similar effects on DA cell firing rates. Recordings were made from over 100 rats; one cell per rat. In the chloral hydrate anesthetized rat, single units recorded in the DA regions of the ventral tegmental area and substantia nigra zona compacta (histologically confirmed) had baseline firing rates of 1-7 Hz. Single units recorded outside these areas (i.e., in reticular formation, red nucleus, zona reticulata) had more variable firing rates, from 2-32 Hz. The firing rates of the cells in the DA regions were decreased by greater than 50% of their baseline firing rates within 5-15 min after an injection of either d-AMP (1 mg/kg) or AFA (1 mg/kg). This reduction by either drug was reversed by a subsequent injection of Hal (1 mg/kg), and the cells returned to or above baseline firing rates within 10 min. The firing rates of the cells outside the DA regions did not respond to the drugs as did those in the DA regions. Thus, although AFA has a different mechanism of action on the DA neuron, it mimics d-AMP in decreasing DA cell firing rates and having this decrease reversed by the DA receptor blocker, Hal.

782 DEMONSTRATION OF BULBOSPINAL NORADRENERGIC NEURONS BY LOCALIZATION IN THE SAME CELL OF BOTH DOPAMINE-β-HYDROXYLASE (DBH) AND RETROGRADELY TRANSPORTED HRP. E.J.Glazer, A.J.Smolen, L.L.Ross, T.H. Joh, V.M.Pickel and D.J. Reis. Dept. Anat., Med. Coll.of Penna.,Phila.,Penna.,19129, Lab.Neurobiol.,Dept.Neurol., Cornell Med. Coll., N.Y.., N.Y. 10021.

In a previous study we have traced the descending noradrenergic input to the sympathetic lateral columns in rat thoracic cord by the immunocytochemical localization of DBH. Noradrenergic axons were observed in the dorsolateral funiculus which terminated predominantly within both ipsilateral and contralateral intermediolateral cell nuclei.

The purpose of this study was to identify the brainstem noradrenergic neurons which project to the spinal cord. This was accomplished by the localization of both DBH and retrogradely transported horseradish peroxidase (HRP) within the same cell. The technique employed was as follows: Sixteen to twenty-four hours following a midthoracic injection of HRP (4 ul 33% HRP, Sigma Type VI) animals were fixed by perfusion and the brainstems serially sectioned at 30 μ on a Vibratome. The sections were then reacted for HRP using benzidine dihydrochloride, H_2O_2 and sodium nitroferricyanide as substrates which yield a blue reaction product. (Mesulam, M., J. Histochem. Cytochem. 24:1273, 1976). Every third section was mounted in glycerin and labeled neurons were photographed. The coverslip was removed and DBH was localized on the same section by the unlabeled antibody enzyme method and PAP complex. The diaminobenzidine-H_2O_2 reaction, which produces a brown precipitate, was used to localize the PAP In addition, adjacent sections were reacted for either transported HRP or DBH.

Neurons with both labels were identified in both the A1 and A2 noradrenergic cell groups in the caudal medulla extending back to the level of the motor decussation. The A1 cell group consisted of a loose network of cells in the ventrolateral reticular formation. Neurons within the A2 cell group were observed in the lateral margins of the commissuralis portion of nucleus solitarius. It should be noted that not all HRP labeled cells in the ventral reticular formation contained DBH. Similarly HRP labeled non-adrenergic neurons were observed in the A2 area and probably represent a solitario-spinal projection. Our method of labeling DBH and retrogradely transported HRP in the same cell enables us to map out bulbo-spinal neurons which synthesize norepinephrine.

Supported by NIH (NSO5195, NSO5392, NS11364 and HL18974).

783 PHARMACOLOGICAL ACTIVATION AND INHIBITION OF NORADRENERGIC ACTIVITY ALTER SPECIFIC BEHAVIORS IN NONHUMAN PRIMATES. Mark S.Gold, and D.E. Redmond, Jr., Dept. Psychiatry, Yale Univ., New Haven,Ct.

Four rigorously chair-trained and acclimatized *M. arctoides* were recorded on split-image videotape with superimposed computer-generated timing and event coding for later blind behavioral rating of sequential and simultaneous behaviors from an ethogram for each one second period. 1 and 2.5 mg/kg of piperoxane but not saline administered through an indwelling venous catheter from outside a sound dampened cubicle increased specific behaviors with a time course that closely approximates the onset of increases in single unit activity in the rat locus coeruleus (LC) after identical doses/body weight (Cederbaum and Aghajanian, BR. RES. 112: 413, 1976). 10 µg/kg clonidine reduced baseline behaviors, prevented many of the behavioral effects, and transiently reversed the behavioral effects of 1 mg/kg piperoxane. Clonidine's onset of behavioral effects also corresponds to the decreased unit activity seen in the rat LC after a similar dose of clonidine (Svensson et al., BR. RES. 92:291, 1975). Epinephrine (E)-containing neurons have been shown to innervate the LC (Hokfelt et al, BR. RES. 66: 235, 1974). In the doses used in this study it is believed that clonidine stimulates and piperoxane inhibits, inhibitory E or norepineprine-responsive "auto" receptors on the cell bodies of the LC to decrease and increase noradrenergic firing rate, release and turnover respectively (Bolme et al, EUR. J. PHARM., 28:98, 1974; Maas et al, BR. RES. 118:167, 1976). Although these drugs also have effects on other neurotransmitter systems, the behavioral effects are possibly relevant to changes in LC activity, as behaviors which are increased by piperoxane are increased by low intensity electrical stimulation of the LC (Redmond, et al, BR. RES. 116: 502, 1976),and behaviors reduced by clonidine are decreased by bilateral lesions of the LC (Huang et al, NEUROSCI. ABS., 1976; Redmond et al, NEUROSCI. ABS. 472, 1976). Behaviors induced by piperoxane administration in monkeys may be relevant to human anxiety since piperoxane has been reported to induce anxiety in humans (Goldenberg et al, JAMA 135: 971, 1947; Soffer, MED. CLIN. N. AM. 38: 375, 1954). Details of the similarities between the behavioral effects of electrical stimulation of the LC and intravenous piperoxane will be presented by Huang, et al.

784 THE EFFECTS OF ESTROGEN ON DOPAMINE TURNOVER, GLUTAMIC ACID DECARBOXYLASE ACTIVITY AND LORDOSIS BEHAVIOR IN SEPTAL LESIONED FEMALE RATS. J. H. Gordon, D. M. Nance, C. J. Wallis* and R. A. Gorski. Dept. Anat. and Brain Res. Inst., UCLA, Los Angeles, CA 90024.

As reported in previous studies, estradiol benzoate (EB) treatment (2.0 µg/day X 3) of septal lesioned (SL) adult female rats produced a marked increase in lordosis quotient (LQ; 66±3) over that of similarly EB primed sham operated (SO; 19±3) animals. Endogenous dopamine (DA) and norepinephrine (NE) were measured and turnover rates were estimated by the rate of decline in endogenous amine following tyrosine hydroxylase inhibition with α-methyltyrosine. No consistent pattern in the level or rate of turnover of NE was noted for any of the treatment groups. No differences in either the level or turnover of DA were seen in the oil treated SL group, relative to SO groups. In the amygdala, corpus striatum, and nucleus accumbens septi of EB treated SL animals there was both a reduction in endogenous levels (20-50%) and a decrease in the synthesis rate (Table 1) of DA relative to both SO groups and oil treated SL animals. In the EB treated SL animals there was a significant negative correlation between DA levels in the corpus striatum and LQ (r = -.850), which is consistent with the proposed inhibitory action of DA on sexual receptivity. Because of the apparently generalized reduction in DA turnover in the EB treated SL animals, glutamic acid decarboxylase (GAD) activity in the substantia nigra (SN) and ventral tegmental region (VTR) was measured to test for any possible alterations in the proposed inhibitory neuronal feedback. GAD activity was reduced in both the SN and VTR of EB treated SO animals (Table 1) but remained comparable to oil treated SO controls in both EB and oil treated SL animals. These data suggest that the reduction in DA turnover, in the EB treated SL animal, may be due to a lack of a compensatory decrease in GAD activity in the regions containing the DA cell bodies. (Supported by Grant HD-01182 and the Ford Foundation.)

TABLE 1: NEUROCHEMICAL ALTERATIONS IN SEPTAL LESIONED RATS

	Sham Operated		Septal Lesioned	
Treatment	Oil	EB	Oil	EB
DA Synthesis Rate				
Corpus striatum	23.19*	20.38	25.86	13.11+
N accumbens septi	17.17	16.55	16.33	11.10
Amygdala	0.64	0.81	0.55	0.22+
GAD Activity				
Substantia nigra	375±24**	196±5+	437±10	356±21+
Ventral tegmentum	143±10	101±5+	157±12	162±6

*Values expressed as pmole/mg/hr; **Values are mean ± S.E. in nmoles/mg/hr; +Significantly reduced from oil treated group.

785 AGE DEPENDENT ALTERATIONS IN DOPAMINERGIC MECHANISMS WHICH ACCOUNT FOR d-AMPHETAMINE'S PARADOXICAL EFFECTS UPON SEIZURE SUSCEPTIBILITY IN SELECTED LINES OF MICE. Charles A. Greer and Herbert P. Alpern. Dept. Psych. and Inst. Behav. Genet., Univ. Colo., Boulder, CO 80309.

A developmental analysis of the effect of d-amphetamine (AMPH) on flurothyl-induced myoclonic convulsions was conducted in two lines of mice (Long-Sleeps [LS] and Short-Sleeps [SS]) which had originally been selectively bred on the basis of susceptibility to ethanol induced narcosis. A total of eight different ages were tested ranging from 15 to 250 days of age. The LS line exhibited minimal developmental changes with AMPH consistently producing a proconvulsant effect. In marked contrast, the SS mice responded with a decrease in seizure susceptibility following AMPH until approximately 80 days of age. The subsequent proconvulsant effect of AMPH in the SS line was essentially equal in magnitude to that seen in the LS line by 120 days of age and remained stable through 250 days of age. In an attempt to determine whether dopamine (DA) or norepinephrine (NE) was mediating this marked alteration in response, either apomorphine, haloperidol, clonidine, or phentolamine plus sotalol was administered to mice 30 and 120 days of age in both lines. Clonidine and apomorphine produced a proconvulsant effect in both age groups of LS mice with a complementary anticonvulsant effect following the respective DA and NE antagonists. In the young SS mice however, while NE compounds produced effects comparable to that seen in the LS line, apomorphine produced an anticonvulsant effect reminiscent of that seen with AMPH while haloperidol resulted in the complementary increase in seizure susceptibility. The 120 days old SS mice, however, exhibited a marked increase in seizure susceptibility following apomorphine with the concomitant decrease following haloperidol while NE manipulations did not significantly alter myoclonic latencies.

These findings clearly reveal a significant developmental alteration in dopaminergic mechanisms in the SS line. Currently, biochemical studies are being initiated in order to elucidate the precise nature of these alterations. Finally, it is of value to note the similarity of the phenomenon described here to the hyperkinetic syndrome in children and its clinical management, in some cases, with AMPH.

786 ANALYTICAL MICROSCOPY OF AMINE POSITIVE STRUCTURES IN PRIMATE SUBSTANTIA NIGRA NEURONS. David Harling , and Joe Wood. JEOL, USA, Medford, MA; Dept. of Neurobiology and Anatomy, Univ. of Tex. Med. Sch. at Houston, Houston, Tex. 77025.

The dopamine (DA) positive neurons of the substantia nigra (SN) have been identified in a number of animals by histofluorescence techniques; however, electron microscopic localization of the DA organelles in SN neurons has been elusive. With use of the glutaraldehyde-dichromate (GDC) technique, biogenic amines have been identified in a number of areas within the central and peripheral nervous systems. Monkeys were perfused with 3% glutaraldehyde (pH 7.2). The SN areas were dissected and treated with GDC solution (pH 4.1). Some glutaraldehyde fixed material was incubated in 2% silver chloride, modified after Tramezzani et al (1964) and other glutaraldehyde fixed tissues were embedded without metal treatment. Electron microscopy shows large (4000 Å) irregularly shaped densities in the cell bodies and processes of SN neurons. These densities were observed in perikarya, axons and dendrites. Analytical electron microscopy of these same structures according to Harling and Wood (1975) produced high chromium (Cr) peaks indicative of the presence of DA. These Cr peaks were compared against chromium crystals and a model system of glutaraldehyde plus DA and potassium dichromate. Model spectra were similar when compared against readings from Cr positive structures with the exception that there was a high sulfur (S) content in the neuronal structures. Many SN dense bodies are suspect of being pigment bodies, therefore, sections were stained with uranyl acetate and/or lead citrate. The amine-Cr positive structures appear different from other nonpositive densities which resemble pigment. Similar results were obtained with silver chloride with the exception that the silver chloride was less consistent and produced reactive artifact. The Cr positive deposits are similar in some respects to those seen previously in the arcuate nucleus but in other respects there are differences in ultrastructural configurations. These results show positive ultrastructural indentification of DA in the dopaminergic neurons of the SN. Also these Cr positive structures are not limited to certain cell areas since they are in perikarya, in dendrites and possibly in axons. Reserpine diminishes the number and size of densities as well as the Cr content. The other possibility exists, that pigment granules exist in different states and that pigment granules may contain DA. In vitro studies using melanin instead of DA produce no reaction. Now that a positive DA method is available, the ultrastructure of the DA storage site can be determined and with analytical electron microscopy, the elemental characteristics of these sites can be evaluated. (Supported by the Salk Foundation of Texas and by Grant #NS10326.)

787 MONOAMINE OXIDASE A AND B IN CULTURED CELLS. Morris Hawkins, Jr* and Xandra O. Breakefield* (SPON: E.L. Giller). Dept. Human Genetics, Yale Univ. Sch. of Med., New Haven, CT 06510.

The degradative deamination of tryptamine by monoamine oxidase (MAO) was compared in several continuous cell lines of rodent origin, including neuroblastoma, hepatoma, melanoma, nephroma, sarcoma and L cells. Homogenates of stationary phase cells show a 300-fold variation in activity against [2-^{14}C]tryptamine with the highest specific activity being 1043 pmol/min/mg/protein in hepatoma line MH_1C_1 and the lowest being 3 pmol/min/mg/protein in neuroblastoma line N1E-115TG2 which lacks hypoxanthine phosphoribosyltransferase (HPRT). Levels of MAO activity vary with the stage of growth in culture. MAO activity was lower in 3 lines lacking HPRT activity as compared to the parental lines from which they were derived; activities were 100-fold lower in N1E-115TG2, and 3-fold lower in both N-18TG2 and PC1A-HPRT$^-$, however, no difference was found between MAO activities in HTC and HTCPRT$^-$ cells. Succinate-cytochrome C reductase (SCCR), another mitochondrial enzyme, showed a 20-fold variation in activity between cell lines, being highest in neuroblastoma line N1E-115 and lowest in hepatome line MH_1C_1, with values of 49 nmol and 2 nmol/min/mg protein, respectively. SCCR and MAO activities appeared to be regulated independently. Clorgyline (1 nm), a selective inhibitor of A type MAO activity, completely blocked deamination of tryptamine in homogenates of all lines except MH_1C_1. Using either clorgyline or deprenyl, a selective B inhibitor, MAO activity in MH_1C_1 homogenates appeared to be 30-60% of the B type and 40-70% of the A type. In neuroblastoma N1E-115 cells in culture, clorgyline (10 nm) completely inhibited MAO activity against tryptamine and dopamine, indicating that the A type of MAO is active intracellularly as in homogenates. In hepatoma MH_1C_1 cells in culture tryptamine deamination, in contract to that seen in homogenates, showed exclusive B type activity.

We conclude that: 1) homogenous populations of a number of peripheral, rodent cell types possess almost exclusively the A type of MAO activity against tryptamine, as measured in homogenates by sensitivity to clorgyline; 2) the lowering of MAO activity seen with HPRT deficiency may depend on factors of intermediary metabolism which vary between lines, or may reflect different mutational or epigenetic events leading to HPRT deficiency; 3) total MAO activity is regulated in culture with the stage of growth and varies independently of at least one other mitochondrial enzyme, SCCR; 4) in mouse neuroblastoma clone N1E-115, MAO activity of the A type against tryptamine and dopamine occurs in living cells, as in homogenates; and 5) in rat hepatoma line MH_1C_1 cells under conditions of growth tryptamine metabolism is mediated by B type activity, but homogenization leads to expression of A type of activity.

788 EVIDENCE FOR NORADRENERGIC SPECIFICITY OF BEHAVIORAL EFFECTS OF ELECTRICAL STIMULATION OF THE NUCLEUS LOCUS COERULEUS. Y.H. Huang, J.W. Maas, and D.E. Redmond, Jr., Dept. Psychiatry, Yale Univ., New Haven, Ct. 06510.

The behavioral effects of low level electrical stimulation of the locus coeruleus (LC) in chair-trained *M. arctoides* were studied after agents which activate or block the functional effects of the locus coeruleus. 10 µg/kg clonidine, which is thought to block the E or NE receptors on the cell bodies of the locus coeruleus, blocks the behavioral effects of electrical stimulation of the locus coeruleus with bipolar, biphasic stimulation (from 0.4 to 0.5 mA intensity, 0.5 msec square wave pulses, and 10-30 Hz frequency). 5 mg/kg of propranolol, a post-synaptic ß-adrenergic antagonist also abolishes the effects of stimulation of the locus coeruleus. Electrical stimulation of the locus coeruleus at these parameters cannot be regularly distinguished from the effects of threatening or frightening situations. All produce mouth movement, scratching, yawning, hand wringing, body jerks, and other behaviors in a pattern which is consistent within animals between the various eliciting stimuli, but differs somewhat between animals, *i.e.* monkeys which hand wring in response to threats also hand wring after piperoxane administration or electrical stimulation of the locus coeruleus. The pharmacologic specificity of the agents which block electrical stimulation of the LC, and the apparent equivalence of the behavioral effects of piperoxane and electrical stimulation of the locus coeruleus support locus coeruleus-noradrenergic mediation of the behavioral effects described here and in the previous paper by Gold and Redmond.

789 DESCENDING MONOAMINERGIC PATHWAYS IN THE ADULT OPOSSUM (DIDELPHIS VIRGINIANA). A.O. Humbertson, Jr., K.A. Crutcher and G.F. Martin.

Catecholamine (CA) and indolamine (IA) varicosities are found at all levels of the spinal cord in the adult opossum. Indolamine terminals are present throughout the gray matter, but are concentrated within the medial ventral horn at cervical levels and the lateral horn at thoracic and upper lumbar levels. Catecholamine terminals are extensive within the dorsal part of the dorsal horn at all levels as well as within the lateral horn. The region surrounding the central canal, throughout its length, is rich in terminals of both types.

Following horseradish peroxidase (HRP) injections of either lumbar, thoracic or cervical cord levels, labelled neurons are present within the nucleus coeruleus, the nucleus coeruleus: pars alpha (Oswaldo-Cruz, Rocha, Miranda, '68), the solitary nucleus and the lateral reticular formation. These areas contain fluorescent cell bodies of the (CA) type in the opossum. Reactive neurons also appear within the pontine and medullary raphe nuclei where fluorescent neurons of the (IA) type are present. In addition, following thoracic (HRP) injections there are labelled neurons in the periventricular nucleus as well as in dorsal and caudal regions of the hypothalamus. Although fluorescent neurons of the (CA) type are present in those areas, they are sparse.

In several cases ^{3}H-amino acids were deposited within those brainstem regions which label in the HRP experiments and which also fluoresce for monoamines. In such cases axons are labelled in regions of the spinal cord which contain fluorescent varicosities when processed by the Falck-Hillarp method. (Supported by USPHS Grants NS-10165 and NS-07410.)

790 CHANGES IN MONOAMINE OXIDASE ACTIVITY IN RABBIT PLATELETS AND BRAIN REGIONS DURING PREGNANCY. S. Huprikar*, A. Mosnaim, L. Black Jones*, G. Oltmans, V. Nair, and E. A. Zeller. Department of Pharmacology, School of Graduate and Postdoctoral Studies, University of Health Sciences/The Chicago Medical School, Chicago, IL 60612, and Department of Biochemistry, Northwestern University Medical School, Chicago, IL 60611.

Evidence for the regulation of monoamine oxidase (MAO; E:C:1:4:3:4) activity in brain and other tissues by steroid hormones has been presented by a number of investigators (Zeller et al., J. Neural Transm., in press). Since the status of these hormones is dramatically changed in pregnancy, it was of interest to study the influence of this condition on platelet and brain MAO activity. New Zealand white rabbits (3 kg; ∿10 months old) were used in these studies. Using ^{14}C-labeled phenylethylamine and serotonin as substrates for MAO types B and A respectively, we now report that during the course of pregnancy the activity of platelet MAO_B steadily decreases, reaching lowest values at term (30-32 days; controls 2.41±0.24, pregnancy 1.49±0.14 nmoles/mg protein/hr), whereas MAO_A showed slight but significant increase (control 1.10±0.05, pregnancy 1.37±0.04 nmoles/mg protein/hr). At term, the activities of both MAO_B and MAO_A did not change in either the caudate, hippocampus, hypothalamus, or cortex, while they were significantly increased in the brainstem (control MAO_B 1995±605, pregnancy MAO_B 3684±212 nmoles/g wet tissue/hr, $p<0.05$; control MAO_A 1147±345, pregnancy MAO_A 3945±1050 nmoles/g wet tissue/hr, $p<0.01$). An increase for MAO_A was also observed in cerebellum (control MAO_A 1402±345, pregnancy MAO_A 2466±383 nmoles/g wet tissue/hr, $p<0.01$). These results suggest the involvement of the gestational hormones-MAO system in the regulation of biogenic amines during pregnancy. 791 DIFFERENTIAL PROJECTIONS OF NEURONS WITHIN THE DORSAL RAPHE NUCLEUS OF THE RAT: A HORSERADISH PEROXIDASE (HRP) STUDY. Barry L. Jacobs, Stephen L. Foote and Floyd E. Bloom. Princeton Univ., Princeton, NJ and Salk Inst., La Jolla, CA.

The efferent projections of the midbrain raphe nuclei dorsalis (DR) and medianus (MR) in the rat have previously been reported to be differential (Jacobs, et al. Brain Res. 1974, Vol. 79, p. 353). The present study examined whether subareas within the DR have different projections, i.e. whether the nucleus is topographically organized. Since the raphe nuclei are symmetrically shaped midline structures, we also examined whether the projections of their constituent neurons were unilateral or bilateral. Unilateral injections of 30% HRP (0.1 - 0.5ul) were placed in one of three areas: dorsal neocortex-hippocampus, corpus striatum, or amygdala-piriform cortex of adult male albino rats. The animals were perfused 24 hrs later with a mixture of paraformaldehyde and glutaraldehyde and the brains were then removed and stored in sucrose buffer for 24 hrs. The brains were then cut (40u thick sections), reacted with 3-3' diaminobenzidine hydrochloride, mounted, cover slipped, and examined with both light and dark field microscopy. The diffusion of HRP at the injection site was often quite extensive, however, in the animals selected for analysis, there was never any overlap of the three injection sites. Some portions of the DR, e.g. the ventromedial cluster of cells, contained HRP positive cells which were common to the three injection sites. On the other hand, some labelled sites within the DR were unique to a particular injection site. For example, only injections into the amygdala-piriform cortex labelled cells in the most posterior aspect of the DR and its caudal extension into B-6. Amygdala injections also yielded more heavily labelled cells in the dorsomedial cluster of the DR than did injections in either of the other two sites. Projections of DR cells are quite lateralized, as evidenced by the appearance of the most heavily labelled cells ipsilateral to the injection site. Some contralateral labelling, especially of cells close to the midline, was also evident. By comparison, cells in the MR appeared to be less lateralized. These data also confirmed our previous studies on the differential projections of DR and MR since we found that MR cells were heavily stained for HRP after dorsal cortex-hippocampal injections and contained little or no HRP positive cells following striatal injections which did consistently label cells in the DR. In conclusion, DR neurons have largely ipsilateral projection fields which are somewhat different from the projection sites of cells located in other areas of the DR as well as from cells in the MR. A previously unreported projection to the amygdala-piriform cortex from B-6 was also observed. (Supported by NIMH grant MH-23433 and NSF grant BNS 76-09318).

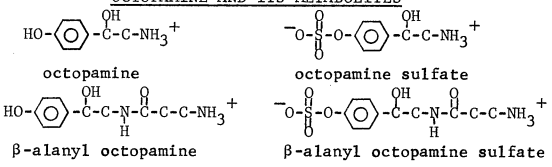
792 AMINE METABOLISM: A DIFFERENT PATHWAY IN LOBSTERS. Mary B. Kennedy* (SPON: E. A. Kravitz). Harvard Med. Sch., Boston, MA 02115.

Previous work from this lab has shown that lobster tissues can take up and metabolize octopamine, dopamine, and serotonin, the three major amines found in lobsters. Yet the tissues do not contain catechol-O-methyl transferase or monoamine oxidase, the enzymes that metabolize the amines in mammals. This report is concerned with the pathway of amine metabolism in lobsters.

Sulfate conjugates: When lobster leg nerves were incubated with ^{3}H-amines, three ^{3}H-products were formed from each amine. Two of the three products were labelled with ^{35}S when $^{35}SO_4$ was also included in the incubation medium. Hydrolysis of one double-labelled octopamine product produced a mixture of $^{35}SO_4$, and ^{3}H-octopamine. Hydrolysis of the other produced $^{35}SO_4$, and varying amounts of ^{3}H-octopamine and a ^{3}H-compound with the electrophoretic mobility of the third, non-sulfate containing, product. This suggested that sulfate conjugates were formed both from octopamine and from the third metabolite. Properties of the products indicated that the SO_4 was esterified to the ring hydroxyl groups. An enzyme system that catalyzed the formation of amine sulfates from the three amines and phosphoadenosine phosphosulfate was found in homogenates of the nerves. Thus, one major pathway of amine metabolism in lobsters is sulfate conjugation.

β-Alanine conjugates: The octopamine conjugate that did not contain SO_4 could be converted back to octopamine by hydrolysis, indicating that it was also a conjugate. The metabolite was reacted with dansyl chloride (DNS-Cl). Hydrolysis of the resulting DNS-derivative produced a DNS-compound that co-chromatographed with DNS-β-alanine in four solvent systems. This suggested that the metabolite was a β-alanine conjugate. Its characteristics indicated that the β-alanine was linked by an amide bond to the amino group of octopamine. An enzyme system that catalyzed the formation of amine products from each of the amines, ATP, and β-alanine was present in leg nerve homogenates. These results suggest that a second major pathway of octopamine metabolism, and possibly of amine metabolism in general in the lobster, is β-alanine conjugation. Supported by NIH.

OCTOPAMINE AND ITS METABOLITES



793 EFFECTS OF REPEATED IMMOBILIZATION STRESS ON PLASMA LEVELS OF EPINEPHRINE, NOREPINEPHRINE AND DOPAMINE-β-HYDROXYLASE. R. Kvetňanský*#, C.L. Sun*, T. Torda*#, C.R. Lake and I.J. Kopin, (SPON: O.H. Viveros).
Laboratory of Clinical Science, NIMH, Bethesda, MD 20014.
#Inst. Exp. Endocrinology, Bratislava, Czechoslovakia.

Repeated immobilization (IMO), daily for 2.5 hrs., increases adrenal medullary catecholamines (CA) and CA-synthesizing enzymes and enhances urinary excretion of CA over the increase produced by a first IMO. Decapitation results in a sudden massive activation of the sympatho-adrenal medullary system with striking increases in plasma levels of CA. Rats decapitated after repeated IMO had greater increases of plasma CA during the first 5 minutes of IMO than did rats IMO for the first time. Repeated IMO for 150 min. daily had a greater effect on increasing levels of plasma CA, in rats decapitated 24 hours after the last IMO, than did IMO for 10 min. daily. The enhancement of the increase in CA produced by decapitation was greatest after 7 days of repeated IMO, but was still significantly enhanced after 45 days. Adrenalectomy resulted in virtual absence of epinephrine in plasma both before and during IMO, while plasma norepinephrine was not essentialy changed. In blood obtained from an indwelling arterial cannula, levels of epinephrine and norepinephrine were much lower than after decapitation (0.07 ng vs. 7.00 ng E and 0.25 ng vs 2.20 ng NE/ml of plasma). IMO resulted in striking increases in plasma levels of both CA, but there were greater increases during the first IMO than during IMO after the 30th repeated exposure. In undisturbed rats, however, basal levels (24 hrs. after the last IMO) of epinephrine and norepinephrine were greater in animals subjected to repeated IMO. Plasma levels of dopamine-β-hydroxylase were higher in repeatedly IMO rats (24 hours after the last IMO) than in unstressed animals. Furthermore, during IMO, levels of the enzyme were increased to a greater extent in the repeatedly stressed rats.

Thus, basal levels of epinephrine and norepinephrine and dopamine-β-hydroxylase activity in plasma are increased when the capacity to synthesize CA is enhanced by repeated IMO stress. This is also reflected by the maximal CA release which follows decapitation. After rats are subjected to repeated IMO, however, although the capacity to discharge CA is increased, plasma levels of CA are not increased to the same extent as in IMO naive rats, presumably as a consequence of reduced CNS response to IMO in the experienced animals.

794 NO DIFFERENCE IN CEREBROSPINAL FLUID LEVELS OF NOREPINEPHRINE IN PATIENTS WHEN ON HIGH VERSUS LOW MONOAMINE DIETS. C.R. Lake, M.G. Ziegler*#, I. Shoulson## and I.J. Kopin. NIMH, Bethesda, MD 20014.
University of Texas Medical Branch, Galveston, TX 77550.
##University of Rochester School of Medicine, Rochester, NY 14627.

In research protocols in which catecholamines are to be determined, the subjects are often maintained on a low monoamine (LMA) diet. Urinary 3-methoxy-4-hydroxyphenylglycol (MHPG), a major metabolite of norepinephrine (NE) reflecting brain NE metabolism, was found to be significantly decreased in depressed patients but unchanged in normal volunteers by the LMA diet, but effects of diet on CSF levels of amines have not been examined. We measured levels of NE in cerebrospinal fluid (CSF) from 5 aliquots of 4 ml each and from plasma and noted blood pressure and pulse rate from each of 6 patients with Huntington's disease while on a LMA diet and again while on a high monoamine (HMA) diet. Huntington's patients had significantly lower levels of NE when compared to age matched controls. Levels of NE in CSF first removed from the lumbar tap needle may have contributions from spinal nerve terminals while NE from higher aliquots of CSF are thought to reflect brain metabolism. When NE from each CSF aliquot was examined using the paired Student t-test, levels of NE were higher while subjects were on the LMA diet but only the second aliquot (ml 4 through 8) was significantly ($p < 0.01$) higher. When CSF levels from all aliquots were compared on the two diets by analysis of variance, there were no differences between CSF levels of NE on the 2 diets. The means ($\pm$ SEM) of all aliquots of all patients were 141 $\pm$ 11 pg/ml and 150 $\pm$ 10 while on the HMA and LMA diets, respectively. Supine plasma levels of NE on the HMA diet was 243 $\pm$ 65 pg/ml and on the LMA diet was 320 $\pm$ 19. Blood pressure and pulse rate were similar on the two diets. The lack of difference in CSF levels of NE under the two dietary conditions presumably reflects an efficient hepatic removal and effective blood-brain barrier for NE. Thus, dietary, restrictions may be unnecessary when examining CSF for NE.

795 THE RELATIONSHIP BETWEEN PLASMA CATECHOLAMINES, CORTISOL, PSYCHOLOGICAL FACTORS AND DURATION OF PARTURITION. Regina Lederman*, Daisy S. McCann, Wayne County General Hospital, Eloise, Mi 48132 & the Depts Nursing and Internal Medicine, The University of Michigan, Ann Arbor, Mi 48109

In last trimester pregnancy measures of plasma catecholamines and cortisol, self-report anxiety, and psychological factors relevant to parturition were obtained from 32 primigravidas, 20-32 years old, with no obstetrical complications. During labor, self-report anxiety and the biochemical measures were also obtained at the onset of first stage active labor and second stage labor. These data were analyzed for relationships to uterine activity (Montevideo Units) and length in each phase of labor.

Poor relationships with the subject's husband and mother, high fears pertaining to pain, helplessness, the loss of self-control and self-esteem, low acceptance of pregnancy, and a history of psychological counseling were significantly correlated with lower uterine activity during active labor. Fears of pain and helplessness, poor identification of a motherhood role, and low acceptance of pregnancy were significantly related to longer active phase labor. The latter two variables were also significantly related to longer second stage labor. Self-report anxiety in pregnancy correlated with the two anxiety measures in labor and with uterine activity in active labor.

During labor the biochemical measures were significantly elevated, but statistically unrelated to one another. The anxiety measure in active labor correlated with epinephrine (E), $r = .60$ ($p<.01$) and with cortisol, $r = .59$($p<.01$), but not with norepinephrine (NE). E and cortisol also correlated significantly and positively with uterine activity, but only E correlated with the length of active labor, $r = .60$($p<.01$). In second stage labor all the biochemical measures correlated positively and significantly with the anxiety measure, but only E correlated with the length of second stage labor, $r = -.30$($p<.05$). There are also significant correlations between first stage active and second stage labor for NE, uterine activity and length of labor, but not self-report anxiety, indicating that progress in the two phases of labor are related, but the determinants of anxiety are different in each phase.

The data reported are consistent with the hypothesis that there are relationships among anxiety, selected biochemical measures, and progress in labor, and suggest a need for a program of early diagnosis and intervention of anxiety.

796 CELLULAR PROPERTIES OF THE MONOAMINE NEURONS IN THE LEECH CNS. Charles M. Lent and Bryan M. Frazer*. Dept. Biology, SUNY Stony Brook, New York 11794.

Nine widely-scattered neurons in leech segmental ganglia contain biogenic monoamines (MA). The large serotonergic pair of Retzius cells (RZ) and seven small interneurons are vitally and selectively stained by Neutral Red dye (Stuart, et. al., Cell Tiss. Res. 55:61, 1974), a procedure potentially facilitating intracellular investigations of a limited population of biochemically-related neurons.

Simultaneous recordings from RZ and each of the small MA cells show a pattern of slow depolarizations producing impulse bursts in temporal register. This pattern apparently results from the activity of a common excitor, and is also seen between pairs of small cells. Thus, the entire MA population receives an excitatory input. This central excitation is probably mediated by cholinergic synapses as the slow depolarizations are blocked by Mg^{++}, reversibly-abolished by atropine, and augmented by eserine.

RZ are coupled to one another by low resistance junctions and to each of the small MA cells by high resistance junctions. The high resistance junctions are Mg^{++}resistant, ohmic in the hyperpolarizing domain and rectify somewhat to depolarization. Similar high resistance junctions between the small cells suggest that the MA cell population is electrotonically-intercoupled.

Anodal break stimulation can produce self-sustaining bursts by the MA cell population. Thus, both patterns of connectivity (coupling and common excitation) assure a concerted impulse activity by the ganglionic MA cells. Furthermore, both types of burst activity are conducted along the ventral nerve cord of the leech generating bursts in adjacent ganglia. We infer from this that the central impulse activity of the monoamine neurons has an integrative function above the ganglionic level.

797 DEVELOPMENT OF THE NORADRENERGIC INNERVATION OF THE NEOCORTEX IN THE RAT. Pat Levitt* and Robert Y. Moore. Department of Neurosciences, School of Medicine, Univ. of Calif., San Diego, La Jolla, CA 92093.

The neocortex of the adult rat receives a diffuse, plexus-like noradrenergic innervation from the locus coeruleus which is identical in organization in all cortical areas. Fibers branch at all cortical levels to undergo extensive collateralization. The molecular layer contains the most dense fiber plexus as a result of terminal horizontal branching. This highly ramifying afferent system has been studied in terms of its role in the development of the neocortex. The present analysis concerns the time of origin and maturation of the noradrenergic fibers in the neocortex. The combined formaldehyde-glyoxylic acid freeze-dry histochemical technique and high affinity uptake of ^{3}H-noradrenaline into tissue slices were used for developmental analysis.

Fluorescence histochemistry reveals a sparse innervation of the frontal, occipital, and lateral cortices by 20 days gestation which is localized to the cortical plate. Innervation of the parietal cortex is not observed until postnatal day 1. Slow development proceeds in all cortical areas up to day 3, when noradrenaline-containing fibers are evident in all cortical layers. Typically, a sparse vertical plexus with few branches is observed in the deep layers, which ramifies into a much more dense horizontal plexus in the molecular layer. By day 6 the developing innervation resembles the adult, though a significant variation in fiber density is evident. At 10 days, the pattern and density look identical to the adult neocortex.

Accumulation of ^{3}H-noradrenaline by high affinity uptake reveals a similar pattern of development. On postnatal day 2 uptake is only 10% of adult values, but rapidly increases to nearly 90% by day 9. Uptake values reach approximately 2.5 times the adult between days 10 and 18. Thereafter, a gradual decrease to adult levels occurs. This suggests that the noradrenergic innervation is complete at an early postnatal stage, prior to the development of the cerebral neocortical neuropil. (Supported by USPHS NS-12080)

798 THE MONOAMINERGIC INNERVATION OF IMMATURE RAT CORTEX: AN EXPERIMENTAL HISTOFLUORESCENCE STUDY. Hart G.W. Lidov and Mark E. Molliver. Departments of Anatomy and Neurology, The Johns Hopkins School of Medicine, Baltimore, Md. 21205. U.S.A.

The monoaminergic (MA) projections from brainstem are among the first axons to invade the developing forebrain and may exert a trophic influence as well as function in neurotransmission. *Ultrastructural studies* of neonatal rat cerebral cortex, from this laboratory, have demonstrated many MA synapses in strata parallel to the pia. Prior efforts to visualize the presynaptic processes using *histofluorescent techniques* have been hampered by low MA levels in infancy. *Biochemical studies* have shown that monoamine neurons develop a MA uptake-storage mechanism in advance of transmitter synthesis, and that immature cortex has a MA storage capacity 10-fold greater than endogenous levels. We have taken advantage of these biochemical properties by treating with MA congeners and thus augmenting the low endogenous levels, in order to demonstrate the full extent of the MA innervation by light microscopic histofluorescence.

Cingulate and lateral neocortex from 6-day old rats was studied with glyoxylic acid induced histofluorescence. Treatment with an MAO inhibitor (nialamide, 100 mg/kg) favors visualization of those fibers with substantial endogenous MA stores; treatment with a MA congener (α-methylnorepinephrine, α-MNE, 75 mg/kg) displays the larger set of fibers with an active MA uptake mechanism. In a third group surgical or chemical lesions were made in the midbrain tegmentum as a control for uptake into non-aminergic axons.

The results are that 1) nialamide treated rats exhibit a sparse MA innervation of layer I; 2) there is a striking increase in the quantity of fluorescent elements after α-MNE; 3) the MA fibers are predominantly in three strata parallel to the pia: at 30μ, 75μ, and a broad peak at 250μ, subpial. These strata are coincident with the primordia of layers I and IV. One interpretation of our findings is that the three strata are the terminal fields of three distinct MA projections to immature cortex. The dense, latent MA innervation in layer IV of cortex corresponds to the major stratum of MA synapses demonstrated ultrastructurally and is the morphological expression of the MA storage compartment defined biochemically [Science 196 (1977) 444]. The existence of fibers which do not exhibit transmitter, but have been shown ultrastructurally to form synapses, suggests that synaptogenesis does occur in the absence of neurotransmitter. 799 EFFECTS OF MANIPULATION OF CENTRAL SEROTONIN ON LEARNED TASTE AVERSIONS IN THE RAT. Joan F. Lorden and Gary A. Oltmans. Dept. Psych., University of Alabama in Birmingham, Birmingham, AL, 35294 and Dept. Pharm., Chicago Medical School, Chicago, IL 60612.

Depletion of central serotonin (5HT) in rats has been shown to facilitate avoidance training when painful electric footshock is used as a stimulus (Lorens et al., JCPP, 77:48, 1971). The experiments reported here examined the effects of 5HT depletion on another type of avoidance behavior, the conditioned taste aversion. Rats made sick following the ingestion of a novel substance will avoid that substance on subsequent presentations. In this paradigm, gastrointestinal distress or other drug effects, rather than cutaneous pain, serves as the unconditioned stimulus. Electrolytic lesions of the dorsal and median raphe nuclei in rats enhanced the avoidance of a saccharin solution that had been paired with a single injection of the toxic drug, lithium chloride (12 mg/kg, ip, of .15M LiCl). A chemically specific lesion of these nuclei made by infusion of 5,7-dihydroxytryptamine produced the same behavioral effect. Neither lesion group differed from control animals in the consumption of an unpaired familiar fluid or an unpaired novel fluid. Both lesions caused a significant depletion (66-68%) of telencephalic serotonin. The data suggested that the enhanced suppression of saccharin intake was due to damage to serotonergic neurons. Rats with electrolytic lesions of the median raphe alone showed a significant enhancement of saccharin avoidance in the taste aversion paradigm. The addition of a dorsal lesion increased 5HT depletion (71 vs 43%) but did not produce a significant increment in saccharin avoidance. Thus, decreased hippocampal or septal 5HT produced by the median lesion may account for the facilitation of the learned aversion.

The behavioral effects of the combined dorsal and median raphe lesions were reversed by pretreatment with DL-5-hydroxytryptophan (75 mg/kg, 5HTP) which has been shown to elevate forebrain 5HTP levels. In rats with dorsal and median raphe lesions, 5HTP administration blocked the formation of a learned taste aversion. In normal rats, attenuation of learned aversions was obtained with a lower dose of 5HTP (50mg/kg). Experiments using the flinch-jump technique to evaluate sensitivity to footshock indicated that treatment with 5HTP did not alter the flinch-jump thresholds of normal rats but did restore thresholds to normal in rats with lesions that depleted 5HT (Harvey & Lints, JCPP, 74:28, 1971). Thus, the conditioned aversion paradigm may be more sensitive than the flinch-jump technique to manipulation of of central 5HT levels.

800 INCREASED TILT-CAGE ACTIVITY FOLLOWING INTRACRANIAL ADMINISTRATION OF 5,7-DIHYDROXYTRYPTAMINE. Robert G. MacKenzie*, Charles Norelli*, Michael E. Trulson and Bartley G. Hoebel. Dept. of Psychol., Princeton Univ., Princeton, N.J. 08540

Previous work has shown that electrolytic lesions of the median raphe nucleus, a region rich in serotonin (5-HT)-containing cell bodies, are followed by increases in 24 hr home cage activity, wheel running, and open-field activity in rats. Synthesis inhibition of 5-HT by i.p. injections of p-chlorophenylalanine (PCPA) is also followed by increased locomotor activity; further suggesting serotonergic control over locomotion. However, recent studies have questioned such a role for 5-HT by demonstrating that depletion of forebrain 5-HT by the neurotoxin 5,7-dihydroxytryptamine (5,7-DHT) is either without effect or actually depresses locomotor activity in the open field.

This report demonstrates an increase in locomotor activity with 5,7-DHT injected either locally or intraventricularly. A 2-fold increase in 24 hr activity was measured by housing rats in tilt cages 3 weeks after administration of 5,7-DHT (8 µg) in the posterior medial forebrain bundle. This treatment caused a 79% depletion of forebrain 5-HT. The daily activity of the 5,7-DHT group remained elevated throughout the 36 consecutive day monitoring period. Intraventricular administration of 5,7-DHT (200 µg) resulted in an approximate 4-fold increase in 24 hr home cage activity, and 5-HT depletions of 83%, 58% and 71% in forebrain, brainstem, and spinal cord, respectively. These rats were housed in tilt cages one month following injection and activity was monitored for 14 consecutive days. The diurnal index of activity, computed as light activity/light & dark activity x 100 was identical for the 5,7-DHT group and controls, suggesting preservation of the normal light-dark activity rhythm which contrasts with the disruption of this rhythm reported in PCPA-induced hyperactivity. Furthermore, unlike rats with median raphe lesions, the behavior of the rats administered 5,7-DHT intraventricularly was undistinguishable from that of controls when tested in the open-field. This result shows that effects obtained from open-field activity cannot be generalized to other measures of locomotion.

It is concluded, in agreement with other reports, that different methods of 5-HT depletion can result in different effects on various behavioral measures, but that this does not appear to be the case for tilt cage hyperactivity. That is, this effect occurs following electrolytic raphe lesions, PCPA or 5,7-DHT. It is, therefore, suggested that this effect is not the result of non-specific damage but rather is due to subnormal 5-HT synaptic activity in the central nervous system.

801 INACTIVATION OF BRAIN TYROSINE HYDROXYLASE BY CYCLOHEXIMIDE IN VIVO. Keith Markey* and Paul Y. Sze. Dept. Biobehavioral Sci., Univ. of Conn., Storrs, CT 06268.

Following an injection of cycloheximide (300 mg/kg, s.c.) in mice, brain tyrosine hydroxylase (TH) activity was rapidly reduced. The decrease began to occur after 1 hr, reaching a minimum of 55-65% of control at 2.5 hrs and recovering to normal by 3.5 hrs. This decrease was observed in whole brain as well as regionally in pons, cerebral cortex and striatum, and also subcellularly in striatal synaptosomes. Kinetic analyses revealed that the apparent K_m of the enzyme for 6-MPH_4 was increased by 2-3 fold after cycloheximide, whereas the K_m for tyrosine remained unchanged. Addition of cycloheximide in vitro had no effect on TH activity. The alteration of K_m, the time course of the action, and the effect in nerve terminals indicate that the decrease of enzyme activity is not due to inhibition of protein synthesis by cycloheximide, directly or indirectly.

The characteristics of this inactivation were examined as follows: (1) Lower enzyme activity could be seen in 40,000 x g supernatant prepared with or without detergents (Triton X-100 or Lubrol), indicating that the effect is not altered by solubilization of enzyme activity. (2) TH from treated animals could be activated but not to normal levels by c-AMP, ATP, and Mg^{++}, or by heparin. (3) Mixing supernatants from treated and control animals yielded mean activity, suggesting the absence of a soluble modifier. (4) Mixing homogenates before centrifugation, however, fully restored the reduced activity to normal. It appears that a factor associated with some particulate material is involved here in modifying the TH activity.

Additional experiments using cycloheximide as a tool are underway to further characterize this inactivation of brain TH.

802 THE DORSAL NORADRENERGIC BUNDLE AND FRUSTRATIVE NON-REWARD. Stephen T. Mason* & Susan D. Iversen* (SPON: H.C. Fibiger). Psychological Laboratory, University of Cambridge, England.

Destruction of the dorsal noradrenergic bundle using 6-hydroxydopamine (6-OHDA) produces a resistance to extinction in a number of behavioral tasks. One mechanism by which this might occur would be an inability to code for non-reward or an alteration in the frustration produced by omission of an expected reward. This is tested by examining the response invigorating effects produced by randomly omitting some of the food deliveries on a fixed interval (FI) schedule. Response rate in the interval following that in which reward was omitted is known to increase in normal rats and thus provide a measure of the invigorating effects of frustration. Male albino rats weighing 200 gms were stereotaxically injected with 8 µg of 6-OHDA base dissolved in 2 µlitres of 0.9% saline with 1 mg/ml ascorbic acid antioxidant infused over 2 mins bilaterally at coordinates - 6mm from bregma, 0.8 mm lateral from midline and 5 mm below dura according to Konig & Klippel. After behavioral testing a biochemical assay of brain regions of these same animals confirmed that they had sustained depletions of cortical noradrenaline (NA) to 4% of controls, hippocampal NA to 11% while sparing cerebellar and hypothalamic NA and brain dopamine. Following the operation the animals were food deprived to 90% of their free-feeding weight and trained for 16 days on a FI 60 sec schedule of 20 FIs per day. No difference was found in acquisition between treated and control rats. When FI performance had stabilized reward was randomly omitted from ¼ of the intervals and the response rate in the following interval compared with that in intervals following presentation of reward. Omission of an expected reward increased the response rate significantly ($p<0.05$) but did so equally for both treated and control animals ($t=0.19$, $df=12$, NS). However, following 10 days of training on this schedule the treated and control rats diverged; with the controls showing a decreased frustration following reward omission but the treated rats continued at the same high initial level ($p<0.01$). Both groups were then retained on a 100% reinforced FI schedule to the same level of responding and extinguished in the complete absence of reward. The treated animals were resistant to extinction showing greater responding ($p= 0.042$) and taking longer to reach an extinction criterion ($p<0.05$). Thus, both biochemical and behavioral measures confirm the validity of the lesion yet it failed to alter the immediate response invigorating effect of reward omission, suggesting that these animals can code adequately for non-reward, but the lesion did prevent the decrease in frustration over time seen in the controls suggesting that the treated animals may be impaired in the memory of or the learning about non-reward.

803 THE EFFECT OF LESIONS OF THE VENTRAL NORADRENERGIC BUNDLE ON SEROTONIN AND NOREPINEPHRINE CONCENTRATION IN DISCRETE NUCLEI. V. John Massari*, Y. Tizabi* and D. M. Jacobowitz (SPON: Alan M. Laties). Lab. Clin. Sci., NIMH, Bethesda, MD 20014; and Dept. Pharmacology, Howard Univ., Washington, D.C. 20059.

Since fluorescence-histochemical studies first noted the close apposition of catecholaminergic (CA) nerve terminals to serotonergic (5HT) cell bodies, increasing evidence has accumulated to suggest that the functional activity of 5HT neurons may be regulated by CA. CA and their synthesizing enzymes have been measured in each of the raphe nuclei (Brain Res. 114: 339, 1976), and drugs which effect CA, such as 6-hydroxydopamine or α-methyl-p-tyrosine, have also been shown to effect 5HT metabolism. Similarly, 5HT neurons have been shown to be capable of influencing NE metabolism. Very little information is available, however, to define specifically which 5HT and noradrenergic (NE) nuclear groups and axon pathways are involved in this interaction. In this study we have severed the caudal aspect of the ventral NE bundle and thereby significantly reduced the A-1 and A-2 cell body contributions to this projection. Subsequent effects on 5HT content in discrete nuclei were examined. Male Sprague-Dawley rats received bilateral knife cut lesions of the ventral NE bundle (caudal to the locus coeruleus). Controls received a sham lesion into the cerebellum. Two weeks later all animals were sacrificed by decapitation and a 3 mm slice of the medulla was taken for histofluorometric confirmation of the accuracy of the lesions. The rest of the brain was processed by the microdissection method of Palkovits. The ventral NE bundle lesions did not effect levels of NE in the locus coeruleus or in two or its terminal projection areas (cingulate cortex, habenula). Similarly, 5HT levels in the dorsal raphe nucleus, interpeduncular nucleus, substantia nigra reticulata, area tegmenti ventralis, lateral mammilary nucleus, median forebrain bundle, retrochiasmatic area, hippocampus, and striatum were also uneffected. However, 5HT levels in the median raphe nucleus were significantly reduced by 40%. These results suggest that, unlike the previously proposed epinephrine projection, there does not appear to be a substantial noradrenergic pathway to the locus coeruleus from the A-1 and A-2 cell groups. This study provides support for the hypothesis that a NE projection to the median raphe nucleus may modulate 5HT neuronal function, although it cannot be excluded that destruction of some other unknown fiber system traveling with the ventral NE bundle may be responsible for the observed effects.

804 EXCESSIVE ELEVATION OF PLASMA CATECHOLAMINES DURING STRESS IN SPONTANEOUSLY HYPERTENSIVE RATS. R. McCarty and I.J. Kopin, Laboratory of Clinical Science, NIMH, Bethesda, MD 20014.

Recent evidence suggests an increased activity of the sympatho-adrenal system of spontaneously hypertensive rats (SHR) when compared to a matched normotensive strain (WKY). This difference is most pronounced in young SHR prior to the elevation in blood pressure (Grobecker et al., Nature, 258: 267, 1975; Nagaoka and Lovenberg, Life Sci., 19: 29, 1976; Nagatsu et al., Science, 191: 290, 1976). We were interested in measuring the responsiveness of the sympatho-adrenal system to acute stress in SHR and WKY rats.

Rats of each strain were obtained at 6,18 and 48 weeks of age. A chronic tail arterial catheter was inserted into each rat while under pentothal anesthesia. Two days after surgery, each rat was transferred from its home cage to a shock chamber and after 5 min received 60 footshocks (2.5mA, 0.4 sec duration) over a 5 min interval. Blood samples were taken from undisturbed animals in the home cage, 3-5 min after transfer to the shock chamber, and at the end of footshock. Plasma levels of norepinephrine (NE) and epinephrine (EPI) were measured by a sensitive radioenzymatic assay.

There were no strain differences in plasma levels of NE or EPI while animals were at rest in the home cage. Transfer from the home cage to the shock chamber resulted in a greater increase in plasma levels of both catecholamines in SHR rats of each age group. A similar pattern was evident after footshock; SHR rats had significantly higher post-shock levels of plasma NE and EPI when compared to age-matched WKY rats. These results demonstrate that the sympatho-adrenal system of SHR rats is more responsive than normotensive rats to stressful stimuli and that this hyperresponsivity is independent of increases in blood pressure. The excessive discharge of EPI and NE into plasma during stress may contribute to the development and maintenance of high blood pressure in SHR rats.

805 LOCOMOTOR BEHAVIOR INITIATED BY THE MICROINJECTIONS OF PICROTOXIN INTO THE VENTRAL TEGMENTAL AREA. G. J. Mogenson, M. Wu* and S. K. Manchanda*. Departments of Physiology & Psychology, University of Western Ontario, London, Canada.

Microinjections of dopamine, L-DOPA or apomorphine, a dopamine agonist, into the nucleus accumbens have been shown to initiate locomotor behavior in rats (Pijnenberg & Von Rossum, J. Pharm. Pharmacol., 1973, 25, 1003-1005; Costall & Naylor, Europ. J. Pharmacol., 1975, 32, 87-92). These compounds are assumed to act on post-synaptic receptors in the nucleus accumbens of dopaminergic (A_{10}) neurons which project from the ventral tegmental area (VTA). Since dopaminergic neurons receive GABA synaptic inputs exerting inhibitory effects (Füxe et al, Med. Biol., 1975, 53, 177-183) an investigation was carried out to see whether blocking these GABA inputs with picrotoxin, a GABA antagonist, would also initiate locomotor behavior. Following bilateral microinjections of picrotoxin (0.10 μg in 0.2 μl) into the VTA of rats the locomotor activity, as indicated by the number of counts in a photocell activity chamber, increased from a mean value of 47 to 134.8 ($p < 0.05$). Increased locomotion was accompanied by decreased grooming responses. These changes in locomotion were dose-dependent when tested with graded doses of picrotoxin (0.05 - 0.2 μg). Locomotor activity was also increased by unilateral microinjections of picrotoxin into the VTA but the magnitude of the response was significantly less. Control injections of strychnine sulphate (0.10 - 0.15 μg in 0.2 μl) or isotonic saline did not increase locomotion. Bilateral microinjections of spiroperidol (1.5 μg in 0.2 μl), a dopamine antagonist, into the nucleus accumbens significantly reduced the locomotor activity induced by picrotoxin (0.15 μg in 0.2 μl) into the VTA from a mean value of 235.6 to 90.6 ($p < 0.05$). The bilateral application of picrotoxin (0.15 μg in 0.2 μl) to the substantia nigra also increased locomotor activity but this increase was less than observed with VTA microinjections. Unilateral infusions of picrotoxin into the substantia nigra were followed by marked rotational behavior to the side contralateral to the stimulation site. These results are consistent with a role for dopaminergic (A_{10}) neurons of the VTA in initiating locomotor activity via projections to the nucleus accumbens. (Supported by the Medical Research Council of Canada and the National Research Council of Canada).

806 LOCUS COERULEUS STIMULATION POTENTIATES PURKINJE CELL RESPONSES TO IONTOPHORETICALLY APPLIED GAMMA AMINOBUTYRIC ACID. Hylan C. Moises and Donald J. Woodward. Dept. Cell Bio., Univ. Tx. Health Sci. Ctr., Southwestern Med. Sch., Dallas, Tx. 75235

We have recently reported that local administration of norepinephrine (NE) can selectively enhance excitatory and inhibitory responses of Purkinje (P) neurons produced both synaptically and by microiontophoretic application of putative cerebellar amino acid neurotransmitters, notably glutamate and gamma aminobutyric acid (GABA). In this study we asked whether NE, released synaptically during activation of the noradrenergic pathway from locus coeruleus (LC) to cerebellum, can modulate P cell responses to iontophoretically applied GABA.

Multibarrel micropipettes were used to apply drugs and to record P cells extracellularly in 20 Halothane-anesthetized rats. Post-stimulus time histograms were used to assess unit activity influenced by electrical stimulation in the region of LC. Histograms were also constructed to quantitate the effects of microiontophoretic pulses (10 sec. duration at 30 sec. intervals) of GABA (15-30 nA) applied before, immediately after (2.5-5 sec.) and during recovery from (60 sec. after) sub-threshold LC stimulation. Results showed in 12 of the 30 neurons studied, that brain stimulation at sites outside LC (brachium conjunctivum, juxtafastigial white matter) produced only transient effects on activity consisting of short latency (2-7 msec.) excitations, followed immediately by brief inhibitory periods (10-150 msec.). Repetitive stimulation in areas outside LC did not alter the inhibitory effects of GABA on any of the 8 cells tested from this group.

Eighteen P cells showed prolonged slowing or cessation of spontaneous discharge to discrete stimulation of LC with trains of shocks (20-100 pulses of 0.1-1.0mA delivered at 10/sec.). This response, which outlasted the stimulation by 3 to 30 seconds, has been attributed to synaptic release of NE. The effects of LC stimulation on inhibitory responses to iontophoretically applied GABA were examined in 6 of these cells. In all 6 cells, the inhibitory effects of GABA were potentiated by short preconditioning volleys (10/sec. for 2.5-5.0 sec.) delivered to LC 7.5 seconds before each GABA pulse. In 4 cells, augmentation of GABA inhibition was observed at stimulation currents which alone elicited no depression of spontaneous discharge. These data provide additional evidence that activation of the noradrenergic pathway from LC to cerebellum acts to modulate Purkinje cell responsiveness to putative cerebellar neurotransmitters. (Supported by NIH Grant NS 13225 and NSF Grant GB 43301 to D.J.W.).

807 IMMUNOHISTOCHEMICAL CHARACTERIZATION OF NORADRENERGIC INNERVATION IN THE RAT NEOCORTEX: A REGIONAL AND LAMINAR ANALYSIS.
Mark E. Molliver, Reinhard Grzanna*, John H. Morrison and Joseph T. Coyle. Depts. Anat., Neurol.,Pharmacol. and Psychiatry, Johns Hopkins Univ. Med. Sch., Baltimore, Md. 21205.

Based on catecholamine histofluorescence, the noradrenergic (NA) innervation of the rat neocortex has been described as sparse, with the highest density of fibres in layer I. An alternative method for the identification of noradrenergic neurons makes use of dopamine-β-hydroxylase (DBH) as a specific antigenic marker. Using an antiserum prepared against rat DBH[1] (which has a 10^4 greater affinity for the rat enzyme than does heterologous antiserum) we have identified an unexpectedly dense NA innervation throughout rat neocortex[2].

The NA fibre distribution in 4 cytoarchitectonic regions of cortex (cingulate, somatosensory, motor and visual) was examined in sagittal and coronal sections prepared from over 100 rats. Cryostat or Vibratome sections were incubated with anti rat DBH and then processed for the immunofluorescence technique or by Sternberger's unlabeled antibody technique (PAP). Photomontages through all of the 4 cortical areas were analyzed.

In each of the 4 cortical regions examined, a dense NA innervation was found with a characteristic pattern in each layer. In layer I of somatosensory cortex numerous long axons run parallel to the pial surface predominantly in a coronal plane. In contrast, layers II and III contain long, radially oriented axons. Layer IV is strikingly different in that it contains numerous short, oblique axon segments. No radial or tangential axons traverse layer IV. Layers V and VI contain a high density of obliquely oriented short as well as long axon segments; in addition, layer VI contains many long tangential axons running in the coronal plane. This general pattern of NA innervation was found in all areas of neocortex with some regional variations in the 4 inspected areas. We have observed many NA axons making contact with cell bodies and proximal dendrites in layers IV to VI (using bright-field and Nomarski optics with PAP stained material); these data reveal a direct NA innervation of cell bodies in deep cortical layers. The demonstration of long, tangential fibres in layers I and VI provide an anatomical substrate by which individual NA axons can influence adjacent cortical columns over long distances in the coronal plane. (Support: USPHS NS-08153, NS-10920, MH-26654, UCP and Deutsche Forschungsgemeinschaft GR 504)

808 A NEW ROLE FOR THE LOCUS COERULEUS.
A.R. Morrison, J.C. Hendricks‡ and R.M. Bowker*, School of Vet. Med., U. of Pa., Phila., Pa.

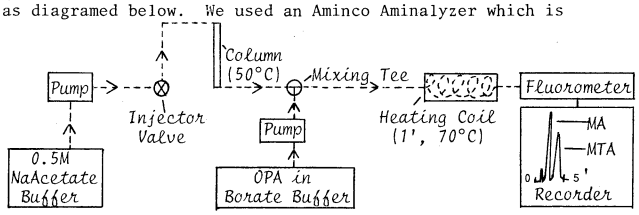
Paradoxical sleep (PS) without atonia is a dramatic phenomenon created by small bilateral lesions in the pons in cats and is characterized as follows: After slow wave sleep, when PS would normally appear, cats raise their heads, make body righting movements, exhibit alternating movements of the limbs, and even attempt to stand. Throughout an episode, which shows all other aspects of PS, cats act as if they are being startled, searching or even attacking an object. During wakefulness they act aggressively. Jouvet maintains that this phenomenon, which supplants normal PS, results from damage of the caudal locus coeruleus (LC); but we have argued that more ventral pontine damage is more critical. Additional results suggest that the complete behavioral syndrome of PS without atonia depends upon interruption of inputs into LC from the pontine tegmentum and relative integrity of LC itself.

We suggest an explanation for PS without atonia drawn from data from the locomotion literature. Decerebrate cats will walk on a treadmill if stimulated electrically in the region of the ponto-mesencephalic isthmus, the "mesencephalic locomotor region". The most effective stimulus sites are adjacent to noradrenergic LC neurons. Activity of this inhibitory noradrenergic system permits movement by releasing an intraspinal neuronal assembly which activates extensor and flexor motor neurons bilaterally in a reciprocal manner. L-DOPA, which releases noradrenalin from spinal terminals, has the same effect.

We propose that pontine lesions interrupt fibers which inhibit LC neurons during PS. They also presumably impair cholinergic mechanisms facilitating atonia. Thus the cats are freed to express elements of locomotor activity. Rather than a combination of electrical stimulation and a treadmill, the stimulus source would be intrinsic, i.e. the neural activity of PS which initially produces"alerting" and "orienting" in these cats prior to "searching" with varying degrees of success at locomotion. Their behavior is more variable than that of the decerebrate locomotor preparation because di- and telencephalic structures can elaborate upon patterns generated in the brainstem; and the cats are free-moving, not on a treadmill. Furthermore, the fact that pontine giant neurons fire during wakefulness if cats are free to move, as well as during PS, suggests that a pontine mechanism designed to act beyond the confines of PS has been revealed. Its role is modulation of movements, especially those generated by novel alerting or startling stimuli of any modality which require immediate control and dampening within the reticular formation lest the animal overreact and run blindly into danger prior to analyzing the stimulus source and significance. Supported by NIH grants RR07083-11,GM02051 andMH15767

809 MEASUREMENT OF THE FALSE TRANSMITTERS, METARAMINOL AND α-METHYL-m-TYRAMINE, IN RAT BRAIN BY HIGH PRESSURE LIQUID CHROMATOGRAPHY: AN INDEX OF NOREPINEPHRINE AND DOPAMINE TURNOVER.
K. W. Perry* and R. W. Fuller. The Lilly Res. Labs., Indianapolis, IN 46206.

The "false transmitters" metaraminol (MA) and α-methyl-m-tyramine (MTA) are formed after injection of α-methyl-m-tyrosine (100 mg/kg i.p.) and are stored in norepinephrine and dopamine neurons, respectively [Dorris and Shore, J. Pharmacol. exp. Ther. 179, 10 (1971)]. The rate of decline of these false transmitters can then be used as an index of norepinephrine or dopamine turnover. We have developed a high pressure liquid chromatography (HPLC) assay for MA and MTA that greatly facilitates their measurement in rat brain. The rat brain (or brain region) is homogenized in 0.4 M $HClO_4$; after centrifugation the supernatant is adjusted to pH 9 with 5 N NaOH. MA and MTA are extracted into ethyl acetate and after evaporation of the ethyl acetate are dissolved in 0.2 ml 0.01 N HCl for injection onto a pellicular cation exchange column (Vydac, 2 mm x 50 cm). The column effluent flows (0.5 ml/min) to a mixing tee where it is mixed with o-phthalaldehyde (OPA, 800 mg/l) in 0.5 M sodium borate buffer pH 10 (flow rate = 0.25 ml/min) then to a heating coil and subsequently to the fluorometer (360 nm excitation, 480 nm emission), as diagramed below. We used an Aminco Aminalyzer which is



specifically designed for HPLC with fluorescence analysis after OPA reaction, however a less expensive instrument could be assembled by the user. Under these conditions the OPA reaction is specific for MA and MTA [Shore and Alpers, Life Sci. 5, 551 (1964)], which are completely resolved by the column, and the maximum sensitivity is about 1 ng for both compounds. We investigated the utility of MA and MTA as an index of turnover by measuring the decline in MA after injection of prazosin, a norepinephrine α receptor antagonist, and the decline in MTA after lergotrile, a dopamine receptor agonist. Prazosin increased the decline in MA, which is consistent with the increased turnover in norepinephrine that a receptor antagonist is expected to produce. Lergotrile decreased the decline in MTA as expected of a dopamine agonist, but it also increased the decline in MA indicating that lergotrile may also be an α receptor antagonist.

810 EFFECTS OF 5-HT DEPLETION ON RAT HOLE-BOARD EXPLORATION: DEPENDENCY UPON METHOD.
Lyle R. Petersen*, Gary J. Rose* and Mark A. Geyer. Dept. Psychiatry, Sch. Med., UCSD, La Jolla, CA 92093

In this series of experiments we studied the influence of the serotonergic system on exploratory nose-poking behavior measured in a hole board. The hole board consisted of a rectangular wooden box (11 x 26 in) with its walls extending below the level of the floor. A nose-poke was scored when a rat dipped its head into one of three holes spaced equally on the midline of the floor. For the duration of each nose-poke a dim light was lit to provide a visual feedback stimulus to the rat. Both the response frequency and mean duration per response (MDPR) were cumulated during each 8 min of a 24-min test period.

Selective electrolytic lesions were made either to the dorsal or median raphe nuclei, which are the origins of the mesostriatal and mesolimbic serotonergic pathways respectively. Median raphe-lesioned rats exhibited a significantly higher response frequency ($p < 0.001$) and MDPR ($p < 0.001$) than sham-lesioned controls. Dorsal raphe lesions produced no significant effect on hole-board behavior.

In another group of animals chemical lesions were made by direct infusion of 5,7-dihydroxytryptamine (5,7-DHT) into the median raphe nucleus (0.25 µl; 10 µg/µl), the hippocampus (bilaterally, each side 5.0 µl; 5 µg/µl), or the lateral ventricle (10 µl; 10 µg/µl). 5,7-DHT is a cytotoxin having preferential effects on serotonergic neurons. To preclude damage to noradrenergic neurons, all animals were pretreated with the catecholamine-uptake inhibitor, desmethylimipramine. 5,7-DHT failed to produce a significant increase in either response frequency or MDPR. These results suggest that the increase in response frequency and MDPR with electrolytic lesions may be due to non-specific damage of fibers passing near the median raphe nucleus. To further examine the relevance of brain serotonin depletion to the effects of median raphe lesions on hole-board behavior, p-chlorophenylalanine (PCPA), a specific inhibitor of serotonin biosynthesis, was administered, 300 mg/kg i.p. 24 and 48 hrs before testing in the hole board. No significant effect on response frequency was observed.

811 IMMUNOCYTOCHEMICAL LOCALIZATION OF SUBSTANCE P CONTAINING AXON TERMINALS IN RELATION TO CATECHOLAMINE CONTAINING NEURONS IN RAT BRAIN. V.M. Pickel, T.H. Joh, D.J. Reis, and S.E. Leeman. Lab. of Neurobiol., Dept. of Neurol., Cornell University Medical College, New York, NY 10021, and Dept. of Physiol., Harvard Medical School, Boston, MA 02115.

The polypeptide, substance P is present in relatively high concentrations in areas containing dopamine neurons (Brownstein et. al., Brain Res 116.299, 1976). We sought to examine the interaction between substance P and catecholamine neurons, both dopaminergic and noradrenergic, by the light and electron microscopic immunocytochemical localization of antisera to substance P and to tyrosine hydroxylase (TH), the enzyme which catalyzes the first step in catecholamine biosynthesis. Adjacent sections of rat brainstem were incubated with either TH antiserum, substance P antiserum, or normal rabbit serum. These sections were then labeled by the peroxidase-antiperoxidase (PAP) technique and processed for light and electron microscopy. By light microscopy, sections incubated with TH antiserum contained labeled neuronal perikarya in nuclear groups containing catecholaminergic neurons (A1-A14) as classified by Dahlstrom and Fuxe (Acta Physiol Scand 62: Suppl, 232, 1964). Adjacent sections incubated with antiserum to substance P contained a dense plexus of labeled axonal varicosities in the areas labeled for TH perikarya. Control sections were devoid of labeled perikarya or processes. By electron microscopy, the specific labeling for TH and substance P was examined only in the A1 and A6 (locus coeruleus) nuclear groups. TH was localized to the cytoplasm of catecholaminergic neurons, particularly in association with the endoplasmic reticulum and microtubules. Substance P was present in axons and in axon terminals. The labeling for substance P was localized in the axon terminals primarily in association with large (80-100 nm) dense cored vesicles, however moderate reaction product was also associated with small clear vesicles. These labeled terminals were in close apposition to dendrites of the catecholamine containing neurons. These findings suggest that the activity of central noradrenergic and dopaminergic neurons may be regulated by neuronal systems which contain substance P.

812 MICROSPECTROFLUOROMETRIC DETERMINATION OF DOPAMINE IN MIDBRAIN CELL AGGREGATES. George M. Powell*, Robert J. Dinerstein* and Beatrice Garber. Dept. Pharm. and Physiol. Sci. and Dept. Biol., Univ. of Chicago, Chicago, Ill. 60637

It has been shown previously (Levitt, Moore and Garber, 1976) that fluorescent cells derived from 14-18 day embryonic mouse mid-brain containing the substantia nigra can be recovered in reaggregated tissues after complete dissociation into single cell suspensions and rotary culture in vitro. Using the Falck-Hillarp histofluorescence method it was found that after 4 or more days in culture the fluorescent cells had selectively associated and extended varicosities into the surrounding tissue. The assay of Coyle and Henry (1973) employing enzymatic conversion of catecholamines to radiolabeled O-methylated derivatives showed that dopamine is the principle catecholamine in these aggregates. Since this biochemical demonstration was indirect evidence for identifying these fluorescent cells as dopaminergic neurons, we have examined these cells by microspectrofluorometry. We have now shown unequivocally by direct measurements that the selectively associated fluorescent cells in these aggregates contain dopamine. The anterior mesencephalic ventral tegmentum was dissected according to a consistent procedure so that dopamine cell groups A9 and A10 (Dahlstrom and Fuxe, 1965) were obtained and other monoamine groups were excluded. The mesencephalon was dissected out from a point just caudal to the pineal primordium to a point in the middle of the presumptive inferior colliculus, then the caudal tegmentum, the tectum, and adhering diencephalon (when present) were removed. Cell aggregates cultured for 5-12 days were harvested after treatment with pargyline HCl (0.375 mg/ml) for 12 hours, and processed by standard Falck-Hillarp techniques using paraformaldehyde equilibrated at 50% RH. Spectra confirmed that the fluorescent cells contained catecholamine with a 410 nm excitation maximum and a 480 nm emission maximum. To distinguish dopamine from norepinephrine the method of Bjorklund, Ehringer and Falck (1972) was used. Sections were partially deparaffinized with xylene and were repeatedly exposed to HCl-vapor over a 15 minute period. Control embryonic tissue in situ showed that with increasing times of exposure to HCl-vapor, norepinephrine in the choroid plexus showed a progressive decline in the 370 nm/320 nm peak intensity ratios of the excitation spectrum. Under the same conditions, dopamine in the substantia nigra of the same embryonic tissue showed no change in excitation spectrum. The catecholamine containing cells of the experimental aggregates showed no 370 nm/320 nm ratio changes under the same conditions, thus confirming the dopaminergic identity of selectively associated histofluorescent cell groups as substantia nigra and ventral tegmental dopaminergic neurons.(PHS NS12324,MH14274,NS10714)

813 COMPARISON OF THE ANTI-APOMORPHINE ACTIVITY OF LENPERONE AND HALOPERIDOL IN RABBITS AND RATS. R. M. Quock and R. A. Louie*. Dept. Physiol-Pharmacol., School of Pharmacy, Univ. of the Pacific, Stockton CA 95211.

Lenperone [4'-fluoro-4-(4-fluorobenzoyl)piperidinyl butyrophenone hydrochloride] is a new antipsychotic compound structurally related to haloperidol and found to be effective in acute schizophrenia (Harris, J. Clin. Pharmacol. 15, 187, 1975). An advantage of this drug over haloperidol is its relatively low incidence of extrapyramidal syndrome (EPS). Since EPS is thought to originate from an action of the drug upon the corpus striatum (Anden, J. Pharm. Pharmacol. 24, 905, 1972), we examined and compared the interactions of lenperone and haloperidol with the dopaminergic agonist apomorphine in rabbits and rats.

In male New Zealand rabbits, haloperidol (0.5 mg/kg iv) abolished the hyperthermic, locomotor stimulatory and stereotypic gnawing responses to apomorphine (5.0 mg/kg iv). At 0.5 mg/kg and even higher doses, lenperone antagonized only the temperature and locomotor responses to apomorphine. In male Wistar rats, haloperidol (0.3 mg/kg ip) blocked the hypothermic, locomotor stimulatory and stereotypic gnawing responses to apomorphine (2.0 mg/kg ip). At the same dose, lenperone antagonized the temperature and locomotor effects; the intensity of stereotypic gnawing was unaltered but the duration of the gnawing response was shortened.

In conclusion, our data indicate that lenperone differs from haloperidol in its spectrum of anti-apomorphine activity in both rabbits and rats. While haloperidol nonselectively antagonized all three apomorphine responses, lenperone selectively blocked the temperature and locomotor responses and spared the gnawing response. Since stereotypic gnawing is thought to originate in the corpus striatum (Ernst and Smelik, Experientia 22, 837, 1966), our data suggest that lenperone possesses greater selectivity of action than does haloperidol. 814 MODULATION OF THE UNITARY ACTIVITY OF CORTICAL NEURONS BY THE BIOGENIC AMINES: A MICROIONTOPHORETIC STUDY. Tomas A. Reader, André Ferron* and Laurent Descarries. Centre de recherche en sciences neurologiques, Université de Montréal, Montréal, Québec, Canada.

In order to investigate the mode of action of biogenic amines in relation to cortical activity, the effects of microiontophoretic applications of dopamine (DA), noradrenaline (NA) and 5-hydroxytryptamine (5-HT) on single cell responses were examined in the fronto-parietal neocortex of adult rats. Unitary activity was assessed by recording the pattern and frequency of discharges before, during and after administration of these compounds (ejection currents: 50-100 nAmp; duration of ejections: 15-30 s). DA, NA and 5-HT were found to inhibit the spontaneous or glutamate-induced firing of a majority of the tested neurons. In the case of spontaneously active units, this inhibition was usually of prolonged duration (4-6 min). It was less abrupt in onset and of lesser magnitude with DA than NA or 5-HT. In glutamate activated cells (40 nAmp, during 8 s at every 20 s), the inhibition intervened more rapidly, persisted throughout the duration of monoamine ejection and ceased sooner thereafter. The interaction between DA, NA, 5-HT and acetylcholine (ACh) was studied on cholinoceptive units showing or not spontaneous activity. In both instances, DA and NA slightly reduced the excitatory response to ACh (45 nAmp during 5 or 10 s at every 90 s), in terms of speed of onset, magnitude, and especially of duration. It was further observed that the inhibition of the ACh response by DA or NA was less prolonged than that produced by these compounds on the spontaneous activity of the same cells. Conversely, the temporal course of DA or NA induced inhibition was shortened when ACh was applied. Under the influence of 5-HT, the excitatory responses to ACh were completely blocked. The return to initial levels of activity was slow and progressive, and the total duration of the inhibitory effect was not shorter than the inhibition induced by 5-HT on the spontaneous activity of the same cells. Moreover, the inhibition by 5-HT of spontaneous cell firing was not modified by ACh. These results are compatible with a modulatory role for biogenic amines in the cerebral cortex and demonstrate an interaction between these compounds and acetylcholine.

815 ANXIETY: THE LOCUS COERULEUS CONNECTION. D.E. Redmond, Jr., Y.H. Huang, and M.S. Gold. Dept. Psychiatry, Yale Univ., New Haven, Ct. 06510

Specific behaviors elicited (1) by "dangerous" situations, (2) by a drug which activates the locus coeruleus (piperoxane), or (3) by weak electrical stimulation of the locus coeruleus (LC) or dorsal noradrenergic bundle (DB) are blocked by agents with demonstrated anti-anxiety effects in humans: (1) diazepam and (2) propranolol. Both of these agents, and other known anti-anxiety agents to be discussed, can be linked to effects on the locus coeruleus and empirically block the behavioral effects of electrical stimulation of the locus coeruleus. Propranolol blocks post-synaptic ß-adrenergic projections from the locus coeruleus (Hoffer et al, BR. RES. 25:523, 1971; Segal and Bloom, BR. RES. 72: 99, 1974). Diazepam presumably blocks locus coeruleus activity by way of the inhibitory γ-amino-butyric acid (GABA) system (Keller et al, NAUN.-SCHM.ARCH.PHARM. 294: 1, 1976; Dray and Straghan, J.PHARM.PHARMAC. 28: 314, 1976) and the GABA receptors on the cell bodies of the LC (Iversen and Schon, NEW CONCEPTS IN TRANSMITTER REGULATION, Plenum, p. 153, 1973) which inhibit its firing (Cedarbaum and Aghajanian, BR. RES. 112: 413, 1976). Piperoxane which increases the same behaviors associated with threats or following electrical stimulation of the LC has been reported to cause anxiety in humans (Goldenberg et al, JAMA 135: 971, 1947; Soffer, MED. CLIN.N.AMER. 38: 375, 1954. Electrical stimulation in the region of the LC in humans has been reported to produce feelings of fear and death (Nashold et al, ADV. NEUROL. 4: 191, 1974). These data support our previous suggestion (Redmond et al, BR. RES. 116: 502, 1976) that the nucleus locus coeruleus may be a brain "alarm" system that is related to the human emotions of fear or anxiety. Further anatomical and neurophysiologic evidence for an essential role for the locus coeruleus in such an "alarm" system will be presented and some objections to this interpretation of the data will be discussed.

816 INDUCTION AND DELAYED ACTIVATION OF TYROSINE HYDROXYLASE IN NORADRENERGIC NEURONS OF A1 AND A2 GROUPS IN MEDULLA OBLONGATA OF RAT. B. Renaud*, T.H. Joh, D.W. Snyder, and D.J. Reis. Lab. of Neurobiol., Dept. of Neurol., Cornell University Medical College, New York, NY 10021.

In the medulla oblongata, two groups of noradrenergic neurons are of importance in regulating the arterial pressure. the A1 group in the area of the lateralis reticularis nucleus which innervates the intermediolateral columns, the locus of preganglionic vasomotor neurons, and the A2 group, in the area of the nucleus commissuralis which innervates the nucleus tractus solitarii (NTS), a site of termination of baroreceptor afferents. We have previously demonstrated that in the pontine noradrenergic nucleus locus coeruleus (LC), prolonged elevation in the activity of the catecholamine synthesizing enzyme tyrosine hydroxylase (TH) can be produced by two distinct mechanisms: the first, induction, elicited by reserpine, is due to production of more enzyme protein (J Pharmacol Exp Ther 193:775, 1975). The second, delayed activation, elicited by the cholinergic agonist oxotremorine, results from an increase in catalytic activity without change in enzyme protein (J Pharmacol Exp Ther 200:523, 1977). In this study we sought to establish if TH in the A1 and A2 neurons of rat brain share common biochemical properties with those of the LC. Rats were treated with reserpine (10 mg/kg s.c.), oxotremorine (1.5 mg/kg s.c.), or vehicle and killed at various days thereafter. The A1, A2, NTS, and LC were removed by microdissection. A single injection of reserpine increased TH activity in A1, A2, and LC by 50, 30, and 300% respectively (P<.01). The onset was seen at 24 h, reached maximal levels at 3 d, and disappeared by 21 d. In NTS a significant (P<.01) 30% increase of TH occurred but was delayed by 24 h after that of A2, suggesting slow transport of enzyme or activator from cell bodies into terminals in NTS. By immunotitration with an antibody to TH the increase of TH in A1 was demonstrated as a consequence of more enzyme protein and hence represented induction. Oxotremorine increased TH activity in A1, A2, and LC comparably in magnitude and time course to reserpine. However immunotitration demonstrated the increase was due to activation. We conclude that the noradrenergic neurons in the medulla of the A1 and A2 groups share comparable biochemical properties with respect to regulation of TH as do those of the LC. Such control may be of importance in the control of blood pressure.

817 PROLONGED DEPLETION OF BRAIN NOREPINEPHRINE AFTER HYPOTHERMIC STRESS: RATE OF REPLETION VARIES WITH AGE AND BRAIN REGION. Sue Ritter* and Nancy L. Pelzer* (SPON: R. C. Ritter). Coll. Vet. Med., Wash. State Univ., Pullman, WA 99164.

Regional brain catecholamine concentrations were measured at 8 time intervals after hypothermic stress in 3 month and 7 month old male Sprague-Dawley rats. Hypothermic stress was produced by restraining rats in wire mesh cones and partially immersing them in 18°C water for 6 hrs. in order to lower body temperature. In 7 month old rats telencephalic norepinephrine (NE) concentrations were reduced to 50% of control and hypothalamic NE concentrations were reduced to 64% of control immediately after removal from the cold. Telencephalic dopamine (DA) was elevated by 25% at this time. Rate of recovery of NE to control values was more rapid in the telencephalon than in the hypothalamus. Telencephalic levels of NE were 88% of control by 6 hrs. and had returned to 100% of control by 24 hrs. Hypothalamic NE was only 67% of normal by 24 hrs. after stress and even at 48 hrs. post stress was only 88% of control. In the 3 month old rats NE levels returned to control values more rapidly than in the 7 month old rats. Both telencephalic and hypothalamic NE levels were normal by 15 hrs. post stress. However, the rate of repletion was still consistently slower in the hypothalamus than in the telencephalon.

The prolonged depletion of NE in the 7 month old rats after this severe stress suggests that brain NE synthesis may be suppressed during the post stress period. In order to begin testing this possibility deamination of brain catecholamines was blocked by administration of pargyline (100 mg/kg) immediately after removal from the cold. Pargyline treated animals displayed hypothalamic DA concentrations that were 221% of control and cortical DA concentrations that were 166% of control by 2 hrs. after pargyline injection. However, pargyline did not cause any elevation of hypothalamic or cortical NE above the levels of nonpargyline treated stressed rats. Failure of pargyline to elevate brain NE levels after stress suggests that although DA synthesis continues during the post stress period NE synthesis during that time is impaired.

In summary, three conclusions may be drawn from these experiments: (1) the rate of NE repletion after stress induced depletion appears to be inversely related to age or to an age related variable; (2) repletion of hypothalamic NE occurs more slowly than repletion of telencephalic NE; and (3) the prolonged time course of NE depletion after severe hypothermic stress appears to be due to impaired synthesis of NE from precursor DA. Ongoing work is investigating the involvement of dopamine-beta-hydroxylase in the specific suppression of NE synthesis after stress exposure.

818 CHANGES IN POSTERIOR HYPOTHALAMIC SELF-STIMULATION FOLLOWING EXPERIMENTAL CEREBRAL INFARCTION IN RATS. Robert G. Robinson and Floyd E. Bloom. Dept. of Psychiat., Johns Hopkins Sch. Med, Baltimore, M.D. 21205 and Salk Institute, San Diego, CA 92112.

Recent studies have demonstrated that cerebral infarction leads to anatomical and biochemical changes in catecholamine neurons in areas of the brain which are uninjured by local ischemia. In an effort to evaluate the behavioral significance of these post-stroke changes in catecholamines, intracranial self-stimulation (ICSS) became a phenomenon of particular interest because it is readily quantifiable and catecholamine neurons are thought to mediate the behavior. Bipolar stimulating electrodes were placed bilaterially in the posterior hypothalamus of rats. After the animals were shaped to self-stimulate at both electrode sites, the right middle cerebral artery was ligated. During the 25 day postoperative period, the rate of ICSS at specified current values was compared with preoperative values. At 2 days after operation, there was a 33% decrease in the maximum frequency of ipsilateral ICSS. However, by 8 days after experimental stroke, there was a 16% increase in the maximal rate of ICSS above the preoperative level. The maximal rate of ICSS then returned to the preoperative level by 20 days after surgery. The minimum current necessary to elicit the maximal rate of response also changed in a biphasic manner, that is, the minimum required current was greater than pre operative control levels until 8 days after operation but then dropped below control level until 20 days postoperative. In other words, until 8 days postoperative, the ipsilateral electrode was less rewarding than it was preoperatively, even though the animal was receiving more current, while from 8 to 20 days after cerebral infarction the same electrode was more rewarding than preoperatively even though the animal was receiving less current. There were no changes in the current or rate of response in the contralateral electrode. This change in the rewarding character of the ICSS was also reflected in electrode preference when the animals were allowed to stimulate each electrode ad libitum. Preoperatively they stimulated both sides with equal frequency and in an alternating manner, that is, stimulating each side 10-20 times before switching over to the other lever. The ratio of right to left lever presses was 1.0 ± 0.03 SEM preoperatively. This ratio fell to 0.5 by 2 days postoperative and then rose to 1.4 by 8 days postoperative. These results demonstrate that stroke leads to important behavioral changes and suggest that these behavioral changes may be the result of neurophysiological changes in post-stroke catecholamine neurons.

819 SYNAPTIC SPECIFICITY DURING THE DEVELOPMENT OF THE AVIAN SYMPATHETIC PREGANGLIONIC NUCLEUS. Leonard L. Ross., Arnold J. Smolen and Leo Cosio*. Dept. Anat., Med. Coll. Penna., Phila., Pa.19129

Removal of a portion of the afferent input of a population of neurons results in a compensatory synaptogenesis of the remaining input. This has been established for a number of systems both central and peripheral, in the adult and during the course of development. To analyze the principles governing deprivation-induced CNS synaptogenesis during development, the embryonic chick spinal sympathetic nucleus, the nucleus of Terni (NT), together with its bulbospinal monoaminergic innervation was chosen as an experimental system.

We have previously shown that the first synapses are evident in the N.T. at 10 days in ovo (d.i.o.). Synaptogenesis proceeds rapidly and the adult synaptic pattern is established by 10 d.i.o. The developmental sequence of monoaminergic uptake in the cord parallels that of synapse formation. Further, the monoaminergic input to the N.T. is exclusively bulbar in origin, there being no spinal aminergic neurons. Thus, cervical spinal cord transection before 10 d.i.o. will (1) prevent the N.T. neurons from receiving a portion of its input at a presynaptogenic stage and (2) test the ability of a non-aminergic input to replace an aminergic input.

In the present study cervical spinal cords were transected at 8 d.i.o. At 20 d.i.o. the embryos were perfused and their mid-thoracic spinal cords studied by ultrastructural quantitative stereology. In control animals at 20 d.i.o. 30% of the neuronal surface synapse coverage is by axodendritic synapses containing dense-cored vesicles which have been shown to be monoaminergic. In the transected animals, total synaptic coverage of the N.T. neurons was reduced by 40%. Most of the loss (70%) was in coverage by those axodendritic synapses containing dense-cored vesicles. There was no reduction in the number of neurons or in the total neuronal surface area (i.e., neuron size). Nor was there any increase in the coverage by synapses containing clear vesicles (non-monoaminergic).

Therefore, (1) a 40% reduction in the input (mainly monoaminergic) to the presynaptogenic N.T. neurons does not appear to affect their structural development. However, a functional defect in rat postsynaptogenic preganglionic neurons has been shown following spinal transection (Hamill, Bloom and Black, '76). And (2) propriospinal, non-monoaminergic axons are not induced to expand their synapse formation as a result of deprivation of the bulbospinal monoaminergic input.

(Supported by NIH grants NS-11364 and NS-05392).

820 CELL DIVISION IN THE DEVELOPMENT OF ADRENERGIC NEURONS. Rothman,T.P., Gershon,M.D., and Holtzer,H.* Departments of Anatomy, University of Pennsylvania School of Medicine, Philadelphia, PA 19174, and College of Physicians & Surgeons of Columbia University, New York, NY 10032.

Mature neurons are non-dividing cells. However, the temporal relationship between the acquisition of a given neuron's definitive characteristics and loss of the cell's ability to divide during development has not been worked out in many systems. The present study was undertaken to analyze this relationship in developing chick sympathetic ganglion cells. Definitive characteristics of these cells include their catecholamine (CA) content and membrane uptake mechanism for CA. CA can be detected by formaldehyde-induced fluorescence (FIF) in primary ganglion cells of the developing chick by 3 1/2 day's of gestation. After incubation with ^{3}H-norepinephrine (^{3}H-NE) all of these cells identified and examined by radioautography were labeled. Uptake of ^{3}H-NE is inhibited by desmethylimipramine. As the primary ganglion cells migrate to form paravertebral and prevertebral sympathetic ganglia and the adrenal medulla they continue to contain CA. Chick embryos between 1.5 and 15 day's gestation were injected with ^{3}H-thymidine (10-50μc) and, after varying survival times, processed for simultaneous demonstration of CA by FIF and ^{3}H-DNA by radioautography. Tissues were embedded in Epon and cut at 2μm so that overlapping cells would not be present in the sections. In some experiments ^{3}H-thymidine was given continuously for varying periods to determine when CA-containing cells withdraw from the cell cycle. In other experiments embryos were processed 2-4 hours after ^{3}H-thymidine-injection so that labeled cells would be fixed while still in S or G2 to determine if cells which already contain CA are able to divide. The first CA cells to leave the cell cycle did so between days 2 and 3. The last CA cells left the cycle between days 13 and 15. Some neurons which already contained CA replicated their DNA. This conclusion was supported by the electron microscopic observation that neurons (neuroblasts) containing perikaryal dense cored vesicles typical of CA-containing cells were labeled by ^{3}H-thymidine and were found in mitosis. Therefore, the correlation between acquisition of transmitter content and uptake mechanisms and withdrawal from the cell cycle is not exact. Either proliferative divisions follow acquisition of these definitive characteristics or these characteristics may be present in cells which still belong to an immature precursor population.

821 PERIPHERAL AND CENTRAL CATECHOLAMINES IN SPONTANEOUS HYPERTENSION. Juan M. Saavedra, Horst Grobecker*, Virginia Weise* and Julius Axelrod. NIH, Bethesda, Md. 20014

The activity of the catecholamine synthesizing enzymes has been studied in specific areas of the brain and in the adrenal glands during the development of the spontaneous hypertension in the rat.

The activity of the epinephrine-forming enzyme, phenylethanolamine-N-methyltransferase (PNMT) was increased in the A1 and A2 areas of the brain stem in young (4 week-old) but not in adult (14 week-old) SH rats.

Decreased norepinephrine (NE) levels were found in a few specific nuclei of the anterior-hypothalamic-preoptic area and in the posterior hypothalamus. The decreased activity of dopamine-β-hydroxylase (DBH) in the same areas indicated that the synthesis of the neurotransmitter is decreased in these regions and a possible absence of noradrenergic neurons. The decrease in the formation of NE in specific brain areas can result in a reduced activation of central alpha receptors in the hypothalamus which may be related to the onset of hypertension. This phenomena could also explain the central mechanism of action of alpha stimulant antihypertensive drugs like clonidine and alpha-methyl-dopa. The activities of catecholamine biosynthetic enzymes (tyrosine hydroxylase, dopamine-β-hydroxylase and phenylethanol-N-methyltransferase) in the adrenal medulla were inhibited early in the development of the SH rats. Adult animals, however, showed enhanced tyrosine hydroxylase activity. This indicates a possible relationship between central and peripheral catecholamine metabolism in the development of hypertension.

822 SELF-STIMULATION AT LOW PULSING RATES IN RATS: SUPPORT FOR CATECHOLAMINE VIEW. E. Schmidt* (SPON: I. Perline) Arizona State Univ., Psych. Dept., Tempe, AZ 85281.

Acquisition of self-stimulation at MFB sites was tested with very short bursts of 60 Hz sine waves (40 msec, 2.5 cycles) delivered at a rate of two short bursts per second. A series of five bursts was delivered for each lever press in an automated shaping procedure. Only two of fourteen rats which proved to be self-stimulators reached a rate of 400 responses/hr by the third daily session. However, most rats began responding over the next nine sessions when (1) the current was increased from 100 to 120 μA, (2) the pulsing rate was increased from 2 to 5 bursts/sec, or (3) the length of each burst was increased from 40 to 180 msec. When retested at the original parameters, seven of the fourteen rats averaged 400 responses/hr over three sessions. Next well trained rats turned a small runged wheel at various turning force requirements (40, 150 & 180 g) to receive 60 Hz, 100 μA stimulation trains on an intermittent schedule. Work output was nearly identical at different turning forces, providing an effort based measure of reward. Work output increased as a function of the duration of each stimulation train (0.3, 0.9 & 2.7 sec). When these trains were broken into a series of short bursts, work output for several rats dropped only slightly to moderately over daily 15 min sessions.

The findings support the view of brain stimulation reward as resulting from catecholamine (CA) release, showing that the reward effect can be obtained at pulsing rates near or below the normal 5-10 spikes/sec firing rates of the CA systems in the brain. Clearly, higher stimulation frequencies or longer duration can potentiate the CA release effect. However, the marginal acquisition and maintenance of self-stimulation at 2 bursts/sec implies that the post-synaptic effect may endure as long as 500 msec. Models of CA inhibition of post-synaptic neurons through the mobilization of an amine-specific adenylate cyclase - cyclic AMP mechanism are supported by these behavioral findings.

823 APOMORPHINE REVERSES THE IPSILATERAL DEPRESSION OF CAUDATOPUTAMEN GLUCOSE CONSUMPTION OBSERVED AFTER UNILATERAL ELECTROLYTIC LESIONS OF THE RAT LATERAL HYPOTHALAMUS. William J. Schwartz. Lab. Neurophysiol., NIMH, Bethesda, Maryland 20014

Experiments using the [^{14}C] 2-deoxy-D-glucose (2-DG) technique for measuring regional brain glucose consumption (*Science* 187: 850) have shown that unilateral electrolytic lesions of the rat lateral hypothalamus (LH) result in decreased forebrain glucose consumption in structures ipsilateral and rostral to the lesion (*Nature* 261: 155). Regions affected are wide-ranging and include, among others, ipsilateral neocortex, caudatoputamen (CP), globus pallidus, and thalamus. This right-left metabolic asymmetry is present at three days and persists for at least fourteen days after the lesion. Moreover, the asymmetry of glucose consumption can be partially reproduced in some of these forebrain structures, *most significantly in CP*, by 6-hydroxydopamine (6-OHDA) injections (4 µg/2 µl) into the substantia nigra (SN).

These data suggest that after unilateral electrolytic LH lesions the resulting right-left asymmetry of at least one structure, the CP, might be due in part to destruction of the ascending dopaminergic nigro-striatal pathway at the level of the LH. As one test of this hypothesis, apomorphine, a dopamine receptor agonist, was administered to LH-lesioned animals to determine whether pharmacological stimulation of denervated striatal dopaminergic receptors could correct the CP metabolic deficit.

Sprague-Dawley albino rats underwent unilateral electrolytic lesions of LH; 14 d. later they were given apomorphine HCl (1 mg/kg) intravenously, followed by an intravenous pulse of 2-DG for the determination of the pattern of regional brain glucose consumption. In these apomorphine-treated lesioned rats, glucose consumption remained ipsilaterally depressed in neocortex, globus pallidus, and thalamus, but the right-left asymmetry of CP glucose consumption had disappeared (and had even reversed in anterior CP). Interestingly, when apomorphine was given to rats 3 d. after LH lesion, there was no effect on the metabolic asymmetry of any of the forebrain structures, including that of the CP.

Therefore, the observed asymmetry of glucose consumption in rat CP after unilateral electrolytic LH lesions can be (1) partially reproduced by 6-OHDA injections in SN, and (2) alleviated by intravenous apomorphine. The observation that a 1 mg/kg dose of apomorphine restores CP glucose consumption 14 d. after LH lesion but is ineffective 3 d. after lesion may possibly be explained by a leftward shift in apomorphine's dose-response curve as a result of the gradual onset of "denervation supersensitivity" of the post-synaptic dopaminergic CP receptors.

824 IN VIVO UPTAKE AND RETROGRADE TRANSPORT OF ANTIBODY TO DOPAMINE-ß-HYDROXYLASE BY CENTRAL NERVOUS SYSTEM NORADRENERGIC NEURONS. Michael A. Silver* and David M. Jacobowitz. Lab. Clin. Sci., NIMH, Bethesda, MD 20014.

Previous reports from this laboratory (Brain Res. 91: 165, 1975; Brain Res. 104: 390, 1976) demonstrated that an intravenous administration of specific antisera to dopamine-ß-hydroxylase (ADßH) resulted in the uptake of this immunoglobulin by sympathetic nerve fibers; intraocular injections suggested that a retrograde flow of dopamine-ß-hydroxylase (DßH) was taking place. The purpose of this study was to determine whether a similar, specific transport system could be detected in DßH-containing noradrenergic neurons of the rat CNS. ADßH or pre-immune serum were stereotaxically injected into either the lateral ventricle (LV, 20 µl) or the medial forebrain bundle - dorsal bundle (MFB-DB, A5150, 2 µl). Animals were sacrificed at 3 hrs to 14 days post injection. Cryostat sections were fixed in chloroform:methanol (2:1) and stained with fluoroscein conjugated IgG. An intense bilateral granular fluorescence was observed 1 day after LV administration of ADßH within processes and cell bodies of the locus coeruleus. This technique also permitted the identification of the ascending dorsal noradrenergic bundle arising from the locus coeruleus in agreement with previous reports. At 3- and 6-hrs, the first detectable fluorescence was observed in fibers of the dorsal bundle. Some cell bodies appeared to fluoresce 10-hrs post-injection. An intense fluorescence in the locus coeruleus was maintained for 4 days but was absent by day 8. Bilateral transection of the dorsal bundle in the rostral mesencephalon at the time of injection effectively blocked the retrograde transport of fluorescent material to the locus coeruleus. Unilateral injection of ADßH into the MFB-DB resulted in bilateral labelling of both the dorsal and ventral noradrenergic bundles, as well as the A_1, A_2, A_4, A_5, locus coeruleus and subcoeruleus cell groups. Control pre-immune serum injections did not result in the fluorescence labelling of any cell groups or fibers. The specificity of this technique is supported both by results in agreement with previous catecholamine histofluorescence and immunocytochemical studies and by a lack of fluorescence in other cell body regions. The significance of a retrograde flow of DßH is unknown. In conclusion, this technique combines retrograde transport of a marker protein, with the sensitivity and specificity of immunocytochemical procedures to provide a new tool for the neuroanatomical study of neurotransmitter systems.

825 MEDIAL FOREBRAIN RESPONSE TO BRAIN STIMULATION REWARD IN RATS. Harry M. Sinnamon, Laboratory of Neuropsychology, Wesleyan University, Middletown, Ct. 06457.

Similar to barpressing rates, the response pattern of most single units in the medial forebrain (<2.5mm from midline) to activation of intracranial self-stimularion (ICSS) sites depends on the pulse frequency of stimulation. A frequency of 100 Hz is far more effective than either 50 or 25 Hz. For recording, rats with chronic stimulation electrodes in verified ICSS sites in the lateral hypothalamus and ventral tegmental area were anesthetized and maintained with minimal levels (0.5%) of halothane for acute recording. Single trains of 50 pulses at 100 Hz (15 sec between trains) changed the activity pattern of the vast majority of 200 units in the anteromedial cortex, anterodorsal cortex, striatum, septum, accumbens and rostral MFB. Most areas had units that responded during the train with either excitation or inhibition. Biphasic patterns (inhibition-facilitation and facilitation-inhibition), and increases in activity lasting several sec after a train were responses especially common in the cortex and striatum. The striatum was also particularly rich in units responding to single pulses with short latency (<20msec) excitation. Biphasic responses and longlasting increases in activity follow time courses similar to the "drive-like" aftereffects that are prominent in ICSS reward.

826 A NEW GROUP OF CATECHOLAMINE-CONTAINING CELLS (A-15?) IN THE RAT DIENCEPHALON. John R. Sladek, Jr. and Thomas H. McNeill. University of Rochester School of Medicine, Rochester, New York 14642.

Catecholamine-containing neurons (A-1 through A-14) have been localized to the mammalian brain stem and hypothalamus. The hypothalamic groups occupy arcuate, periventricular, and other regions. Non-mammalian vertebrates possess an additional group of catecholamine-containing cells located subependymally within the diencephalon. Such cells have not been reported, however, in mammals. The present investigation represents the search for catecholamine-containing subependymal cells within a member of the mammalian order Rodentia.

Formaldehyde- and glyoxylic acid-induced histofluorescence was examined in the avian (duck, pheasant) and mammalian (rat) brain. Catecholamine- and serotonin-containing cells are known to exist subependymally in the avian brain, principally within the paraventricular organ. A dual population of intense blue and yellow cells was seen lining the wall of the avian third ventricle. Microspectrofluorometric analysis characterized the blue fluorophor as a catecholamine, and the yellow fluorophor as the indoleamine, serotonin. Similar cells were not seen routinely in the rat brain following formaldehyde histochemistry. However, glyoxylic acid histochemistry revealed a previously undescribed population of catecholamine-containing subependymal cells which lined the entire third ventricle of the rat diencephalon. The cells were 10µm in diameter and possessed two fluorescent processes, one extending toward and the other away from the third ventricle. They yielded a blue fluorescence which was characteristic of a catecholamine as analyzed spectrally. Additional animals were pretreated pharmacologically with a combination of reserpine, L-dopa, and a peripheral dopadecarboxylase inhibitor (MK486). This treatment resulted in the persistence of the catecholamine fluorescence of dopaminergic (e.g., median eminence-contact zone, arcuate nucleus), but not noradrenergic (e.g., supraoptic nucleus) areas of the hypothalamus. Following this treatment, the subependymal population of catecholamine cells also retained their fluorescence, indicating the probability that they are dopaminergic. The location of these cells along the ventricular wall is reminiscent of monoamine-containing subependymal cells of non-mammalian vertebrates and may represent a species homologie in the mammal. These cells are not to be confused with arcuate (A-12) and periventricular (A-14) dopamine neurons. Ultrastructural identification is needed to define the cells as neuronal, ependymal, or otherwise.

Supported by USPHS NS-11642.

827 LOCALIZATION OF AVIAN BULBOSPINAL MONOAMINERGIC NEURONS BY FLUORESCENCE HISTOCHEMISTRY AND RETROGRADE TRANSPORT OF HRP. Arnold J. Smolen, Ellyn J. Glazer and Leonard L. Ross. Dept. of Anat., Med. Coll. Pa., Philadelphia.,Pa. 19129.

We have recently studied the synaptic arrangement within the preganglionic sympathetic nucleus of the chicken (Nucleus of Terni, NT), and have described the existence of boutons in the neuropil which represent the bulbospinal noradrenergic and serotonergic pathways. In the present study the cell bodies of origin of these bulbospinal projections are identified.

Catecholaminergic (CA) and serotonergic (5-HT) cell bodies were identified in the brainstem by fluorescence histochemistry. Other animals received a thoracic spinal cord injection of 0.4 µl of a 33% solution of HRP (Sigma Type VI). The animals were sacrificed after 24 hours. Serial sections through the brainstem were cut at 50 µm on a Vibratome. The sections were then reacted with sodium nitroferricyanide, benzidine dihydrochloride and hydrogen peroxide according to the method recently described by Mesulam (J. Histochem. Cytochem. 24, 1976). This results in a blue granular reaction product within labeled neurons, which contrasts with the neutral red counterstain, and makes possible unambiguous localization using bright-field microscopy.

Localization of fluorescing perikarya in the brainstem was found to correspond with that already described for the chicken by Ikeda and Gotoh (Jap. J. Pharmacol. 21, 1971). One group of HRP labeled neurons was found in the caudal and ventral portion of the medullary raphe which corresponds to the 5-HT group B2. Another group of neurons containing HRP was found in the ventrolateral reticular formation at the level of the closed medulla corresponding to the CA group A1. A third group of HRP labeled cells was found in proximity to the dorsal motor nucleus of the vagus and nucleus solitarius, also at the level of the closed medulla. This group corresponds to the CA cell group A2. Finally, there was a small group of labeled neurons in the ventrolateral reticular formation at the level of the abducens nucleus corresponding to the CA group A4. Other brainstem areas,in addition to these monoaminergic groups, were also labeled with HRP following thoracic spinal cord injection. These areas include the inferior olivary nucleus, the reticular formation, the vestibular complex, and the red nucleus.

It may be concluded that the noradrenergic innervation to the avian thoracic spinal cord arises from cell groups A1 and A4 in the ventrolateral medullary reticular formation, and A1 more dorsally in the region of the vagal nuclei. The serotonergic projection arises from the caudal portion of the ventral raphe, group B2.

828 CONTRIBUTION OF LOCUS COERULEUS-NORADRENERGIC SYSTEM TO CARDIO-ACCELERATION IN NONHUMAN PRIMATES. Daniel R. Snyder, Y.H. Huang, and D.E. Redmond, Jr., Neurobehavioral Lab., Sect. Comp. Med., and Dept. Psychiatry, Yale Univ., New Haven, Ct. 06510.

Following bilateral lesions of the nucleus locus coeruleus (LC), chair-restrained *M. arctoides* failed to show the cardio-accelerator response of normal and sham operated monkeys to threatening stimuli. In addition to absence of increased heart rate, lesioned monkeys also failed to show generalized excitement or escape behaviors when receiving or anticipating the receipt of inescapable shock. Standardized, threatening stimuli used to test cardiovascular responsivity included directed threat from a human, blood pressure cuff inflation, and punishment from a hand-held electrical shocking device. The fact that bilateral LC lesions do not affect resting pulse rate suggests that the locus coeruleus affects cardiovascular function primarily in response to environmental events such as threats or stress. This is consistent with the reduced emotional behavioral response to threats after LC lesions (Huang, et al, NEUROSCI. ABS. 2: 489, 1976).

Electrical stimulation of the LC causes complex cardiovascular responses (Przuntek and Philipu, ARCH. GES.PATH.PHARMAK. 276: 119, 1973; Ward and Gunn, BR. RES. 107:401, 1976) which contrast with the effects of precise bilateral LC lesions. These data are consistent with the hypothesis that the LC mediates specific behavioral and cardiovascular responses which are components of an alarm or fear reaction to threatening stimuli.

829 MATERNAL BEHAVIOR IN THE FEMALE RAT: CONTROL BY THE NORADRENERGIC FIBER SYSTEM. Marianne K. Steele, David L. Rowland and Howard Moltz*. Dept. of behavioral Sciences, University of Chicago, Chicago, Ill. and Millikin University, Decatur, Ill.

The noradrenergic fiber systems in the brain were manipulated in primiparous female rats, 6-10 days post coitum. Lesions of the far-lateral hypothalamus, resulting in depletion of hypothalamic NE, produced deficits in maternal behavior when observed over a two week testing period. Brainstem lesions of the dorsal NE bundle resulted in a loss of hippocampal NE which was similarly associated with deficits in pup care. In contrast, 6-OHDA infusion into the ventral tegmentum produced profound depletions of NE in cortex, hippocampus and hypothalamus with no observable detrimental effects upon maternal behavior. However, direct manipulation of the fiber connection (fornix) between the hippocampus and hypothalamus resulted in deficits in maternal behavior and a loss of NE from the hippocampus.

These data therefore suggest that a balanced noradrenergic relationship between the hippocampus and the hypothalamus is critical for the onset of maternal behavior. Depletion in either one or the other of these brain areas disrupts the initiation of pup care in the primiparous female rat.

830 CONTRIBUTION OF HISTAMINERGIC AND ALPHA ADRENERGIC RECEPTORS TO ENDOGENOUS CAMP PRODUCTION IN RAT CEREBRAL CORTEX: Anita A. Suran, Dept. Pharmacol., Coll. Med., Howard Univ., Washington, D. C. 20059.

CAMP production was measured in cortical slices prelabelled with ^{14}C-Adenine [J. Neurochem 16, 1609 (1969); the procedure was modified by incubating in air, using 0.05 M Tris buffer at pH 7.4 and 0.2% glucose]. Histamine-stimulated-CAMP accumulation (H), optimal at 1 mM, ranged from 150-200% of basal values (B). Using methoxamine as an alpha agonist, methoxamine-stimulated-CAMP production (M) averaged about 110% B, and was optimal at 0.1 mM. The H1 and H2 antagonists pyribenzamine (Py) and cimetidine (Ci) at concentrations in the range 0.01-10 uM depressed H to 62% B and 83% B respectively; similiarly, M was reduced by 10 uM Py to 80% B and by 10 uM Ci to 84% B. In the absence of agonist, B was depressed to 83% by Py and to 83% by Ci, and using alpha antagonists values were reduced to 81% by phenoxybenzamine (Phb) and to 65% B by phentolamine (Pht); B was reduced by Phb to 95% and by Pht to 90%. 0.1 mM clonidine (Cl), an alpha agonist, stimulated CAMP to 110% B, and significantly potentiated the inhibitory effects of antagonists to both histamine and methoxamine, reducing B to 48% by Ci, to 60% by Py, to 75% by Phb. Both histaminergic and alpha adrenergic stimulated CAMP accumulations, as well as B, were inhibited by H1, H2, and alpha antagonists, and the depression in CAMP accumulation caused by agonist plus antagonist was equal to or greater than with antagonist alone. To investigate the nature of the enhanced antagonisms and to differentiate histamine and methoxamine specificities of the cortical system, B was partially depressed by a mixture of Py and Ci, each 1 mM, then increasing amounts of histamine or methoxamine were added. It was anticipated that the antagonism would be competitively reversed; quite the opposite was observed. In a dose response, histamine, in the range 1-20 mM, increasingly diminished CAMP levels to 20% B at 10 and 20 mM; methoxamine in the range 0.1-5 mM produced a decrease to 20% B. In the presence of 10 uM Pht, histamine (1-5 mM) caused a maximal decrease to 39% of B, and methoxamine (0.1-5 mM) decreased CAMP to 64% B. In the antagonist-free system, 10 mM histamine- or 5 mM methoxamine- stimulated CAMP accumulations were only slightly less than optimal so that high agonist concentrations per se are not inhibitory; therefore, it appears that a true potentiation of the antagonist activity was observed. The dose responsive potentiated antagonism suggests involvement of altered or "new" receptors for histamine or methoxamine, which become available only in the presence of inhibitors which occupy the "normal"agonist sites mediating CAMP accumulation. In this system an interrelationship among histaminergic and α-adrenergic receptors has been demonstrated.

831 VALINE-INDUCED ALTERATIONS OF ENHANCED 5 HYDROXYINDOLE SYNTHESIS THAT OCCURS FOLLOWING PRECURSOR LOADING OR SYNAPTIC RECEPTOR BLOCKADE. R.F. Thomas, J.J. Poulakos*, A. Siegel and J.H. Jacoby, Depts. of Pharmacology and Anatomy, CMDNJ, New Jersey Medical School, Newark, N.J. 07103.

Plasma neutral amino acids that compete with tryptophan for uptake into brain prevent the subsequent rise of brain tryptophan and 5-hydroxyindoles (serotonin + 5-hydroxyindole-acetic acid) that might otherwise occur (Fernstrom and Wurtman, Scient. Am. 230: 84, 1974). We have made use of the administration of a neutral amino acid i.e., valine, concomitant with either precursor loading with tryptophan or serotonin receptor blockade with methiothepin (which consequently leads to a compensatory increase of serotonin synthesis) to determine the ability of such a pharmacologic manipulation to compete with tryptophan for uptake into brain and to impair the subsequent acceleration of 5-hydroxyindole synthesis. Fasted male Sprague-Dawley rats (135-150g) were injected with saline or methiothepin (20 mg/kg) followed 15 min. later with tryptophan (50 mg/kg) and varying doses of valine, and killed 60 min. later. Increasing concentrations of valine decreased brain accumulation of tryptophan in a dose-related manner and decreased the subsequent rise of brain 5-hydroxyindoles in a non-dose related manner. When tryptophan was administered to methiothepin pretreated animals, the subsequent elevation of brain tryptophan was much higher than observed following a similar dose of tryptophan without methiothepin. Valine (600 mg/kg) when given together with tryptophan, prevented the methiothepin-induced enhancement of tryptophan uptake into brain, yet total brain 5-hydroxyindoles levels were still higher than similarly treated animals not receiving methiothepin. However, the reduction of total brain 5-hydroxyindoles induced by valine given to either tryptophan loaded rats with or without methiothepin pretreatment was the same. These results suggest that competition with tryptophan for uptake into brain can effectively diminish 5-hydroxyindoles production even during states of enhanced synthesis, and that the effects of drugs acting upon brain serotoninergic systems may be altered by changes in peripheral amino acid availability.

(These studies were supported by NINCDS Grant NS 12876).

832 EFFECT OF P-CHLOROAMPHETAMINE ON CATECHOLAMINE CONCENTRATION OF DISCRETE BRAIN AREAS. Y. Tizabi*, V. John Massari* and D. M. Jacobowitz (SPON: R. M. Kostrzewa). Dept. Pharmacology, Howard Univ., Washington, D.C. 20059; and Lab. Clin. Sci., NIMH, Bethesda, MD 20014.

P-Chloroamphetamine (PCA) has been shown to have a long term and irreversible neurotoxic effect on serotonergic systems of the brain. A single dose of PCA in rats reduces the brain serotonin content for at least a period of 4 months. Its effects are believed to be mainly restricted to serotonergic nerve terminals. Morphological and biochemical data also suggest that the drug is toxic to neurons of the B-9 cell group. PCA has also been shown to have a short term effect on brain catecholamine (CA) turnover. Recently, however, Hattori et al. (Neurochem. Res. 1: 451, 1976) have reported that administration of 10-15 mg/kg i.p. PCA causes the ultrastructural appearance of two types of terminal degeneration in the striatum of rats. They postulate that this is due to the destruction of both dopaminergic and serotonergic axon terminals. We have studied the effect of PCA on CA content of the striatum and other discrete areas of the brain. Male Sprague-Dawley rats were injected with 10 mg/kg i.p. PCA or saline and were sacrificed 3 or 9 days after the injection. Brains were quickly removed, frozen, and cut into 300 μm thick slices. Discrete areas (arcuate nucleus, striatum, A-10 cell body area, substantia nigra, central grey CA area, A-5 and locus coeruleus) were punched out for norepinephrine (NE) and dopamine (DA) measurements. The arcuate nucleus of the 3 day treated rats showed a significant decrease (48%) in DA content when compared with its control. This difference was absent in the 9 day treated rats. There was no significant difference in either NE or DA content of any other area at either time interval under study. In conclusion, these results do not support the hypothesis that PCA is also toxic to dopaminergic neurons.

833 CORTICOSTERONE MODULATION OF THE RESPONSES OF NIGRONEOSTRIATAL AND TUBEROINFUNDIBULAR DOPAMINE NEURONS TO RECEPTOR BLOCKADE. Glen R. Van Loon* and Chul Kim* (SPON: J.W. Scott). Department of Medicine, University of Toronto, Toronto, Canada M5S 1A8.

Previous studies have failed to demonstrate clearly an interaction between corticosterone and central dopaminergic neurons. Recent studies from our laboratory have suggested that alterations in plasma ACTH and corticosterone are associated with changes in brain dopamine (DA) metabolism. Hypophysectomy in rats results in increased concentration of homovanillic acid (HVA) in ventral hypothalamus (VH); this increase is entirely prevented by ACTH administration. These findings were not duplicated in striatum. In the present studies, we have examined the effect of corticosterone (B) administration on the HVA response in VH and the dihydroxyphenylacetic acid (DOPAC) and HVA responses in striatum to the DA receptor blocking agent, haloperidol (HPD). Although several previous studies have examined the effect of HPD on DOPAC and HVA in nigroneostriatal DA neurons, no similar studies have been performed on tuberoinfundibular (TI) DA neurons. HPD, 0.1 mg/kg, produced a maximal increase in striatal HVA when examined 2 hr later. HVA increased from 0.72 ± 0.03 to 1.32 ± 0.04 ug/g ($p<0.001$); increasing HPD further to 0.7 mg/kg failed to produce any further increase in striatal HVA. Similarly HPD, 0.1 mg/kg, produced a maximal increase in striatal DOPAC from 0.81 ± 0.02 to 2.01 ± 0.05 ug/g($p<0.001$). Administration of B, 20 mg/kg but not 7.5 or 2 mg/kg, inhibited both the HVA and DOPAC responses to HPD, 0.1 mg/kg. The dosage of HPD necessary to increase HVA maximally in the presence of B, 20 mg/kg, was increased to between 0.1 and 0.3 mg/kg. HPD, 0.1 mg/kg, produced a maximal increase in HVA in VH also, from 0.061 ± 0.005 to 0.086 ± 0.008 ($p<0.05$). B, 20 and 7.5 mg/kg but not 2 mg/kg, inhibited the HVA response to HPD, 0.1 mg/kg. The dosage of HPD necessary to increase HVA maximally in the presence of B, 20 mg/kg, was increased to between 0.3 and 0.7 mg/kg. Thus the dose of B necessary to inhibit the HVA response to HPD is lower in VH than in striatum, and the dose of HPD necessary to overcome the inhibitory effect of B, 20 mg/kg, is greater in VH than in striatum. Furthermore, B alone in absence of HPD decreased basal HVA concentration in VH (0.038 ± 0.003 ug/g;$p<0.05$), but not in striatum (0.69 ± 0.02 ug/g). Thus the TI DA neurons appear more sensitive than nigroneostriatal DA neurons to B. It seems likely that corticosterone produces this effect by binding to pre- or postsynaptic DA receptors, especially since the interactions between B, HPD and HVA appear dose-related. These data provide firm support for an interaction between corticosterone and brain DA metabolism, and raise the possibility that TI DA neurons play a role in the feedback regulation of ACTH secretion by corticosterone. (Supported by MRC MA-5183 and OMHF 534-75B)

834 EFFECT OF ADRENERGIC STIMULATION AND ESERINE ON THALAMOCORTICAL RECRUITMENT. William G. VanMeter, Dept. Vet. Anat., Pharmacol., and Physiol., Col. Vet. Med., ISU, Ames, IA 50011.

EEG activity was monitored and the effect of adrenergic stimulation on thalamocortical recruitment (T-C rct) was observed in restrained, conscious albino rabbits and encephale-isolé cats. Recruiting responses were analyzed by computer averaging techniques for comparison of treatment effects. MAOI by pargyline in amounts to 12.5 mg/kg i.v. was found inadequate to antagonize T-C rct and did not potentiate the effect of a subthreshold dose of Eserine (50.0 mcgm/kg i.v. as base) on the evoked responses but induced a desynchronization of the EEG. Approximately 50.0 mg/kg i.p. of L-DOPA was required to induce a slight attenuation of T-C rct and this effect was noted 60 minutes post injection. The effect of the subthreshold dose of Eserine was slightly enhanced and an EEG desynchronization was induced. Treatment with pargyline (12.5 mg/kg i.v.) and L-DOPA (20.0 mg/kg i.p.) was found to be the optimal combination of doses to enhance the antagonism of T-C rct by Eserine (50.0 mcgm/kg i.v.).

Amphetamine given in amounts to 20.0 mg/kg i.v. was found to induce an EEG desynchronization but failed to attenuate T-C rct. However, a marked potentiation of the subthreshold dose of Eserine was routinely observed.

Chlorpromazine (3.5 mg/kg i.v.) failed to antagonize the evoked responses while D-INPEA in doses of 4.0 mg/kg i.v. revealed a slight attenuation of T-C rct.

835 NOREPINEPHRINE IS THE MONOAMINE OF THE SIF CELLS OF THE GUINEA PIG SUPERIOR CERVICAL GANGLION: IMMUNOCYTOCHEMICAL DEMONSTRATION. James K. Wamsley*, Asa C. Black Jr., Jan Redick*, James R. West*, and Terence H. Williams. Dept. Anat., Univ. Iowa, Iowa City, Iowa 52242.

We have studied the morphology of the small, intensely fluorescent (SIF) cells of the guinea pig superior cervical ganglion (SCG) using the glyoxylic acid procedure of Chiba and Williams (1). Clusters of SIF cells were seen in close proximity to blood vessels. Varicose processes of varying length were seen emanating from some SIF cells; many of these passed directly to nearby blood vessels, while others ran toward the principal ganglionic neurons. The SIF cells localized an antibody to dopamine β-hydroxylase, using the fluorescein isothiocyanate method of Hartman (2). A second group of sections exhibited localization of dopamine β-hydroxylase to the SIF cells, using the peroxidase-antiperoxidase technique of Sternberger (3). None of the SIF cells exhibited localization of phenylethylamine-N-methyl transferase, demonstrating that epinephrine is not the transmitter for SIF cells in the guinea pig SCG. Building upon the observations of Libet (4), Greengard and his coworkers have developed a model of the role of cyclic AMP in neural transmission in the rabbit and cow SCG (5). This model involves a dopaminergic SIF cell/interneuron which liberates dopamine at its synapse with the principal ganglionic neuron, causing increased intracellular generation of cyclic AMP, and generation of a slow inhibitory postsynaptic potential (s-IPSP). The guinea pig SCG seems to differ in several respects from the rabbit, however. Its SIF cells contain norepinephrine rather than dopamine; moreover, the guinea pig SCG does not exhibit a s-IPSP (4). Incubation of guinea pig SCG with exogenous dopamine in vitro did not lead to elevation of cyclic AMP levels. However, incubation in vitro with isoproterenol led to marked increases in cyclic AMP levels in the guinea pig SCG, indicating the existence of a β-adrenergic receptor--adenylate cyclase complex in this species. We hypothesize that the presence of a β-adrenergic receptor--adenylate cyclase complex rather than a dopamine receptor--adenylate cyclase complex may be related to the presence of norepinephrine as a transmitter in this species. Elucidation of the mechanisms underlying SIF cell function in the guinea pig SCG may lead to better understanding of the role of SIF cells in ganglionic transmission. (1) Cell Tis. 836 PHYSIOLOGICAL AND ANATOMICAL EVIDENCE FOR SEROTONERGIC AXON COLLATERALS IN THE RAT MIDBRAIN RAPHE. Rex Y. Wang and George K. Aghajanian, Depts. Psychiat. & Pharmacol., Yale Univ. Sch. Med., New Haven, CT 06508

A number of previous studies have suggested the existence of serotonergic (5-hydroxytryptamine; 5HT) axon collaterals in the midbrain raphe nuclei. To test for collateral influences directly, antidromic responses were evoked in 5HT cells of the midbrain raphe by stimulation of the major ascending 5HT pathway in the midline of the ventromedial tegmentum (VMT). Experiments were done in cerveau isolé or chloral hydrate anesthetized rats. To rule out the possibility of simultaneous stimulation of afferent fibers, some experiments were performed on animals with various lesions including pre-VMT-transected (forebrain deafferented) rats. To determine whether VMT-induced effects are mediated through antidromic invasion of collaterals in the 5HT pathway, 5,7-dihydroxytryptamine (5,7-DHT; 10 μg in 5 μl) was injected directly into the VMT area to destroy selectively 5HT axons; 6-hydroxydopamine pretreated rats served as controls. Parallel degeneration studies were carried out at both the light (cupric-silver staining) and electron microscopic level 24-48 hrs after the injection of 5,7-DHT (200 μg) into the lateral ventricle. Rats were pretreated with a norepinephrine (NE) uptake blocker, desipramine (DMI; 25 mg/kg) to protect the NE system. In all 5HT cells studied (except those cells recorded from 5,7-DHT pretreated rats) there was a period of suppressed firing following stimulation of the VMT. The duration of the suppression was proportional to the stimulus intensity, indicating that this effect was due to synaptic summation rather than the refractory period of the cell membrane. The suppression was prevented when 5HT axons in the VMT were destroyed but not when other systems were lesioned. Iontophoresis of 5HT directly onto identified 5HT cells invariably produced inhibition. Both the 5HT inhibition and the post-stimulus inhibition were potentiated by iontophoretic application of a 5HT uptake blocker (chlorimipramine) but not by a NE uptake blocker (DMI) or a γ-aminobutyric acid receptor antagonist (picrotoxin). In addition to the physiological evidence for direct 5HT collateral inhibition, degenerating 5HT axon terminals were observed making specialized synaptic junctions onto disintegrating 5HT cell bodies and dendrites after intraventricular 5,7-DHT. In conclusion, the results indicate the existence of 5HT axon collaterals and that these exert an inhibitory influence upon 5HT neurons, presumably via "autoreceptors". This self-regulating system may have a role in maintaining the slow, regular firing of 5HT neurons; it may also underlie the fact that 5HT neurons are highly sensitive to drug and precursor induced changes in the availability of 5HT. (USPHS Grant MH-17871 and the State of Connecticut).

837 DECREASED LOCOMOTOR ACTIVITY AND ATTENUATION OF AMPHETAMINE-INDUCED HYPERACTIVITY WITH INTRACEREBROVENTRICULAR INFUSIONS OF SEROTONIN IN RAT. John D. Warbritton, III,* R. Malcolm Stewart and Ross J. Baldessarini. Dept. of Psychiatry, Harvard Medical School, Massachusetts General Hospital, Boston, MA 02114 and McLean Hospital, Belmont, MA 02178.

Serotonin (5-HT) is implicated as an inhibitory neurotransmitter in the central nervous system (CNS), with behaviorally depressant effects. Continuous (150 min) intracranial infusion of 5-HT into the right lateral cerebral ventricle of male rats through a chronically implanted cannula diminished motor activity recorded with a Stoelting electronic activity monitor. This effect was dependent on the dose of 5-HT infused, from 2 to 15 μg/min (at 1.5 μl/min); higher doses of 5-HT produced toxic side-effects, including generalized seizures and death. The approximate half-maximally effective dose (ED_{50}) of 5-HT was 5 μg/min. Saline infused at up to 10 μl/min had only small excitatory effects. Acute administration of d-amphetamine (2.5 mg/kg, i.p.) markedly increased locomotor activity without inducing stereotypy. This hyperactivity was attenuated by the intraventricular infusion of 5-HT (ED_{50}=7.5 μg/min). Parallel decreases in both spontaneous and amphetamine-stimulated activity following the direct infusion of 5-HT into the lateral ventricle supports the view that 5-HT functions as a behaviorally inhibitory neurotransmitter in the mammalian CNS.

838 STUDIES ON THE ROLE OF THE NUCLEUS ACCUMBENS IN AMPHETAMINE INDUCED LOCOMOTION. David Wirtshafter, Karen E. Asin and Ernest W. Kent. Dept. Psych., Univ. Il. at Chicago Circle, Chicago, Il. 60680.

Recently a number of investigators have suggested that the hyperkinetic effects of amphetamine (AMPH) may be mediated through the release of dopamine in the nucleus accumbens (NAc). In support of this contention we have observed (Neurosci. Abst. II,#738) that injections of 6-hydroxydopamine (6-OHDA) into the olfactory tubercle at the ventral border of the NAc severely attenuate the locomotor response to amphetamine. In the studies reported in the current communication we have attempted to further clarify the functional role of the NAc by examining the AMPH response in rats with large electrolytic lesions of the NAc.

Relative to controls, animals in which 80-90% of the NAc was destroyed displayed a marked increase in spontaneous motility. In contrast to animals with 6-OHDA lesions, however, 2 mg/kg d-AMPH produced a clear increase in locomotion in these subjects. To test the possibility that this response was mediated through the activation of dopamine receptors in the remaining portions of the NAc, we examined the response of lesioned and control animals to 1 mg/kg of the direct dopamine receptor agonist apomorphine. Apomorphine produced an immediate increase in activity in control subjects but was almost without effect in NAc lesioned animals. This result was obtained even when subjects were allowed 4.5 hours to habituate to the photocell box in which activity was measured; at this time the activity baseline of lesioned and control animals was similar. The finding that direct dopamine receptor activation in NAc lesioned animals had little effect on locomotion suggested that the persistent AMPH response may have been mediated through the release of noradrenalin rather than dopamine. In support of this view we have found that AMPH hypermotility in NAc lesioned animals can be suppressed by phenoxybenzamine or diethyldithiocarbamate at doses which have little effect in intact animals.

It seems rather paradoxical that 6-OHDA lesions of the NAc abolish AMPH induced activity whereas electrolytic lesions do not. We would like to suggest that in the absence of a dopaminergic innervation the NAc may exert some sort of inhibitory influence on locomotion which may override the effects of increased noradrenalin release produced by AMPH. Electrolytic NAc lesions, by removing this inhibition, might allow noradrenalin release in other parts of the nervous system to influence activity.

839 ATTENUATION OF FOOD REWARD BY DOPAMINE RECEPTOR BLOCKADE IN RATS. Roy A. Wise. Center for Research on Drug Dependence, Dept. Psychology, Concordia Univ., Montreal, Canada H3G 1M8.

Lever-pressing for food was attenuated by pimozide (0.5-2.0 mg/kg) in hungry rats. Initial responding was normal and subsequent responding was only minimally attenuated on the first pimozide test in naive animals; thus drug-induced ataxia was not significant. Responding was progressively more attenuated in subsequent pimozide tests. Parallel effects were seen with conditions of non-reward. Initial responding was normal and subsequent responding was only minimally attenuated on the first day of non-rewarded testing in naive animals. Responding was progressively more attenuated as animals received experience in subsequent non-rewarded testing. The parallel effects of pimozide and non-reward experience suggested an equivalence of pimozide and non-reward conditions. This seemed confirmed by the additional finding that responding was minimal even on the first day of pimozide testing in animals that had prior experience with non-reward.

Normal responding under pimozide at the beginning of sessions and for the whole first session in naive animals rules out any pimozide-induced motor or performance difficulties. Thus pimozide appears to block the rewarding quality of food for hungry animals, just as it appears to block the rewarding qualities of brain stimulation and intravenous amphetamine and cocaine. These data suggest that a common dopaminergic substrate plays a critical and perhaps specialized role in mediation of reward. It is paradoxical that dopamine receptor blockers should block the impact of hedonic (rewarding) stimuli in animals, since they are used in man to alleviate the symptoms of schizophrenia, one of which is reported to be anhedonia.

840 ALTERNATE SECTION HISTOFLUORESCENCE/CYTOCHEMISTRY OF IDENTIFIED AMINERGIC NEURONS. Joe Wood and John R. Sladek Jr., Dept. of Neurobiology & Anatomy, Univ. of Tex. Med. Sch., Houston, Tex. 77025; Dept. of Anatomy, Univ. of Rochester, Rochester, N.Y. (SPON: T.F. Burks).

The correlation of fluorescence microscopic and electron microscopic identification of amine containing neurons is difficult due to methodological incompatibilities. Both paraformaldehyde and glyoxylic acid (GA) induced histofluorescence render tissues nonadaptable for specific cytochemical amine localization. Additionally, electron microscopic glutaraldehyde-dichromate (GDC) treatment for amines prevents any histofluorescence reaction. Therefore, a method which can utilize the same brain where one technique can be compared against the other on identified nuclear groups or single identified aminergic neurons is needed. Rat brains were perfused with cold Ringer's solution. Brain sections (30 μ) were made on a Vibratome @ 1-2°C for light microscopy (both histofluorescence and GDC) and at 300 microns for electron microscopy. 30μ sections were immersed in 2% GA for 2 min, air dried at 45°C for 15 minutes and baked for 5 minutes at 100°C with one gram of GA per coplin jar. Tissues for GDC were soaked 1 hr in 3% glutaraldehyde then transferred to the GDC mixture (pH 4.1). GDC tissues were also processed for electron microscopy. Brain areas examined were the arcuate nucleus (A-12), the median eminence, the median raphe and the substantia nigra (SN). Identifiable positively fluorescing neurons can also be identified in thick sections at the light microscopic level with the GDC technique. The same cell areas are positive when viewed with the electron microscope. In the median raphe, fibers containing sharp puncate varicosities were seen with fluorescence and similar fibers were seen in GDC sections. This technique provides the advantage of the enhancement of the histofluorescence for point to point evaluation of neuron relationship. Thus, even when histofluorescence itself does not have the capability of demonstrating ultrastructural organizational relationships, a chemico-morphological relationship can be established with histofluorescence used in conjunction with GDC and GDC identified ultrastructural amine foci with the use of analytical electron microscopy. Thus, this procedure greatly facilitates the perusal of complex areas of the central nervous system in that routine, rapid histofluorescence can identify areas for GDC treatment and ultrastructure evaluation. It remains to be seen which technique has the greater sensitivity, but in the interim such methodologies when applied permit a greater latitude in study during physiological and pharmacology manipulations of animal model systems. (Supported by Salk Foundation of Texas and Grant # USPHS NS 11642.)

841 THE ORIGIN OF MONOAMINERGIC SYNAPSES IN CEREBRAL NEOCORTEX OF IMMATURE RAT: LESION AND ELECTRON MICROSCOPIC STUDIES. Nada R. Zecevic* and Mark E. Molliver (SPON: J.C. Hedreen). Departments of Anatomy and Neurology, The Johns Hopkins University School of Medicine, Baltimore, Md. 21205. U.S.A.

A major innervation of immature rat neocortex by monoaminergic (MA) axons was described by Molliver and Kristt [Neurosci. Lett. 1 (1975) 305]. Previously unrecognized due to their low neurotransmitter levels, the immature MA terminals have a large uptake-storage capacity for catecholamines [Coyle and Molliver, Science 196 (1977) 444]. Monoamine terminals in the CNS can be identified ultrastructurally by the presence of small granular vesicles (SGV), which are the storage sites for catecholamines. In young animals, the blood-brain barrier is incomplete and the visualization of SGVs in central MA terminals can be enhanced by axonal uptake of systemically administered 5-hydroxydopamine (5-OHDA). In the studies cited above, the possibility that non-aminergic terminals were labeled was not excluded; nor were the cells of the origin of these terminals demonstrated.

In order to test the hypothesis that SGV synapses in the lateral neocortex of the infant rat arise from monoaminergic cell bodies in the brain stem we performed three types of experiments; in all three, the distribution of SGV synapses following the administration of 5-OHDA was quantitatively analyzed by an electron microscopic method previously described (cf. Molliver and Kristt, idem.). 1) The neurotoxic amine, 6-OHDA (100 mg/kg), was injected subcutaneously at days 0, 1 and 2. This treatment substantially decreased the number of SGV synapses in lateral cortex compared to their number in the control animals. These results show that the selective destruction of central noradrenergic terminals by 6-OHDA virtually eliminates terminals with the capacity to take up 5-OHDA. 2) the intracerebral injection of 6-OHDA (15 μg/10 μl at age P-2), placed in the mid-brain tegmentum in order to destroy the dorsal CA bundle, significantly lowers the number of SGV synapses in ipsilateral neocortex. 3) a knife lesion in the mid-brain tegmentum also significantly reduces the number of cortical SGV synapses ipsilateral to the lesion. The mechanical lesion controls for the possibility (in #2) of diffusion to the cortex from a local injection of 6-OHDA. These findings confirm that SGV synapses in immature lateral neocortex, concentrated in the primordium of layer IV, are formed primarily by monoaminergic fibers originating from the brain stem. These fibers constitute a major, direct monoaminergic (presumably noradrenergic) projection from brain stem to immature cortex. [Support: USPHS NS-08153, NS-10920 and United Cerebral Palsy Grant R244-71].

842 ASCORBATE BLOCKS AMPHETAMINE-INDUCED TURNING BEHAVIOR IN RATS WITH UNILATERAL NIGRO-STRIATAL LESIONS. John W. Zemp, Lelland Tolbert*, Thomas N. Thomas, and Lawrence D. Middaugh. Dept. of Biochemistry, Medical University of South Carolina, Charleston, S.C. 29403

We have recently reported that ascorbate in physiological concentrations irreversibly inhibits dopamine stimulation of adenyl cyclase in rat corpus striatum in vitro. This report extends this observation to demonstrate an in vivo effect of ascorbate on dopaminergic transmission. Unilateral injection of 6-hydroxydopamine into the substantia nigra produces a degeneration of the dopaminergic neurons with cell bodies in this area. Rats so prepared, when treated with amphetamine, have dopamine released on the side contralateral to the lesion causing pronounced and progressive circling behavior in the direction of the lesioned side six, eight, and ten days after the injection of 6-hydroxydopamine.

Twenty-four Long-Evans rats received unilateral injections of 6-hydroxydopamine (4 μg) into the substantia nigra. The animals were assigned to one of two groups. Six days after lesions were made, all animals were injected with d-amphetamine sulfate (2 mg/kg I.P.). Twenty minutes after injection the number of turns in the direction of the lesion was assessed over a twenty-minute period. The procedure was repeated on day eight with animals in the experimental groups receiving ascorbate (1 g/kg) ten minutes before amphetamine injection while animals in the control group were injected with saline then amphetamine. A final assessment was made with amphetamine only in both groups on day 10. Injection of ascorbate produced a significant decrease in the turning behavior on day eight. No differences between the two groups were found on day six or ten. Ascorbate therefore appears to block dopaminergic transmission in vivo reversibly and may have potential as a therapeutic agent. MOTOR SYSTEMS

843 COMPARATIVE ELECTROPHYSIOLOGICAL STUDY OF CEREBRAL AND PERIPHERAL NERVE PROJECTIONS TO N. INTERPOSITUS AND DENTATUS IN MONKEY.
G.I. Allen, P.F.C. Gilbert*, R. Marini*, W. Schultz*, and T.C.T. Yin. Lab. Neurobiology, Dept. Physiol., State Univ. of New York, Buffalo, New York 14214.

The cerebellum has long been known to receive different cerebral and peripheral inputs over its cortical surface. Because the cerebellar cortex projects onto discrete cerebellar nuclei, which in turn project to different systems ascending toward the cerebrum or descending toward the spinal cord, all apparently involved in the control of movement, it is important to know what cerebral and peripheral signals are integrated by the neurons within n. interpositus and n. dentatus. Several cerebral areas and peripheral nerves were stimulated in cebus monkeys anesthetized with nitrous oxide while recording from individual cerebellar nuclear neurons. The most common inputs to interpositus neurons are from primary motor (MI: 82%), primary somatosensory (SI: 57%), peripheral nerves (53%), premotor cortex in area 6 (PM: 42%), and supplementary motor area of area 6 (SMA: 32%). The most common inputs to dentate neurons are PM (64%), SMA (49%), MI (32%), frontal (30%), and SI (20%), with nerves only influencing 6% of the dentate neurons. The strength of the individual inputs follows the same pattern as the frequencies of these inputs. Superimposed upon these inter-nuclear differences, there is a rostral-caudal gradient. Within both nuclei the neurons located rostrally tend to receive inputs related to the hindlimb (hindlimb MI, SI, and nerves) and from SMA and medial PM. In contrast, the neurons located caudally receive inputs related to forelimb and from lateral PM. Thus, in interpositus the "hindlimb" neurons integrate signals principally from MI (96%), nerves (70%), SI (65%), SMA (35%), and medial PM (24%), whereas the "forelimb" neurons integrate signals from MI (94%), SI (59%), lateral PM (45%), and nerves (36%). Based upon these observations and those from clinical neurology, neuroanatomy, and recordings made in alert, trained monkeys, it is concluded that the lateral cerebellum cooperates with frontal association areas of the cerebral cortex in the planning of movement, whereas the intermediate cerebellum cooperates with sensorimotor cortex and peripheral nerves in up-dating the evolving movement. Furthermore, since the forelimb and hindlimb neurons of the cerebellar nuclei receive inputs that are apparently functionally different, it seems likely that forelimb and hindlimb movements are controlled in different ways.

844 MODE OF PROJECTION FROM A SMALL AREA OF THE MOTOR CORTEX TO THE SPINAL CORD IN THE MONKEY.
H. Asanuma, E. Jankowska*, P. Zarzecki, T. Hongo* and S. Marcus*. The Rockefeller University, New York, NY 10021.

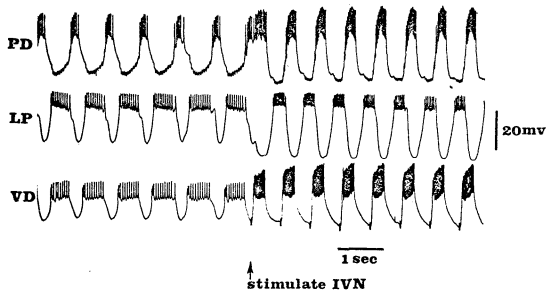
Whether a group of pyramidal tract (PT) cells located close together projects to a given motoneuron pool has been an issue of continuing controversy. We have studied the problem by exploring the pattern of terminal branches of individual PT cells in the spinal cord. Nembutalized monkeys were used. A group of PT cells was recorded simultaneously through the same electrode in the motor cortex while stimulating the lumbar cord through a microelectrode. The lumbar electrode was moved step by step forming a fine grid to detect every branch of a given PT cell group.

It was found that a group of PT cells sent branches to various parts of the lumbar cord. Each PT cell sent branches to motoneuron pools as well as to intermediate regions of the gray matter. In addition to this divergent distribution of branches from a group of PT cells, there was a small area in the ventral horn where all or the majority of the group of cells sent at least one of their branches. The results suggest that when a group of PT cells becomes active, the largest effect appears in a given motoneuron pool with lesser effects in other regions of the spinal cord. (Supported by the NIH grant NS-10705).

845 MONOSYNAPTIC CONTROL OF INTER- AND INTRA-OSCILLATOR COORDINATION OF AN ENDOGENOUS PACEMAKER NETWORK.
Joseph Ayers and Allen I. Selverston, Dept. of Biology, UCSD, La Jolla, Calif. 92093

The pyloric rhythm of the lobster stomatogastric ganglion is driven by a network of three electrically coupled endogenously bursting neurons. The response of this network to periodic monosynaptic inputs was examined in isolated nervous systems. The effect of both EPSP and IPSP inputs depends on the phase at which they occur in the endogenous pacemaker (PD) cycle. Both EPSPs and IPSPs can advance or delay PD subsequent bursts and exhibit qualitatively different phase response curves. The endogenous rhythm can be entrained over a broad range of frequencies by both classes of input. The phase relationships of the discharge of the pacemakers in stimulus cycle are qualitatively different when the cyclic stimulus is slower or faster than the endogenous rhythm for both classes of inputs.

The ventricular dilator neuron (VD) is both inhibited and electrically coupled to the PD pacemaker neurons and its discharge normally alternates with that of the PDs. The inferior ventricular nerve input (IVN) makes monosynaptic EPSP connections with both PD and VD and repetitive trains (ca. 300 msec in duration) in the IVN unit can both entrain the rhythm and shift the phase of VD discharge by 180° so that the VD neuron now bursts synergistically with the PDs (see fig. below). The VD neuron now remains silent between PD bursts. It is concluded that such endogenous pacemaker networks are extremely flexible in their output characteristics for they can both ce coordinated with cyclic monosynaptic inputs and exhibit intra-oscillator phase shifts similar to those observed in more complicated locomotory systems.



846 TEMPORAL RECRUITMENT AND SERVO-PROPERTIES OF PRIMATE MOTOR UNIT RESPONSES TO ANGULAR WRIST DISPLACEMENTS.
P. Bawa* and W. G. Tatton* (SPON.: R.G. Lee). Div. of Physiol., U. of C., Canada.

Imposed angular wrist displacements produce three major, short-latency peaks (termed the M1, M2 and M3 peaks) in the averaged gross EMG activity of the muscles resisting the displacements (Br. Res. 96:108, 1975). Various origins have been suggested for the peaks including synchronised oscillations of motoneuron activity or a series of EPSPs reaching the motoneurons from specific spinal and supraspinal pathways with different loop times.

The subjects (three macaques and four humans) held a handle in a narrow zone. Angular wrist displacements were imposed by step loads produced by a computer controlled torque motor. Up to five different loads (60 gm to 540 gm for monkeys and 0.6 Kg to 6.0 Kg for humans) were presented at random intervals and in random sequence on maintained background "preloads" (up to 180 gm for monkeys and 1.0 Kg for humans). Surface EMG was recorded with silver disc electrodes while single motor units were recorded by "floating", bipolar microelectrodes. Individual motor units were identified and separated using a computer "shape-fitting" program. Average response histograms (ARHs) were constructed for 20 to 75 repetitions of the different step loads. The output was determined from the integrated area of the peaks computed from averaged, rectified gross EMG and from the spike prob./msec of the ARH peaks. Input was taken as the imposed load or as the initial velocity of the displacement. The ARH's showed that 63% of the individual motor units responded significantly (histogram peak includes 95% of spikes occurrences above baseline) over a time course corresponding to only one of the surface-recorded peaks. Two separate unit response peaks were found to occur over the interval of the M1 surface peak (termed M1a and M1b). Twenty-nine % of the units responded over two of the surface peaks. Although the probability of firing increased with increasing loads which ranged from recruitment threshold to the maximal load the monkey could tolerate, the time course of the unit response was maintained. All three surface peaks and the four corresponding motor unit ARH peaks increased monotonically with increasing step loads or initial displacement velocity under all conditions of preload. Human motor units showed responses which corresponded to the surface EMG peaks in a similar manner.

These investigations establish: 1) that the peaks of EMG activity do not merely represent synchronized oscillations in motoneuron activity but result largely from the activation of separately-responding subpopulations of the motoneurons innervating the stretched muscle. 2) that motor unit responses generating the peaks are servo-like in nature. These results will be considered with regard to the size principle of motoneuron recruitment.

847 **PERIOD ANALYSIS OF FAST AND SLOW MUSCLE EMG IN FREELY MOVING CATS.** Bill Betts*, J. L. Smith, and V. R. Edgerton. Dept. of Kinesiology, Brain Res. Institute, Univ. of Calif., Los Angeles, Calif. 90024 U. S. A.

Telemetered EMG from fast-contracting lateral gastrocnemius (LG) and lateral triceps brachii (LT) and slow-contracting soleus (SOL) and anconeus (ANC) in six cats, during unrestrained movement, were sampled at 5000 samples/sec and analysed to detect events defined by maxima and minima which differed in amplitude by more than 120 μv. Intervals between consecutive maxima and minima were computed and expressed as frequencies, while amplitudes were computed between maxima and minima. The reduced data was displayed as a three dimensional histogram.

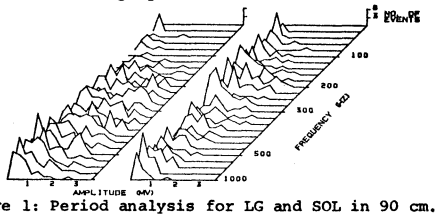


Figure 1: Period analysis for LG and SOL in 90 cm. jumps

During stepping, SOL exhibited a constant median frequency, peak and median amplitude of 180-320 Hz, 2000-3300 μv, and 4-800 μv respectively; while LG was inactive in some steps and exhibited 180-300 Hz, 500-2000 μv, and 3-700 μv for the same parameters in others. The propulsive phase of a series of jumps to a platform placed 30, 45, 60, 75, and 90 cm. above the floor elicited values for SOL similar to stepping; while LG increased in all three parameters during low jumps maintaining a steady peak of 350-750 Hz, 1300-3500 μv, and 650-1500 μv respectively for higher jumps. During treadmill runs, ANC increased slightly between 0.45 and 0.7 m/s in median frequency (250 to 300 Hz) and amplitude (400-650 to 650-900 μv) remaining level at higher speeds (2.0 m/s). The peak amplitude for ANC remained constant throughout the series at 2000-3200 μv. LT maintained steady median frequency, median and peak amplitude at 350 Hz, 400-670 μv, and 1200-2000 μv respectively through 1.1 m/s where it increased to 500-700 Hz, 900-1200 μv, and 2500-3500 μv respectively through 2.0 m/s.

In conclusion, period analysis shows increased recruitment of fast muscle and steady recruitment of slow muscle with increasing treadmill speed and jump height as does integrated EMG but has the advantage of showing both frequency and amplitude parameters. **Supported by USPHS Grant (NS 10423-03).**

848 ROLE OF CENTRAL SEROTONINERGIC MECHANISMS IN AUTOMATIC AND REFLEX SWALLOWING IN RATS. Detlef Bieger, Sch. Basic Med. Sci. and Dept. Physiol. & Biophysics, Univ. of Illinois, Urbana, IL 61801

Rats under urethane anesthesia swallow spontaneously once every 2 to 3 minutes. After acute denervation of larynx and upper trachea, local anesthetization of the oropharyngeal mucosa, and sectioning of all salivary ducts, deglutitive activity persisted in ca. one third of animals. Under such conditions, regardless of the level of basal activity, the serotonin receptor agonists, L-5-HTP and quipazine (QPZ), increased the rate (up to 80 per min) and force of automatic swallowing in a dose-dependent manner over a dose range of 10 to 100 mg/kg and 0.3 to 30 mg/kg (i.v.), respectively. Iproniazid pretreatment (100 mg/kg) enhanced basal activity and shifted the L-5-HTP dose-response curve to a tenfold lower dose range. Harmaline produced analogous effects. QPZ retained its stimulatory activity after pretreatment with iproniazid or with reserpine, which abolished all basal activity.

Selective antagonistic effects were obtained with methysergide and LSD 25, 0.05 to 0.5 mg/kg (i.v.). With administration via the vertebral artery, threshold effects were elicited at agonist and antagonist dosages 8 to 10 fold lower than those required with systemic injections. The effects of either agents persisted after acute precollicular decerebration and those of QPZ were enhanced by bilateral acute vagotomy at the level of the nodose ganglion.

Clonidine stimulated automatic swallowing at doses of 0.05 to 0.15 mg/kg (i.v.). Methysergide antagonized clonidine excitation and unmasked a powerful inhibitory action.

The 5-HT receptor agonists exerted analogous stimulatory effects on reflex swallowing elicited by electrical stimulation of the superior laryngeal nerve. LSD 25 and methysergide counteracted the facilitatory action of the agonists at the same dose levels that antagonized the activation of the swallowing automatism; substantially higher doses of antagonists were necessary to achieve a partial inhibition of the swallowing reflex in the absence of stimulation with agonists.

The data support the hypothesis that the neural apparatus of the swallowing automatism is contained within the pontomedullary region. Serotonin neurons form important links in local neural circuits which operate to set the central excitatory bias for the swallowing 'center' and thus the threshold for its activation by peripheral sensory and suprabulbar inputs. Serotoninergic activation is likely to involve the internuncial neuron network interposed between solitary tract nucleus and effector motoneurons. Supported by the Illinois Department of Mental Health.

849 THE ORGANIZATION OF IA AFFERENT-MOTONEURONAL CONNECTIONS: SOMATOTOPIC ASPECTS AND A NEW HYPOTHESIS. M.D. Binder, J.L. Smith, R.M. Reinking* and D.G. Stuart. Dept. of Physiol., Univ. of Arizona, Coll. of Med., Tucson, AZ 85724.

It has been demonstrated that single Ia afferents from cat medial gastrocnemius (MG) produce EPSPs in >75% of their homonymous motoneurons and in >50% of their heteronymous (lateral gastrocnemius and soleus) motoneurons (Mendell and Henneman. J. Neurophysiol. 34, 171-187, 1971; Scott and Mendell. J. Neurophysiol. 39, 679-692, 1976; Watt et al. J. Neurophysiol. 39, 1375-1392, 1976). In addition to the difference in these projection frequencies, the mean "single fiber" EPSP amplitude is considerably greater in the homonymous cells, strengthening the argument for "species specificity" in Ia afferent-motoneuronal connectivity. Moreover, it has recently been suggested that Ia afferents exhibit a "location", as well as "species specificity" (Scott and Mendell, 1976). As a more stringent test of this latter hypothesis, spike-triggered averaging (STA) was used to measure the distribution and amplitudes of monosynaptic EPSPs produced by single MG Ia afferents in cat MG motoneurons located throughout the rostral-caudal extent of the motoneuronal pool. Following each recording session the point of cord entry of the afferent fiber was traced, and the distance from this point to each motoneuron studied was determined. The motoneurons were divided into two groups; one with locations within 2.5 mm of afferent cord-entry, the other with locations from 2.6-5.0 mm from afferent cord-entry. The projection frequency to the proximal group was 80%, which was slightly higher than the 74% found for the distal group. However, there was no significant difference in the mean EPSP amplitudes of cells in the two groups. In addition, the amplitudes of the EPSPs were not correlated with either motoneuronal or Ia afferent "size" (both measured as axonal conduction velocities). These results suggest that the pattern of Ia afferent connectivity onto homonymous motoneurons cannot be explained solely on the basis of cell proximity. We would propose that Ia afferent connectivity within the homonymous motoneuronal pool displays "functional specificity"; that the "sensory partitioning" which has been shown to exist between motor units and muscle spindles within skeletal muscles (Binder et al. J. Physiol. 257, 325-336, 1976) is complemented by congruent "synaptic partitioning" between spindle afferents and motoneurons within the spinal cord. We would predict that the amplitude of a Ia-motoneuronal EPSP (assessed by STA) is related to the degree of mechanical coupling (quantitated by cross-correlation analysis) between the afferent's receptor and the muscle unit innervated by the motoneuron. (Supported in part by the Fan Kane Foundation and USPHS Grant NS 07888.)

850 ORIGINS OF DESCENDING SPINAL PROJECTIONS FROM THE BRAINSTEM IN MONKEY. A.J. Castiglioni*, M.C. Gallaway* and J.D. Coulter. Marine Biomed. Inst. and Depts. of Physiol. & Biophys. and Psychiat., Univ. of Texas Medical Branch, Galveston, TX 77550.

In 20 monkeys (M. mulatta and M. fascicularis) the cells of origin of brainstem pathways to the spinal cord were identified using the retrograde horseradish peroxidase (HRP) technique. In the vestibular complex, large neurons, scattered in the lateral portion of Deiters' nucleus, were labeled ipsilateral to HRP injections in the lumbosacral cord. Injections of HRP at cervical cord levels labeled neurons in the more medial-dorsal portion of Deiters' and bilaterally in the adjacent medial vestibular nucleus and part of the inferior nucleus. Neurons of the caudal vestibular cell group f were also labeled. At this brainstem level, numbers of cells in the ventral part of the raphe nuclei as well as the large neurons of the medial reticular formation (N. gigantocellularis), mainly ipsilaterally, were labeled from all spinal levels. In the cerebellum, HRP labeled cells were found in the rostral fastigial and adjacent interpositus nuclei contralateral to injections of the upper cervical cord. Scattered large multipolar labeled cells were also located laterally in the brainstem around and dorsal to the facial nucleus where they could be followed anteriorly into pontine levels. Ipsilateral to spinal injections, large neurons of the pontine reticular formation were labeled, mainly in N. pontis caudalis. Laterally, neurons of the nucleus subcoeruleus, adjacent pontine tegmentum, and occasionally of the locus coeruleus proper, were labeled from all spinal cord levels, but were most numerous ipsilateral to HRP injections in the thoracic cord. In the midbrain, the magnocellular red nucleus, in its lateral part, contained neurons labeled from the lumbosacral cord, while neurons towards the medial portion were labeled by injections at higher spinal levels. Labeled neurons were distributed in the midline and adjacent ventral central gray between the trochlear and oculomotor nuclei. HRP injections in the upper cervical cord labeled populations of cells ipsilaterally in the periaqueductal gray, the nucleus of Darkshewitsch, the interstitial nucleus, and the adjacent mesencephalic tegmentum. Groups of labeled neurons were also found, in the deep layers of the superior colliculus and ventrally in the nucleus cuneiformis. Rostral to the red nucleus, a major concentration of labeled neurons was present in the ventral mesencephalic tegmentum. Large multipolar cells were scattered over the central and deep tegmental gray, while smaller elongated neurons were located predominantly in a medial position, such that their axes came to be oriented perpendicular to the third ventricle more rostrally in the medial hypothalamus. 851 ARE THE "LATE" EMG RESPONSES TO LIMB DISPLACEMENT SERVO-CONTROLLED OR "TRIGGER" RELEASED? C.W.Y. Chan* and R.E.Kearney* (SPON: D.G.D.Watt). Aviat. Med. Res. Unit & Biomed. Eng. Unit, McGill University, Montreal, Canada H3G 1Y6.

Recent findings in humans and primates suggest that the "late" electromyographic (EMG) response to sudden limb displacement, gen-erated with the intention to oppose the stimulus, might be mediated via a long transcortical loop acting in the manner of a servo-system. In the present investigation, we tested this hypothesis by examining the neuromuscular responses elicited in the gastrocnemius (GS) and tibialis anterior (TA) in five normal subjects instructed to resist sudden, servo-controlled RAMP displacements (lasting 500msec) about the ankle joint and comparing them to those elicited by sudden PULSE displacements (lasting 60msec) of the same amplitude and rise time. No significant differences were found in the latency and pattern (shape and area) of EMG response in GS opposing dorsiflexing ramps and pulses; nor in TA opposing plantarflexing ramps and pulses. This lack of difference between responses to two quite different input patterns is not consistent with the behaviour of a response that is servo-controlled. It is however compatible with the concept of the triggered release of a pre-programmed pattern of response. Therefore it is concluded that if a long transcortical pathway is involved, it would probably serve to release preformulated patterns of intended motor control independently of the specific pattern of limb displacement, rather than acting in the manner of a servo-mechanism.

852 COMPARISON OF SPIKE-TRIGGERED AVERAGES AND STIMULUS-TRIGGERED AVERAGES OF FOREARM MUSCLE ACTIVITY FROM IDENTICAL MOTOR CORTEX SITES IN BEHAVING MONKEYS. P.D. Cheney and E.E. Fetz, Dept. of of Physiology and Biophysics and Regional Primate Research Center, Univ. of Washington, Seattle, WA 98195

In monkeys alternately flexing and extending the wrist against spring-like loads we recorded activity of covarying motor cortex cells and 12 identified forearm muscles (6 flexors and 6 extensors). For some cells spike-triggered averages (SpTA) of rectified EMG activity revealed a transient post-spike facilitation (PSpF) of activity of one or more covarying muscles, probably mediated by corticomotoneuronal (CM) connections of the recorded cell. After documenting the pattern of PSpF produced by a CM cell we stimulated through the microelectrode at the same cortical site with single biphasic pulses during comparable active movements (stimulus duration: .1 or .2 ms; intensity 2-40 μa, usually 5 or 10 μa). Frequency of stimulation was sufficiently low (15/sec or less) to preclude temporal facilitation. Stimulus-triggered averages (StTA) of rectified EMG activity were compiled for the same muscles under comparable conditions at 20 sites where CM cells had produced a distinct pattern of PSpF. Of 83 instances of PSpF of a muscle, all but 6 also showed post-stimulus facilitation (PStF). At 8 cortical sites the relative magnitudes of PStF in each muscle exactly matched the profile of PSpF in the same muscles. At 10 other sites the strongest PStF appeared in the same muscles showing the strongest PSpF. The PStF usually built up much more rapidly than the PSpF, even at stimulus intensities of 5 μa or less. As stimulus intensities were increased above threshold (typically below 3 μa) the relative magnitude of PStF in different muscles remained constant, even though the absolute magnitude increased continuously. At higher stimulus intensities PStF was sometimes followed by suppression. Microstimulation during movements in the opposite direction often produced a post-stimulus suppression in StTA of antagonist muscle activity.

The similarity in pattern of PSpF and PStF supports the conclusion that PSpF is mediated by the recorded cell. The fact that the pattern of PStF was similar to but much stronger than the pattern of PSpF suggests that microstimuli recruited a cluster of CM cells whose terminals are similarly distributed to motoneuron pools. The post-stimulus suppression of antagonist muscles suggests that the spinal connections of the cluster are reciprocally organized.

853 REVERSALS OF RECRUITMENT ORDER IN MEDIAL GASTROCNEMIUS PRODUCED BY STIMULATION OF DEITERS' NUCLEUS. H.P. Clamann and C.G. Kukulka*. Department of Physiology, Medical College of Virginia, Richmond, Va. 23298.

The responses of single medial gastrocnemius (MG) motoneurons were recorded from their axons in the intact L7 ventral root (VR) of chloralose-anesthetized cats with glass micropipettes. MG motoneurons were identified by their responses to supramaximal stimulation of the MG muscle nerve. Critical firing level (CFL) of an MG motoneuron was determined by stimulating L7 and S1 dorsal roots (DR) with graded single shocks at 1/2 sec while simultaneously measuring the magnitude of the MG reflex response in the muscle nerve, and the response of the motoneuron in L7 VR. CFL was defined as the reflex magnitude at which the unit might or might not respond; if the reflex response was larger, the unit always responded, and if it was smaller, the unit was invariably silent.

A 10 msec train of pulses at 500/sec was applied to the caudal portion of the ipsilateral Deiters' nucleus with stereotaxically placed electrodes. This conditioning stimulus ended 1-2 msec before a single test shock was applied to L7 and S1 DR. Stimulation of Deiters' nucleus increased the monosynaptic reflex response of MG by 100-300%.

60% of MG motoneurons changed their CFL response to stimulation of Deiters' nucleus: cells whose axons had high conduction velocities (> 100 m/sec) showed lower CFL, and slowly conducting motoneurons (< 85 m/sec) showed increases in CFL. The responses of small motoneurons might be due either to inhibition by the conditioning stimulus, or it might have occurred because facilitation of large cells made them relatively easier to recruit.

In several experiments a small motoneuron could be made to respond without fail to L7 and S1 DR stimulation. The addition of a conditioning stimulus from Deiters' nucleus silenced this cell. A component of vestibulospinal input to the MG motoneuron pool appears to be inhibitory to cells of slow conduction velocity.

854 SPACE-TIME FORM PRINTING BY THE HUMAN CENTRAL NERVOUS SYSTEM. Manfred Clynes. Biocybernetic Institute, La Jolla, California, 92037 and N.S.W. State Conservatorium of Music, Sydney, 2000, Australia.

Repetitive limb movements begun with a single voluntary decision such as tapping, preserve the rate (with some drift). (See e.g., Clynes 1969, in Information Processing in the Nervous System, Ed. K. N. Leibovic, Springer, N.Y., page 186.) But is was not noted before that the particular space-time form of the movement is also preserved without need of further commands and attention. Such a free hand movement may be chosen as a reciprocating straight line motion, oval or circular pattern, or arbitrary free form, and even complex angular movements, and the programmed pattern will maintain itself throughout the repetitions without need of further command and attention. The initial voluntary act which decides the repetition rate also programs the form of the movement. The shape of the movement is preserved by the nervous system.

To produce a subsequent modification of the repetitive pattern, only a single decision is required which takes place in the usual time for voluntary motor action decisions. The pattern modified by such single voluntary action will then continue to maintain itself in the same way as the original pattern.

A single voluntary decision is also required to end the repetitive motion.

Once a person has begun such a "repetitive mode" of a movement form of his choice, he can devote his attention to other activities such as talking, for example, and yet the movement will continue in similar shape while he talks. In changing the pattern however, his attention has to be momentarily focused on the change and talking or other forms of activity may need to be interrupted. This type of generation of repetitive movement, called time-form printing, exists in the frequency range of approx. 5 - 0.4 Hz. It implies a special kind of short term memory. It is amenable to study by average evoked potential techniques.

In spite of the unaware or subconscious nature of the "printing" process, different patterns chosen will tend to influence a person's state of mind differently. Thus a sharp angular movement repeated "mechanically" and a rounded, smooth movement repeated "mechanically" have a different effect on the mental state.

Time-form printing is a "mechanical" carrier phenomenon, whose "non-mechanical" modulation by superimposed decisions provides a basis for a theory of musical rhythm. It appears also to be significant for understanding differential effects of various mantra words in repetitive meditation techniques, the embodiment of the inner pulse of the composer in the musical score, and obsessive compulsive repetitive movement behaviour.
