1 MORPHOLOGY AND PHYSIOLOGY IN THE VENTRAL NUCLEUS OF THE LATERAL LEMNISCUS. JOE C. ADAMS LNO, NINCDS, NIH, BETHESDA, MD 20014

In the ventral portion of the ventral nucleus of the lateral lemniscus (VNLL) there are two broad categories of cells as seen with the light microscope, electron microscope, and electrophysiological recordings. In Protargol impregnations there is a class of cells in this region that receive large terminals similar to those found in the anterior cochlear nucleus and medial nucleus of the trapezoid body. When visualized following injections of HRP into the trapezoid body these terminals resemble end bulbs of Held seen in rapid Golgi impregnations of the cochlear nucleus. Seen with the electron microscope, the two categories of cells include those whose somata are covered with terminals and those with very few terminals on their somata. Most terminals contain large, clear, round synaptic vesicles but some contain pleomorphic vesicles. Single unit response patterns in this region are mostly "chopper" and "on" types. The waveform of some "on" type cells shows a positive prepotential preceding every unit discharge. It is likely that cells having this waveform are those with the large terminals and that these terminals originate from octopus cells in the contralateral cochlear nucleus. Further, it seems likely that cells that respond with "chopper" patterns are those with few if any terminals on their somata. These findings suggest that mechanisms underlying stimulus coding in the VNLL are similar to those in the cochlear nucleus.

2 PARALLEL AUDITORY PATHWAYS FROM MIDBRAIN TO THALAMUS IN THE RAT. K. D. Ahmann* and G. C. Thompson (SPON: H. E. Heffner). Dept. of Psychology, Duke University, Durham, N. C. 27706.

Numerous parallel neural pathways exist in the central auditory system of mammals. In the hindbrain alone, the cochlear nucleus projects to the inferior colliculus 1)directly, 2)via the ipsilateral superior olivary complex ⟶ contralateral inferior colliculus pathway, 3)via the contralateral medial nucleus of the trapezoid body ⟶ superior olivary complex ⟶ inferior colliculus pathway, 4)via the contralateral ventral nucleus of the lateral lemniscus ⟶ inferior colliculus pathway, 5)via the contralateral dorsal nucleus of the lateral lemniscus ⟶ inferior colliculus pathway. It would therefore be surprising if the continuation of auditory pathways beyond the inferior colliculus was limited solely to the well-known classical route through the ventral division of the medial geniculate. Utilizing retrograde transport techniques, we have demonstrated that parallel auditory pathways do also exist from midbrain to thalamus.

Horseradish peroxidase (HRP) dissolved in dimethyl sulfoxide (DMSO) in tris buffer was electrophoretically injected into the medial geniculate of white rats. Each animal was sacrificed at 24 hrs. and the tissue ultimately processed with benzidine dihydrochloride (BDHC) or tetramethyl benzidine (TMB). Retrogradely labeled cells in the subdivisions of the inferior colliculus were counted and the percentage of total labeled cells was calculated for the pericentral nucleus, the dorsomedial division of the central nucleus, and the ventrolateral division of the central nucleus.

Of the cells labeled after injection of HRP into the caudal third of medial geniculate, 79% were localized in the pericentral and dorsomedial divisions, while only 21% were localized in the ventrolateral division. Of the cells labeled after injection into the rostral third of medial geniculate, only 23% were localized in the pericentral and dorsomedial divisions, while 77% were localized in the ventrolateral divisions.

These results demonstrate two parallel pathways from the inferior colliculus to medial geniculate, one originating in the pericentral and dorsomedial divisions, and a second originating in the ventrolateral division. A more complete interpretation of the injection sites described above suggests that the pathway originating in the pericentral and dorsomedial divisions terminates primarily in the caudal tip of medial geniculate while the pathway originating in the ventrolateral division terminates primarily in the ventral division of medial geniculate.

3 RESPONSES OF MEDIAL GENICULATE NEURONS TO VOCALIZATIONS IN SQUIRREL MONKEY. Garrett E. Alexander, David Symmes and John D. Newman
Laboratory of Developmental Neurobiology, NICHD, Bethesda, Maryland 20014.

The responses of 269 medial geniculate (MG) neurons in unanesthetized squirrel monkeys to tape recorded species-specific vocalizations is described. We have examined in considerable detail the degree to which the vocalization response is predictable from or follows similar dynamic constraints as the response to clicks, tone bursts, and noise. Analysis of aural dominance, response timing, response direction, and rate-level functions suggest that in the MG nucleus vocal and artificial stimuli are processed by similar neural mechanisms. Frequency tuning curves of neurons obtained from tone burst stimulation are less relevant to vocal responses, but still contribute to predictability to some extent. These conclusions are illustrated by a number of examples from our sample, and represent an initial attempt at parametric comparison of neuronal responses to artificial and species-specific auditory stimuli.

4 AUDITORY CORTICAL FIELDS OF CAT: DIRECT DEMONSTRATION OF RECIPROCITY BETWEEN FIELDS; BANDED CORTICO-CORTICAL CONNECTIVITY; SIMILARITY OF PROJECTION ONTO STRIATUM. Richard A. Andersen
Coleman Lab., Univ. of Calif., San Francisco, Ca. 94143.

Partial maps of one or more auditory fields were made using microelectrode recording techniques. Microinjections of orthograde (tritiated leucine or proline) and anterograde (HRP) tracers were made at physiologically defined loci. In some experiments, both tracers were introduced at the same loci.

Restricted AI injections produced, in the frontal plane, a radial, banded pattern of alternating heavy and light labeling for both tracers in the contralateral AI. The banded patterns of the two tracers appear to be directly superimposeable on one another in the tangential plane, suggesting the existence of reciprocal connections between the binaural response-specific bands within the two fields.

Multiple injections along a single "isofrequency lamina" in AI produced one reciprocal, banded focus of label in the contralateral field. Two single injections, one at a high best frequency and one at a low best frequency position, produced one rostral and one caudal focus of banded label in the contralateral AI. This topography of projection is consistent with a homotypic connectivity of the cochlear representation of the two AI fields. AI also projects in the form of a banded reciprocal array to at least the ipsilateral anterior auditory field (AAF).

Preliminary results indicate that AII projects to at least four different ipsilateral cortical regions as well as to the contralateral AII. All of the projections are reciprocal. Three of the ipsilateral projections are in the form of bands.

These experiments indicate that reciprocal connectivity and the vertical organization of connections within bands are important rules of structure for the auditory cortex.

AI, AII and AAF all project onto the striatum in a remarkably similar pattern. With single injections in any of these fields, there is a single restricted lamina of terminals in the caudal putamen that extends across the dorsal to ventral dimension of the nucleus and occupies an intermediate position along the mediolateral axis. There is a very light and diffuse termination in the tail of the caudate nucleus. Thus, these three fields appear to converge on the same regions of the striatum.

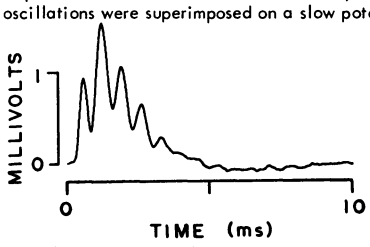
5 DEPENDENCE OF INTRACELLULAR RESPONSES ON SOUND STIMULUS PARAMETERS IN HAIR CELLS AND SUPPORTING CELLS OF THE ALLIGATOR LIZARD COCHLEA. Keld Baden-Kristensen* and Thomas F. Weiss. Eaton-Peabody Laboratory of Auditory Physiology, Massachusetts Eye and Ear Infirmary, Boston, MA 02114.

Electric responses to sound were recorded with micropipets from hair cells and supporting cells which were distinguished by electrophysiological criteria (Weiss et al., J. Acoust. Soc. Am. 55: 606, 1974). All cells with click response magnitudes exceeding 2mV peak to peak (and up to 13mV) were inferred to be hair cells. Stable resting potentials and stable response magnitudes were obtained for intervals as long as ½ hour for hair cells and 3 hours for supporting cells.

Click responses of hair cells were independent of repetition rate from 10 to 150 clicks/sec. At low click levels, response waveforms were oscillatory and symmetric about the baseline, and response amplitude increased linearly with increasing click level. At higher click levels, response waveforms became less oscillatory and more asymmetric, i.e. oscillations were superimposed on a slow potential (see figure), and the response amplitude saturated as level increased. The slow potential generally had a positive polarity. However, immediately after cell penetration, some cells were temporarily depolarized, and the slow potential could be temporarily negative without a concomitant change in the polarity of the oscillatory component. Thus the two components exhibit a degree of independence. In a few cases, the fundamental component of the response to tones was measured as a function of frequency for constant sound-pressure level at the tympanic membrane. These frequency-response curves showed sharp tuning at low levels and broader tuning at higher levels. At low stimulus levels, the best frequency of the frequency response was equal to the frequency of the oscillations in the click response.



Responses of supporting cells had a click-rate insensitive component, presumed to be of hair cell origin and a longer latency, rate-sensitive component, presumed to be of postsynaptic (neural) origin. Frequency responses were relatively broadly tuned, often exhibiting two best frequencies.

6 RESPONSE CHARACTERISTICS OF SUPERIOR OLIVARY COMPLEX NEURONS IN THE DECEREBRATE CAT. William E. Brownell, Paul B. Manis*, Louis A. Ritz, and James W. Fleshman*. Dept's. of Neuroscience and Surgery (ENT), University of Florida, Gainesville, Fla., 32610.

Anesthetics have been demonstrated to alter single unit activity in auditory nuclei peripheral and central to the superior olivary complex (SOC). Previous single-unit investigations of the SOC have been carried out in anesthetized animals. This study examines the discharge characteristics of SOC neurons in unanesthetized, decerebrate cats. Features such as tonotopic organization, shapes of excitatory tuning curves and the shapes of interspike interval histograms resemble those previously reported. However, most units display more spontaneous activity than has been reported in studies of the SOC of barbiturate anesthetized animals. This difference is particularly pronounced in the lateral superior olive (LSO) which is usually described as having little or no spontaneous activity. The mean spontaneous rate for LSO units in our sample is six spikes/sec (range 0 - 27). The mean activity for units anatomically localized to the medial nucleus of the trapezoid body is 18 spikes/sec (range 0 - 74), while units in the medial superior olive have a mean spontaneous activity of about six spikes/sec (range 0 - 11). All ipsilaterally excited and contralaterally inhibited cells (regardless of anatomical localization) have displayed some spontaneous activity (1.3 - 14 spikes/sec). The presence of spontaneous activity has permitted the demonstration of inhibitory sidebands for some LSO neurons. The significance of these observations for binaural interaction in the SOC will be discussed. (Supported by USPHS grant 1 R01 NS12209).

7 CYTOARCHITECTURE OF THE DORSAL COCHLEAR NUCLEUS IN THE TWO YEAR OLD MOUSE C57BL/6. Robert H. Browner and Alice M. Baruch, Department of Anatomy, New York Medical College, Valhalla, NY 10595.

The cytoarchitecture of the dorsal cochlear nucleus (DCN) was analyzed in 10 animals. Brains were stained in Cresyl Violet or impregnated in the Golgi-Kopsch technique (120-160 um). The DCN at its most medial aspect is tucked caudal to the inferior cerebellar peduncle. It sweeps rostrolateral to overlie the posterior ventral cochlear nucleus (PVCN) to the entrance of the eighth nerve. The rostrocaudal extent of DCN is 831 um, while dorsoventrally it is 505 um and 1380 um thick.

The DCN is divided into three regions: superficial molecular, fusiform and granular cell layers. The molecular layer is 84 um thick and contains few ovoid cells. The fusiform layer is at the interface of the molecular and granular layers. The granular layer is the central region containing (small) ovoid and (larger) multipolar cells. The multipolar cells tend to concentrate in the dorsal and ventral portions of this layer.

The long axes of the fusiform cells (30 x 9 um) are perpendicular to the cross-sectioned surface of the DCN, except dorsally where they are parallel to the surface. These cells are not uniformly distributed in the dorsoventral axis but accumulate intermittently. They have eccentric nuclei and homogeneous Nissl substance. There are two stout dendritic trunks from both ends, with few dendritic spines and 2^{o} branches. The dendritic field is at least 228 um dorsoventral by 101 um mediolateral. The Nissl substance of the multipolar cells (16 um) is densely stained and evenly distributed and a central nucleus is characteristic. Three to five main dendritic trunks radiate in all directions. The dendrites have varicosities, elongate spines and do not enter the center of DCN, but run parallel to the surface. A dendritic field is 236 um dorsoventral by 230 um mediolateral. The ovoid cells (9 um) have a large nucleus surrounded by a thin rim of cytoplasm. This is the most numerous cell type. It has two dendritic trunks, 2^{o} branches and spines on distal segments. The dendrites enter or run parallel to the molecular layer. The field is 100 um mediolateral, 83 um dorsoventral and 164 um rostrocaudal. The cells appear to be organized in columns from deep regions to the periphery. (Grant #'s - 1-78-61N-A-PS002r; 41-979-1).

8 PROJECTIONS OF THE COCHLEAR NUCLEUS AND SUPERIOR OLIVARY COMPLEX TO THE INFERIOR COLLICULUS OF THE RAT. J. Timothy Cannon* and Glenn J. Giesler, Jr. (SPON: J.C. Liebeskind). Dept. Psych., UCLA, Los Angeles, CA 90024.

Golgi preparations, retrograde and anterograde degeneration procedures and other classic anatomical techniques have provided valuable information pertaining to the sources of afferents from lower brainstem auditory relays to the inferior colliculus (IC) of the rat. With the advent of the powerful retrograde cell marker horseradish peroxidase (HRP), however, it has become possible to re-examine these connections with the intent of better defining their cells of origin in terms of location and cellular morphology. For that purpose, pressure or iontophoretic injections of HRP were made into the IC and the surrounding mesencephalon of the rat. After 17 to 48 hours the animals were sacrificed and their brains processed for the presence of HRP using either o-dianisidine or tetramethyl benzidine. Unilateral IC injections of HRP labeled approximately equal numbers of cells bilaterally within the lateral superior olivary n. In contrast, cells of the medial superior olivary n. and superior paraolivary n. were primarily labeled ipsilaterally. HRP-positive cells were only rarely encountered in the medial n. of the trapezoid body. IC injections produced large concentrations of HRP-positive cells throughout the dorsal and ventral subdivisions of the contralateral cochlear n. (CN) with only sparse labeling ipsilaterally. The occurrence of dense reaction products in many instances allowed the identification of the pyramidal cells of the dorsal and most cell types of the ventral CN as contributors of afferents to the IC (Figure). IC injections of HRP also produced labeling within the cells of the contralateral acoustic nerve n.

9 EFFECTS OF PUTATIVE AMINO ACID NEUROTRANSMITTERS ON RESPONSE PATTERNS OF NEURONS IN THE COCHLEAR NUCLEI. D.M. Caspary and D.C. Havey*. Division of Neurobiology, Department of Medical Sciences, Southern Illinois University School of Medicine, Springfield, IL 62708.

GABA, glycine, and L-aspartate have been proposed as agents which may govern transmission in the cochlear nuclei (CN) (Godfrey et al., J. Histochem. Cytochem. 25, 1977; Wenthold and Gulley, Brain Res. 138, 1977). The present study examined changes in auditory evoked and spontaneous single unit activity in chinchilla CN induced by iontophoretically-applied amino acids. In all cases, poststimulus time histograms (PSTH's) and interspike interval histograms (ISIH's), at best-frequency, were obtained before, during, and subsequent to the iontophoretic application of the putative neurotransmitter or antagonist being tested. Histological reconstruction of electrode tracts was carried out on all preparations, and patterns of PSTH's and ISIH's were used to aid in the localization of the recordings. As previously reported (Caspary and Havey, Neurosci. Abs. 5, 1977), the application of glycine onto dorsal cochlear nucleus (DCN) neurons displaying a pauser or build-up type pattern resulted in a profound inhibition of the response with a selective effect on the early portion of the response. The application of GABA also resulted in inhibition of activity in DCN neurons with many of these neurons sensitive to both GABA and glycine. The relative effectiveness of the two substances was evaluated by comparing the degree of inhibition resulting from the application of these agents onto the same neuron from different barrels of the same electrode. Results in DCN neurons indicate that glycine inhibition occurred at lower dose levels than those for GABA. In ventral cochlear nucleus (VCN), glycine and GABA significantly reduced the level of spontaneous activity to a greater extent than that of driven activity. Thus, complete inhibition of spontaneous activity and near-threshold driven activity was observed with many VCN neurons with the application of relatively small amounts (0-50 nA) of GABA and glycine. However, few neurons could be totally inhibited when driven at moderate intensities (20-40 dB above best-frequency threshold) without the use of larger amounts (50-150 nA). All CN neurons inhibited by GABA and glycine required increased amounts of these substances to achieve similar levels of inhibition at higher stimulus intensities. Glycine effects in both DCN and VCN could frequently be reversed by concurrent application of strychnine. Application of the putative afferent neurotransmitter L-aspartate onto VCN neurons often resulted in excitation, primarily of spontaneous activity. These data support the hypothesis that glycine, GABA and aspartate may be neurotransmitters of the CN. (Supported in part by SIUMS Research Fund)

10 DEVELOPMENT OF THE EMBRYONIC CHICK'S STATOACOUSTIC GANGLION. G. M. Cohen and C. D. Fermin*. Department of Biological Sciences, Florida Institute of Technology, Melbourne, Florida 32901.

In embryonic White Leghorn chicks, myelination of the statoacoustic neurons first begins on the neurites and then advances proximally to the perikarya (somata). By the 6th day, when this study began, processes from several adjacent Schwann cells have formed loose boundaries around large groups of neurites; at this age the naked bipolar neurons are packed closely together and are not readily distinguishable from Schwann cells except by relative position or by tracing the neurites back to their perikaryal origins. By the 8th day, the extraneous coats covering the external surfaces of Schwann cells are more distinct than their counterparts covering the inner surfaces closest to the neurites. The Schwann cells clutch the neurites more tightly as they extend processes between groups of neurites to divide them into successively smaller bundles. By the 11th day, the neurites, now termed dendrites and which have penetrated the basilar membrane earlier, innervate the hair cells. By the 13th day, the first compact myelin sheaths consisting of 2-6 layers surround some dendrites and within 2 days compact myelin begins to appear regularly; by the 21st day (hatching) 12-18 layers surround many dendrites, though the rates of myelination vary considerably among dendrites in adjacent bundles. By comparison, perikaryal compact myelin first appears by the 18th day; the larger perikaryal girths (about 15-30x) may account for the lag. Perikaryonal myelination requires the cooperation of several satellite cells and the myelin regularly alternates from compact to loose around each perikaryon during this period. By the 14th day after hatching, compactly myelinated perikarya, which are usually as thickly layered as the dendritic, greatly outnumber the loosely myelinated. Each bipolar neuron is filled with a large, eccentrically positioned nucleus that contains prominent nucleolar complexes. The nucleus, though continuing to enlarge during development, occupies a progressively smaller proportion of perikaryonal volume. Until the 14th day of incubation, perikaryonal cytoplasm is relatively pale centrally but is denser peripherally because of abundant free ribosomes, rough endoplasmic reticula, and numerous small mitochondria. Thereafter, orgenelles become more evenly distributed except that the perinuclear cytoplasm remains denser. To date only one type of bipolar neuron, the granular, has been identified. Once Schwann cells have committed themselves to dendritic segments, collagen fibrils ply between adjacent fibers. Numerous capillaries of different sizes thread through these groups of bipolar neurons, frequently contacting satellite and Schwann cells. (Supported in part by NIH Grant No. 1-508-RR09032-01).

11 ORGANIZATION OF THALAMIC PROJECTIONS TO AUDITORY CORTEX IN RAT. J. Coleman, W.E. Wells*, B. Crumpler*, D. Marsh* and W.J. Clerici*. Depts. Psychol. and Physiol., Univ. of South Carolina, Columbia, SC 29208.

A fundamental understanding of the nature of auditory thalamocortical pathways exists for certain mammalian species. Although similarities appear in organization of the auditory thalamus, organization of auditory areas of cortex seems to vary in monkey, cat and squirrel. Because of the limited number of species chosen for investigation, the study of other mammals may further reveal a particular pattern of generalized thalamo-cortical organization of the auditory pathways. In the present investigation retrograde transport of horseradish peroxidase (HRP) was used to study thalamic projections to auditory cortex of the albino rat. Micro-iontophoretic HRP injections made into auditory cortex were followed by 24 hour survival and HRP histochemical processing.

The primary auditory cortex (AI) of rat was identified by Nissl and myelin stains and found to be located within the boundaries of Krieg's area 41. HRP injections of AI resulted in a restricted band of labelled cells confined to the ventral division of the medial geniculate nucleus (GMv). Injections of various portions of AI revealed a topographical projection from GMv to AI. In addition to the core projection from GMv other subdivisions of the auditory thalamus project to at least three auditory belt areas. HRP injections of cortex immediately caudal to AI resulted in labelled cells in the dorsal division of GM and in Po. Restricted injections in a cortical belt located lateral and caudal to AI produced labelled cells concentrated in the caudal division of GM; labelled cells in a thalamic region below GMv also appeared. An additional belt area rostral to AI extending medially and laterally was identified. Injections of this area resulted in thalamic label chiefly located in the magnocellular division of GM and in Po with more sparse labelling of the dorsal division of GM. Cases involving cortex medial to this area resulted in labelling of the lateral posterior nucleus, while injection into more rostral cortex labelled cells of Po and CIN. This study demonstrates the presence of several subdivisions of auditory cortex which receive overlapping or individual projections from different ascending thalamic pathways. Organization of auditory thalamo-cortical pathways in rat appear to fit a basic mammalian plan of restricted projections (of GMv) to auditory core cortex, and belt areas receiving input from other thalamic divisions.

12 RESPONSE LATENCY OF VERTEBRATE HAIR CELLS: KINETICS OF AN IN VITRO MICROPHONIC. D. P. Corey* and A. J. Hudspeth* (SPON: M. Konishi). Div. Biol., Cal. Inst. Technol., Pasadena, CA 91125.

The delay with which a sensory receptor responds to a stimulus provides information about the steps involved in transduction of the stimulus into an electrical signal. The latency of response of hair cells, the primary receptor cells of the vertebrate acousticо-lateralis system, is not precisely known, in part because stimuli reach the cells through complex mechanical linkages with unknown delays, and in part because analysis of the extracellular receptor potential (the microphonic) is confused by complex current paths in the organs. We have investigated the response latency of hair cells with an in vitro system which largely circumvents these difficulties.

The sensory epithelium of the bullfrog sacculus, containing some 3000 hair cells, was removed and mounted as a partition separating two chambers both ionically and electrically. The potential difference across the epithelium was measured with an electrode in each chamber; a second pair was used to pass current to determine the passive electrical properties of the epithelium. The in vitro microphonic potential recorded in response to stimulation was the product of the net transduction current across the epithelium and the epithelial impedance.

Hair cells were stimulated en masse by moving the overlying otolithic membrane, into which the hair bundles insert, with a piezoelectrically driven stimulus probe. By monitoring with a photodiode the projected image of either the probe or the membrane, we could measure within 5 μs and 0.01 μm the stimulus delivered to the hair cells.

A fast pulse stimulus (200 μs duration, 0.4 μm amplitude) evokes a response with a rapid (∿100 μs) rising phase and an exponential decay. Because the time constant of the decay (350 μs) exactly matches the RC time constant of the epithelium, we believe the response waveform is largely determined by the passive electrical properties of the epithelium. After correction for the epithelial capacitance with an active filter (transfer function: $V_o = V_i + \tau dV_i/dt$), the response waveform closely mimics that of the stimulus, with slight broadening and a distinct delay of 40-50 μs. This short latency, and its modest sensitivity to temperature (Q_{10} = ∿2.5), suggest that there is not a complex series of processes intervening between the receipt of a mechanical stimulus and the resulting membrane conductance change. The short latency excludes, for instance, intermediate messengers diffusing over distances of greater than about 0.2 μm.

13 AUDITORY CORTEX LESIONS AND BRIEF TONE AUDIOMETRY IN CATS: EVIDENCE FOR DISASSOCIATION BETWEEN DETECTION AND DISCRIMINATION ABILITIES. Jerry Cranford, Dept. Otorhinolaryngology, Baylor College of Medicine, Houston, Texas, 77030.

In recent years, a number of investigators beginning with Gershuni, Baru, and Karaseva (1967) have provided evidence that the auditory cortex has a critical role in both the detection and discrimination of brief sounds. Dogs and humans with lesions of the neocortical auditory centers have been reported to exhibit significantly elevated detection thresholds for signals which are shorter than 16 msec. in duration. In tests of frequency discrimination, the same subjects also exhibit severe deficits whenever the tonal signals are shortened to less than 20-40 msec. in length.

In contrast to the Russian findings, we recently obtained evidence in our laboratory that cats with large bilateral auditory cortex lesions are unimpaired in their ability to detect 1- and 16-KHz tone pulses of 16 msec. duration or less (Cranford & Igarashi, 1977). In more recent unpublished experiments, we have been further investigating the auditory decorticate cats' ability to discriminate changes in the frequency of brief 1-KHz tone pulses. In support of the Russian findings, these new experiments have revealed that operated cats, while exhibiting normal difference limens for tones of 100 msec. duration, have significantly elevated thresholds for discriminating tones of 8 and 2 msec. duration. Of more significance is the finding that, with further testing, the same operated cats which exhibit elevated discrimination thresholds for brief tones can be shown to have normal detection thresholds. Thus, it appears that the presence of intact auditory cortex, rather than being essential for detecting the occurrence of brief sounds, may be more important for recognizing the nature of such sounds.

14 PHASE-LOCKING IN GOLDFISH 8th NERVE FIBERS: RELATION TO FREQUENCY DISCRIMINATION CAPACITIES. Richard R. Fay* (SPON: John Trimble). Loyola Univ. of Chicago, Chicago, Il. 60626.

The otolithic ears of fishes appear to be incapable of the degree of mechanical frequency analysis performed by the mammalian cochlea. Yet, behavioral frequency discrimination thresholds (Fay, JCPP, 73: 175, 1970) fall within the range of mammalian variation below 1000 Hz. This suggests that information about sound frequency is coded in the temporal structure of neural activity rather than in the across-fiber distribution of discharge rates. This hypothesis is evaluated for the goldfish by comparing the accuracy of phase-locking in single saccular neurons with the accuracy with which behavioral discriminations are made (the just-noticable-difference for stimulus period, ΔP).

Phase-locking accuracy was measured in over 60 saccular neurons as the standard deviations (sd) of period histograms obtained for tonal stimuli at the frequencies and amplitudes used in the behavioral study. For frequencies between 70 and 1000 Hz, log sd decreased approximately linearly with log frequency, with a mean period histogram sd of about 100 microsec at 1000 Hz. The behavioral ΔP values fall within the range of the smallest neural sd values obtained at each frequency.

A simple temporal coding hypothesis holds that stimulus period lengths are estimated by the measurement of the temporal intervals between nerve impulses. The discrimination problem may be viewed as a decision as to whether two samples of neural intervals are drawn from the same, or two different underlying distributions. Assuming the means of these distributions to be equal to the periods of the signals to be discriminated, and that the distributions' variance is completely determinec by the phase-locking variance, then one would expect threshold-like behavior to occur when the difference between the means (ΔP) is approximately equal to the distributions' sd; that is, when $d' = \Delta P/sd = 1$. The results show that this is indeed the case for the smallest sd values at each of the frequencies studied. Thus, peripheral phase-locking variance accounts well for the errors made in behavioral frequency discrimination, under the assumption that the decisions are based upon the small percentage of neurons transmitting the best information.

15 DESCENDING PROJECTIONS FROM AUDITORY CORTEX TO THE THALAMUS AND TECTUM OF GALAGO SENEGALENSIS. D. Fitzpatrick*, I. T. Diamond and D. Raczkowski*. Dept. of Psychol., Duke Univ., Durham, N. C. 27706.

We have investigated the descending projections from the auditory cortex of the lesser Galago by examining the anterograde transport of tritiated amino acids from the various subdivisions of the cortex to the thalamus and midbrain and by identifying labeled cells in the cortex following electrophoretic injections of HRP in the auditory thalamus and midbrain. The two methods complement each other so that it is possible to draw conclusions which are not revealed by one method alone.

Regarding the descending pathways from cortex to thalamus, each cortical subdivision has a unique pattern of projections and at the same time all cortical subdivisions share a common target. Concerning the different patterns, auditory koniocortex (Ak) projects in a topographic manner upon the ventral division of the medial geniculate body (GMv). The cortical regions surrounding Ak project to subdivisions other than GMv. The cortical area lateral to Ak projects heavily onto the dorsal division and to a lesser extent to Po. The cortex situated on the lateral bank of the sylvian fissure, medial to Ak, projects to a region of small cells situated rostral to the magnocellular division and medial to GMv. The cortex ventral to Ak projects to the caudal part of the medial geniculate body. The cortical area occupying the most dorsal extent of the temporal lobe has, as its main target, the suprageniculate nucleus. In addition to these distinctive patterns of projection, all subdivisions of the auditory cortex project diffusely to the magnocellular division of the medial geniculate body. The results from our HRP experiments suggest that the cortical projection to the magnocellular division may arise from layer V neurons. In contrast, the corticofugal pathways to the remainder of the auditory thalamus originate in layer VI.

Regarding the descending pathways from cortex to the midbrain a distinctive difference between the projections of Ak and the surrounding belt regions emerges. Auditory koniocortex projects to the central nucleus of the inferior colliculus and the terminations are distributed in a laminar fashion. On the other hand, the descending projections from the belt regions terminate in the pericentral nucleus of the inferior colliculus and in the deep layers of the superior colliculus. All of these corticotectal pathways originate from layer V of auditory cortex.

In summary, we have demonstrated that Ak and the surrounding belt regions stand in contrast to each other with regard to their pattern of descending projections to the thalamus and midbrain and that each cortical region is reciprocally related with its source of ascending afferent input. 16 CAT COCHLEAR NERVE FIBER SPIKE DISCHARGES: RECOVERY CHARACTERISTICS AS A FUNCTION OF INTER-SPIKE TIME. Roger P. Gaumond*, Charles E. Molnar*, and Duck O. Kim. Dept. Physiol. and Biophysics, Sch. of Med., Washington U., St. Louis MO 63110.

We have investigated the recovery of spike discharge probability of cat cochlear nerve fibers as a function of interspike time τ by collecting histograms of the intervals between spikes with and without single tone stimulation. Estimates of $\phi(\tau)$, the hazard function (Cox, Renewal Theory, J. Wiley, 1962), were formed by dividing the number of intervals of length τ by the number of intervals of length greater than or equal to τ. In most fibers, $\phi(\tau)$ for spontaneous discharges increases rapidly between τ of 1 and 4 msec, and continues to increase more slowly from 4 to 40 msec. Observed differences among fibers include a tendency of some fibers to show an "early peak" in $\phi(\tau)$ at .75 to 1.0 msec, while others never responded until at least 2.0 msec. These observations are generally consistent with Gray (Biophys. J. 7,759,1967).

Hazard functions were estimated for spike discharge responses to high frequency (>5 kHz) acoustic stimulation of sufficient intensity to cause at least a doubling of discharge rate over spontaneous rate. For discharges in response to such tones, $\phi(\tau)$ was nearly equal to $\phi(\tau)$ for spontaneous discharges multiplied by a scale factor. A Markov chain model has been developed which is consistent with this observation. An extended version of the model predicts cochlear nerve fiber discharge patterns in response to single low frequency (<5 kHz) tones. These predictions will be compared with experimental results.

17 TIME CONSTANTS OF AUDITORY ADAPTATION - ELECTRICAL STIMULATION VS ACOUSTIC STIMULATION. Chi-ming Huang.* (SPON: L. E. White). Dept. of Physiology, College of Medicine, Univ. South Alabama, Mobile, AL 36688.

Amplitudes of auditory evoked potentials change readily with repetition rate and duration of acoustic stimulation. A quantitative model was proposed to explain such changes. Electrical stimulation of the acoustic nerve was compared with acoustic stimulation in order to separate the effect due to refractory periods of auditory periphery and central elements. The model included a decrementing process due to the stimulus and a spontaneous recovery process; both having exponential time course. Results indicated that during acoustic stimulation the time constants were 10-15 and 100-120 msec for the decrementing and recovery processes, respectively. Interactions of these time constants determine the amount of response decrement in the steady state. The response decrement may be up to 90% as the stimulus rate was varied from 1 to 200/sec and the stimulus duration was varied from 1 to 1000 msec, taking care that temporal overlap between stimuli did not occur. During electrical stimulation of the acoustic nerve, the time constant for spontaneous recovery shortened and the amount of response decrement was smaller relative to the results from acoustic stimulation. It was concluded that mechanisms at the hair-cell and acoustic nerve junction may be chiefly responsible for the observed results.

18 IN VITRO ELECTROPHYSIOLOGICAL ANALYSIS OF N. MAGNOCELLULARIS AND N. LAMINARIS OF THE CHICKEN. Hunter Jackson, John T. Hackett, and Edwin W Rubel. Depts. of Physiology and Otolaryngology, Univ. of Virginia, Charlottesville, VA. 22901.

We have recently developed an in vitro preparation of the chicken brain stem, including first, second, and third order elements of the auditory system; these are the auditory (8th) nerve, n. magnocellularis (NM), and n. laminaris (NL), respectively. The system is stimulated by means of bipolar surface electrodes positioned on the 8th nerve stumps. Using micropipettes filled with potassium citrate or horseradish peroxidase (HRP) solution, we have recorded field and single cell potentials in NM and NL. The findings summarized below were obtained from late embryos, aged 17-19 days.

Field potentials recorded from NM and NL in response to 8th nerve stimulation are characterized by three distinct negativities. The first negativity (N1) is recorded from a circumscribed area comprising NM. N1 is evoked by ipsilateral nerve stimulation only, and reflects postsynaptic currents in NM elicited by 8th nerve input. The second negativity (N2) is recorded from the dorsal neuropil region of NL. Like N1, N2 is evoked only by ipsilateral 8th nerve stimulation. The latency of N2 is 3-5ms longer than that of N1; this is consonant with the view that the 8th nerve does not project directly to NL, and that N2 results from synaptic activation of dorsal NL dendrites by ipsilateral NM neurons. The final negativity (N3) is recorded at the level of the ventral neuropil of NL. N3 is evoked by contralateral nerve stimulation only and reflects the synaptic input to ventral NL dendrites from the contralateral NM.

We have also undertaken an analysis of the postsynaptic potentials generated by 8th nerve stimulation. All postsynaptic potentials thus far recorded from NM were excitatory. This has also been true for NL units regardless of whether the ipsi- or contralateral nerve was stimulated. Two types of unitary EPSPs have been recorded from NM; the first has a 2-3ms rise-time and 5-7ms duration, whereas the second has a rise-time of about 5ms and a duration of about 50ms. It is possible that these two types of EPSPs correspond to the two morphologically separable types of nerve terminals seen in NM.

In contrast to NM, NL neurons show graded EPSPs with increasing intensity of stimulation. We have traced terminal arborizations of individual NM cells following intracellular injections of HRP and found that axons from single NM neurons contact a number of adjacent NL cells. Taken with the graded EPSPs recorded from NL neurons, this indicates that terminals from several NM neurons converge on individual NL cells. (Supported by NSF grant #BNS 78-04074, the Deafness Research Foundation, and NINCDS RCDA #NS00305-01 to EWR, and RSDA 5K02 DA 00009 from NIDA to JTH.)

19 COCHLEAR INJECTIONS OF LABELLED ASPARTATE OR GLUTAMATE PRODUCE LOCALIZED GRAINS IN AUTORADIOGRAPHS. Eileen S. Kane, Dept.Anat., Univ. of Mass. Med. Sch., Worcester, Ma 01605.

Small volumes (0.5-0.7 µl) of ^{3}H-labelled L-aspartate or L-glutamate (New Eng. Nuc.,Boston) diluted in sterile saline (final conc. 30-50 µCi/µl), were injected unilaterally into cochleas of adult cats. After survival periods of 3-30 hrs, cats were perfusion-fixed, brains immediately removed and blocked, and frozen sections of stems cut (30 µm), mounted and routinely prepared for LM autoradiography. Dense grains were localized in the ipsilateral cochlear nucleus in patterns identical to those after ^{3}H-leu injections (1977, Am. J. Anat., 150:641). Heaviest grains were found in the posteroventral (PVCN) and anteroventral (AVCN) cochlear nucleus subdivisions, notably in and around the nerve root, and in the deep dorsal (DCN) cochlear nucleus into the fusiform cell layer (FCL). Sparsest grains occurred in the granule cell caps and in the DCN molecular layer. Evidence of transneuronal transport appeared with survival times over 24 hours for both ^{3}H-asp and ^{3}H-glu. Non-specific label (over unrelated stem nuclei) was heavy after 24-hr survivals. Both amino acids produced significantly higher average grain counts in zones of the ipsilateral cochlear nucleus known to receive heaviest primary inputs. For example, average counts in experimental OCA were about 70/100 µm^2 for asp and about 110/100 µm^2 for glu while average counts in the contralateral OCA were about 30/100 µm^2 for both ^{3}H-asp and ^{3}H-glu. Liquid scintillation counts of both cochlear nerve roots were significantly higher for the injected vs. the uninjected sides (a 10:1 ratio for ^{3}H-asp, a 7:1 ratio for ^{3}H-glu). Our results strongly support neurochemical findings from other labs that both aspartate and glutamate may be the neurotransmitters (or their precursors) used by primary auditory fibers.

20 LOCALIZATION OF SOUNDS IN SPACE BY RATS WITH BILATERAL LESIONS OF AUDITORY CORTEX. Jack B. Kelly, Psychol. Dept., Carleton University, Ottawa, Ontario, K1S 5B6.

In cats, dogs and monkeys, the ability to localize an auditory stimulus in space is dependent upon auditory cortex. In these animals bilateral lesions of auditory cortex result in profound deficits in localization, even though little impairment is found in absolute sensitivity to sounds or ability to discriminate along other auditory dimensions such as frequency and intensity. Heffner and Masterton (1975) have shown in monkeys that deficits in sound localization are not due simply to an inability to discriminate between left and right but, rather, are related to the response demands of the task. In other words, in order to demonstrate a deficit it is necessary to test animals in a maze which requires a spatial response to either left or right stimuli presented briefly at the onset of each trial. In a task of this sort, monkeys with bilateral lesions of auditory cortex fail to perform above a chance level even though the same animals can discriminate left from right in a non-spatial task. We have attempted to replicate this result using albino rats as subjects. The animals were trained to localize single clicks in a two-choice spatial maze with loudspeakers separated by 180° azimuth. Further testing was then done with speakers separated by 60°. Difficulty was experienced by some animals following cortical lesions, but this did not correspond with the extent or location of the damage. More significant was the fact that most animals with large bilateral lesions of auditory cortex were still capable of high levels of performance with speaker separations of 180° and 60°. This behavior was clearly based upon the location of the sound rather than other qualitative differences between loudspeakers because responses dropped to chance when the speaker angles were reduced to 12°. Therefore, in contrast to results with monkeys, rats with bilateral lesions of auditory cortex are still able to localize sounds in space. Furthermore, because of the close similarity of testing procedures used in studies of sound localization, it seems likely that our results reflect a species difference in cortical dependency of auditory localization.

21 EFFECT OF INTER-AURAL TIME DELAY ON AUDITORY CORTEX UNIT RESPONSES. L.M. Kitzes* (SPON: J.E. Swett). Dept. of Anatomy, College of Medicine, U.C.I., Irvine, Calif., 92717.

Auditory cortex has been implicated by behavioral research in the lateralization of a sound source. The sensitivity of single neurons in primary auditory cortex of cat to inter-aural time of stimulation was examined.

The pinnae of Halothane anesthetized cats were removed and an ear piece sealed in each external auditory meatus. A Beyer DT-48 earphone was coupled to each ear piece by a short plastic tube. Pt-Ir electrodes were advanced into primary auditory cortex using a hydraulic microdrive controlled from outside a double-wall acoustic chamber. Fifty msec best frequency tone bursts (rise/fall time 5 msec) presented at moderate stimulus levels relative to unit threshold were used. Stimulus level was equal at the two ears.

Inter-aural time differences between the contralateral stimulus leading by 20 msec and the ipsilateral stimulus leading by 50 msec were explored. The most common effect observed is a reduced discharge rate when stimulation of the ipsilateral ear precedes contralateral stimulation. The reduction is observed whether or not ipsilateral stimulation alone evokes discharge activity. When ipsilateral stimulation alone does not evoke discharges, there frequently is no apparent effect of such stimulation unless it precedes contralateral stimulation. Ipsilateral suppression frequently asymptotes at contralateral delay values of 3 to 15 msec and may be effective throughout the duration of the ipsilateral signal. The pattern of the contralaterally evoked response normally remains unchanged while the evoked discharge rate varies as a function of inter-aural delay.

While other mechanisms are clearly possible, the relevance of the long inter-aural time delay functions to the lateralization of a sound source could derive from intensity differences at the two tympanic windoes due to the presence of the head in the sound path to the distal ear. This difference approaches 10 dB for high frequency signals. At near threshold levels mean response latency of AVCN cells decreases by several msec with each 10 dB intensity increase (Kitzes et al, J. Neurophysiol., in press). The latency difference between responses of the two AVCN cell populations excited by a distant sound source, arising from an inter-aural intensity difference, could result in central delay functions similar to the inter-aural delay functions presently under study.

22 AUDITORY RECEPTIVE FIELDS: CENTER-SURROUND ORGANIZATION. Eric I. Knudsen and M. Konishi. Div. of Biology, 216-76 Beckman Laboratories,California Inst. of Technology, Pasadena CA 91125

The spatial receptive fields of specialized auditory units in the midbrain of the barn owl (Tyto alba) are subdivided into separate excitatory and inhibitory areas similar to the center-surround receptive field organization described for other sensory systems. These specialized units were located in the lateral and anterior portions of the midbrain auditory nucleus (mesencephalicus lateralis dorsalis, MLD), the avian homologue of the inferior colliculus. Units in this region respond only to sounds originating from a restricted area of space (receptive field), and are arranged according to the location of their receptive fields so as to form a physiological map of auditory space. The inhibitory areas of these units were mapped under free-field conditions by using two movable sound sources; one source positioned inside a unit's receptive field to drive the unit; while a second source, positioned at various locations outside its field, tested for inhibitory effects.

Noise bursts presented outside of a unit's receptive field inhibited these units. The strength of the inhibition depended upon the location of the source, and the intensity and spectral content of the sound stimulus. Inhibition increased as the source moved in from the periphery and approached the borders of a unit's receptive field. As the source entered the unit's field, the effect of the noise changed from inhibitory to neutral or excitatory within a few degrees. Increasing noise levels resulted in stronger inhibition and an expansion of the unit's inhibitory area toward the periphery. Tone bursts also inhibited these units, but the effect was weaker. The range of sound frequencies that contributed to inhibition was wide, and changed with sound source location. Thus frequency-response curves measured using different speaker locations were often qualitatively different: inhibitory frequencies at one location being neutral or excitatory at another.

The fact that the auditory system has created center-surround receptive fields based on functional properties of the input, and independent of the topography of the sensory surface, argues strongly for the importance of center-surround organization in spatial analysis of sensory input. 23 INTERAURAL INTERACTIONS IN MONKEY AUDITORY CORTEX. Alan D. Legatt, Joseph Arezzo*, and Herbert G. Vaughan, Jr. Dept. of Neuroscience, Albert Einstein College of Medicine, Bronx, New York 10461.

The effects of stimulus laterality on auditory evoked responses provide evidence about neural mechanisms related to sound localization and dichotic intensity effects. We examined gross potential fields and multiple unit activity (MUA) within primary auditory cortex in the alert monkey; these data supplement the literature on stimulus laterality effects in subcortical structures.

100 μsec 95 dBSPL clicks were delivered monaurally and binaurally at a rate of 2/sec. Three-dimensional field mapping delineated primary auditory cortex on the basis of potential gradients, polarity inversions, and MUA maxima. In the region of the largest evoked potentials, the initial cortical response to a contralateral click was surface positive, with a peak latency of 11 msec. When the click was delivered ipsilaterally, this initial positive wave occurred .5 msec earlier, and was reduced in amplitude by almost 50%. The initial positive component following binaural stimulation was double-peaked, and intermediate in amplitude between the responses to ipsi and contra monaural clicks. When the contra click was held at 95 dB and the ipsi click increased from 0 to 105 dB, the amplitude of the initial positive component decreased systematically. In the converse situation, the wave amplitude increased as the contra click was increased from 0 to 105 dB. MUA recorded in this region showed a phasic increase, whose peak latency ranged from 8 to 12 msec at different depths. The effect of stimulus laterality was similar to the pattern for the P11 component: The MUA response to an ipsi click was smaller than that to a contra click, and the response to a binaural click was intermediate in amplitude.

Longer-latency gross potential components displayed different patterns of interaural interaction. The waveform in the region from 20-35 msec is different for ipsi and contra clicks, while a negative peak at approximately 50 msec is unchanged between these two stimulus conditions. The negativity following a binaural stimulus retains the same latency, but its amplitude is greater than that of the monaural response by about 50%. No increases in MUA corresponding to any of the later evoked potential components were observed at any of the recording sites in the mapping.

To further investigate the mechanisms of sound localization, delays of up to 1000 msec were introduced between clicks of equal intensity presented to the two ears. When the contra click led, the amplitude of the initial cortical component was larger than that of the response to simultaneous clicks, while the initial component amplitude was decreased when the ipsi stimulus led.

24 BINAURAL RESPONSE-SPECIFIC BANDS WITHIN AI IN THE CAT: SPECIALIZATION WITHIN ISOFREQUENCY CONTOURS. John C. Middlebrooks*, Robert W. Dykes, and Michael M. Merzenich* (SPON: R.L. Snyder). Coleman Mem. Lab., UCSF, San Francisco, CA 94143.

The spatial distribution of neurons with different response properties has been studied within the three dimensions of AI in the cat. This work confirms and extends the observations of Imig and Adrián (Br.Res.138:241, 1977). Vertical and topological distributions of neurons falling within characteristic binaural response classes have been mapped by recording the responses of single units and small clusters of units to dichotic stimulation. Nearly all units and clusters (98.4%) were excited by stimulation of the contralateral ear with tones near their characteristic frequencies. Simultaneous stimulation of the ipsilateral ear facilitated ("excitatory/excitatory" or "EE" neurons; 57.7% of recordings), inhibited ("excitatory/inhibitory" or "EI"; 34.3%), or did not alter ("EO";6.4%) the response to contralateral stimulation. A few neurons (1.6%) were driven by stimulation of the ipsilateral ear and strongly inhibited by stimulation of the contralateral ear. Within any given penetration, neurons studied fell within the same binaural response class (e.g., EE, or EI, or EO, or IE) in most of 800 penetrations introduced perpendicular to the cortical surface. Long electrode penetrations made parallel to isofrequency contours traversed the mediolateral extent of AI through the middle layers of the cortex (24 penetrations in 6 cortices). A sharp segregation of units by binaural response class was observed in these penetrations. Regions in which only EE responses were recorded were 200 to 3400μ wide. Regions of EI responses ranged from 100 to 2000μ across. These regions of uniform response to binaural stimulation formed vertical units of organization that were elongated in the rostrocaudal dimension and, thus, intersected the lines of re-representation of the cochlear sensory epithelium. In most cases, there were three prominent, continuous bands of EI units separated by two broad bands of EE units. In some cats, the bands of uniform binaural response types were apparently not continuous, although regions were still elongated along rostrocaudal axes. These results suggest that AI, a single auditory cortical field containing a continuous representation of the cochlear sensory epithelium, is spatially subdivisible into functionally distinct response-specific bands apparently specialized for the coding of unique aspects of binaural stimuli.

25 NEURONS IN THE INFERIOR COLLICULUS OF THE CAT WITH ASCENDING PROJECTIONS. D. L. Oliver and D. K. Morest, Dept. of Anatomy, University of Connecticut Health Center, Farmington, CT 06032.

The inferior colliculus is the major source of ascending auditory afferents to the medial geniculate body. To identify the neurons which contribute to this projection, we made injections of horseradish peroxidase (HRP) in the medial geniculate body. After 1-2 days' survival, the midbrain was prepared for light and electron microscopy and reacted for HRP with diaminobenzidine, Hanker-Yates mixture, or tetramethyl benzidine (TMB). Most HRP-labeled cells were found ipsilaterally in all major divisions of the inferior colliculus (central nucleus, lateral zone, and dorsal cortex); but some were scattered contralaterally. The present report centers on the ipsilateral central nucleus (partes medialis et centralis). Most frequently labeled were medium-sized neurons with oval somas, 14-23μm in diameter. These cells include the medium-sized disc-shaped neurons, the principal type that forms the dendritic layers of the central nucleus in Golgi preparations. Next in frequency were labeled medium-large cells (23-28μm) resembling the large disc-shaped neurons in Golgi impregnations. Both cell types are also characterized by dispersed Nissl substance, seen best in unosmicated tissue embedded in water soluble plastic and stained with toludine blue. Less frequently labeled were large neurons in excess of 30μm. Some of the labeled cells could be medium-to-large stellate neurons with dendrities crossing the laminae. Our best evidence for labeled stellate neurons comes from TMB-incubated material that reveals HRP in primary and secondary dendrites oriented across the laminae. A small number of labeled neurons also contain distinctly clumped Nissl bodies which may correspond to stellate cells with thalamic projections. Least frequently labeled with HRP were small cells. Some of these could correspond to the neurons observed in the Golgi material to have an axon with extensive local arborizations.

In electron micrographs, we identified the two most commonly labeled cell types. Both lack stacked cisterns of rough endoplasmic reticulum. The medium disc-shaped cell is distinguished from the large disc-shaped cell; the large cells display abundant axosomatic synapses and an irregular nuclear envelope.

Thus, several different types of neurons project from the central nucleus to the medial geniculate body. Possibly these are represented by the varieties of ascending axonal endings observed in the medial geniculate body in Golgi and electron microscopic preparations (Morest, JCN 162, 1975: Winer & Morest, this volume).

26 EFFECTS OF AROUSAL AND OF AUDITORY CORTEX COOLING ON GENICULATE SPIKE PATTERNS. Steven S. Orman and Gordon L. Humphrey. Dept. Physiol. and Research Resources Ctr., Univ. Il., Med. Ctr., Chicago, IL. 60680

Spontaneous and sound-evoked medial geniculate (MG) single spike discharges were recorded in chronically implanted, unanesthetized, paralyzed cats. Comparisons were made between activity during high-voltage ("h") and low-voltage ("l") ECoG periods (i.e. during different states of cortical arousal) and between periods of normal auditory cortex temperature and cooled ("c") auditory cortex (i.e., during normal and reduced corticogeniculate activity).

Both spontaneous arousal shifts and cortical cooling led to consistent MG activity changes. Chief among these were: a) Both "h" and "c" states reduced the spontaneous rate of discharge significantly for almost all cells examined. Both conditions caused a significant increase in long intervals but also tended to lead to a higher percentage of extremely short intervals. Thus, cells became more "bursty". b) Moderately short intervals with a relatively steady (and overall higher) discharge rate characterized "l" states with normal cortex temperature. c) Both "c" and "h" states caused modified responsiveness to sounds, i.e., increases or decreases in the long-latency components of the responses. While post-stimulus reverberations were generally absent in this unanesthetized preparation, subdued reverberations were sometimes seen during "h" and "c" periods. d) With respect to effects of cortical temperature and arousal states, no distinctions were obvious between ventral and dorsal divison cells.

Our spontaneous discharge rate data suggest that descending fibers from the auditory cortex are predominantly excitatory and of the subtle modulatory variety. Since the effect on MG neural activity of "h" (cortical non-arousal) was much the same as the effect of "c" (reduced corticogeniculate discharge), one consequence of reduced arousal seems to be a reduction of this cortical modulating discharge to the MG. Increased burst activity and reverberation during sleep and during cortical cooling may be "released" among relay and local circuit elements as a result of decreased cortical input. These may be less extreme examples of the same phenomena that produce bursting and enhanced reverberation in MG in the presence of barbiturate anesthesia.

27 EVIDENCE FOR TRANSNEURONAL DEGENERATION IN THE GUINEA PIG AUDITORY SYSTEM. John Persing, Oswald Steward, and Edwin W. Rubel. Departments of Neurosurgery, Physiology and Otolaryngology, Univ. of Virginia, Charlottesville, Virginia 22901.

Young adult guinea pigs underwent unilateral surgical ablation of the organ of Corti. Following post-lesion survival periods ranging form 5 to 28 days, the midbrain and brainstem were processed by reduced silver impregnation methods. Additionally , unilateral HRPinjections were placed in the round window and individual coils of the cochlea to visualize the afferent and efferent connections of the organ of Corti. Lesions of the cochlea resulted in dense degeneration throughout the ipsilateral cochlear nucleus. Moreover, terminal degeneration was also present in the superior olivary complex bilaterally at 5 days post lesion, slightly increased in intensity at 10 days, and thereafter, decreasing in intensity, such that at 28 days no argyrophilic fragments were identifiable. Ipsilaterally, degenerating terminals were apparent in the lateral superior olive(LSO), the lateral trapezoid nucleus (LTN), and the lateral aspect of the medial superior olive(MSO); contralaterally, degenerating terminals were present in the medial trapezoid nucleus(MTN), dorsomedial(DMPO) and ventromedial(VMPO) periolivary nuclei, and the medial aspect of MSO. Because terminal degeneration was seen beyond the cochlear nuclei in the olivary complex, and, because direct projections to the olivary complex in primates were recently proposed(Carpenter et al, J Comp Neurol 179 517, 1978), HRP was injected into the cochlea to examine the orthograde and retrograde transport of this enzyme in the cochlear nucleus and olivary complex. In all cases, dense accumulations of reaction product were observed in segments of the cochlear nucleus. These injections also resulted in retrograde HRP labeling of large numbers of cells, fibers and less well defined pericellular HRP reaction product ipsilaterally in LSO and LTN,and, contralaterally fewer cells,fibers and pericellular reaction product in MTN and ventral trapezoid nucleus(VTN), DMPO and lateral lemniscal nuclei (LLN). Anterograde HRP terminal field labeling, however, was not seen in LTN, VTN, MSO, LLN or IC. In conclusion, silver impregnation methods demonstrated terminal degeneration similar to that seen with isolated lesions of VCN, and retrograde HRP cellular labeling described the origin of the olivocochlear bundle. Although alternative interpretations of these observations are possible (direct cochlear nerve to olivary complex projections and/or degeneration associated with associated with olivocochlear bundle collaterals) we believe the pattern of terminal degeneration and the apparent absence of orthograde terminal field HRP labeling of the olivary complex indicate that lesions of the cochlea result in transneuronal degeneration of VCN terminals in the olivary complex.

28 TONOTOPIC ORGANIZATION AND RESPONSE PATTERNS TO FREQUENCY MODULATED SIGNALS IN THE INFERIOR COLLICULUS OF HORSESHOE BATS. George Pollak and Gerd Schuller*. Fachbereich Biologie, Frankfurt Univ., FRG.

Horseshoe bats (Rhinolophus ferrumequinum) emit sounds having a long constant frequency (10-100 msec) portion that ranges in frequency from about 77-86 kHz during Doppler-shift compensation behavior. These bats are thought to utilize the frequency and amplitude modulation patterns superimposed on the echo CF by the beating wings of an insect for prey identification. Neurons tuned between 77-86 kHz show a number of special adaptations that include sharp tuningwith typical Q10 dB values of 100-200. In the present experiment the responses to sinusoidally frequency modulated (SFM) signals were studied. Most high frequency neurons responded to tone bursts with a phasic-on or tonic pattern but responded to SFM signals with firings that were tightly synchronized to the modulating envelope. Modulation heights as small as + 50-100 HZ evoked synchronized firings in some units. Synchronized firings were evoked even at very low signal intensities (0-40 dB SPL) in the majority of cells. Some units were unresponsive to CF signals yet fired briskly and in a highly synchronized fashion to SFM sounds. These units apparently are specialized for detecting the FM modulation patterns in the echo CF component.

A disproportionately large volume of the colliculus is devoted to processing the CF component. About 60% of the units are tuned to frequencies between 77-86 kHz. Moreover, these high frequency cells have an unusual tonotopic arrangement being organized in the anterior-posterior axis in contrast to the lower frequencies (10-70 kHz) whose tonotopic arrangement is in the familiar dorsal-ventral plane. In a given penetration units in the initial 500-700μ of tissue had progressively higher best frequencies (BF) but in the remaining 1300-1500μ the BFs were nearly constant, assuming values of from 77-86 kHz depending upon the penetration site.

The unusual tonotopic arrangement and disproportionate amount of neural space for the frequency range of the CF component results in a spacial segregation of activity evoked be the emitted cry and Doppler-shifted echo while the specialized response features to SFM sounds suggests that these cells can encode important target features required for prey identification.

29 THE EFFECT OF SIMULATED SONIC BOOMS ON THE INNER EAR STRUCTURE AND FUNCTION. Stanislav Reinis, Chris Tsaros* and James W. Featherstone*. Dept. Psychology, Univ. of Waterloo, Waterloo, Ont. and the Univ. of Toronto Institute of Aerospace Studies, Toronto, Ont., Canada.

Repeated simulated sonic booms of medium intensity, about 100 Pa, cause bleeding into the basal turn of the cochlea of C57BL/6J mice and chinchillas. Single superbooms of 200 to 500 Pa have the same effect. High frequency sounds are perceived in the basal turn of the cochlea. Experimental animals exposed to simulated sonic booms therefore show a permanent threshold shift to tone with the frequency above 20KHz. Similar experiments have been replicated with Rhesus monkeys.

30 ALTERATIONS IN THE STRIA VASCULARIS OF THE GUINEA PIG COCHLEA AFTER TREATMENT WITH KANAMYCIN/ETHACRYNIC ACID AND ETHACRYNIC ACID ALONE. N. J. Russell*, K. E. Fox* and R. F. Brummett*. (SPON: C. J. Russell) University of Oregon Health Sciences Center, Portland, Oregon 97201.

Previously we reported that injection of a single 400 mg/kg dose of kanamycin (KAN) s.c. followed 2 hrs later by a single 40 mg/kg dose of ethacrynic acid (EA) i.v. resulted in the rapid destruction of outer hair cells (OHC) (Fed. Proc. 36: 412, 1977). Early OHC damage, visible within 2-1/2 hrs after EA administration, was accompanied by swelling of the stria vascularis (SV) which was greater than that seen after treatment with EA alone. Since a functional relationship exists between the SV and the OHCs, it is possible that the SV is the primary site of KAN/EA interaction. To investigate this we examined the SV by electron microscopy (EM) at 5 periods post-EA (1/3, 2, 2-1/2, 4, 6 and 24 hrs). In each series guinea pigs were given either KAN/EA, saline (SAL)/EA, KAN/SAL or SAL/SAL. Cochlear function was monitored continuously by recording the AC cochlear potential generated by a 7 kHz tone and determining the DC endocochlear potential prior to cochlear fixation.

EM studies of tissue fixed at 20 min (1/3 hr) post-EA show SV swelling of similar severity after KAN/EA and SAL/EA. In each case, extracellular fluid had accumulated around the intermediate cells and the marginal cells were pushed outward causing the stria to bulge into the endolymphatic space. Numerous large vesicles were seen along the luminal surface of the marginal cells. At this time the AC and DC potentials had dropped to low levels. By 2 to 2-1/2 hrs post-EA, the SVs of the KAN/EA animals were significantly more swollen than those of the SAL/EA animals although vesicles were more prevalent in the marginal cells of the latter. Areas where the SV had ruptured were seen 2 hrs after KAN/EA. Dying cells were evident within these areas and in the nearby endolymphatic space. Although the AC potential was low at these times, the DC potential had returned to normal levels. By 4 to 6 hrs, SV recovery had begun whereas the DC potential had decreased and OHC loss was evident. Most SV swelling was gone by 24 hrs. However, the SV of the KAN/EA animal was thinner than normal and degenerating cells were occasionally seen indicating that prolonged edema causes considerable loss of SV cells. These results indicate that KAN adds to the swelling caused by EA either directly or by impeding the recovery process. (Supported by a grant from NINCDS 5R01 NS 12808-02.)

31 DEVELOPMENT OF BRAINSTEM AUDITORY POTENTIALS IN KITTENS. Carl Shipley*, David Geary*, Robert Norman and Jennifer Buchwald. Department of Physiology, MRRC, BRI, UCLA, CA 90024.

Brainstem auditory evoked potentials (BAEP) were recorded from ten kittens (three litters) over the first two months of life.The kittens were lightly anesthetized with Ketamine during recording sessions.Click stimuli were presented at rates of 1, 10, 50 and 100 per second.Various active-reference electrode configurations were studied.It was found that click stimuli evoked activity from all locations near the skull as referenced to a front paw.The pattern of development of the BAEP recorded at the vertex, bulla, or tongue referenced to the paw was found to be generally similar although there were consistent differences in the appearance of some of the potentials.The waves were observed as early as 7 to 8 days after birth and were present in all kittens by day 10.At this early age, all of the waves were extremely sensitive to click repetition rates faster than 1/sec.With increasing age, all waves showed a systematic decrease in latency across development which was reflected in both a decrease in the latency of the first wave as well as a non-linear decrease in the interpeak intervals between the first wave and successive waves.Several changes in the form of the waves appeared across development.As it emerged, wave 2 had two distinct components which tended to merge as the animals became older.Wave 3 also showed two separate components in the young kittens which appeared during the second week.Waves 4 and 5 appeared later than waves 1-3 and were very sensitive to stimulus repetition rate in younger animals.This sensitivity was particularly pronounced in wave 5 which was generally absent at rates of 50 or 100/sec during the first month of life.Marked increases in latency occurred in all waves when repetition rates were increased from 1/sec to 100/sec; these latency effects diminished to approximately adult values by 6 weeks.These results are interpreted in terms of possible maturational sequences in the brainstem auditory nuclei.(Supported by NIH Grant MH-24344 and HD-05958.)

32 EFFECTS OF PERILYMPH COLLECTED DURING AUDITORY FATIGUE ON COCHLEAR ELECTROPHYSIOLOGY. M. Tachibana*, C. H. Norris, W. F. Sewell* and P. S. Guth. Depts. of Pharmacology and Otolaryngology, Tulane Univ. Med. Sch., New Orleans, LA 70112.

Previously we reported the release of auditory nerve activation substance (ANAS) into perilymph during sound stimulation (Soc. Neurosci. III, 11, 1977). Recently, experiments designed to increase the output of ANAS were carried out using more intense sound stimuli during the perilymphatic collection periods. In these experiments, compound VIIIth nerve action potentials and cochlear microphonics were measured. The more intense auditory stimuli caused changes in these potentials reminiscent of auditory fatigue. Perilymph, collected during periods of auditory fatigue, when infused back into the guinea pig cochlea during silence caused changes in cochlear potentials identical with those seen during auditory fatigue. Such cochlear electrical changes are not seen with perilymph collected during quiet periods. These results suggest that ANAS and/or another substance released during sound stimulation may be responsible for the changes in cochlear electrical activity seen during auditory fatigue. These results may point to a chemical basis for auditory fatigue and such related phenomena as temporary threshold shift. 33 AFFERENT AUDITORY PROJECTIONS TO THE INFERIOR COLLICULUS OF BUSH BABY (GALAGO SENEGALENSIS). G. C. Thompson. Dept. of Psychology, Duke University, Durham, N. C. 27706.

The inferior colliculus of bush baby can be divided, based on its cytoarchitecture, into a central nucleus which is surrounded dorsally, medially and caudally by a pericentral nucleus and surrounded laterally and rostrally by an external nucleus. The central nucleus can be further subdivided into dorsomedial and ventrolateral divisions. To discover the cells of origin of the afferent projections to these subdivisions, horseradish peroxidase was electrophoretically injected into the inferior colliculus of 20 bush babies. Each animal was sacrificed at 24 hrs. and the tissue processed with either diaminobenzidine (DAB), catechol/p-phenylendiamine, benzidine dihydrochloride (BDHC), or tetramethylbenzidine (TMB). Labeled cells were counted in each central auditory nucleus and then converted to a percentage of the total number of labeled cells found in each case.

Considering the inferior colliculus as a whole, the results indicate that it receives bilateral input from the dorsal and ventral cochlear nuclei, lateral superior olives, medial superior olives, and dorsal nuclei of the lateral lemniscus. However, the ipsilateral projection from the cochlear nucleus is not nearly as strong as the contralateral projection, while the opposite is true for the projection from the medial superior olives (MSO). In fact, since the contralateral projection of MSO is revealed only by the more sensitive processing techniques, it probably represents collateral connections from the ipsilateral pathway. Exclusively unilateral pathways arrive at the inferior colliculus, one originating in the ipsilateral ventral nucleus of the lateral lemniscus and another originating in the opposite inferior colliculus. The final major auditory center to contribute afferents to the inferior colliculus is layer V of auditory cortex.

Turning now to the subdivisions of inferior colliculus, two major points stand out. First, the superior olivary complex projects mainly, if not exclusively, to the ventrolateral division of central nucleus, but not to the dorsomedial division. Second, auditory cortex projects mainly, if not exclusively, to the pericentral nucleus and dorsomedial division of central nucleus, but not to the ventrolateral division. These mutually exclusive projection areas suggest that interaction between third order auditory nuclei (which are probably sensory in nature) and sixth order auditory nuclei (which are probably motor in nature) is accomplished via complex interneuronal connections within the inferior colliculus itself.

34 PATTERNS OF SYNAPTIC ORGANIZATION IN THE COCHLEAR NUCLEUS OF THE CAT. L.P. Tolbert and D.K. Morest. Dept. Neurobiology, Harvard Med. Sch., Boston, MA, and Dept. Anat., U.Conn., Farmington, CT.

The cochlear nucleus comprises distinct cell groups, whose synaptic connections form the basis for all further integration in the auditory system. The posterior subdivision of the anteroventral cochlear nucleus of the cat, as visualized with the Nissl stain, contains two types of neurons. Globular neurons are characterized by dispersed Nissl substance and a small number of thin dendritic trunks; multipolar neurons have large Nissl bodies and many large dendritic trunks. We have previously demonstrated that globular cells correspond to the bushy cells identified in Golgi impregnations and that these are the cells which form the large synaptic calyces of Held in the medial nucleus of the trapezoid body (Neurosci. Abstr. III:12). Adams (personal communication) has shown that multipolar cells send their axons to the inferior colliculus. It was therefore of interest to investigate the types and sources of synaptic input to these two cell types.

It is possible to identify the two cell types in the electron microscope, on the basis of the established correspondence between Nissl substance and rough endoplasmic reticulum. Globular cell bodies are found to receive numerous synaptic inputs; 85% of the surface of the cell body is closely apposed to synaptic terminals. In contrast, multipolar cell bodies are almost entirely wrapped by thin glial sheets; synaptic terminals contact less than 15% of the cell body surface and tend to cluster at the bases of the dendrites. Synaptic terminals are of three kinds, types 1, 2, and 3, which contain 58 nm round, 52 nm round, and pleiomorphic synaptic vesicles, respectively. Terminals of all three kinds synapse on both types of cells. However, only globular cell bodies receive the largest of the type 1 terminals, which, on the basis of sheer size, correspond with endbulbs, seen in Golgi impregnations to arise from cochlear nerve axons. To determine which other terminals are of cochlear origin, we examined cochlear nuclei from cats surviving 1, 2, and 4 days after unilateral cochlear ablation. Cochlear ablation leads to degeneration of type 1, but not type 2 or type 3, terminals.

We conclude that globular cells, which are known to project to the medial trapezoid nucleus, receive heavy input to their cell bodies from the cochlear nerve. Multipolar cells, which project to the inferior colliculus, receive very little cochlear nerve input to their cell bodies; presumably the synaptic organization of their dendrites plays a significant role in determining the properties of the projection to the inferior colliculus. 35 DUAL OLIVOCOCHLEAR BUNDLES: DIFFERENTIAL ORIGINS AND TERMINATIONS IN THE CAT. W. Bruce Warr and John J. Guinan, Jr.* The Boys Town Institute for Communication Disorders in Children, Omaha, NE,68131 and Eaton-Peabody Laboratory of Auditory Physiology, Massachusetts Eye & Ear Infirmary, Boston, MA 02114.

The axonal projections of olivocochlear neurons, which provide an efferent innervation to the organ of Corti, were investigated by the technique of anterograde axonal transport of radiolabelled protein. Ten adult cats received injections of 0.5-12.0 uCi of ^{35}S-methionine in aqueous volumes of 0.02-0.08ul in various locations within the superior olivary complex. Following post-injection times of 11-36-hrs, the animals were perfused with an aldehyde mixture, the cochleas post-fixed in OsO_4, decalcified in EDTA, embedded in soft Araldite, serially sectioned at 3-10u, and mounted for autoradiography with Kodak NTB-2 emulsion. Injection sites were confirmed in autoradiographs of frozen sections. Projections to the cochlea were quantified by counting the number of silver grains in 12 x 12u boxes under the inner hair cells and under each of the three rows of outer hair cells and by plotting these data versus the graphically reconstructed distance along the organ of Corti. Our findings show that the olivocochlear bundle (OCB) can be divided into two parts: 1) One component which originates from cell bodies near the lateral superior olivary nucleus (LSO) and projects to a region underlying the inner hair cells of both cochleas, and 2) a second component which originates in the cell groups medial and ventral to the medial superior olivary nucleus (MSO) and terminates predominantly, if not exclusively, in the region beneath the outer hair cells of both cochleas. In cases analyzed so far, injections within or near the LSO produced grain counts which reflect strongly preponderant ipsilateral projections, the distributions of which were not necessarily symmetrical in the two cochleas. In contrast, injections in the region medial to the MSO produced counts which reflect predominantly crossed projections, the distributions of which appeared to be bilaterally symmetrical. Our data complement the available experimental observations with the electron microscope which show that the outer hair cells receive a major efferent innervation from the crossed OCB, and that the afferent dendrites of spiral ganglion cells, located beneath the inner hair cells, receive a major efferent innervation from the uncrossed OCB. However, our division of the OCB, which encompasses both zone of origin and site of termination, appears to provide a more functionally meaningful basis of classification than the previous scheme which was based upon whether the axons were crossed or uncrossed. (Supported by PHS Grant No.'s NS07720 and NS13126).

36 COCHLEAR NUCLEAR PROJECTIONS FROM OUTER HAIR CELLS. Molly Webster* and Douglas B. Webster. Kresge Hear. Res. Lab., Sch. Med., LSU, New Orleans, LA 70119.

The left bony cochlear shell was surgically removed in one-month-old guinea pigs, causing degeneration of the organ of Corti and gradual loss of most spiral ganglion neurons. There is good evidence that the lost neurons innervated inner hair cells, and that the few remaining after long-term organ of Corti loss innervated outer hair cells. At about one year of age a second surgery removed or destroyed the modiolus, thus destroying the axons of the residual few spiral ganglion neurons. Six days later the animals were sacrificed and the projection of the residual neurons from outer hair cells to brainstem was charted by the Fink-Heimer method and compared with appropriate controls. The ears were serially sectioned and stained with Luxol fast blue-cresyl violet to demonstrate neurons and myelinated fibers.

In one animal the initial surgery destroyed almost the entire nerve, and the second surgery missed the remainder. In this ear a few healthy neurons remain; the brain shows no degenerative debris and therefore serves as an additional control. The left ears of six other animals show the combined effects of the two surgeries; where portions of the spiral ganglion remain, the residual few neurons and their fibers are degenerating.

Degenerative debris was found in the following cellular regions of the cochlear nucleus: central region of dorsal cochlear nucleus, and multipolar, octopus, globular, small spherical, and large spherical cell regions of ventral cochlear nucleus. The debris is much less than that found after severing the cochlear nerve or destroying the organ of Corti by removing the bony shell (the first surgery done here). Nevertheless, this experiment shows that neurons innervating outer hair cells project basically in the same manner as does the entire cochlear nerve. The significance in the central nervous system of the functional differences between the two populations of hair cells therefore lies elsewhere than in their areas of projection. (Supported by Grants NS-12510 and NS-11647.)

37 CYTOARCHITECTURE OF THE GUINEA PIG COCHLEAR NUCLEUS. D. B. Wexler* and R. L. Gulley. (SPON: J. A. Paterson). Department of Anatomy, Case Western Reserve University, Cleveland, Ohio.

The cochlear nucleus of the guinea pig was studied in frozen and paraffin sections stained with thionin or by the Protargol technique to obtain information about its organization for biochemical and experimental studies. These data were correlated with radioautographs showing the distribution of primary auditory terminals labelled by perilymphatic perfusion with H^3-proline and leucine. The rostral anteroventral cochlear nucleus (AVCN) has a homogenous population of spheroidal neurons. Dorsally, these neurons are larger and more rounded than in the remainder of the region. The smallest and most densely packed spheroidal cells are found at the rostral tip. In autoradiographs, spheroidal neurons are encircled by dense accumulations of silver grains which presumably are labelled end bulbs of Held. Caudally, the spheroidal neurons are replaced dorsally by small and medium-sized neurons. These neurons are round or multipolar and are interspersed with scattered giant cells. The rostral extent of these neurons is greater medially than laterally. Ventrally, the caudal AVCN has many globular cells, which are often aligned along the ascending branch of the auditory nerve. In radioautographs, the globular neurons are surrounded by punctate accumulations of silver grains. The soma of some of the other, less numerous, neuronal types in the caudal AVCN also receive primary auditory input. Similar cell types including the globular cells, are seen within the nerve root, and in the ventral portion of the posteroventral cochlear nucleus (PVCN). The distribution of silver grains around the soma of these neurons also is similar to that seen in the globular cell region of the caudal AVCN. The anterodorsal part of PVCN has a heterogeneous neuronal population including many rounded multipolar neurons. The density of labelling around these neurons is variable. At the caudal-most aspect of the PVCN, octopus cells are interspersed with other neuronal types typical of the PVCN. In the laminar structure of the dorsal cochlear nucleus (DCN), pyramidal cells are arranged radially in the granule cell layer. Irregularly-shaped giant neurons are found within the granule cell layer and central region of the DCN. Small neurons, which frequently are round, are found throughout the DCN. The density of silver grains over the DCN is light, and it is confined to the neuropil of the granule cell layer and central region. The pyramidal neurons have scattered clusters of silver grains only along their basal dendrites. The cytoarchitectural organization of the guinea pig cochlear nucleus most closely resembles that of the rat.

38 NEURONAL ORGANIZATION AND AFFERENT CONNECTIONS OF THE MOUSE INFERIOR COLLICULUS. F.H. Willard*, J.M. Hudson* and D.K. Ryugo. Depts. Anat., Univ. Vermont, Burlington, VT 05401, and Harvard Med. School, Boston, MA 02115.

The neuronal organization of the inferior colliculus(IC) of the albino mouse was examined in Golgi, Nissl and fiber-stained material. Two major components were identified: (1) a core area or central nucleus(CN) which is composed of disc-shaped neurons whose dendrites generate a laminar arrangement, parallel to the incoming fibers of the lateral lemniscus; and (2) a cellular rind which surrounds this core and is composed of small, medium and large multipolar neurons. On the basis of cell size, cell density and dendritic organization, this rind may be further subdivided into an external nucleus, pericentral nucleus, dorsomedial nucleus and interstitial nucleus of the IC commissure.

The afferent connections of the IC were determined using the techniques of retrograde transport of horseradish peroxidase(HRP) and anterograde degeneration. Following discrete injections of HRP into CN, only ascending projections were revealed by the presence of HRP-labelled cells: (1) contralateral and topographical projections from CN and the cochlear nucleus(AVCN,PVCN and DCN); (2) bilateral projections from the lateral superior olive, dorsal nucleus of the lateral lemniscus and IC rind; and (3) ipsilateral projections from the medial superior olive and ventral nucleus of the lateral lemniscus.

Disregarding minor connectivity differences between subdivisions of the rind, HRP injections restricted to the rind demonstrated ascending projections similar to those of CN with two important exceptions: (1) AVCN does not project to the rind and (2) the rind receives a heavy projection from the dorsal column nuclei. In addition, the rind receives descending ipsilateral projections from the deep layers of the superior colliculus, the nuclei of the brachium of the IC, the dorsal and medial divisions of the medial geniculate body and layer V of auditory cortex.

The data demonstrate that the IC core(CN) receives only ascending auditory projections and projections from the surrounding rind; in contrast, the IC rind receives both ascending and descending projections from cell populations associated with auditory, somatic and visual functions. These observations are consistent with the notion of "lemniscal-line" and "lemniscal-adjunct" pathways(Graybiel, Brain Beh. Evol. 6:363, 1972) traversing the midbrain. (Supported by U.Vt. GRS Grant PSH 5429-40 and NIH Grant NS 13126)

39 SENSITIVITY OF MOUSE ACOUSTIC STARTLE BEHAVIOR AND INFERIOR COLLICULUS MULTIPLE-UNIT RESPONSES TO STIMULUS RISE-TIME AND REPETITION RATE. James F. Willott, Gregory P. Urban* and Allan Shnerson*. Dept. Psychol., Northern Illinois University, DeKalb, IL. 60115.

Various studies have implicated the inferior colliculus (IC) in the acoustic startle response. One might predict, therefore, that some neurons in the IC and the startle behavior would respond in a related manner to various acoustic parameters. To test this prediction, the influence of stimulus repetition rate and rise-time were evaluated at 3 tone frequencies (5,10,&20 kHz) in both behavioral and electrophysiological experiments with inbred C57BL/6J mice.

In behavioral experiments, mice were tested for the startle response using a stabilimeter. At the 3 frequencies used, 80 dB SPL tones (200ms duration) were effective in eliciting the startle; 5ms rise-times were more effective than 20ms rise-times; 1 per sec stimuli were less effective than stimuli presented at variable intervals (VI) of 15-30 sec. Latencies to response onset were typically 10-12ms when stimuli had 5ms rise-times and 15-17ms for 20ms rise-time stimuli.

Multiple-unit activity was recorded in the ventrolateral (central) nucleus of the IC (ICVL) and in the pericentral and external nuclei (ICP-ICX) in 22 tranquilized mice. Responses having latencies sufficiently short to mediate the startle response were analyzed (4-15ms for 5ms rise-times; 4-20ms for 20ms rise-times). Stimulus manipulations similar to those used in behavioral experiments revealed that some populations of neurons were sensitive to rise-time and repetition of 80 dB tones in ways appearing to parallel the startle behavior. Using conservative response criteria 14% of unit clusters in ICVL responded better (more discharges per 10 stimuli) to VI stimuli than to 1/sec stimuli; For clusters in ICP-ICX, 42% responded better to VI stimuli; No clusters responded better to 1/sec stimuli. In ICVL, 5% of clusters responded better to 5ms rise-times than to 20ms rise-times, while 44% of ICP-ICX clusters responded better to 5ms rise-times. In some cases, frequency influenced sensitivity to one or both parameters.

The data indicate that ICVL neurons are considerably less sensitive than ICP-ICX neurons to two acoustic parameters influencing startle behavior. The ICP and/or ICX appear well-suited to mediate the startle response.

40 MORPHOLOGY OF NEURONS AND AXONS IN THE DORSAL NUCLEUS OF THE MEDIAL GENICULATE BODY OF THE CAT: STUDY WITH THE GOLGI METHOD. J. A. Winer and D. K. Morest. Department of Anatomy, University of Connecticut Health Center, Farmington, Connecticut 06032

The dorsal nucleus is one of the largest subdivisions of the medial geniculate body, but its structure and function are much less known than that of the ventral nucleus, which has an input from the inferior colliculus and projects to the primary auditory cortex. The dorsal nucleus receives axons from the midbrain tegmentum and projects to the non-primary auditory cortex. Both nuclei receive cortico-thalamic inputs but differ in their intrinsic structure, as seen in material from cats 6-41 days old impregnated by the rapid Golgi method. The ventral nucleus is layered and contains only disc-shaped principal neurons and Golgi type II cells; in contrast, the dorsal nucleus contains at least four neuronal types (A-D) and six types of axonal endings (1-6), without obvious lamination: (A) is a large principal neuron with a spherical soma and dendritic field, and a recurved axon without collaterals on the initial part; (B) is an irregularly shaped neuron found caudodorsally; (C) is a somewhat elongated cell--the axon bifurcates, one branch ramifying among the parent cell's dendrites, while the other branch arborizes in the adjacent neuropil (it is uncertain if this cell projects beyond the dorsal nucleus); (D) is a small Golgi type II cell, drumstick-shaped, with a small dendritic field usually polarized away from the axon which arborizes repeatedly to form 15-60 branches. The axonal endings consist of (1) thin axons resembling bundles of ivy tendrils with terminal twig-like collaterals; (2) very fine axons, with a relatively straight trajectory, which bifurcate and form short terminal side-branches; (3) axons of the small Golgi type II cell; (4) slender, undulating axons with few branches ending in a burst of claw-like terminals; (5) axons with extensive collateral systems which, running in parallel bundles, ramify at right angles; (6) and axons of type C cells.

The small Golgi type II cells resemble their counterparts in the ventral nucleus but have many more axonal branches; type 1 axons are like certain fibers ascending from the inferior colliculus to the ventral nucleus; type 2 axons correspond to the cortico-geniculate fibers: these findings suggest some parallels in synaptic organization. Superimposed on this common background, the additional types of cells and axons in the dorsal nucleus evince a more complex synaptic organization, perhaps related to more heterogeneous sources of input from the midbrain tegmentum and outputs to the auditory cortex.

Supported by USPHS grants 1 F32 NS05485 and 5 R01 NS14347.

41 TEMPORAL ASPECTS OF RESPONSES OF AUDITORY-NERVE FIBERS TO STEADY-STATE VOWELS. E. D. Young* and M. B. Sachs* (SPON: N. K. Woolf), Dept. of Biomedical Engineering, Johns Hopkins School of Medicine, Baltimore, MD 21205.

To evaluate the way in which features of the spectra of multi-component stimuli are represented in the discharge patterns of auditory-nerve fibers, responses to steady-state synthetic vowels with spectra characteristic of /a/, /ɛ/, /u/, and /I/ were recorded. Large numbers of fibers (as many as 350) were studied in each cat and responses to one vowel were recorded at a number of sound pressure levels. In this way, it was possible to estimate the response of the whole population of auditory-nerve fibers to each vowel. Plots of average discharge rate versus fibers' best frequency showed separate peaks at the resonances in the vowel's spectra (formants) only at low levels (below 60-70 dBSPL) and only for vowels with widely spaced first and second formants. At high levels, the spread of tuning curves, rate saturation, and two-tone suppression combined to eliminate such peaks (Sachs and Young, J. Acoust. Soc. Am. 63, suppl. 1, S76, 1978). Thus there are no direct "place" cues for formant location which survive changes in sound level.

In this paper, we will present data on periodicity-based cues, which are one alternative. The temporal structure of the responses of auditory-nerve fibers to synthetic vowels is largely dominated by the components at the formant frequencies. For example, auditory nerve fibers responding to /a/ are locked to the first formant or second formant, depending upon the fiber's best frequency; the first two formants of this vowel are closely spaced (768 and 1152 Hz.) and separate peaks corresponding to the formants are not seen in rate versus best frequency plots at any sound level. At high sound levels, locking to the first formant predominates at the expense of the higher formants, but even so, there seems to be better representation of the characteristics of the spectra of the vowels in the periodicity information than in the place information.

42 TECTORIAL MEMBRANE AS A POSSIBLE MECHANISM FOR SHARP COCHLEAR FREQUENCY SELECTIVITY AND TWO-TONE SUPPRESSION. J. J. Zwislocki and E. J. Kletsky*. Institute for Sensory Research, Syracuse University, Syracuse, NY 13210.

Recent recordings from cochlear inner hair cells have indicated that the frequency selectivity seen in basilar-membrane (BM) vibration is sharpened mechanically at or distally to the hair cells. Excitation of the hair cells is believed to result from radial deflection of their stereocilia as a result of shear motion between the tectorial membrane (TM) and the reticular lamina (RL) in which the cells are embedded. Since the endolymph in the narrow gap between TM and RL must participate in the shear motion, the mechanism should be effective even if the stereocilia were not attached to TM. We were able to show analytically that the magnitude of the shear motion at any given cochlear location must depend on the mechanical coupling of TM to the organ of Corti and to the spiral limbus as well as on the longitudinal coupling within TM and the wavelength on BM. According to an analytical solution and computer and network simulations, TM is nearly completely entrained by the organ of Corti, and the shear motion practically vanishes, in cochlear regions where the BM waves are long compared to the longitudinal space constant of TM. This is true provided TM mass is negligible and the TM coupling to the spiral limbus is substantially weaker than to the organ of Corti. Around the vibration maximum of BM, where the waves are relatively short, the shear motion is preserved. The model distribution of shear-motion magnitude leads to a dramatic sharpening of frequency selectivity below and above the vibration maximum. The sharpening is sufficient to completely account for the tuning curves found in cochlear-nerve fibers and inner hair cells.

When, in the network simulation, the coupling between the organ of Corti and TM is made to increase with the relative radial displacement between TM and RL, two-tone suppression arises below and above the frequency of the vibration maximum. The frequency location of the two suppression maxima relative to the best excitation frequency is consistent with the available experimental data. The suppression effect is accompanied by strong distortions of the wave form of the shear motion. Whether this distortion is reflected in the BM motion or not must depend on the impedance relationships between BM and TM.

AUTONOMIC FUNCTION

43 BLOCKADE OF HYPOTHALAMIC-INDUCED INHIBITION OF VAGAL BRADYCARDIA BY γ-AMINOBUTYRIC ACID (GABA) ANTAGONISTS. Susan M. Barman, Craig A. Johnston* and Gerard L. Gebber. Dept. of Pharmacol., Michigan State Univ., East Lansing, MI 48824.

Gebber and Snyder (Am. J. Physiol. 218: 124, 1970) have previously demonstrated that baroreceptor induced vagal bradycardia is inhibited upon electrical stimulation of the lateral hypothalamus. The present study describes the effects of the GABA antagonists, bicuculline and picrotoxin, on this phenomenon. Experiments were performed on unanesthetized, high spinal (C_1 transected) cats which were artificially respired and paralyzed with decamethonium. Phenylephrine was infused intravenously (10-20 µg/min) to maintain blood pressure at a level (>100 mmHg) sufficient to reflexly activate the cardiac vagus. Stimulation (15 v; 1 msec; 5-50 Hz) of the lateral hypothalamus (A9, L2, HO to H-4) increased heart rate under these conditions. This effect can be attributed solely to inhibition of vagal bradycardia. The increase in heart rate produced by hypothalamic stimulation was blocked in a dose-related fashion by bicuculline (0.5-2 mg/kg, i.v.) or by picrotoxin (0.5-2 mg/kg, i.v.). Blockade of hypothalamic-induced effects was accompanied by a statistically significant decrease in basal heart rate. Bicuculline or picrotoxin also blocked the increase in heart rate produced by stimulation of the medullary reticular formation in high spinal cats which were decerebrated at the midcollicular level. Basal heart rate was not changed in these experiments. In contrast to the effects produced by the GABA antagonists, convulsive doses of strychnine (0.1-0.7 mg/kg, i.v.) or pentylenetetrazol (5-50 mg/kg, i.v.) failed to influence inhibition of vagal bradycardia produced by hypothalamic stimulation. These results indicate that the inhibitory effect of hypothalamic stimulation on vagal bradycardia is blocked in the brain stem by agents which interfere with GABAergic transmission. Moreover, the ability of bicuculline and picrotoxin to lower basal heart rate in high spinal cats which were not decerebrated suggests that the hypothalamic inhibitory system is tonically active. (Supported by PHS Grant HL13187.)

44 A SPINAL SYMPATHO-INHIBITORY ACTION OF CHLORPROMAZINE IN THE CAT. Patricia J. Bernthal* and Michael C. Koss. Dept. Pharmacology, Univ. Okla. Health Sciences Center, Oklahoma City, Oklahoma 73190

Chlorpromazine (CPZ) has been shown to depress several autonomic systems (Schallek & Zabransky, Arch. int. Pharm. Ther., 1966, 161, 126; Sigg et al., Neuropharmacology, 1971, 10, 621), probably by a central mode of action (Wang et al., J. Pharmacol. Exp. Therap., 1964, 144, 186). We have reported that CPZ has a dose-dependent inhibitory action on the sympathetic-cholinergic electrodermal response (EDR) evoked by either central brainstem (Davison & Koss, Neuropharmacology, 1976, 15, 197) or reflex (Bernthal & Koss, Neuroscience Abstr., 1977, 3, 17) stimulation. An observed lack of effect of CPZ on the peripherally evoked EDR (Davison & Koss, 1976) supports a central site of action of this agent. The present studies were undertaken to investigate the possibility that CPZ acts at the level of the spinal cord. Six cats were anesthetized with 36 mg/kg pentobarbital. After the cats were paralyzed with gallamine and artificially respired, the spinal cord was cut at the level of C_1. CPZ (0.03, 0.10, 0.30, 1.0, 3.0 mg/kg, cumulative doses) was administered intravenously while eliciting EDRs by stimulating the spinal cord at the level of C_3 with a submaximal frequency. CPZ depressed the electrodermal response in a dose-dependent fashion. The mean ED_{50} was approximately 0.1 mg/kg. This same dose had no effect in four cats when the EDR was elicited by stimulating the sympathetic preganglionic fibers which innervate the sweat glands. The present results suggest that CPZ acts at the level of the spinal cord to depress centrally evoked sympathetic responses. 45 ANATOMICAL, PHYSIOLOGICAL AND BEHAVIORAL EVIDENCE FOR MEDULLARY RAPHE INHIBITION OF SYMPATHETIC PREGANGLIONIC NEURONS. J.B. Cabot, J.M. Wild*, D.H. Cohen, Dept. Physiol., Univ. of Virginia School of Medicine, Charlottesville, VA 22901.

A series of studies on the pigeon (Columba livia) has established a direct influence of the medullary raphe on sympathetic preganglionic neurons (SPNs) and demonstrated the importance of this pathway in the requlation of cardiovascular function.

First, the following anatomical results documented an avian raphe-spinal system that includes a direct projection upon the SPNs: (a) dense labelling of raphe neurons throughout their rostrocaudal medullary extent after injections of horseradish peroxidase in brachial, thoracic and lumbar spinal cord, (b) the presence of silver grains overlying SPNs subsequent to ^{3}H-proline injections in the medullary raphe, and (c) light degeneration within the sympathetic preganglionic cell column after lesions of the raphe.

Second, electrophysiological experiments indicated that stimulation of the rostroventral medullary raphe inhibits the discharge of SPNs which were identified by antidromic activation and collision. The inhibition begins within 10 msec of stimulus onset, is maximal by 30 msec, and shows temporal summation. On the basis of such evidence, the conduction velocity of this pathway is conservatively estimated at 4-12 m/sec. More direct estimates of conduction velocity were obtained in experiments where the sympathetic preganglionic cell column was stimulated to antidromically activate raphe neurons; these neurons also satisfied the collision criterion. All identified neurons to date have been localized to the ventral division of the medullary raphe. Raphe-spinal axons in these studies conducted at 6-23 m/sec.

Third, physiological and behavioral experiments indicated the importance of this system in cardiovascular control. Electrical stimulation of the rostroventral medullary raphe elicited significant depressor responses, with systolic and diastolic pressures decreasing 20.5±0.85 (mean±S.E.) and 28.1±1.19 mmHg respectively; response latency was 0.86±0.07 sec. The behavioral effects of raphe lesions were then assessed in a classical conditioning paradigm which reliably produces conditioned cardioacceleration and in a control sensitization paradigm. The raphe lesions markedly enhanced cardioacceleratory responses in both conditioning and sensitization paradigms, suggesting that interruption of the inhibitory raphe projection to the SPNs compromised an important pathway for limiting cardioacceleration in response to exteroceptive stimulation.

46 THE ROLE OF CENTRAL ADRENERGIC PATHWAYS IN THE CONTROL OF ARTERIAL PRESSURE IN NORMOTENSIVE RATS.

Luiz A.A. Camargo*, Wilson A. Saad, José A.C. Machado*, Gildo N.A. Rodrigues* and Vanderley J. Menani*. Dept. Physiol., Sch. Dent., UNESP, Araraquara, SP, Brazil, 14.800.

In studies of central regulation of arterial pressure related to cardiovascular effects, several areas were stimulated with adrenergic and adrenolytic substances, and dual responses, both hypertensive and hypotensive, were observed (De Jong et al, 1975). The hypothalamus has been studied by several investigators, and has been found to play an important role in the central regulation of arterial pressure. An important question revolves around the relationship between the hypothalamic structures and their α and β adrenergic receptors in the regulation of arterial pressure. The following experimental conditions were used to study the participation of hypothalamic α and β adrenergic receptors in this regulation. Rats with cannulae implanted into the hypothalamus were injected with 20 nmol noradrenaline, alone, or preceded by administration of phentolamine and propranolol in a 3- fold molar relationship in respect to noradrenaline (60 nmol).

Adrenergic stimulation of the middle hypothalamus showed two types of distinct responses: hypertension induced by noradrenaline (Mean of 18 rats= 35 mmHg, SE ± 7 from a baseline of 90 mmHg) and blocked by the β -adrenolytic agent propranolol, but not by the α -adrenolytic agent phentolamine, the other response was hypotensive (Mean of 16 rats= 31 mmHg, SE ± 5 from a baseline of 98 mmHg), and blocked by phentolamine.

These results lead us to postulate the existance of two adrenergic centers in the middle hypothalamus participating in the control of arterial pressure, the α pathway controlling hypotension and the β pathway controlling hypertension. In the lateral hypothalamic area, instead, hypertension would be determined by α receptors (Mean of 16 rats= 32 mmHg, SE ± 6 from a baseline of 102 mmHg), and hypotension by β receptors (Mean of 20 rats= 41 mmHg, SE ± 8 from a baseline of 95 mmHg).

47 CLONIDINE-INDUCED HYPOTENSION AND BRADYCARDIA IN CATS: THE ROLE OF MEDIAL MEDULLARY RETICULAR α-ADRENOCEPTORS AND VAGUS NERVE. Yih Huey Chen and Samuel H.H. Chan. Dept. Life Sci., Indiana State Univ., Terre Haute, IN 47809.

Clonidine-induced hypotension and bradycardia have been attributed to its activation of postsynaptic α-adrenoceptors in the medulla, resulting in a modification of the autonomic cardiovascular outflows. Based on microinjection and lesion experiments, Chan and Koo (Neuropharmacol., in press) have recently identified in the rat that the medial medullary reticular formation (MMRF) may be a critical bulbar site that is related to such clonidine actions. The present study further investigates the roles played by the α-adrenoceptors in the MMRF and vagus nerve in the clonidine-elicited cardiovascular effects.

Cats (2-4 kg) lightly anesthetized with pentobarbital sodium (35 mg/kg, i.p.) were used in the present study. Tracheotomy, cannulation of left carotid artery and left femoral vein were routinely performed for the facilitation of ventilation, measurement of arterial blood pressure and injection of drugs. The animal was thereafter paralyzed with Flaxedil (4 mg/kg, i.v.) and artificially respired. The head of the animal was placed on a stereotaxic apparatus followed by an appropriate craniotomy and tentoriotomy. Local injection was administered by means of a 27-gauge syringe needle which is connected to a microinjection-device. EKG was recorded for the determination of heart rate.

Intravenous injection of clonidine (10 μg/kg) produced an initial, transient rise in arterial blood pressure, followed by a prolonged hypotension lasting 35 min. Significant bradycardia was also observed for 60 min postinjection. In animals pretreated with haloperidol, an α-adrenoceptor blocking agent, which was microinjected (10 μg/kg, 1 μl) into the bilateral MMRF, systemic injection of clonidine (10 μg/kg) could only elicite the initial vasopression with no vasodepression and bradycardia, implicating the presence and participation of α-adrenoceptors in this brain stem area in the central action of clonidine. In cats receiving bilateral vagotomy, the injection of clonidine at the same dose again induced only the initial hypertension without subsequent hypotension and bradycardia, indicating that the vagus nerve is also involved in the control of the latter cardiovascular events.

It is concluded that clonidine may excite the neurons in the MMRF by activating the α-adrenoceptors, which in turn facilitate the vagal outflow to the heart, resulting in clonidine-induced hypotension and bradycardia.

(We acknowledge the generous supply of clonidine HCl from Boehringer Ingelheim and haloperidol from Janssen Pharmaceutica used in the present study.)

48 A MORPHOLOGICAL STUDY OF THE CANINE AREA POSTREMA AND ADJACENT MEDULLA. C.L. Chernicky,* K.L. Barnes, J.P. Conomy, and C.M. Ferrario. Division of Research and Dept. of Neurology, Cleveland Clinic Foundation, Cleveland, Ohio, 44106.

Sustained arterial pressor responses can be elicited by either electrical stimulation or delivery of angiotensin into the canine area postrema (AP), implying a function in cardiovascular control for this structure. Conversely, electrical stimulation of the solitary tract nucleus (NTS) immediately ventrolateral to the AP evokes depressor responses. The anatomic proximity of these two structures suggests the possibility of functional interaction between them. Since anatomic study of the canine AP has been relatively neglected in comparison to studies of its function, we have undertaken a morphological study of the dog's area postrema.

Successful Golgi impregnations of the brainstem were achieved on 8 adult mongrel dogs according to the methods of Ramon-Moliner (Stain Technol. 33: 19, 1958; Stain Technol. 39: 65, 1964). Sections were cut serially at 50-150μ in the coronal, sagittal, or horizontal plane. For orientation purposes alternate sections were counterstained with cresyl violet. The Bodian silver technique (Bodian, Anat. Rec. 65: 89, 1936), counterstained with cresyl violet, was done on 10μ serial sections to demonstrate axonal elements and Nissl substance. Compared to other structures in the dog brainstem, the AP is rather sparsely populated with neurons. In Golgi sections the architecture of the canine AP can be subdivided into 3 regions: the periventricular mantle zone, an intermediate medullary layer, and a junctional region at the boundary between AP and NTS. In the mantle layer some of the neuronal cell bodies are located at the ventricular surface, while others slightly more ventral have dendrites which appose the ventricular surface. These complex stellate cells adjacent to the ventricular surface appear to be unique to the canine AP. The mantle zone also contains glialoid cells, whose neural or glial character cannot be determined from Golgi preparations. In the intermediate medullary region small stellate cells extend short processes to the mantle and junctional layers. Small neurons which are abundant in the junctional zone have delicate processes extending dorsally into the intermediate medullary layer and ventrally to the NTS. In addition the dog AP contains modified ependyma, glialoid cells, a network of fine axons, and densely packed capillaries.

Previous studies from this laboratory have indicated that the AP pressor response is mediated by a neural mechanism originating within the AP. The architecture of the canine AP described in this study provides support for the existence of such a neural pathway. Supported by grants from NIH, HL-6635; American Heart, #76 646; and the Reinberger Foundation.

49 EFFECTS OF UNCARINE A, CLONIDINE AND 5-(4'-CHLORO) BUTYLPICOLINIC ACID (FD 008) ON BLOOD PRESSURE AND SYMPATHETIC ACTIVITY IN UNANESTHETIZED SPONTANEOUSLY HYPERTENSIVE RATS. C.C. Chiueh, S.M. Nespor* and C.C. Chang.* Geron. Res. Ctr., NIA, Balto. City Hos., Balto., Md. 21224 and Pharmacol. Inst., Col. Human Med., Natl. Taiwan Univ., Taipei, Taiwan

Chronic indwelling tail arterial cannulae (Chiueh and Kopin, J. Pharmacol. Exp. Ther. 205: 148, 1978) were used for monitoring of blood pressure and withdrawal of blood samples from the conscious, spontaneously hypertensive (SHR) rats. Arterial blood samples (0.5 ml) were taken before and after administration of uncarine A, an alkaloid obtained from Uncaria formosana and Uncaria rhynchophylla which have been used in Chinese herbal medicine, clonidine, or FD 008 and assayed radioenzymatically for plasma norepinephrine (NE) and epinephrine (EPI). The plasma levels of catecholamines are found to be a good index of the sympathetic medullary activity in SHR rats (Chiueh, et al., Neuroscience Abstract 3: 18, 1977). As it had been previously shown, both clonidine (10 - 40 μg/kg) and FD 008 (10 - 100 mg/kg) effectively decreased systolic and diastolic blood pressure in the conscious SHR rats. Uncarine A (2 - 40 mg/kg) produced a long-lasting hypotensive effect in SHR rats but not in normotensive control rats. The hypotensive effect of uncarine A lasted for 20 - 48 hr after a single administration of this drug not only in SHR rats but also in renal hypertensive rats. The central inhibitory effect of clonidine on sympathetic tone was supported by the observation of a decrease in plasma levels of NE (0.61 ±0.08 - 0.32 ±0.06 ng/ml) and heart rate (325 ±17 - 265 ±26 beats/min) after intraventricular administration of this agent (5 μg). FD 008 (100 mg/kg) caused an increase in heart rate (340 ±12 - 488 ±8 beats/min) and a concomitant increase in plasma levels of NE (0.64 ±0.09 - 3.91 ±0.38 ng/ml), EPI (0.49 ±0.05 - 9.10 ±1.14 ng/ml) and dopamine (0.08 ± 0.02 - 0.30 ±0.03 ng/ml). Thus, the notion that the hypotensive effect of FD 008 is attributable to the decrease in NE release from the sympathetic nerve needs to be reconsidered. After 2 mg/kg of uncarine A, the blood pressure of SHR (174 ± 10/158 ± 10 mmHg) decreased to normotensive range (131 ± 10/118 ± 11 mmHg) without significant effect on heart ratesor plasma catecholamines. A high dose of uncarine A, 40 mg/kg, decreased the blood pressure to less than 100 mmHg and hence increased heart rates slightly to 380 ± 15 beats/min and plasma levels of NE and EPI to 1.41 ± 0.04 and 2.99 ± 0.98 ng/ml, respectively. The hypotensive mechanism of uncarine A should be studied further since the present results rationalize the use of Uncaria genus for the treatment of essential hypertension in Chinese herbal medicine.

50 PARAVENTRICULAR AND SUPRAOPTIC, HYPOTHALAMIC NUCLEI: WHAT ARE THEIR ROLES IN CENTRAL REGULATION OF HEART RATE? J. Ciriello and F. R. Calaresu, Dept. of Physiology, Univ. of Western Ontario, London, Canada N6A 5C1.

Recent anatomical studies have demonstrated that the paraventricular nucleus (PAH) projects directly to "cardiovascular" sites in the medulla (Brain Res. 117: 305, 1976) and receives a direct projection from the nucleus tractus solitarius (NTS) (Anat. Rec. 187: 693, 1977). In addition, units in the supraoptic nucleus (SON) have been shown to alter their discharge rate during selective excitation of baro- and chemoreceptors (Brain Res. 126: 551, 1977). To investigate the role of these hypothalamic nuclei in the regulation of heart rate, three series of experiments were done in chloralosed, paralyzed and artificially ventilated cats. In the first series, the response of 185 units in the PAH and the SON to electrical stimulation of the carotid sinus nerve (CSN) was recorded. The firing frequency of 57% (106/185) of these units was altered: 48 were excited (mean latency, 27 ± 2 ms), 40 responded with excitation (mean latency, 31 ± 2 ms) followed by inhibition, and 18 were inhibited (mean latency, 72 ± 11 ms). In the second series, histologically verified sites in PAH and SON were stimulated (80 Hz, 0.2 ms, 50-150 μA) and were shown to elicit marked increases in heart rate. The response to stimulation of the SON was due to vagal inhibition, as it could be elicited in cats with spinal transection at C2 and was abolished by either the administration of atropine or bilateral vagotomy in these spinal animals. On the other hand, the response to stimulation of the PAH was shown to be due to both vagal inhibition and sympathetic excitation, as the response could be elicited in either spinal cats or in bilaterally vagotomized animals. In the final series, to investigate the effect of stimulation of PAH and SON on the bradycardia elicited by stimulation of the CSN, NTS, nucleus ambiguus (AMB) and external cuneate nucleus (ECN), the PAH or SON was stimulated simultaneously with one of these structures in spinal animals. Electrical stimulation of either the PAH or SON abolished the reflex vagal bradycardia to stimulation of either the ipsilateral or contralateral CSN. However, stimulation of these hypothalamic nuclei did not significantly alter the magnitude of the bradycardia elicited by stimulation of either the ipsilateral or contralateral NTS, AMB and ECN. These results indicate that the PAH and SON are hypothalamic areas which a) receive inputs from cardiovascular afferents, b) play an important role in the integration of cardiovascular reflexes, c) exert inhibitory effects on reflex vagal bradycardia through crossed and uncrossed descending pathways, and d) receive information from the cardiovascular system which may be integrated to produce responses concerned with homeostasis of body fluids. (Supported by MRC of Canada)

51 REGIONAL CEREBRAL BLOOD FLOW IN MIGRAINE SUBJECTS DURING SELF-REGULATION OF SKIN TEMPERATURE. James L. Claghorn, Roy J. Mathew*, John W. Largen*, Ken Dobbins*, John S. Meyer*. TRIMS, Houston, Tx. 77030

A study was undertaken to determine the effect of biofeedback induced skin temperature changes on migraine headache activity and regional cerebral blood flow. The results of earlier studies suggest that the biofeedback technique maybe effective in significantly reducing the frequency, intensity, and duration of migraine attacks. A typical classic migraine attack is characterized by a biphasic pattern of vasomotor behavior. The prodrome stage involves the reduction of intracranial blood flow followed by a reactive dilatation of the intracranial and extracranial arteries. It has been hypothesized that hand-warming through biofeedback training may result in a decrease in sympathetic outflow, thereby, interrupting the vasomotor pattern of change in a migraine headache.

Earlier research in our own laboratory, utilizing normal subjects, indicated that the mean cerebral blood flow for both "hand-warming" and "hand-cooling" groups tended to remain unchanged or shift in similar directions though the subjects self-regulated their skin temperature in significantly opposite directions. The present study was undertaken to determine if a similar pattern held true of migraineurs as well.

Twelve right-handed female volunteers, aged 27-52, were selected on the basis of the following characteristics: manifesting either classic or common migraine and having a minimum of two migraine attacks per month. Each volunteer was randomly assigned to either a hand-warming or a hand-cooling temperature biofeedback group and given extensive training in skin temperature self-regulation in a series of 12-15 sessions.

Each of the migraine subjects were subsequently given two measures of regional cerebral blood flow (rCBF) utilizing the non-invasive ^{133}Xe inhalation technique. One rCBF run was given during a relaxation/steady-state condition and a second while subjects were attempting to manipulate their skin temperature in the trained direction.

Extensive records of headache activity were made pre-, during, and post-training. Data will be presented comparing regional intracerebral and extracerebral blood flow measures between relaxation/steady-state and skin temperature self-regulation runs. Comparisons between hand-cooling and hand-warming groups will be made as well as correlations between migraine headache activity, skin temperature control and changes in regional cerebral blood flow.

52 CENTRAL BLOOD PRESSURE REGULATION : POSSIBLE ROLE OF OPIOIDS. Bernard DELBARRE, Danielle SENON*, Monique DUFRAISSE*, Monique DUPONT*. Lab.Chir.Exp.,Fac.Méd. 37032 TOURS CEDEX, FRANCE.

Previous work suggests that cAMP and drugs known to change adenylate-cyclase activity may be involved in the central blood pressure (BP) regulation (SENON, Thesis Poitiers 609, 1976). The possibility that cyclic AMP and cyclic GMP may interact with opioids and prostaglandins is suggested by numerous reports.

In this regard we have investigated the action of these drugs in chloralose-anesthetized (AN) and unanesthetized (UN) cats.
Injection of morphine (20 $\mu g.kg^{-1}$), in the third ventricle of UN cats, induces excitation and a short lasting increase of BP. The same dose of methionine-enkephalin, a pentapeptide which exert analgesic action by interacting with naturally occuring "opiate receptors" induces an increase of BP, and an important raise of heart rate (HR), in the unrestrained cats, but this drug, at the same dose, is ineffective in the third ventricle of AN cats.
A more stable D.alanine derivative of Met.Enkephalin namely D.Ala Met.Enkephalin, at a dose of 20 $\mu g.kg^{-1}$ increases BP, HR and produces important respiratory disturbs ten minutes after its administration in the IIIe ventricle of AN cats.
In the AN cats, PGE_1, at the doses of 2 $\mu g.kg^{-1}$ and 100 $\mu g.kg^{-1}$, induces hypotension, and for the highest dose, a simultaneous raise of HR and respiratory rate.
PGF_2 (1 $\mu g.kg^{-1}$) and arachidonic acid (100 $\mu g.kg^{-1}$) are ineffective on the BP. Baclofen, a structural derivative of GABA, induces a fall of BP, HR and evokes Mayer waves twenty minutes after administration of 20 $\mu g.kg^{-1}$ in AN cats.
Substance P may have dual action in brain, releasing endorphines at very low doses and directly exciting neuronal activity in nociceptive pathways at higher doses (R.C. FREDERICKSON and al., Science 199, 1359, 1978). Injection of 1 $\mu g.kg^{-1}$ of this drug in the third ventricle of UN cats induces a slight increase of BP, and no significative modification of HR, while in AN cats, Substance P (10 $\mu g.kg^{-1}$) produces no significative increase of BP and HR.

PGE_1 and baclofen induce an hypotension. PGE_1 does not affect the synthesis of cAMP (HAVEMANN and al., Naunyn Schmied.Arch. Pharmacol., 302, 103-106, 1978). The analgesic activity of baclofen is different from that of morphine since baclofen analgesia is not antagonized by naloxone (LEVY and PROUDFIT, J.P.E.T., 202, 437, 1977). Morphine and enkephalin as cAMP increase BP and HR. It is known that these drugs induce an increase of cAMP synthesis. These findings add further support to the hypothesis that cAMP may participate in the modulation of central blood pressure regulation.

53 CHANGES IN HIPPOCAMPAL RHYTHMIC SLOW ACTIVITY DURING INSTRUMENTAL CARDIOVASCULAR CONDITIONING IN THE RHESUS MONKEY. Bernard T. Engel*, and J. A. Joseph. NIA, Gerontology Research Center, Baltimore, MD 21224.

Analyses among 4-8Hz electrical activity of the hippocampus (theta, T), heart rate (HR), systolic (S) and diastolic (D) blood pressure and gross bodily movement (M) were carried out during experiments in which three monkeys were operantly conditioned to slow HR, to speed HR or during control periods. Each experiment consisted of a 512 sec. baseline during which all responses were continuously monitored (except M which was time-sampled), and a 2048 sec. performance session during which HR speeding was signaled by a green light, HR slowing by a red light. Correct performance was signaled by a white light, and incorrect performance was negatively reinforced by a 10 ma., .05 sec. shock to the tail on an FI, 8 sec. schedule. Control periods were unsignaled and unreinforced. Each experimental period was divided in 16, 128 sec. blocks and 20 samples were taken from each period as follows: speeding, blocks in which the animal increased HR >4 beats/min from the previous block; and blocks in which the animal speeded less than 4 beats/min from the previous block; slowing in which the animal decreased HR >4 beats/min; and in which the animal decreased HR <4 beats/ min. Equal numbers of blocks were taken from control sessions to match each set of experimental samples. Correlational analyses (Kendall's coefficient of concordance, W; Spearman's rank order correlation, R) showed that there was a high degree of consistency among animals in each response measure across experimental conditions (Ws: HR=.98, S=.92, D=.92, T=.61, M=.81). T was inversely related to each of the other measures during contingent HR slowing when decreases >4 beats/min were examined--i.e., T increased between blocks--but was positively related to the other measures during control periods when HR decreased >4 beats/ min. T also was positively correlated to the other measures during contingent and non-contingent speeding. For example, while HR and M are always highly correlated (R=.87 for all animals) correlations between HR and T and M are significantly increased if the contingent slow condition >4 beats/min is removed (e.g., monkey HR T with slow R=.57, without R=.89 TM R=.45, R=.91 respectively). These results suggest that T reflects both motor and success/failure related components. During contingent speeding the success/failure correlation is masked by the concomitant motor activity, however, during contingency slowing this correlation is revealed because motor activity is reduced while T is increased.

54 A NEW ASCENDING SPINAL CARDIOVASCULAR PATHWAY. A. I. Faden and T. P. Jacobs*, Dept. of Medical Neurosciences, Walter Reed Army Institute of Research, Washington, DC 20012.

Previous work in this laboratory has demonstrated that increases in blood pressure, heart rate and cardiac contractility may be seen after electrical stimulation of the zona intermedia in the lower thoracic and upper lumbar cat spinal cord and that sites of maximal cardiovascular response (SMCR) can be histologically localized to the intermediolateral nucleus (ILN) (Faden et al, Exp. Neurol. in press; Faden and Woods, Neurology 28:322, 1978). On the other hand, evidence from peripheral nerve stimulation has shown that inotropic and chronotropic responses can only be elicited from the first five thoracic ventral roots. One hypothesis which reconciles the findings from peripheral and central nervous system stimulation is that axons of preganglionic sympathetic neurons may traverse long distances intraspinally before exiting through distant ventral roots. That the changes in heart rate and cardiac contractility are mediated through an ascending intraspinal pathway was shown by making spinal cord transections or hemisections two to four segments rostral to a lower thoracic or upper lumbar SMCR. Such lesions completely blocked the chronotropic and inotropic responses elicited from these more caudal segments. In order to localize this pathway, after SMCR had been identified in the lower thoracic region a second SMCR was located ipsilaterally two or three segments rostrally. Just lateral to this rostral site a progressively enlarging electrolytic lesion was made until the cardioacceleratory response from the more caudal site had been markedly reduced or abolished. The location of the rostral electrode was chosen to correspond to Bok's intermediolateral fasciculus. In two animals the rostral lesions completely blocked the cardioacceleratory response and these lesions involved the white matter immediately adjacent to the ILN. Two other lesions resulted in a marked reduction but not ablation of the cardioacceleratory response; interestingly these lesions spared small areas of white matter adjacent to the ILN. In all animals the superficial white matter of the dorsolateral funiculus as well as the region of the apex of the dorsal horn were spared. These findings suggest the existence of an ascending intraspinal cardiovascular pathway which is located in the deep white matter adjoining the ILN. The recent anatomic demonstration of an intraspinal sympathetic preganglionic pathway (ISPP) (Faden and Petras, Brain Res. 144: 358-362, 1978) with a suspected localization corresponding to that of the cardiovascular pathway described in these experiments, strongly suggests that the ascending cardiovascular pathway and the ISPP are the same.

55 LOCALIZATION OF CARDIAC VAGAL PREGANGLIONIC SOMA. G. Steven Geis and Robert D. Wurster. Department of Physiology, Loyola University of Chicago, Stritch School of Medicine, Maywood, Illinois 60153.

Horseradish peroxidase (HRP) was injected subepicardially in anesthetized cats for retrograde labeling of cardiac vagal preganglionic soma. The injections were made in 3 groups of animals: (1) after left cervical vagotomy (LCV), (2) after right cervical vagotomy (RCV) and (3) after combined left cervical vagotomy and section of the right cranial and caudal cardiac vagal branches (LCV-CCX). After a 48 hr survival period the cats were reanesthetized, perfused and fixed. The brain stems were removed, cut in 40 µm serial cross-sections and developed with 3,3'-diaminobenzidine tetrahydrochloride.

Approximately 350 labeled soma were identified in brain stems of cats with LCV and RCV. Distribution and morphological characteristics of the cell bodies were common among the animals. The soma were ipsilateral to the intact vagus, extending 2.8 mm caudal and 4.8 mm rostral to the obex. Distinct aggregations of cell bodies were apparent in the nucleus ambiguus (NA), the dorsal motor nucleus of the vagus (DMNX) and an intermediate zone (IZ) between the NA and DMNX. In each animal about 78% of the soma were in the NA while 17% and 5% were located in the DMNX and IZ, respectively. Approximately 72% were fusiform and 28% were round in shape. Fusiform soma had an average long axis of 28.27 µm and an average short axis of 16.96 µm. The round cell bodies demonstrated a diameter of 22.29 µm. About 27 soma were labeled in each LCV-CCX cat. It is therefore concluded that 6.7% of the identified cells in LCV and RCV animals were associated with non-cardiac tissue or the result of HRP uptake by axons traveling to the heart by vagal branches other than the cranial and caudal cardiac vagal branches.

The data demonstrate the presence of cardiac vagal preganglionic soma in the NA, DMNX and IZ. The cell bodies are predominately fusiform in shape and give rise to axons exiting the ipsilateral brain stem. The separate populations of labeled cells suggest the possibility that different cardiac vagal nuclei modulate different myocardial functions. (Supported by NIH grant HL08682.)

56 EFFECTS OF DIENCEPHALIC AND BRAINSTEM LESIONS ON HAEMOPOIETIC STEM CELLS

N.R. Hall, J.K. Lewis*, R.D. Schimpff, R.T. Smith*, A.M. Trescot*, H.E. Gray, S.E. Wenzel*, W.C. Abraham and S.F. Zornetzer

Division of Tumor Biology, Department of Pathology, University of Florida College of Medicine, Gainesville, FL 32610

A functional axis between the central nervous system and bone marrow has been postulated based upon several types of evidence. Haemopoietic cells possess receptors for certain neurotransmitter substances, nerve endings not associated with blood vessels are present in bone marrow and haemopoietic cells exhibit a light responsive circadian rhythm. To test for the existence of a brain-bone marrow axis, C57BL/6J and Swiss Webster mice received bilateral electrolytic lesions (300 µA anodal current for ten seconds) of the anterior hypothalamus, posterior hypothalamus, locus coeruleus or cerebellum. A standard in vivo technique was used to assess the number of haemopoietic stem cells. Six weeks after lesioning, the animals were exposed to a sub-lethal dose of radiation which stimulated the formation of colony forming units on the surface of the spleen (CFU-S). Only those subjects that had received locus coeruleus lesions had significantly reduced numbers of CFU-S when compared with control values. Macro-autoradiography following the injection of Fe^{59} revealed many of these colonies to be erythrocytic. An in vitro clonal assay was used to assess the number of granulocytic progenitor cells. Bone marrow cells seeded into either soft agar or methyl cellulose produced significantly reduced numbers of granulocyte macrophage colonies (GM-CFC) when the donor animals had received locus coeruleus lesions. This reduction was more pronounced in animals with bilateral lesions than in animals with unilateral lesions. Preliminary evidence suggests that this effect can be reversed by administering amphetamines. Animals with locus coeruleus lesions were also found to have lower peripheral blood white cell counts when compared with controls, however, the lesions had no effect on the differential cell count. Haemaglutinating antibody titers five days after the injection of sheep red blood cells were not affected by the locus coeruleus lesions.

These data suggest an interaction between the nucleus locus coeruleus and haemopoietic stem cells in the bone marrow. The mechanism by which this interaction is able to occur is currently under investigation.

57 PUTATIVE SHORT-LATENCY BAROSENSORY CIRCUIT LINKING THE BARORECEPTORS, CAUDAL DIENCEPHALON, AND DORSAL VAGAL NUCLEUS IN RABBITS. ROBERT B. HAMILTON, JEFFREY H. WALLACH, GUY K. PETRIK,* AND NEIL SCHNEIDERMAN. Dept. of Psychology, Univ. of Miami, Coral Gables, Florida 33124.

Electrical stimulation (10 sec trains, 100 pulses/sec, 0.5 msec pulse duration, <180 µA) of specific areas within anterior hypothalamus, lateral hypothalamus, rostral zona incerta (at the thalamus-hypothalamic border), and lateral zona incerta of the subthalamic region in barbiturate anesthetized rabbits elicited primary bradycardia (M= -119 bpm; SD= ±10) accompanied by only a small decrease in mean arterial pressure (M= -6.0mm Hg; SD= ±8.3). These responses were abolished by bilateral vagotomy, but were not significantly attenuated by unilateral section. Single-pulse aortic nerve (AN) stimulation (pulse duration 0.1 msec) activated neurons, thereby defined as barosensory-sensitive, in the above areas. Electrical stimulation (10 sec train duration, 100 pulses/sec, 0.1 msec pulse duration < 35 µA) was used to identify the cardioinhibitory region of the dorsal vagal nucleus (DVN) of the medulla. Single-pulse stimulation of this region activated units in the rostral and lateral zona incerta at latencies under 10 msec. These same units were also activated by single-pulse AN stimulation at latencies as short as 4 msec. Stimulation of bradycardia-sensitive sites in the rostral and lateral zona incerta in the same region where barosensory-sensitive units were found, resulted in the activation of neurons in the bradycardia-sensitive area of DVN, which were also activated by AN stimulation. Mean onset latency of the response of these DVN units to zona incerta stimulation was 6 msec (SD= ±1 msec) (Kaufman, Hamilton, Wallach, Petrik, & Schneiderman, in preparation).

The present data suggest that the time period for barosensory information to reach the caudal diencephalon, and for information from this region to project back to the cardioinhibitory region of DVN may be as short as 15 msec or less. Our findings are also consistent with the possibility that a feedback circuit may exist linking the cardioinhibitory region of DVN with the zona incerta (Supported by NSF Grant BMS 75-10967 and by grants from the Heart Association of Greater Miami and Florida Heart Association).

58 INTRACELLULAR RECORDINGS FROM THE INFERIOR MESENTERIC GANGLION OF THE CAT. Yvon Julé* and Joseph H. Szurszewski. Dept. Physiol. & Biophysics, Mayo Med. Sch., Rochester, MN 55901.

Intracellular, in vitro recordings have been obtained from more than 200 cells of the inferior mesenteric ganglion (IMG) of the cat. Two types of cells were impaled: inexcitable and excitable cells. Ten percent of the cells impaled were inexcitable cells. They had a high resting membrane potential (up to 75 mV) and they never produced an action potential either to direct intracellular depolarizing current or to preganglionic nerve stimulation. In these cells, repetitive stimulation of a preganglionic nerve trunk gave rise to a slow depolarization which was frequency dependent. The inexcitable cells found in this study have properties in common with glial cells of the central nervous system. Ninety percent of the cells impaled were excitable cells. They received excitatory synaptic input from preganglionic nerve fibers and produced action potentials in response to a direct intracellular depolarizing current. Their resting membrane potential ranged from -45 to -85 mV (mean -56 mV), their input resistance ranged from 20 - 280 MΩ (mean 80 MΩ) and the membrane time constant ranged from 2 - 12 msec (mean 8 msec). Action potentials in these cells often had an overshoot of 10 to 25 mV. An afterhyperpolarization up to 20 mV and lasting 150 - 300 msec followed each action potential. In 50% of the excitable cells tested long intracellular depolarizing pulses (up to 1 sec) triggered a phasic discharge of action potentials; in 40% of the cells there was a tonic discharge. The excitable cells have properties in common with principal ganglion cells found in prevertebral ganglia of the guinea pig. Excitatory synaptic input was recorded from principal ganglion cells in response to stimulation of hypogastric, intermesenteric, inferior splanchnic and colonic nerves. More than 55% of ganglion cells received input from all extrinsic nerves. This suggests that marked convergence of central input and peripheral input occurs on ganglion cells in the IMG of the cat. (Supported by NIH Grant AM 17632.)

59 METABOLIC MAPPING OF NEURAL PATHWAYS INVOLVED IN GASTROSECRETORY RESPONSE TO INSULIN HYPOGLYCEMIA. Massako Kadekaro, Helen E. Savaki* and Louis Sokoloff. Lab. of Cerebral Metabolism, NIMH, Bethesda, MD 20014.

It has been known since 1927 that hypoglycemia induced by insulin increases gastric secretion. This response is mediated by the central nervous system inasmuch as vagotomy completely prevents its occurrence. Little is known, however, about the neural pathways involved in this response. The objective of the present studies was to attempt to identify these neural pathways by means of the recently developed [^{14}C]deoxyglucose method.

Fifteen albino Sprague-Dawley male rats weighing between 340-430 g were studied. Each animal was initially prepared by surgical construction of a chronic gastric fistula. One week after the surgery the animals were fasted for 18-24 hours and then anesthetized with urethane injected intraperitoneally at a dose of lg/kg. A femoral artery and vein were then catheterized. Basal gastric secretion was collected for 30 min after which insulin was administered intravenously at a dose of 0.05-0.3 units, depending on the initial plasma glucose concentration. Collection of gastric secretion continued for another 90 min. In control experiments saline was injected instead of insulin. Forty-five min after the injection of the insulin or saline a pulse of [^{14}C]deoxyglucose was administered at a dose of 125 μCi/kg. During the following 45 min timed arterial blood samples were drawn for assay of the plasma [^{14}C]deoxyglucose and glucose concentrations. At the end of the 45 min period the animals were decapitated, and the brains processed for quantitative autoradiography. During the experiments blood pressure, body temperature and blood gases were monitored. Local cerebral glucose utilization was quantitatively determined as previously described (Sokoloff et al., J. Neurochem. 28:897, 1977).

The results showed that in fourteen of the eighteen structures examined, including, for example, the ventromedial medial nucleus of the hypothalamus, globus pallidus, zona incerta and n. ambiguus, the glucose consumption remained unchanged over the 84-215 mg% range of plasma glucose concentrations. There were, however, significant inverse correlations between plasma glucose concentration and rate of glucose utilization in the n. solitary tract, perifornicial area, dorsal motor nucleus of the vagus and the superior olivary nuclei. With the exception of the superior olivary nuclei all the structures affected by low plasma glucose concentrations have been shown to be involved in the gastrosecretory response to the blockade of glucose utilization provoked by pharmacological doses of 2-deoxy-D-glucose (Kadekaro et al., Neuroscience Abstracts 29:21, 1977) suggesting that these same nuclei are also activated by hypoglycemia.

60 BARORECEPTORS, CATECHOLAMINES, NUCLEUS SOLITARIUS, AND THE AREA POSTREMA: A CARDIOVASCULAR CONNECTION? David M. Katz and Harvey J. Karten, Depts. of Biology (DMK) and Psychiatry (HJK), S.U.N.Y., Stony Brook, N.Y. 11794

The anterograde transport of horseradish peroxidase (HRP) was used to visualize the central projections of the aortic arch depressor nerve (DN) to the nucleus solitarius (nS) in pigeons. The distribution of DN afferents was compared with the distribution of monaminergic neurons within nS as revealed by fluorescence histochemistry. The relationship between the DN projection area and the area postrema (AP) was also examined.

HRP was applied to the proximal cut end of the aortic depressor nerve by means of a small implanted chamber fastened around the nerve stump. Following 2-3 day survival times, HRP granules were seen in neurons in the nodose ganglion and within axons in the tractus and nucleus solitarius. HRP labelling within nS was confined to the neuropil of only one nuclear subgroup, the subnucleus sulcalis dorsalis (Sd). Sd lies dorsal to the tractus solitarius and extends from 0.8 to 2.0 mm rostral to the obex. The caudal portion of Sd lies below the floor of the fourth ventricle at the point of attachment of the taenia choroidea.

The region surrounding the taenia chorcidea had previously been suggested to encompass the area postrema in birds (Moll,J. & Hilvering,C.,Proc.Konin.Neder.,54,1951). Because of the proximity of this region to Sd, we decided to more precisely define the extent of the area postrema in the pigeon using intravenous injections of HRP(Broadwell,R.D.,&Brightman,M.W.,J.Comp.Neur.,166,3,1976). This technique revealed that the rostral portion of the area postrema lies immediately adjacent to the caudal portion of Sd.

Combined glyoxylic acid/paraformaldehyde-induced fluorescence revealed that Sd is extremely rich in catecholamine-containing neurons. Except for a more extensive rostro-caudal distribution, the fluorescent neurons within Sd overlapped precisely with the DN projection area. Fluorescent fibers extended from the caudal portion of Sd into the adjacent area postrema and taenia choroidea.

These data indicate that depressor nerve afferents have a restricted distribution within the nucleus solitarius in pigeons. Our data also provide strong evidence for the involvement of catecholaminergic neurons within nS in a central cardiovascular sensory pathway. In addition, our data suggest an anatomical association between tha area postrema, which lacks a blood-brain barrier, and the DN projection area within nucleus solitarius. Functional connections between these two regions may be partly responsible for the cardiovascular effects of blood-borne substances, such as angiotensin 2, which are mediated by the central nervous system (Joy,M.D., and Lowe, R.D., Nature, 228,1970).

61 INTESTINAL BLOOD FLOW AND MOTILITY ACCOMPANYING INCREASED SYMPATHETIC OUTFLOW INDUCED BY BULBAR STIMULATION AND A SPINAL REFLEX. K. Alan Kelts, John W. Oehlert*, and Julie Johns*. Dept. of Neuro., Sch. Med., Stanford Univ., Stanford, CA 94305.

Efferent postganglionic sympathetic nerve activity may be increased by electrical stimulation of the "pressor" area in the medulla or by activation of spinal reflex arcs. The aim of this work was to assess changes in intestinal motility and blood flow associated with the increasing nerve activity during those two stimuli. Fifteen cats were anesthetized with chloroform and chloralose-urethane (40 - 80 mg/kg). A proximal jejunal loop was prepared for recording intraluminal volume (GV), efferent mesenteric nerve activity (NA), and venous blood flow (BF). A femoral artery was cannulated for blood pressure (BP). Further preparation involved craniectomy for 60 Hz electrical stimulation of the dorsomedial bulbar reticular formation (RFS) or cannulation of a more proximal jejunal loop for mechanical stimulation of an intestino-intestinal inhibitory reflex (I_3-R). Control and stimulation periods were divided into 6 sec intervals, data quantitated (including integration of NA and calculation of vascular resistance, VR), and significance of changes assessed by a 2-tailed T-test. RFS produced significant increases in NA ($p < 0.0005$) and in GV ($p = 0.001$) during the first 6 sec, and in VR ($p = 0.01$) after 10 - 18 sec. I_3-R's resulted in significant increases in NA ($p < 0.0005$) and in GV ($p = 0.001$) within 6 sec, but no significant change in BF. Therefore, both RFS and I_3-R produced increased mesenteric sympathetic efferent discharge and intestinal relaxation, but only RFS caused a significant increase in vascular resistance. These data suggest separate populations of efferent sympathetic fibers passing in mesenteric nerves to intestinal and vascular smooth muscles. Moreover, these populations may be activated independently by different stimuli.

62 PATTERNS OF SINGLE UNIT ACTIVITY IN SYMPATHETIC POSTGANGLIONIC NERVES (CARDIAC AND VERTEBRAL NERVES). Mark Kollai and Kiyomi Koizumi. Dept.of Physiol., State University of New York, Downstate Medical Center, Brooklyn, N.Y. 11203.

Activity patterns of single postganglionic fibers of inferior cardiac and vertebral nerves were analyzed in chloralose anesthetized and artificially ventilated cats. They were divisible into three categories according to firing patterns. The first group, 72% of cardiac fibers and 38% of vertebral nerve fibers showed rhythmic discharges which were clearly synchronized with phrenic activity during normal ventilation. Other fibers of this group originally showing irregular firing patterns became synchronized with phrenic activity during slight hypoventilation or chemoreceptor stimulation. Although only a few of these fibers showed activity synchronized with cardiac cycle pulses all were strongly affected by baroreceptor excitation. The second group, 38% of vertebral but none of the cardiac fibers, showed very regular discharges which were not related to phrenic nor to cardiac rhythms. Interspike intervals ranged from 200 msec. to 10 sec. and the discharge frequency was very constant in any given fiber for a considerable period of time; occasionally in some units the frequency shifted. The third category, 28% of cardiac and 24% of vertebral nerve fibers, showed irregular firing patterns which could not be made synchronous with phrenic nor cardiac rhythms by various maneuvers. They were unaffected by activation of baroreceptors but increased their activity greatly under asphyxia. It is hoped that such analyses of single postganglionic fibers will give us more information concerning the properties of postganglionic neurons as well as the function of the autonomic ganglia. (Supported by grants from USPHS #NS00847 and New York Heart Association.)

63 INHIBITION OF CARDIOPULMONARY SYMPATHETIC EFFERENT NERVE ACTIVITY DURING LUNG INFLATION IN THE CANINE. David R. Kostreva and John P. Kampine*. Depts. Physiol. and Anesthesiol., Med. College of Wisconsin and Wood VA Ctr., Milwaukee, WI 53193

Positive pressure lung inflation in open chested dogs resulted in short latency inhibition of cardiopulmonary sympathetic efferent nerve activity (CPSENA) before and after bilateral vagotomy. Mongrel dogs, 20-30 kg, were anesthetized using sodium pentobarbital, 35mg/kg i.v. The animals were intubated and placed on positive pressure ventilation. The chest was split transversely between the second and third ribs, to allow unimpeded access to both stellate ganglia and adjacent ansae subclaviae. CPSENA was recorded from the cut central end of one of the left or right ansae. The CPSENA was amplified, filtered and time averaged using a half-wave rectifier. Central venous pressure and systemic blood pressure were monitored from the femoral vein and artery respectively. Tracheal pressure (TP) was monitored from a large bore needle inserted into the endotracheal tube. The electrocardiogram (ECG) was monitored from leads placed in a lead II configuration. Averaged CPSENA, ECG and the pressures were recorded using a polygraph.

Prior to vagotomy, lung inflation to 15 mmHg TP resulted in a marked inhibition of CPSENA traversing the left and right ansae subclaviae. At the onset of expiration, CPSENA immediately returned to or momentarily exceeded pre-inflation levels. Each inflation consistantly resulted in a depression of CPSENA. Immediately following bilateral vagotomy, baseline CPSENA decreased markedly. However, within one minute post-vagotomy, each inflation continued to produce a short latency inhibition of CPSENA. The degree of inhibition of CPSENA in most animals was attenuated after vagotomy. This may have been due to the marked decrease in baseline CPSENA produced by vagotomy. Bilateral sympathectomy by sectioning the remaining intact ansae resulted in a further depression of baseline CPSENA. Lung inflation to 15 mmHg TP after sympathectomy did not result in an inhibition of CPSENA. However, in several animals the ventilator was shut off for several minutes and the animals attempted to breath spontaneously. During expansion of the chest, CPSENA was immediately depressed without lung inflation. This study suggests that either chest wall somatic afferents or central respiratory centers can inhibit CPSENA. This study has also provided some evidence indicating that some vagal and sympathetic cardiopulmonary afferents can have an excitatory effect on CPSENA while other vagal and sympathetic cardiopulmonary afferents can have an inhibitory effect on CPSENA. (Supported by Grant HL 16511 and Young Investigator Research Award HL 21042 from HLBI, and the Medical Research Service of the VA.)

64 IDENTIFICATION OF PATHWAYS IN THE ABDOMINAL PREVERTEBRAL GANGLIA WITH RETROGRADE TRANSPORT OF HORSERADISH PEROXIDASE. David L. Kreulen* and Joseph H. Szurszewski. (SPON: J. C. Lynch). Dept. Physiol. & Biophysics, Mayo Med. Sch., Rochester, MN 55901.

Electrophysiologic experiments on the abdominal prevertebral ganglia of guinea pigs indicate that there is viscerotopic organization of the postganglionic outflow of these ganglia to the colon. The celiac ganglia (CG), the superior mesenteric ganglion (SMG) and the inferior mesenteric ganglion (IMG) were dissected as a single preparation, pinned to the floor of an organ bath, and superfused with oxygenated Krebs at 37° C. Two major groups of nerve fibers leave the ganglia for the periphery: the celiac nerves and the lumbar colonic nerves. The celiac nerves project from the more cephalad CG while the lumbar colonic nerves project from the more caudad IMG. Solid horseradish peroxidase (HRP) was placed on crushed regions of these mesenteric nerve trunks 5 to 8 mm from the ganglia. After 1 - 6 hours the preparation was fixed and 42 μ thick frozen sections of all the ganglia were processed in benzedine. When HRP was placed on the lumbar colonic nerves, labelled neurons were found in the IMG, SMG and CG. However, labelling appeared more dense in the IMG than in the other ganglia. This indicates that while most of the axons in the lumbar colonic nerves have their cell bodies in the IMG some of the axons come from CG and SMG. When HRP was placed on the celiac nerves, labelled neurons were again found in all the abdominal prevertebral ganglia; however labelling was most dense in the CG and least dense in the IMG. This indicates that some of the axons in the celiac nerves are from cell bodies located in the IMG. These experiments show that while there is cephalad-caudad distribution of postganglionic outflow from the abdominal prevertebral ganglia there is some crossover of this outflow. That is, some neurons located in the cephalad ganglia pass through the caudad ganglia and out caudad nerve trunks. Also, some neurons located in the caudad ganglion pass through the cephalad ganglia and out the cephalad nerve trunks. This organization may be important for mediating reflexes between viscera in different regions of the abdomen. (Supported by Grants AM 17632 and T32 RL 7111-02.)

65 AUGMENTATION OF SYMPATHETIC VASOMOTOR AND RESPIRATORY NEURAL DISCHARGES BY A DERIVITIVE OF γ-AMINOBUTYRIC ACID. Peter M. Lalley. Dept. Physiology, Sch. Medicine, U. Wisconsin, Madison, WI 53706

A derivitive of γ-aminobutyric acid (Lioresal^{R}, Ciba-Geigy) was found in the present study to augment neural discharges recorded from sympathetic vasomotor fibers, and from intercostal motoneurons in cats anesthetized with urethane, pentobarbital or chloralose. Under control conditions, conditioning electrical stimulation of depressor fibers in the aortic nerve (AN) or cervical vagus nerve (XN) abolished the reflex discharges evoked in sympathetic nerves by single test shocks applied to the carotid sinus nerve (CSN). After injections of lioresal (0.5-2 mg/kg I.V.), CSN-evoked sympathetic discharges were markedly augmented by conditioning AN or XN stimulation. Similar effects were produced by supplemental subanesthetic doses (5-10 mg/kg I.V.) of pentobarbital or methohexital. Lioresal or the barbiturates also caused further enhancement of the post-tetanic facilitation of CSN-sympathetic reflexes which followed stimulation (30-50 Hz) of the ipsilateral or contralateral CSN. Lioresal also increased (25-50 mmHg) resting mean blood pressure in several experiments, in concert with an increase in spontaneous sympathetic neural discharges. In other experiments, intercostal expiratory motoneurons, identified by antidromic activation of axons in the internal intercostal nerves, also increased their rate of spontaneous discharge following lioresal administration. The effects on sympathetic discharges are consistent with the results of an earlier study (Lalley, 1978) in which lioresal consistently converted the hypotensive episodes evoked by CSN, AN or XN stimulation to pressor responses. The depressor responses were temporarily restored by picrotoxin or bicuculline, but not by strychnine or metrazol. The neuronal mechanisms responsible for these unexpected effects, including a possible GABA-mimetic action, are currently under investigation. (Supported by American Heart Association Grant No. 75 899.)

66 FIRING PATTERNS OF PREGANGLIONIC NEURONS AND INTERNEURONS IN THE SACRAL AUTONOMIC NUCLEUS OF THE CAT. R.J.Milne*, A.M.Booth* and W.C.deGroat, Dept. Pharmacol., Univ. of Pittsburgh, School of Medicine, Pittsburgh, PA 15261

Extracellular unit recordings were obtained from neurons in the region of the sacral autonomic nucleus of anesthetized cats. Preganglionic neurons of two types were identified by antidromic invasion in response to stimulation of the sacral ventral roots. Preganglionic neurons which were fired by rectal stimulation or during spontaneous colonic contractions exhibited slow axonal conduction velocities (less than 2 m/sec), whereas preganglionic neurons activated by distension of the urinary bladder or during spontaneous bladder contractions had fast axonal conduction velocities (3-10 m/sec). The mean firing rate of bladder preganglionic neurons increased monotonically from 0 to a maximum of 2-5 Hz when bladder pressure was raised from 0 to 30-40 cm H_2O pressure. At low bladder pressures, bursts of spikes preceded and corresponded to brief rhythmic bladder contractions. At higher pressures the interval between rhythmic contractions decreased and firing became continuous. Over the same range of bladder pressures the frequency of bladder contractions was proportional to the mean rate of firing of preganglionic neurons. The preferred interspike interval (range, 25 to 125 ms), as defined by the peak of the time interval histogram, was generally independent of the mean firing rate.

Interneurons exhibiting firing rates which were correlated with bladder activity were also encountered, generally slightly dorsal to the location of the preganglionic neurons. At zero pressure, while bladder preganglionic neurons were quiescent, these interneurons maintained a slow rhythmic pattern of firing. At higher pressures the firing rate increased linearly with bladder pressure and the firing became essentially continuous. The preferred interspike interval was similar to that of preganglionic neurons and was independent of the mean firing rate. Bladder interneurons were inhibited by antidromic activation of the ventral roots and by rectal stimulation.

In summary, preganglionic neurons in the micturition reflex pathway respond to afferent input from the bladder with bursts of activity. The frequency of firing within bursts is independent of bladder pressure, whereas the interval between bursts is directly related to bladder pressure. Excitatory input to preganglionic neurons may be mediated by sacral interneurons which also fire in conjunction with bladder contractions. Inhibition of these interneurons may be responsible in part for recurrent inhibition in the sacral outflow to the bladder as well as inhibitory interactions between intestinal and bladder reflex pathways.

67 IDENTIFICATION OF VISCERAL AFFERENTS TO THE SACRAL CORD OF THE CAT USING HORSERADISH PEROXIDASE. Charles Morgan, William C. de Groat, Irving Nadelhaft. Dept. Pharmacol., Univ. of Pittsburgh Sch. of Med. and V.A. Hospital, Pittsburgh, PA 15261

The parasympathetic preganglionic efferents to the pelvic viscera leave the sacral spinal cord and travel together in the pelvic nerve before separating to innervate the bladder, colon, and sex organs. Afferents from these organs also travel in the pelvic nerve and enter the spinal cord in dorsal roots S1,2,3. By cutting the pelvic nerve, exposing the central portion to a 25% solution of HRP and allowing 35-60 hrs. transport time, we have been able to label both the efferents and afferents from the pelvic viscera to the sacral cord. Frozen sections of spinal cord (42 μ) were processed in benzidine and examined with darkfield illumination. Preganglionic neurons of the sacral parasympathetic nucleus were observed in 7 cats. The distribution of HRP reaction product in primary afferent (PA) axons or terminals is shown on the right in Figure 1. The PA were observed primarily in the dorsal root entry zone, Lissauer's tract, the apex and lateral edge of the dorsal horn (DH) in the marginal layer often continuing into the region of the dorsal band of the SPN. Less frequently PA were also found on the medial side of the DH. The position of the SPN at the mid-S2 level is shown on the left in Figure 1.

Cells of the dorsal SPN often send their dendrites along the lateral edge of the DH possibly to meet incoming afferent fibers. In order to determine that the PA in that region were not actually preganglionic dendritic processes, the sacral ventral roots in one cat were cut before exposing the pelvic nerve to HRP. The distribution of PA was identical to that observed in the other cats.

In another cat the direct exposure of the S2 dorsal root to HRP showed, in addition to the commonly described afferent path through the medial DH, an extremely heavily labelled axonal path along the lateral DH, identical in position to the distribution of PA observed in the pelvic nerve experiments. Many afferent terminals labelled so strongly that they outlined the shapes of the cells with which they synapsed.

We conclude that pelvic visceral afferents to the sacral spinal cord reach the region of dorsal band of the parasympathetic nucleus by traveling primarily along the lateral edge of the dorsal horn.

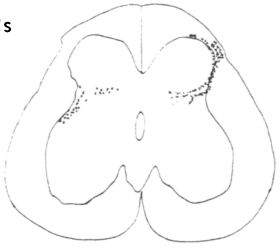

Fig. 1, Left, SPN. Right, PA.

68 BARORECEPTOR REFLEX GAIN DURING HYPOTHALAMIC ACTIVATION IN SPONTANEOUSLY HYPERTENSIVE(SHR) AND NORMOTENSIVE(WKY) RATS. S. Morrison and D. Whitehorn, Dept. of Physiology and Biophysics, Univ. of Vermont, College of Medicine, Burlington, Vt. 05401

Baroreceptor reflex mechanisms, acting at spinal and medullary levels attenuate changes in blood pressure (BP) by inhibiting sympathetic activity (SA). Stimulation of posterior hypothalamus (PH) produces sudden increases in SA and BP which are larger in the SHR than the WKY. This could be explained by a diminished baroreceptor reflex effectiveness in the SHR. To test this hypothesis we have measured the gain of the baroreceptor reflex during a step increase in hypothalamic activity.

Rats (10 WKY,8 SHR) anesthetized with alpha-Chloralose (100mg/kg) were instrumented with a femoral arterial cannula, a bipolar recording electrode on the preganglionic splanchnic nerve (SA) and a concentric bipolar stimulating electrode in the PH (AP4.5, ML .5,DV2.5). Square wave pulses (0.1 msec duration) were applied to the PH for 3 second periods at 60 or 100 Hz., at twice the intensity required to produce a discernible (5mm) change in BP. After 6 periods of stimulation at each frequency sinoaortic denervation was performed and stimulation repeated.

In the intact preparation, SA changes during stimulation exhibited three phases: an initial rapid rise beginning 65 msec and ending 150 msec after stimulation onset; a short, rapid fall (150-400 msec); and a third phase (400-2000 msec) during which SA declined more slowly. The accompanying BP increase occurred during the third phase, reaching a sustained peak at 2-2.5 seconds after stimulation onset.

After denervation the third phase was no longer present and can thus be attributed to baroreceptor reflex inhibition of SA. Denervation also resulted in a rapid increase in the level and lability of resting SA and BP. Significant differences in the extent of these increases could not be demonstrated between SHR and WKY. The SA and BP response to PH stimulation was greater in each animal after denervation, although the increase in SA during the first phase, expressed as percent of control changed only slightly and continued to be larger for SHR's.

In the intact animal, the baroreceptor reflex gain was measured as the slope of the relationship between SA(percent control) and BP during the third phase. The reflex gain was the same during 60 and 100 Hz. stimulation. The gain in the SHR ($5.58 \pm .72$) was significantly greater ($p<.01$) than that in the normotensive rats ($2.20 \pm .38$).

We conclude that the hyperresponsiveness of the SHR to PH stimulation is not due to a reduced baroreceptor reflex effectiveness. The results are expressed in a quantitative model of certain medullary and spinal components of the cardiovascular control system. (Support from Vt. Heart, 75-333).

69 THE ROLE OF THE ANTEROVENTRAL THIRD VENTRICLE (AV3V) IN DEVELOPMENT OF NEUROGENIC HYPERTENSION. Michael T. Mow*, J.R. Haywood*, A.K. Johnson, and Michael J. Brody* (SPON: W.W. Kaelber). Depts. of Pharmacology, Psychology, and Cardiovascular Center, The University of Iowa, Iowa City, Iowa 52242.

The region of periventricular tissue aroung the AV3V has been identified as the central site at which intraventricularly administered angiotensin produces its dipsogenic and pressor responses in the rat. Lesioning the AV3V region prevents the development of 1- and 2-kidney models of renal hypertension as well as DOC-salt hypertension, an experimental model with suppressed renin levels. The present experiments were conducted in an effort to determine whether the AV3V is also involved in the development of neurogenic hypertension produced by lesioning of the nucleus tractus solitarius (NTS), the brain stem region where baroreceptor afferents terminate. This form of hypertension is acute and within 4-5 hours of lesioning, rats die from pulmonary edema and heart failure. Electrolytic lesions of the NTS were performed under ether anesthesia on two groups of rats prepared 3-4 weeks earlier; one group which had received AV3V lesions and the other group which had received sham AV3V lesions. Blood pressures were recorded in the conscious state from indewlling arterial catheters and were monitored before and several hours following lesioning of the NTS. Lesioning of the NTS produced hypertension in both groups of animals. However, in the group with AV3V lesions, blood pressure rose only 40 mm Hg compared to a peak increase of 74 mm Hg in the sham lesioned group. Furthermore, the AV3V lesioned animals showed no signs of pulmonary edema. These data demonstrate that the region of the AV3V plays an important role in neurogenic hypertension. Since hypertension produced by NTS lesions is dependent upon the integrity of structures lying above the midbrain (mid-collicular decerebration will abolish and prevent NTS hypertension; Doba and Reis, Circ. Res. 32: 584, 1973), it appears that the AV3V may be a portion of long loop reflex arcs existing between the anterior hypothalamus and brainstem.

70 EFFERENT CARDIAC PROJECTIONS OF THE RIGHT STELLATE GANGLION IN THE CAT. Michael L. Niehoff* and James M. Sullivan* (SPON: P.A. Young). Dept. Anat., St. Louis Univ. Sch. Med., St. Louis, MO 63104.

Fluorescence microscopy has demonstrated extensive adrenergic periarterial plexuses around the coronary arteries. The sinoatrial and atrioventricular nodes have also been shown to be richly innervated. Using autoradiographic techniques, the present study has attempted to demonstrate the distribution of the postganglionic sympathetic cardiac fibers originating in the right stellate ganglion. A total of 500 microcuries of tritiated leucine was injected into the right stellate ganglion of the cat. After a three day postoperative survival period the animals were sacrificed. Transverse and longitudinal serial sections were made of the heart, great vessels, and trachea. The majority of the right stellate ganglionic fibers traveled between the trachea and aortic arch, and entered the cardiac plexus. Passing through the plexus these fibers coursed between the ascending aorta and the pulmonary arterial trunk to reach the left coronary artery. Periarterial and subepicardial plexuses then arose from these nerves. Most fibers formed a periarterial plexus which followed the distribution of the ventral descending branch of the left coronary artery. A few followed the circumflex artery. The conspicuous subepicardial plexus formed was most prominent in the cranial half of the left ventricle. Other fibers arising from the right stellate ganglion descended between the cranial vena cava and the right branch of the pulmonary artery. These ramified on the dorsal surface of the right atrium, and formed a large bundle which passed caudally through the interatrial septum. In the caudal part of the septum they turned ventrocranially and ascended in the septum for a short distance. They then ramified among the septal myocardial cells. In conclusion, sympathetic postganglionic fibers from the right stellate ganglion projected mainly to the left side of the heart. Periarterial and subepicardial plexuses were formed along the left ventricular myocardium. Other projections formed a subepicardial plexus in the right atrium and ramified in the interatrial septum.

71 CONTROL OF THE RESPIRATORY CYCLE BY THE MIDBRAIN RETICULAR FORMATION. John Orem and Ralph Lydic. Dept. Physiol., Texas Tech Univ. Sch. Med., Lubbock, TX 79409.

Several studies have shown that the midbrain reticular formation (MRF) influences breathing. The MRF is essential to waking consciousness, and its role in breathing may pertain to the wakefulness stimulus for respiration. We demonstrate here that the MRF can control the respiratory cycle independent of other known control systems (the pneumotaxic centers, vagal and intercostal reflexes).

Twelve anesthetized (Nembutal, 35 mg/kg) cats (Ss) were used. Stimulation of the MRF (50 pulses, 0.5 msec, 200 cps) during expiration (E) caused a phase-switch to inspiration (I). In some cases stimulation of the same site also produced I-to-E switching. Phase-switching was easier the greater the stimulus intensity and the longer the delay after the end of I or E (if testing for E-to-I or I-to-E switching respectively). This was expressed as: Switch Factor = Log % Response (1/mA·s) where "% Responses" was the percentage of switches at a given intensity-delay combination; "mA" was the stimulus intensity in milliamps, and "s" was the delay in seconds after which the stimulus was applied. The factor was fairly constant at all intensity-delay combinations. For E-to-I, the average factor across animals was 12; I-to-E factors ranged from 6 to 14. After extensive bilateral pontine lesions (the pneumotaxic centers) the duration of I (determined from diaphragmatic e.m.g.s) increased slightly from a mean of 1.74 to 2.0 across Ss, but the duration of E greatly lengthened from a mean of 4.3 to 20.3 s. Inspiration was initiated by MRF stimulation with an average switch factor of 1.5. Stimulation of the same MRF sites produced I-to-E switching in every case (average factor = 2.0). When pontine lesions were combined with spinal cord transection at C8 and bilateral vagotomies, rhythmic breathing ceased. Inspiration or expiration, once begun, did not spontaneously terminate. However inspiration could be initiated (factor = 1.1) and terminated (factor = 0.6) by stimulation of the MRF. In these cases, MRF stimulation provided complete control of respiration.

We conclude that, although phase-switching becomes more difficult with progressive lesions, the MRF can control breathing independent of the pneumotaxic centers and intercostal and vagal reflexes.

72 EFFECT OF FENFLURAMINE AND PARACHLOROPHENYLALANINE UPON CIRCADIAN BODY TEMPERATURE, OXYGEN CONSUMPTION AND ACTIVITY LEVELS IN RATS. P.E. Penn+, R.L. Gerber*, J.D. Sibonga*, and B.A. Williams*. NASA-Ames Res. Ctr., Moffett Field, CA 94035.

It has been reported that injections of the anoretic drug fenfluramine (Fen) and of p-chlorophenylalanine (pCPA) produce long term depletion of brain serotonin by different mechanisms and possibly in the process causing an initial rapid release of serotonin. Involvement of serotonin in temperature regulation has long been implicated, so the effect of Fen and pCPA on body temperature and other circadian variables was studied.

Using male rats maintained at 22°C, daily variations in body temperature (TB) and activity levels (A) were measured every minute by an inductively-powered telemetry system newly developed at Ames. Oxygen consumption (O_2) and other data were stored on a computer. Five days of control data were collected prior to injections which were made in the afternoon just before the circadian increase in the measured variables. The drugs tested were injected intraperitoneally in doses previously reported to produce significant neurochemical and behavioral effects. Fen (20 mg/kg) produced an immediate significant ($p<.05$,n=5) drop in TB, which was lowest after four hrs., when compared to the same rats' pre-injection TB (1.27°C), paired controls (1.38°C) or the same animals' TB at the same time on a previous day (1.53°C). This drop in TB was accompanied by a significant drop in O_2 of approximately 33%($p<.05$,n=5) when compared to the same three controls (1.27, 1.58 and 1.93 W/kg). Activity levels showed no consistent change. Food and water consumption were lower for 24 hrs. Before 24 hrs. had passed, all variables measured returned to normal levels and normal cycling. These initial responses were in contrast with those obtained following injections of 300 mg/kg pCPA. TB and O_2 also significantly dropped immediately following injection (TB -2.02°C,n=5;O_2 -25%). However, normal cycling did not occur for several days, with O_2 remaining at a low normal level and TB returning to and remaining at a high normal level. Food and water intake was lower during this time. Destruction of the B9 serotonergic cell bodies by Fen does not appear to have long term effects upon TB, O_2, A and food and water consumption while more extensive serotonin depletion by pCPA does. It is possible that the initial falls in the TB and O_2 were due to the immediate release of serotonin posited to occur with Fen and pCPA. The serotonin precursor tryptophan (Try) has been reported to cause an immediate, short term increase in serotonin levels and, probably, release. Injections of Try (300 mg/kg) produced significant short lasting drops in TB (2.30°C,n=3) which were lowest at two hrs. Although other causes cannot yet be ruled out, serotonin release may be responsible for the immediate short term falls in TB and O_2 seen with Fen and pCPA. (+NRC assoc. at Ames)

73 ALTERED UPTAKE OF NOREPINEPHRINE BY THE CARDIOVASCULAR SYSTEM OF SPONTANEOUSLY HYPOTENSIVE RATS.
Joon H. Rho* and Natlie Alexander* (Spon: B. Newman). Clinical Pharmacol., Dept. Med., Sch. Med., USC, Los Angeles, CA 90033.

The uptake of exogenous tritiated norepinephrine (H^3-NE) by the cardiovascular blood vessels of spontaneously hypertensive rats (SHR) and normotensive Wistar Kyoto (WKR) rats have been investigated. The isolated tissues were incubated with H^3-NE and the storage vesicles were isolated by means of sucrose density gradient centrifugation. Studies of H^3-NE incorporation into the isolated storage vesicles indicate that the portal-mesenteric vein synaptic vesicles of 12 week old SHRs take up less H^3-NE than those of WKRs (approximately 56% of the WKR), and it appears to be even less in the 36 week old SHRs. The mesenteric artery and branches to the gut wall have been processed in the same manner as the portal-mesenteric vein. In contrast to the results on the latter, the mesenteric arteries of SHRs showed an increase in uptake from 63 to 100% over that of the WKR control. A similar trend has been noted in atria. These results indicate that the neurotransmitter uptake is different on the low and high pressure sides of the circulatory system. Studies of H^3-NE incorporation into isolated storage vesicles of the tissues, thus, permit an assessment of vesicular uptake and binding mechanisms and their possible alterations in hypertension. These results will be discussed with regard to a possible defect in the neuronal membrane transport system.

74 EFFERENT PROJECTIONS OF THE PARABRACHIAL NUCLEUS. C.B. Saper and A.D. Loewy, Depts. Anat. & Neurobiol. and Medicine, Wash. Univ. Sch. Med., St. Louis, MO 63110

Interest has been focussed on the parabrachial (PB) nucleus because this region, surrounding the brachium conjunctivum in the dorsolateral pons, receives key inputs from the hypothalamus, amygdala and nucleus of the solitary tract, and is thought to be important in central autonomic regulation.

In order to study efferent projections from the PB nucleus, we made small injections of a mixture of ^3H amino acids into the region of the PB nuclei of rats and after 5 to 7 days survival, the brains and spinal cords were processed using the autoradiographic method. We have found major differences in the efferent projections from each of the subdivisions of the PB complex. The lateral PB appears to project rostrally through the contralateral medial lemniscus to the ventrobasal complex of the thalamus, lateral hypothalamic area, zona incerta, lateral preoptic area, and central nucleus of the amygdala and ipsilaterally in the central tegmental fields to reach the dorsal tip of the cerebral peduncle, and to enter the stria terminalis. From here, this bundle projects to the bed nucleus of the stria terminalis and the central nucleus of the amygdala. Descending fibers which appear to originate from the region of the Kölliker-Fuse nucleus travel in the ventrolateral medulla and along the medial edge of the spinal trigeminal nucleus. Some fibers appear to go as far as the spinal cord, traveling through the dorsal part of the lateral funiculus to innervate the intermediolateral cell column. The medial PB projects rostrally mainly through the ipsilateral central tegmental fields to enter the lateral hypothalamic and preoptic areas, dorsomedial, ventromedial and paraventricular nuclei of the hypothalamus, zona incerta, central nucleus of the amygdala and bed nucleus of the stria terminalis. Other fibers ascend through the central gray to the periventricular nuclei of the thalamus and hypothalamus. Ipsilateral fibers enter the ventral supraoptic commissure and cross to the contralateral lateral hypothalamic and preoptic areas. Descending fibers appear to travel in a similar trajectory similar to that described for axons from the lateral PB complex but none have yet been traced as far as the spinal cord. Various portions of the PB complex appear to give rise to separate portions of the total projection, as small differences in injection sites may cause certain pathways not to be labeled. We conclude that the PB complex may play an integral part in the highly interrelated central autonomic control system. Supported by USPHS grant #12751 and American Heart Association grant #77 797.

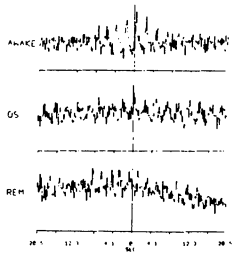
75 FUNCTIONAL CHARACTERIZATION OF SYMPATHETIC CARDIAC AFFERENT FIBERS. Jeanne L. Seagard* and John P. Kampine* (SPON: A. Sances, Jr.). Depts. Physiol. and Anesthesiol., Med. College of Wisconsin and Wood VA Ctr., Milwaukee, WI 53193

Evoked potentials were employed to functionally characterize the numbers and types of cardiac afferent fibers present in the thoracic sympathetic nerves of dogs.

Ten mongrel dogs were anesthetized with sodium pentobarbitol (35 mg/kg, i.v.) and placed on positive pressure ventilation. The second to fifth ribs along with the adjacent sternum were removed from the left side to expose the thoracic nerves. The ventrolateral (VLCN), ventromedial (VMCN), and left stellate (SCN) cardiac nerves were isolated and sectioned, with the central end retained for stimulation. The left sympathetic chain and T_2-T_4 white rami communicantes were isolated by sectioning the chain below T_4 and each white ramus at its junction with the spinal nerve. The T_2-T_4 chain and corresponding rami were placed in a nerve chamber filled with warm mineral oil for recording purposes. Each ramus was desheathed and dissected into smaller bundles of fibers. Individual bundles were sequentially placed on tungsten-carbide recording electrodes which were connected to high gain preamplifier-amplifier system in series with an Ortec averaging computer. VLCN, VMCN, and SCN were individually positioned across bipolar stimulating electrodes connected to a constant current stimulator. Supramaximal parameters of 3 Hz, 0.5 msec, and 12-15 ma resulted in the stimulation of both Aδ and C fibers. Stimulation of each nerve, while recording from T_2-T_4 white rami, evoked a greater percentage of C fiber potentials (0.31-1.8 m/sec) than Aδ fiber potentials (2.1-16.4 m/sec). Stimulation of the SCN and VMCN produced a greater number of potentials than did stimulation of the VLCN. The VLCN contained few fibers with conduction velocities greater than 2 m/sec. There did not appear to be any preferential distribution of cardiac afferent fibers arising from any ramus examined in this study (T_2-T_4). This study has demonstrated that 1) both Aδ and C fibers carry sympathetic cardiac afferent activity and 2) there is a greater percentage of C fibers than Aδ fibers involved with the transmission of this cardiac afferent activity. (Supported by Grant HL 16511 and the Medical Research Service of the VA.)

76 RESPIRATORY RELATED DISCHARGE OF PONTINE NEURONS DURING SLEEP AND WAKING STATES IN FREELY-BEHAVING CATS. G. C. Sieck* and R. M. Harper. Dept. Anat. and Brain Research Inst., Sch. Med., UCLA, Los Angeles, CA 90024.

Single neuron activity of the nucleus parabrachialis medialis (NPBM) was examined in unanesthetized, freely-behaving cats during sleep-waking states. A bundle of 10 fine wire (62 nichrome) electrodes was implanted together with electrodes for monitoring cortical, hippocampal, and lateral geniculate EEG, eye movements, and EKG. Respiratory movements were monitored using a piezoelectric strain gauge placed across the rib cage. Relationships between neuronal activity and respiratory movements during sleep-waking states were determined by cross-correlation techniques. Sleep-waking states were assessed using established criteria. Discharge rates of neurons in the NPBM fell into two categories with respect to sleep-waking states: (1) cells showing no specific relation to state charge and no relation to the respiratory cycle; (2) cells showing state-dependent changes in discharge rate which were correlated with respiration. The latter group of cells tended to have greatly increased firing rate during active sleep and comparable firing rates during quiet waking and quiet sleep. The increase in firing of NPBM cells during active sleep was not related to the phasic events of this state, and in fact firing often slowed during eye movements. A respiratory pattern of discharge in NPBM cells was present in each sleep-waking state. The degree of coupling to respiration and the phase relationship to the respiratory cycle depended upon the sleep-waking state and the cell being examined. Increased coupling was observed in active sleep in some cells; however, other cells showed a decreased coupling during both active and quiet sleep compared to the awake pattern (see figure). These findings demonstrate respiratory related discharge of neurons in the pneumotaxic center of non-vagotomized, unanesthetized cats. Alterations in the firing of these cells during different sleep-waking states may provide a basis for the varying respiratory control characteristic of these states.



Cross-Correlated Histograms Between Respiration & NPBM Neurons During Waking, Quiet Sleep, & Active Sleep

77 AN AUTORADIOGRAPHIC STUDY OF VAGAL PREGANGLIONIC FIBERS TO RAT BRONCHI, HEART, AND LOWER ESOPHAGUS. J.M. Sullivan* and N. Connors* (Spon: K.R. Smith). Dept. Anat., St. Louis Univ. Sch. Med., St. Louis, MO 63104.

Silver techniques have previously been used to demonstrate the visceral motor parasympathetic fibers that originate from the dorsal motor nucleus of the vagus. There is a minimum of information concerning the anatomical relationships of these preganglionic fibers within the bronchial and epicardiac ganglia and within the myenteric plexus of the lower part of the esophagus. The exact mode and arrangement of terminations has not yet been elucidated. The purpose of this study was to demonstrate by autoradiography the terminal branches of these preganglionic fibers on the postganglionic neurons within the bronchial and epicardiac ganglia and the myenteric plexus of the lower part of the esophagus. Twelve adult albino rats of both sexes were studied. The right dorsal vagal nuclei in six animals and the left nuclei in another six animals were injected with 250 microcuries of tritiated leucine. Following a postoperative survival period of three days, the animals were perfused with 10% buffered neutral formalin and serial sections of each lung, heart, and lower part of the esophagus were processed for autoradiography. Microscopic examination indicated a specific arrangement of preganglionic fibers within the vagus. The bronchial and heart tissue contained heavily labelled vagal fibers in close proximity to the postganglionic neurons. The bronchial ganglia containing labelled vagal axons consisted of clusters of postganglionic neurons located in close relationship to the smooth muscle down to and including the respiratory bronchioles. Epicardiac ganglia containing labelled vagal axons were located along the epicardial surface of the right atrium. The number and location of the epicardiac ganglia varied slightly in each animal. The esophageal preganglionic fibers of the vagus did not appear to be heavily labelled. Our results show a large labelled vagal preganglionic input to the bronchial and epicardiac ganglia but few labelled vagal preganglionic axons to the myenteric plexus of the lower esophagus.

78 SELECTIVE PROTECTION AGAINST BETHANECHOL-INDUCED DEPLETION OF SMALL INTENSELY FLUORESCENT (SIF) CELL HISTOFLUORESCENCE IN SYMPATHETIC GANGLIA. E.J. Tsevdos*, A.O. Humbertson, Jr., A.E. Langley* and R.W. Gardier*. The Ohio State University, College of Medicine and Dentistry, Columbus, Ohio 43210

Electrical recordings of the superior cervical ganglionic surface potential in cats indicated that gallamine or pancuronium inhibit the muscarinic mediated hyperpolarization (s-IPSP) without affecting slow depolarization (S-EPSP) by selective blockade of postsynaptic cholinergic receptors, typed M_i on the ganglionic interneuron (Gardier et al., J. Pharmacol. Exp. Ther. 204:46-53, 1978; Gardier et al., Fed. Proc. submitted). Since the development of the s-IPSP theoretically results from sitmulation of dopamine receptors on the ganglion cells, the effect of haloperidol was investigated and found not to affect the s-EPSP but to intensify the s-IPSP presumably by a preeminent blockade of dopamine receptors on the interneuron.

The selective postsynaptic blockade by gallamine or pancuronium suggested from the surface potential studies was evaluated further by the histochemical fluorescent technique of Falck et al. (J. Histochem. Cytochem. 10:348-354, 1962). In vitro exposure of rat superior cervical ganglion (SCG) to bethanechol, a muscarinic stimulant, reduced fluorescence in both ganglionic neurons and interneuronal (SIF) cells. Treatment of rat SCG with gallamine (in vivo and concomitant with bethanechol in vitro) or pancuronium (in vivo) prevented the decrease in SIF cell fluorescence resulting from in vitro exposure to bethanechol. Pretreatment of the SCG with gallamine or pancuronium alone had no observable effect on either ganglionic neuronal or SIF cell fluoresence. Exposure of the SCG to haloperidol in vivo as well as during in vitro exposure with bethanechol produced a depletion of SIF cell and ganglionic neuronal fluorescence comparable to that from bethanechol alone. The failure of haloperidol to protect against histofluorescence depletion in the ganglionic cell conforms to its lack of effect on the s-EPSP. These data provide further documentation for two pharmacologically distinct muscarinic receptors (M_i and M_e) in sympathetic ganglia.

79 SPINAL PROJECTIONS OF LEFT VENTRICULAR AFFERENTS
W. Hugh Vance and Robert M. Bowker*. Dept. of Cardiology and the Marine Biomedical Inst., University of Texas Medical Branch, Galveston, TX 77550.

The location of the cells of origin of the spinal afferents innervating the left ventricle in the area of the left anterior descending artery (LADA) have been determined in the cat and dog using the retrograde transport of the enzyme horseradish peroxidase (HRP).

Adult animals were anaesthetized with barbiturate anaesthetic and intubated with a tracheal tube. A routine thoracotomy was performed and the animal was maintained by artificial respiration throughout the surgical procedure. After the pericardial sac was opened, the LADA was identified and 15 injections consisting of 10 µl each of 1% HRP solution were injected subepicardially in the region of the LADA. After a survival period of 72 hours the animal was perfused with 0.5% paraformaldehyde and 2.5% glutaraldehyde in phosphate buffer. Dorsal root ganglia (DRG) of levels C7 through T6 were collected bilaterally and serially sectioned at 50µm. The sections were treated with tetramethyl benzidine according to the method of Hardy and Heimer (1977) in order to obtain reaction product.

Labelled neurons have been found at spinal levels C8 through T5 but predominantly at T2 and T3 with respectively 40% and 49% of the labelled cells found so far being at these levels. The labelled cells are also of relatively small size, being approximately 20µm to 40µm in diameter.

Our data is then in general agreement with but extends the classic work of Nettleship (1936) who described the cells innervating the "endocardial net at the apex of the ventricles and the wall of the coronaries" as being located at levels T1 through T5; as well as that of Ellison and Clark (1975) who injected HRP into the left and right ventricles and atria and found reaction product in the left T2 DRG.

Supported by Texas Heart Association grant #1-19511-488009.

80 RENAL NERVE RESPONSES TO ACTIVATION OF CARDIAC SYMPATHETIC AFFERENT NERVES BY CORONARY OCCLUSION AND BY TOPICAL APPLICATION OF AUTOCOIDS TO THE MYOCARDIUM. Lynne C. Weaver, Dept. of Physiology, Michigan State University, E. Lansing, MI 48824.

Activation of cardiac sympathetic afferent fibers by ventricular stretch induces reflex excitation of renal nerve activity (Weaver and Macklem: Fed. Proc. 37:743, 1978). Cardiac sympathetic afferent fibers also can be excited by coronary occlusion or by topical application of autocoids such as bradykinin, prostaglandin E_2 or histamine to the myocardial surface. Reflexes evoked by these stimuli may resemble those induced by natural activation of ventricular sympathetic afferents. Therefore, these stimuli were used to excite cardiac sympathetic afferent fibers to assess their influence on renal nerve activity and systemic blood pressure. Experiments were performed in α chloralose anesthetized, vagotomized, sino-aortic denervated cats. Occlusion of one or both branches of the left coronary artery caused myocardial ischemia and reflexly excited renal nerve activity by 23-94%. Occlusion of the left descending coronary artery appeared most effective. This increase in renal nerve activity was not observed in cats whose stellate ganglia and thoracic sympathetic chains had been removed. Coronary occlusion also caused systemic blood pressure to fall; however, equivalent decreases in blood pressure induced by hemorrhage failed to elicit similar increases in renal nerve activity. Solutions (1 ml) containing various concentrations of bradykinin (0.1-50 µg/ml), prostaglandin E_2 (0.1 µg/ml), or histamine (1-50 µg/ml) were perfused over the cardiac ventricles. After a latency of 5-10 sec., this application of bradykinin increased systemic blood pressure by as much as 90 mm Hg and increased renal nerve activity by 17-131%. The duration of the responses was 30 sec. to 3 min. Tachyphylaxis was apparent upon repeated administration of one concentration of bradykinin. Blood pressure responses were attenuated and renal nerve responses eliminated by removal of the stellate ganglia and thoracic sympathetic chains. Similar responses could not be evoked by intravenous or intramuscular administration of bradykinin. Increasing blood pressure with intravenously administered phenylephrine (equivalent to the pressor response to bradykinin) did not excite renal nerve activity. Application of prostaglandin E_2 or histamine to the ventricles also induced increases in systemic blood pressure and renal nerve activity. However, responses to these agents were less consistent than those to bradykinin. In summary, activation of cardiac sympathetic afferent fibers by coronary occlusion or by bradykinin, prostaglandin E_2 or histamine can reflexly increase renal nerve activity. This reflex may be responsible for some of the changes in kidney function associated with cardiac dysfunction. (Support: Mich. Heart Assoc. and NIH HL 21436.)

81 ACUTE CHANGES IN BODY FLUIDS AFTER BARORECEPTOR DENERVATION.
A.H. Werber* and G.D. Fink* (SPON: J. Thornburg), Dept. of Pharmacol., Mich. State Univ., E.Lansing, Mich. 48824

In 1964, Krieger reported the production of hypertension in rats by sinoaortic (SAD) or aortic baroreceptor denervation (ABD). In 1973, Guyton and co-workers reported that after SAD in dogs, although blood pressure (BP) was more variable, there was no rise in the 24 hr average level of mean arterial blood pressure (MABP). Guyton postulated that any rise in BP due to interruption of baroreceptor pathways would be transient, with restoration of BP occurring through an enhanced renal excretion of salt and water, contraction of the plasma volume and reduction in cardiac output. Nevertheless, recent results indicate that interference with baroreceptor function can result in prolonged hypertension (Jones and Hallback, 1978; Scher, 1978; Doba and Reis, 1973). Fluid volumes and renal function were not determined in these latter studies.

The present experiment was designed to examine the effects of ABD on cardiovascular and body fluid parameters in the conscious rat. Heart rate (HR), MABP, water intake (WI), urine ouptut (UO), body weight (BW), urinary sodium excretion ($U_{Na}V$), urinary potassium excretion (U_KV), plasma volume (PV), and extracellular fluid volume (EFV) were measured. Water balance (WB), a parameter derived by subtracting UO from WI was also measured. MABP was measured directly in the freely moving animal by means of an indwelling aortic catheter. PV and EFV were measured by dilution of Evan's blue and thiocyanate, respectively. WI, UO, $U_{Na}V$, U_KV were determined for 24 hr periods in rats housed individually in metabolism cages. The duration of the study was 7 days.

BP was significantly elevated 1, 2 and 3 days after ABD. HR was increased significantly 1, 2, 3 and 4 days after ABD. WI was significantly depressed on all days following ABD, with the smallest intake the day after ABD. UO was not increased after ABD, and decreased 2, 3 and 4 days after ABD. WB was reduced 1, 2 and 3 days after ABD, with the largest fall on the first day after ABD. BW was significantly lower all 5 days after ABD. $U_{Na}V$ was decreased 2, 3 and 4 days after ABD. U_KV was decreased all days after ABD. Five days after ABD, PV and EFV were 15% lower than preoperative values. There were no significant changes in any of these parameters in sham operated control rats.

These results confirm that in the rat an acute neurogenically-induced rise in BP results in contracted fluid volumes, and a tendency for blood pressure to return to control levels. However, it appears that this phenomenon is not dependent upon increased salt and water excretion by the kidney.

82 LOCALIZATION OF FROG PREGANGLIONIC SYMPATHETIC CELL BODIES USING HRP. Robert D. Wurster. Department of Physiology, Loyola University of Chicago, Stritch School of Medicine, Maywood, Illinois 60153.

On 6 bull frogs anesthetized by ice water immersion the 9th and/or 8th paravertebral ganglia were injected with 30% horseradish peroxidase solution. The frogs were returned to room temperature and allowed to survive for 48 hours. The animals were then pithed, perfused and fixed. The spinal cords were removed, sectioned and reacted according to the diaminobenzidine technique. Labeled cell bodies are located in the lateral horn about 275 to 575 µm from the lateral surface of the spinal cord and 425 to 625 µm from the dorsal surface. The cell bodies occur in clusters of 2-4 cells at about 70 µm intervals in the longitudinal direction. Interspersed between the clusters are nerve fibers communicating between the white and gray matter. These cell bodies have 2 to 3 processes and have a major diameter of 8 to 22 µm (mode of 14 µm) and a minor diameter of 8 to 16 µm (mode of 10 µm). These cell bodies are smaller and are more localized in the lateral horn than those of the cat. (Chung, et al., Brain Research 91: 126-131, 1975.) (Supported by NIH grant HL08682.)

83 IN VITRO STUDIES ON THE FUNCTIONAL ANATOMY OF SYMPATHETIC GANGLIA USING HORSERADISH PEROXIDASE. R.E. Zigmond, C.W. Bowers* and B.D. Wise*. Dept. of Pharmacol., Harvard Med. Sch., Boston, MA 02115.

We have recently used horseradish peroxidase (HRP) in vivo to study the location of neurons in the rat superior cervical ganglion (SCG) which use particular postganglionic trunks to reach their target tissues (Fed. Proc. 37: 526 (1978)). These studies showed that the ganglion can be divided into a caudal group of neurons whose axons project out the external carotid nerve and a rostral group of neurons whose axons project out the internal carotid nerve.

Since many other autonomic ganglia are located in regions of the body which are not as easily accessable as the SCG, we have developed an in vitro method to study them. A ganglion is removed from an animal together with as much of its pre- and postganglionic trunks as possible and placed in a petri dish. A small teflon ring is coated on the bottom with a layer of vacuum grease and placed over one of the cut trunks to isolate it from the ganglion cell bodies and the other trunks. The compartment created by the teflon ring is then filled with a 10% solution of HRP and the rest of the petri dish is filled with Ringer's solution. After 15 min the HRP solution is removed. The ganglion is then maintained in organ culture for about 18 h. The tissue is processed for the HRP reaction using normal procedures.

In vitro studies on the postganglionic trunks of the SCG produced the same distribution of labeled neurons in the SCG as found in vivo. Studies on the cardiac nerve of the inferior cervical ganglia demonstrate that the neurons whose axons project out this trunk are localized in a distinct region of this ganglion. Labeled neurons were observed only in the medial half of the ganglion and were particularly clustered near the exit of the cardiac nerve. These results demonstrate that sympathetic ganglia are not homogeneous structures but are made up of regions containing neurons innervating specific tissues. Our in vitro method should be useful in further studies on the anatomy of these ganglia. (Supported in part by Amer. Heart Assoc. grant #76723.)

AXONAL TRANSPORT

84 THE EFFECTS OF VARIOUS CATIONS UPON THE INCORPORATION OF PROLINE INTO THE MACROMOLECULES OF LARGE CELLS WITHIN THE DORSAL COLUMN NUCLEI OF CATS. K. J. Berkley, H.H. Molinari and D. C. Mash. Dept. Psychol., Fl. St. Univ., Tallahassee, FL 32306.

Many different amino acids appear to be incorporated nearly equally into the macromolecules of all of the different types of neurons located in the vicinity of an injection site. Proline, however, differs in that it appears to be incorporated preferentially only into the macromolecules of certain types of neurons. This pattern has so far been observed in the cerebellum (Felix and Künzle, 1974) the lateral reticular nucleus (Künzle and Cuénod, 1973) and the dorsal column nuclei (Berkley, 1975) of the cat. In these experiments, ^{3}H-proline was not incorporated as heavily by Purkinje cells of the cerebellum or by large cells of the lateral reticular n. and dorsal column n. as it was by other neurons in these regions.

The mechanisms which underly this preferential incorporation pattern are not yet clear, as the pattern seems to be unaffected by many experimental or technical manipulations (Berkley, et al. 1977). One variable which does affect this pattern, however, is the presence of calcium in the injection solution. If ^{3}H-proline is dissolved in a solution of calcium chloride and injected into the dorsal column nuclei of cats, the ^{3}H-proline appears to be incorporated by large as well as by small neurons throughout the injection site. If the ^{3}H-proline is dissolved in distilled water, or solutions of sodium-, potassium-, or magnesium chloride, however, the preferential incorporation pattern is unaffected. This ion-specific effect is consistent with the suggestion that the failure of the large cells within the dorsal column nuclei to incorporate extracellularly available proline into its macromolecules is occasioned at least in part by some active property of the membrane of the large cells.

85 PROTEINS IN THE WAVEFRONT OF FAST AXONAL TRANSPORT. Mark A. Bisby, Division of Medical Physiology, Faculty of Medicine, University of Calgary, Calgary, Alberta, Canada, T2N 1N4.

L-[^{35}S]-methionine was used to label axonally transported proteins in rat sensory neurons of the L5 dorsal root ganglion (DRG). 1-2 h after injection of precursor into the DRG, in some experiments the DRG were removed. In all experiments the dorsal roots and sciatic nerves were removed 3-4 h after precursor injection and cut into segments. Some segments were prepared for scintillation counting while others were processed for SDS polyacrylamide gel electrophoresis and run on exponential slab gels.

Profiles of protein-incorporated ^{35}S activity along the length of the nerves revealed waves of activity characteristic of the rapid axonal transport of protein (Ochs: J. Physiol. 227, 627-645, 1972). Fluorographs of gels containing extracts from different regions of the wave of activity showed that the same transported polypeptides were present in all parts of the wave. However, the forward edge of the wavefront, containing the fastest transported proteins, was enriched in two polypeptides (S_1 and S_2) with apparent molecular weights (MW) of 24,300 and 20,700 daltons. Using the fluorographs as a guide, regions of gel containing specific labeled polypeptides were excised and counted. This quantitative data confirmed the results of fluorography. Slight differences were noted between the fluorographic banding patterns of gels containing dorsal root and sciatic nerve segments. The possibility that these differences arise as a result of diffusion of precursor along the dorsal roots cannot yet be eliminated.

Segments situated nearer to the cell bodies, containing more slowly transported proteins, were not enriched in polypeptides of lower MW, as would be predicted by the micro-stream hypothesis of transport (Gross & Weiss, Neurosci. Lett. 5, 15-20, 1977). On the other hand, the preferential transport of specific polypeptides at the fastest velocity may support the transport-filament hypothesis of Ochs (Ann. N.Y. Acad. Sci. 228, 202-223, 1974).

86 RETROGRADE TRANSPORT OF NERVE GROWTH FACTOR TO LUMBAR SPINAL GANGLIA IN THE CHICK EMBRYO. J.K. Brunso-Bechtold and V. Hamburger, Dept. Biology, Washington University, St. Louis, Mo 63130.

Retrograde transport of nerve growth factor (NGF) has been reported in postnatal and adult rodents (Hendry, et al., Br. Res. 68:103, 1974; Stoeckel, et al., Br. Res. 89:1, 1975). Since NGF, delivered systemically, is known to produce an enlargement of spinal ganglia only in the embryo, it was of interest to find out whether retrograde transport of NGF to the spinal ganglia occurs in the embryo. ^{125}I-NGF impregnated pellets of polyacrylamide gel were implanted into the lower leg of stage 36 (10 day) chick embryos. The embryos were sacrificed 8 hours after injection and processed for routine autoradiography. Inspection of the leg shows heavy concentrations of silver grains in distal leg tissues in the region of the pellet, but virtually no grains above background at the base of the leg. Hence, there appears to be no spread of ^{125}I-NGF to the trunk by diffusion. Heavy labelling is seen within the lumbar sensory nerves along their extent to the ganglia as well as in the ganglia themselves, but the dorsal roots, ventral roots, and lateral motor columns are unlabelled. No label above background is found in any of the contralateral sensory roots or spinal ganglia. It can therefore be concluded that NGF is selectively picked up by neurons of the spinal ganglia, and transported retrogradely to the cell bodies, but not beyond them. (Supported by NIH grant NS05721 and Jerry Lewis Neuromuscular Disease Research Center grant.)

87 TRANSPERIKARYAL PASSAGE OF HORSERADISH PEROXIDASE ALONG PERIPHERAL SENSORY NERVES OF THE RAT. Thomas M. Brushart* and Marek-Marsel Mesulam. Neurological Unit, Beth Israel Hospital, Boston, Massachusetts.

Anterograde degeneration (Sprague & Ha, Prog. Brain Res., 1964) and HRP (Proshansky & Egger, Neurosci. Lett., 1977) methods for tracing the central terminations of individual somatosensory nerves require axonal interruption or HRP application proximal to the dorsal root ganglion (DRG). These studies thus reveal the central connections of individual dorsal roots rather than those of specific peripheral nerves. We now report a method which demonstrates nearly all central sensory connections after HRP application to peripheral nerves.

The proximal ends of cut rat sciatic nerves were anchored within HRP-filled microtubing (10 µL 10-20% Miles HRP). In other rats intramuscular HRP injections were made in the peroneal nerve distribution. After 24°-48° survival, the rats were perfused and the tissue reacted with tetramethyl benzidine (TMB) as described by Mesulam (J. Histochem. Cytochem., 1978).

Retrograde transport of HRP produced intense labeling of anterior horn neurons. In addition, granular HRP label was seen in DRG neurons as well as their peripheral and central processes. HRP-labeled axons could be followed into the dorsal root, the Tract of Lissauer, and the fasciculus gracilis. HRP reaction product suggestive of axon terminations was found in: (1) Rexed laminae I-IV; (2) the internal basal nucleus (medial laminae V-VI); (3) the nucleus of Clarke; (4) discrete sites in the intermediate zone and ventral horn; (5) the nucleus gracilis in the medulla.

When compared with 24° survival, 48° gave more consistent visualization of sensory connections. Few sensory connections were demonstrated with intramuscular HRP injection so that continuous exposure of cut nerves to HRP was clearly superior. Retrograde transport was not as susceptible to these manipulations. The importance of the sensitive TMB procedure was also demonstrated: motoneuron labeling was attenuated and the labeling of sensory connections abolished in matching sections processed with DAB.

Although Proshansky and Egger (op. cit.) produced exquisite axonal detail, they had to apply HRP proximal to the DRG and could only follow axons for 2.5 cm. In contrast, the present technique has resulted in trans-perikaryal passage of HRP from peripheral nerve through the DRG into the spinal cord and brainstem, and may thus be used to trace the central connections of many sensory fibers in peripheral and cranial nerves.

88 ANTEROGRADE TRANSPORT OF HORSERADISH PEROXIDASE IN THE VISUAL SYSTEM OF THE TREE SHREW. Russell G. Carey* and Michael Conley* (SPON: M. Wolbarsht). Dept. of Psychol., Duke Univ., Durham, N.C.

The purpose of the present study was to demonstrate that the enzyme horseradish peroxidase (HRP) can be used as a sensitive anterograde tracer and compares favorably with the autoradiographic (ARG) techniques used to demonstrate the anterograde transport of amino acids. We examined the retinal projection of the tree shrew (Tupaia glis) by making intraocular injections of either 50 µl 30% HRP or 150-500 µCi of tritiated proline or a proline-leucine mixture. Survival times range from 8 hours to 6 days.

The HRP tissue was processed with benzidine dihydrochloride (BDHC), 3,3', 5,5'-tetramethyl benzidine (TMB) and 3,3' diaminobenzidine (DAB). Best results were obtained with BDHC or TMB. Little or no transport could be demonstrated with the use of DAB. Labeled terminals could be identified in contralateral visual nuclei (e.g., lateral geniculate, superior colliculus, pretectum, etc.) as early as 8 hours post injection. The optimal results, however, were obtained after 48 hour survival times. In these cases labeled axons could be traced in the optic tract to the sites of retinal termination. No evidence of transneuronal transport was apparent even with the longer survival times and multiple injections.

In terms of sensitivity every retinal terminus identifiable with the ARG method was shown with the same clarity using the HRP methods, and in certain instances the results from the HRP method were superior to those of the ARG. For example, the ipsilateral projections to the pretectal complex and medial terminal nucleus were much more distinct in the HRP cases than in the ARG material. Also, the ipsilateral "puffs" in the superior colliculus, often difficult to see in the ARG material, were well defined with HRP. Further, the anterograde transport of HRP has allowed us to confirm the contralateral retinal projection to the anterior dorsal nucleus first demonstrated by Conrad & Stumpf (Exp. Brain Res., 23, 1975).

In conclusion, these results demonstrate that anterograde transport of HRP can be used as an effective means for tracing retinofugal projections. The comparable sensitivity and the time saving advantages of this method indicate that is is a valuable alternative to the ARG and anterograde degeneration techniques. We are currently applying this method in the study of corticofugal systems in the tree shrew and these results suggest that this method may be valuable in tracing these connections as well.

89 LIGHT AND ELECTRON MICROSCOPIC STUDIES OF THE CELLS OF ORIGIN OF THE INFRAORBITAL NERVE UTILIZING RETROGRADE AXONAL TRANSPORT OF HORSERADISH PEROXIDASE AND A NONCARCINOGENIC SUBSTITUTE FOR DIAMINOBENZIDINE. Keith A. Carson, Warner J. Lucas*, John M. Gregg* and Jacob S. Hanker. Dental Research Center, School of Dentistry, and the Neurobiology Program, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina 27514.

Neuroanatomical studies have been greatly facilitated through the use of retrograde axonal transport of horseradish peroxidase (HRP). The technique for histochemically demonstrating HRP has recently undergone refinement, including the introduction of paraphenylenediamine-pyrocatechol (PPD-PC; Polysciences), a more specific and more sensitive noncarcinogenic substitute for diaminobenzidine (Hanker et al., Histochem. J., 9:789-792, 1977).PPD-PC proved to be readily oxidized to a dark, insoluble, osmiophilic copolymer by HRP, but unlike DAB it was only slightly active or inactive as a substrate for endogenous peroxidases, catalases, hemoproteins, and mitochondrial enzymes. Light and electron microscopy have been combined with HRP techniques to investigate the somatotopic localization and nature of the cells of origin of the infraorbital branch of the trigeminal nerve.

Following surgical exposure of the infraorbital nerve bilaterally on four Sprague Dawley rats, the main trunk was sectioned at its exit from the infraorbital foramen. Crystals of HRP (Type VI, Sigma) were applied directly to the isolated proximal stump and allowed to remain for 15 minutes. All animals were sacrificed 48 hours later and the trigeminal ganglia were sectioned, stained, and prepared for light and electron microscopy.

Light microscopic examination of the ganglia revealed the presence of many neurons filled with dark granules. Staining due to endogenous peroxidases and hemoproteins was negligible. Labeled cells had generally consistent topographical locations in all ganglia. Counts of labeled cells demonstrated that approximately 60% of cells with axonal processes in the infraorbital nerve were stained. Mapping techniques showed the labeled cells to be consistently in the middle of the ganglion just rostral to the point of separation of the mandibular branch. Dorsal sections in the horizontal plane showed labeled cells located medially while in more ventral sections labeled cells were situated laterally. Electron microscopic studies showed that the reaction product filled large membrane-bound granules and endoplasmic reticulum and showed no evidence of diffusion. In addition, these experiments demonstrated the advantages of PPD-PC for demonstrating HRP at light and ultrastructural levels and its applicability to many systems.

Supported by NIH grants DE 02668, DE 00288, 1-RO1-DE04730-01, RR05333, MH14277, and a grant to the Neurobiology Program from the Alfred P. Sloan Foundation.

90 THE CYTOSKELETON OF AXOPLASM EXAMINED BY HIGH VOLTAGE STEREO ELECTRON MICROSCOPY; A POSSIBLE VEHICLE FOR AXOPLASMIC TRANSPORT. M. H. Ellisman° and K. R. Porter+. °Dept. Neurosci., Univ. Calif., San Diego; +Dept. Molec. Cell & Devel. Biology, Univ. Col., Boulder.

Axoplasmic streaming is a dramatic example of cytoplasmic motility. Constituents of axoplasm migrate as far as 400 mm/day or at about 5 µm/second. Thin section studies have identified the major morphological elements within the axoplasm as being microtubules, neurofilaments (100 A filaments), vesicles of the smooth endoplasmic reticulum, and finally a matrix of ground substance in which the tubules, filaments, and vesicles are suspended. In the ordinary thin section image, the ground substance is comprised of wispy fragments which, in not being noticeably tied together, do not give the impression of representing more than a condensation from what might otherwise be a homogenous solution of proteins.

Using the high-voltage microscope on thick (0.5 µm) sections, we have noticed that the so-called wispy fragments are part of a three-dimensional lattice. The individual strands or trabeculae radiate into the ground substance often at right angles to the microtubules and neurofilaments. In thus reaching out, they interconnect the filamentous components of the axoplasm with each other and with vesicles of the endoplasmic reticulum, with multivesicular bodies, and the undersurface of the plasma membrane. The axoplasm is found to have the same structured ground substance as has been reported for the general cytoplasm of other cells, particularly where viewed in whole cells.

Better ways of staining the trabecular lattice to allow a more complete visualization in thick sections also are being examined. Uranyl-acetate block stains or tannic acid glutaraldehyde fixation appear to improve visualization of the matrix through an enhancement of its electron density. Thus, with improved staining of the trabecular material in sections, it should be possible to visualize, in detail, any changes in the lattice associated with motion of endoplasmic reticulum cisternae (containing, for example, transported protein) within the axoplasmic column.

91 BIDIRECTIONAL AXONAL TRANSPORT OF MACROMOLECULAR (16S) ACETYLCHOLINESTERASE. Barry W. Festoff and Hugo L. Fernandez. Dept. of Neurology, University of Kansas Med. CTR. and Neurobiology Research Lab., VA Hosp. Kansas City, Mo. 64128

The restricted presence of macromolecular acetylcholinesterase (AChE) in innervated, end-plate enriched skeletal muscle regions of rat (16S) and chicken (19.5S) has suggested their role in nerve-muscle communication (see Vigny et al 27: 1347,1976). It was suggested that this AChE form was exclusively myogenic (Hall, J. Neurobiol. 4:343,1973; Vigny et al J. Neurochem. 27:1347,1976) because it could not be detected in central or peripheral nervous tissue. Recently, however, a small amount of 16S AChE was detected in rat sciatic nerve, which increased in a time-dependent fashion in the proximal stump after neurectomy (Digiamberardino and Couraud, Nature 271: 170,1978) suggesting that it moved with the rapid phase of axonal transport. In studies concerning trophic regulation of end-plate AChE, transport of 16S AChE could provide a source of the enzyme to the end-plate. For this reason evaluation of molecular forms of AChE were evaluated in control nerves, proximal, distal and between double ligatures in experimental nerves.

Sciatic nerves of Sprague-Dawley rats were ligated with fine silk thread and animals sacrificed 4,6,12,16,20,42 and 72 hrs later. Control nerves were divided into 3 equal 1 cm sections which were obtained proximal to the 1ST ligature, distal to the 2nd and between both ligatures. Nerves were homogenized in high ionic strength buffer containing 1% lubrol-WX and molecular forms of AChE separated on linear sucrose gradients. AChE (sensitive to BW 284C51) was estimated by a sensitive radioassay. Our results indicate that 16S AChE is present in control nerves representing approximately 3% of total AChE. Futhermore, this macromolecular form accumulates proximal to the 1st and distal to the 2nd ligature. No accumulation of 16S AChE occurred between the ligature. Although 10S and 4S AChE are present in blood only 10S showed proximal but not distal accumulation. 6.5S, an AChE form which may be specific to nerve, showed slight proximal and distal accumulation. Our emphasis, however, is on 16S AChE and confirms its presence in peripheral nerve. Its proximal and distal accumulation indicate its bidirectional transport. Such data shed light on trophic nerve-muscle interaction. Present experiments are concerned with estimating its transport rate and effects of agents known to block axonal transport.

92 RAPID AXONAL TRANSPORT OF [^{3}H]FUCOSE AND [^{35}S]SULFATE-LABELLED MACROMOLECULES IN RAT VISUAL SYSTEM. Jeffry F. Goodrum*, Arrel D. Toews, and Pierre Morell. Dept. of Biochem. and Biol. Sci. Res. Ctr., UNC, Chapel Hill, NC 27514

The axonal transport of [^{3}H]fucose and [^{35}S]sulfate-labelled macromolecules in retinal ganglion cells of 16 day Sprague-Dawley rats was investigated following simultaneous intraocular injection of precursor. Maximal incorporation of fucose into acid insoluble material in the retina was at 8 h, followed by a slow decline. Transported [^{3}H]fucose was in the optic nerve (ON) and tract (OT) by 2 h and in the lateral geniculate body (LGB) and superior colliculus (SC) by 3 h after injection, indicating a rapid rate of transport. Labelled fucose continued to accumulate in the SC for 8-12 hours, and began a slow decline by 24 h. More than 98% of the acid insoluble [^{3}H]fucose in the SC was in glycopeptides. Proteins in the SC were fractionated on 7.5% SDS polyacrylamide gels. There were no radioactive peaks present by 24 h that were not also present at 3 h, suggesting that there is little heterogeneity of fast transport rates for fucose-labelled material. However, over the 24 h period a 45,000 MW peak accounted for a progressively increasing fraction of radioactivity on the gel; possibly a function of its greater metabolic stability relative to other nerve terminal glycoproteins.

In contrast to fucose, incorporation of [^{35}S]sulfate into acid insoluble material in the retina was maximal at 2 h after which there was a rapid decline. The appearance of [^{35}S]sulfate in ON, OT, LGB, and SC preceded by a short time that of the [^{3}H]fucose. Consistent with the pulse labelling of the retina by sulfate, the total transported sulfate in the SC peaked by 4-6 h and was decreased by 65% at one day. At all times, acid insoluble [^{35}S]-sulfate in the SC was equally divided between glycopeptides and glycosaminoglycans, indicating these macromolecules are transported at the same rate. Fractionation of sulfate-labelled protein on gels revealed a prominent radioactive doublet between 70,000 and 80,000 MW at 3 h which was diminished at 4 h and absent at 8 h implying extremely rapid turnover of the sulfate moiety in these two proteins.

These results suggest that there is a delay of about 1 h before injected fucose becomes incorporated and available for transport in contrast to sulfate which begins transport very soon after injection. Once transport is initiated, labelled macromolecules of both species are rapidly transported at a single rate (approx. 200 mm/day). Upon arrival at nerve terminals the macromolecules turn over at different rates; of particular interest are two proteins containing sulfate moieties with a half-time of turnover of the order of hours.

Supported by U.S.P.H.S. grants NS11615 and HD03110.

93 HORSERADISH PEROXIDASE EVALUATION OF LATERAL HYPOTHALAMIC AREA INTERCONNECTIONS. R. Guevara-Aguilar, H.U. Aguilar-Baturoni, F.C. Barone and M.J. Wayner. Departamento de Fisiología, Facultad de Medicina, U.N.A.M., Mexico and Brain Research Laboratory, Syracuse University, Syracuse, New York, USA.

Horseradish peroxidase (HRP, Sigma Type VI, 4 to 40 percent) was applied in the mid-lateral hypothalamic area (LHA) of female rats. HRP was administered by two different techniques in order to cross-validate results and eliminate non-specific damage associated with large cannula used for infusions of the enzyme into the brain. In some cases, macrocannulae (250 µm) were used to infuse 0.1 µl into the LHA. In other cases the HRP was applied to the LHA by microiontophoretic ejection from glass micropipettes with tips broken to 25 µm. Positive DC current, 1.0-1.5 µA, was applied for 8 to 20 min. After 24 to 48 hr survival time, all animals were perfused intracardially with 1 percent formaldehyde and 2 percent glutaraldehyde in 0.1 M phosphate buffer at pH 7.4. The brains were sliced in the frontal plane on a freezing microtome in 30 to 50 µm sections. Some sections were processed with DAB tetra HCl for the brown reaction, and others with BDA for the blue reaction according to the Nauta Technique. Labeled neurons were identified and photographed under the light microscope. Results were analyzed by means of mapping the results from several sequential sections onto copies of plates extracted from the König and Klippel rat brain atlas. HRP was observed to move rostrally, following the Diagonal Band of Broca and the Medial Forebrain Bundle , into the Lateral Septal Nucleus and as far as the Anterior Olfactory Nucleus. Axons containing HRP were identified at the level of the Globus Pallidus. Movement in the caudal direction was also determined. Many labeled neurons were observed in the Parafasiculis Nucleus, Posterior-Medial Thalamic Nucleus, the Ventral Thalamic Nucleus as well as the Zona Incerta.

94 ISOLATION OF RAPIDLY SYNTHESIZED CALCIUM BINDING PROTEIN FROM SYNAPTOSOMAL AND SOLUBLE FRACTIONS OF RABBIT BRAIN CORTEX AFTER TOPICAL APPLICATION OF ^{3}H-LEUCINE. Zafar Iqbal and Sidney Ochs. Dept. Physiology and Medical Biophysics, Indiana University School of Medicine, Indianapolis, IN 46202.

In our earlier work the presence of a calcium binding protein (CaBP) of 15,000 daltons was reported in cat brain synaptosomes (Iqbal & Ochs, Neurosc. Abs., 2:47, 1976). We now report the rapid labeling in situ of this protein. The incorporation of ^{3}H-leucine was studied by applying the precursor topically to the exposed parietal occipital cortex of anaesthetized rabbits. The animal and temperature of the cortex was maintained at 38°C by means of a thermoregulator device controlling a heating lamp shined through Saran wrap covering the cortex so as to prevent dehydration. Three to 3.5 hr after the application of the precursor, the cortex was removed, washed and homogenized in 0.32 M sucrose. Subcellular fractionation of the homogenate performed according to the method of Gray and Whittaker showed an incorporation of ^{3}H-leucine into proteins of all fractions with 6.9% in the synaptosomal (P_2B) and 33.6% in the soluble (105,000 xg/1h, S_3) fractions. The soluble fraction was filtered through Amicon Diaflow DM-5 membranes to remove low molecular weight components and the retentate analyzed by gel filtration chromatography on BioGel A5m columns. Using a 10 mM phosphate buffer of pH 7.5 for elution, 6.4% of the radioactivity was found to be present in the first peak (Ia) eluting with the void volume. The amount of radioactivity in the proteins of 40,-180,000 daltons (second peak, Ib) was 53.9% whereas the third peak, Ic, containing proteins of less than 20,000 daltons had 25.7% of the radioactivity. On further analysis of Ic peak proteins by electrophoresis on 10% acrylamide gels containing 0.1% SDS, among other proteins a significant amount of the 15,000 dalton protein was found to be labeled with radioactivity. This protein had earlier been found to have calcium binding properties. Similarly, when the synaptosomes or the synaptosomal soluble fraction obtained from synaptosomes after hypotonic shock was analyzed on SDS containing acrylamide gels, the protein band of 15,000 daltons was observed to be labeled with radioactivity. The protein present in the synaptosomes and the soluble fraction (S_3) show similarities to the CaBP of 15,000 daltons isolated from cat sciatic nerve which has recently been shown to be transported at a fast rate (Iqbal & Ochs, J. Neurochem., 1978 in press). Supported in part by the NIH,grant PHS RO1 NS 8706-09, & the NSF,grant BNS 75-03868-A03.

95 AXONAL PROTEIN TRANSPORT IN THE NIGROSTRIATAL AND MESOLIMBIC NEURONAL PATHWAYS IN THE RAT. Edgar T. Iwamoto. Dept. Pharmacol., Sch. Med., UCSF, San Francisco, CA 94143.

Axonal transport of tritiated protein was investigated in Sprague-Dawley rats after an injection of tritiated lysine into the ventral mesencephalic tegmentum (VMT), or into the substantia nigra (SN). Five, 60, 120 and 180 minutes after the injection of labelled lysine into the VMT, approximately 4, 35, 57 and 80 percent, respectively, of the radiolabel recovered from the midbrain injection site was present as TCA-insoluble protein; less than one percent of the label two hours after lysine injection was tritiated water. Three days after injecting 3 to 6 µCi of labelled lysine in 0.1 to 0.5 µl of artificial CSF into either the VMT or the SN, over 95 percent of the radiolabel recovered in thin-sections of the forebrain was bound to protein. VMT injections resulted in the preferential accumulation of labelled protein in known limbic projections (nucleus accumbens, olfactory tubercle, septum); less than 12 percent of forebrain radiolabel was located in the adjacent neostriatum. SN injections of labelled lysine resulted in the preferential accumulation of labelled protein principally in the nucleus caudatus-putamen. Coinjection of 1 µg of colchicine with the labelled lysine into VMT depressed recoverable forebrain radiolabelled protein by over 60 percent without altering midbrain amino acid pools. Coinjection of 1 µg of cycloheximide decreased labelled lysine incorporation into midbrain protein by over 75 percent and also diminished labelled protein recovery from limbic termina. Tritiated lysine injections in the SN of rats with chronic, 6-hydroxydopamine-induced lesions of the SN resulted in reduced recovery of radiolabelled protein from both limbic and neostriatal brain regions to less than 50 to 11 percent of control. 6-hydroxydopamine lesions of thd caudate nucleus decreased labelled protein accumulation in the neostriatum, but not in the nucleus accumbens or olfactory tubercles. Unilateral kainic acid lesions of the caudate nucleus, which presumably spare axons of passage and nerve terminals, did not appreciably alter the accumulation of radiolabelled protein in any brain region after SN injection of labelled lysine. The data demonstrate that axonal transport of protein from the VMT and SN region to both limbic and striatal termina in rat brain is sensitive to inhibitors of both microtubule assembly and protein synthesis, and may depend upon the integrity of a 6-hydroxydopamine-sensitive neuronal pathway. (Supported in part by a Research Starter Grant from the Pharmaceutical Manufacturers Association Foundation).

96 RAPID AXOPLASMIC TRANSPORT OF (U-^{14}C)PHENYLALANINE LABELED MATERIAL IN THE DORSAL SENSORY NEURON OF THE CAT. Jeffery L. Johnson and Jong-Hwan Kim*. Section on Physiology, Div. Biochem/Phys/Pharm, Univ. So. Dak. Sch. Med., Vermillion, SD 57069.

Even though the clinically important amino acid phenylalanine (PA) is necessary for normal neuronal function as evidenced by the neurological effects of PA deficiencies or excesses, very little is known about the importance of this amino acid with respect to neuronal constituents migrating via the rapid axoplasmic flow process down the axons. CNS studies (J. Neurochem. 23, 1974, 1065) at least, have suggested that analysis of such a process for phenylalanine labeled proteins would be quite fruitful using a branched neuron such as that seen in the sensory ganglia where a length of fiber can be easily separated and divided for analysis. (U-^{14}C)Phenylalanine (>480 mc/millimole) was injected into the seventh lumbar dorsal root ganglia bilaterally and at times ranging from 1-8 hrs following injection, the proximo-distal distribution of label in successive 3 mm segments was analyzed. Evident was a clear proximo-distal advancing front of labeled material peripherally (sciatic nerve) and centrally (dorsal root) moving at an average rate of 380 mm/day. Background counts distal to this front ranged from 2-20 cpm, suggestive of very little diffusion or extra-axonal spread of injected label. 5 x 10^{-3} g/ml puromycin markedly suppressed the amplitude of this advancing front and a nerve freeze resulted in a marked damming proximal to the freeze zone. This suggests that intraaxonal phenylalanine which has been incorporated into protein is a major component of the advancing front. A marked accumulation of phenylalanine labeled material in the dorsal spinal cord gray where much of the incoming dorsal root fibers terminate was noted, and this appeared to be greater than the amount advancing up the dorsal white tracts containing the ascending dorsal root fibers. A precise linear relationship between the counts in the ganglionic (perikeryal) injection site and the counts in the sciatic nerve advancing front was uncovered over the entire range of injected PA used (0.8-17 μc), suggestive of a precise relation between perikeryal protein formed and protein in the advancing sciatic plateau AND a lack of saturation of the protein synthetic mechanism by the amounts here injected. Following an early rapid flow component of high labeling in the dorsal root which was cleared from the dorsal root between 3-4 hrs after ganglionic injection, the dorsal root counts were consistently less than that seen in the sciatic nerve. Reasons for the difference will be discussed. (Supported by the Ralph W. Parsons Medical Research Fund.)

97 BRAIN STEM AND SPINAL CORD PROJECTIONS OF VAGAL SENSORY AND MOTOR FIBERS IN THE CAT USING THE TETRAMETHYL BENZIDINE (TMB) REACTION FOR HORSERADISH PEROXIDASE (HRP). Madhu Kalia and Marek-Marsel Mesulam. Dept. Physiol., Hahnemann Med. Col, Phila, PA 19102 and Harvard Neurological Unit, Beth Israel Hosp, Boston, MA 02115

In the past, investigations of the sensory and motor terminations of the vagus nerve have posed great technical difficulty since these studies were based on degeneration techniques. The recent availability of sensitive HRP methods has made it possible to study the afferent and efferent connection of the peripheral nerves and in the present study we have applied these techniques to the vagus. In adult cats the cut central end of the rt. vagus nerve at the level of the larynx was continuously immersed in 33% HRP (Type VI Sigma) for the 48 hrs; the brains perfused with 2.5% buffered glutaraldehyde and the tissue reacted with TMB (Mesulam J.Histochem. Cytochem. 26:106,1978). Uncounterstained sections were examined under dark-field illumination for HRP reaction product. During the survival period if the animals remained anesthetized (Chlorolose), the amt. of HRP reaction product visualized was significantly less than that seen in unanesthetized cats. The HRP label was seen in 3 types of structures within the brain stem: neurons, nerve fibers and patterns that seemed to be nerve terminals. Retrogradely labeled neurons were seen in: 1) Dorsal Motor Nucleus (DMN) of vagus; 2) Nucleus Ambiguus (NA); 3) Nucleus retroambigualis (NRA); 4) Isolated labeled neurons were located in what seems to be the reticular formation of the medulla. We cannot exclude the possibility that these are aberrant neurons of the DMN or NA; 5) In upper cervical segments of spinal cord labeled neurons were seen just lateral to the central canal and medially in the ventral horn. HRP labeled fibers were seen entering through the dorso-lat. side of the medulla. These fibers could be classified into two groups, one belonging to axons of labeled neurons and the other belonging to the central processes of Nodose Ganglion (NG) cells. Virtually all HRP labeled axons were directed at the DMN. Some of these axons joined labeled neurons of the DMN and some other axons looped ventrolat. to reach labeled neurons in NA. The central processes of NG neurons reached and coursed within the Tractus Solitarius. Some of these fibers seemed to form terminal patterns in the components of the Nucleus of the Tractus Solitarius (NTS) such as: lat. NTS, med. NTS and subnucleus gelatinosa of NTS. Such afferent terminals also seemed to be present within the DMN. Thus, this procedure enables the demonstration of afferent and efferent connections which characterize the peripheral components of the vagus nerve and illustrates that the transperikaryal passage of HRP across the Nodose Ganglion may be demonstrated with the use of sensitive histochemical procedures. 98 **AXONAL TRANSPORT OF ENZYMES REQUIRED FOR PHOSPHOLIPID SYNTHESIS.** **M. H. Kumara-Siri* and Robert M. Gould, Dept. Neurochem., Inst. Basic Res. Ment. Retard., Staten Island, NY 10314.**

Lipids and proteins used for the maintenance and integrity of neuronal processes and terminals are synthesized in the perikaryon and axonally transported to the sites of utilization in the axolemma and distant terminal regions. Previously it has been shown by autoradiographic techniques that, in addition to this mechanism, inositol lipid synthesis takes place locally in the mammalian axon (Gould, 1976, Brain Res. 117, 169-174). In the present investigation we have demonstrated that enzymes required for the synthesis of phosphatidylinositol and phosphatidylcholine are being supplied to the processes by axonal transport. Studies of the transport of the enzymes were performed with in vivo ligature paradigm using the sciatic nerves of adult male rats. Activities of CDP-diglyceride: inositol transferase (IT) and 1,2 diglyceride:choline phosphotransferase (CPT), the terminal enzymes of phosphatidylinositol and phosphatidylcholine synthesis, were optimized in homogenates of sciatic nerves using CDP-dicaproin (for IT) and 1,2 diolein (for CPT) as substrates. Specific activity for IT was 38.0 ± 2.58 (S.E.M. n=33) and that for CPT was 0.36 ± 0.031 (S.E.M. n=35) nmoles product formed per mg protein per hr. Ligatures were left for 2-72 hr periods and proximal segments (5mm) were removed at sacrifice, along with control segments (5mm), from same and contralateral side. Enzyme activities (both IT and CPT) in homogenates of proximal segments increased in a time dependent manner compared with the controls. Our results suggest that the two enzymes are axonally transported at slow rates. Build-up of IT in the proximal segment was at all times greater than that for CPT. IT activity was found to double at 40 hr after ligation, whereas at this time activity of CPT enzyme was increased approx. 60%. These results provide additional evidence for a specific need of local inositol lipid metabolism within the processes and perhaps in nerve terminal.

99 DESHEATHED SPINAL NERVE TRUNKS EXHIBIT A DIVALENT CATION REQUIREMENT FOR FAST AXONAL TRANSPORT DISTINCT FROM THAT IN GANGLIA. P.-A. Lavoie*, F. Bolen* and R. Hammerschlag. Div.of Neurosciences, City of Hope Med. Ctr., Duarte, CA 91010

The amount of [^{3}H]protein undergoing fast axonal transport in primary afferent neurons of bullfrog is depressed when ganglia but not when nerve trunks are incubated in medium with either calcium removed or cobalt added (R.H.,Dravid,& Chiu,Science 188: 273,1975; R.H. et al, J.Neurobiol. 8:439,1977). Our proposal, based on these observations, was that a calcium-dependent step occurs in the soma prior to translocation of proteins by the transport system. This has been brought into question by recent studies showing that axonal transport is blocked in desheathed mammalian nerve exposed to calcium-free medium (Ochs, Worth, & Chan, Nature 270: 748, 1977). To assess whether, in bullfrog, desheathing reveals a similar dependence of transport on calcium, a 4 mm region of sheath was removed from 8th and 9th spinal nerves. Preparations were preincubated for 5 h with ganglia in normal medium and nerve trunks in calcium-free medium containing 1 mM EGTA with or without 4 mM $MgCl_2$. Ganglia were pulse-labeled for 1 h with [^{3}H]leucine,and incubation was continued for 17 h at 18°C with nerve trunks selectively exposed to the appropriate calcium-free medium. Similarly desheathed preparations maintained in normal medium served as controls. [^{3}H]protein transported beyond the desheathed region was depressed by 53 ± 9% (n=10) in nerves exposed to calcium-free medium lacking Mg^{++}, whereas no depression of transport was detected with Mg^{++} added to the calcium-free medium (104 ± 9%, n=10). These results suggest that ongoing fast transport in axons has a divalent cation requirement that can be met by Ca^{++} or Mg^{++}. The effects of desheathing on transport were also tested in nerves incubated in medium containing 0.18 mM $CoCl_2$. Ganglia were pulse-labeled for 1 h and preparations were initially transferred to normal medium for 5 h to allow labeled fast-transported proteins to enter the nerve trunks. Ganglia were then removed and the isolated nerve trunks were placed in cobalt-containing medium for an additional 12 h at 18°C. The amount of transport through the desheathed region was similar in nerves incubated in medium with and without cobalt. These results suggest that cobalt does not compete with calcium for the axonal divalent site involved in fast transport. The divalent cation requirement for transport in axons differs from that in ganglia since, in axons, Mg^{++} can replace Ca^{++}, and Co^{++} does not act as a Ca^{++} antagonist. The original proposal that calcium is required in the soma for initiation of transport is therefore not affected by the finding of a calcium requirement for maintenance of transport in the axon.

100 EFFECTS OF COLCHICINE AND CYTOCHALASIN B ON AXONAL TRANSPORT IN NORADRENERGIC NEURONS OF THE RAT BRAIN. B.E. Levin. College of Medicine and Dentistry of New Jersey and VA Hospital, East Orange, NJ 07019.

Proteins labelled with [^{3}H] leucine are transported in four waves in the ascending noradrenergic neurons of the locus coeruleus. Waves I (72-192 mm/d) and II (24-48 mm/d) correspond in rate and subcellular distribution to two waves of [^{3}H] fucose labelled glycoproteins. Norepinephrine (NE) is also transported at a rate of 48 mm/d. Waves III (13-20 mm/d) and V (1.4-2.9 mm/d) travel at intermediate and slow rates respectively. The effect of colchicine and cytochalasin B on axonal transport within these neurons was compared to that for 6-hydroxydopamine (6-OHDA), a specific toxin for catecholamine axons, by injecting 1 μl of the three drugs stereotaxically into the ascending dorsal noradrenergic bundle (DB) at various times prior to precursor injections into the locus coeruleus. Colchicine (5 μg/ μl) caused a time dependent block in net transport (correction was made for changes in precursor incorportion) of [^{3}H] proteins, glycoproteins and [^{3}H] NE comparable to that for 6-OHDA in waves I, II and V. Wave III was only partially blocked (70%) by colchicine when compared to 6-OHDA (100%). Cortical levels of NE and dopamine-B-hydroxylase (DBH), the vesicle bound glycoprotein enzyme which synthesizes NE, were decreased distal to colchicine DB lesions comparably to 6-OHDA lesions. Cytochalasin B (24 μg/ μl) significantly reduced net transport of only waves I and III and failed to alter cortical NE and DBH levels. There were no specific ultrastructural changes in microtubles or neurofilaments found in the lesioned areas by electron microscopy. The differential effects of colchicine and cytochalasin B on the four waves transported in this system suggest that the various subcellular constituents in each wave are transported by differing mechanisms. The similar effects of both drugs on transport of wave II proteins and glycoproteins and NE, as well as similar changes in cortical levels of NE and DBH, suggest that both are transported in this wave by a similar mechanism. This supports the hypothesis that both DBH and NE are transported together within the same vesicles in noradrenergic neurons.

101 RETROGRADE AXONAL TRANSPORT OF NERVE GROWTH FACTOR (NGF) IN THE CILIARY GANGLION OF THE CHICK. S.R.Max, M.Schwab*, M.Dumas* and H.Thoenen, Biocenter of the University, CH 4056 Basel, Switzerland

Retrograde axonal transport of NGF has been demonstrated in peripheral sympathetic and sensory neurons, but not in motor neurons. We have investigated the possibility that NGF is also transported in parasympathetic neurons. This was accomplished by measuring the accumulation of radioactivity in the ciliary ganglia of 1-2 day post-hatching chicks following unilateral intraocular injection of ^{125}I-NGF. The difference in radioactivity between ganglia on injected (I) and uninjected (U) sides is a measure of specific transport. We have substantiated this technique for peripheral systems in other species. To study selectivity of transport, we also tested ^{125}I-labelled tetanus toxin, wheat germ agglutinin (WGA), and cytochrome C.Tetanus toxin and WGA have been shown to be transported in all peripheral and central neurons thus far investigated. Cytochrome C, which has physical properties similar to those of NGF, is not transported in these systems. NGF was transported in the ciliary ganglion (I/U=2.2), as were tetanus toxin (I/U=2.5) and WGA (I/U=3.8). Cytochrome C was not transported (I/U=1.0). Autoradiographic studies support the biochemical evidence for selective retrograde axonal transport of NGF in the ciliary ganglion. Thus, in contrast to generally held views, NGF may have a physiological function in the parasympathetic nervous system. (Supported by the Swiss National Foundation and by the Roche Research Foundation).

102 OUABAIN INHIBITION OF FAST AXOPLASMIC TRANSPORT: Robert O'Neill,* Fred Samson and J. Alejandro Donoso. Ralph L. Smith Research Center, University of Kansas Medical Center, Kansas City, Kansas 66103. The intracellular ionic environment is probably important in fast axoplasmic transport (FAXT). Since the intracellular ion composition can be altered by inhibition of the Na-K ATPase, we have studied the effect of ouabain, which causes a Na^+ gain and K^+ loss intracellularly, on FAXT and axonal ultrastructure. Ouabain, at low concentration, has no effect on tubulin/microtubule polymerization in vitro, structures believed to be involved in FAXT. FAXT of protein in the cat cervical vagus nerve was studied in vitro. ^{3}H-leucine was microinjected into the nodose ganglion; after 2 hrs (for labelling of proteins and initiation of transport) the nerves were removed, incubated for 2.5 hr in Krebs-Ringer solution with 1, 10 or 100 μM ouabain and the FAXT character ascertained from the radio-activity in 2 mm nerve segments. In control experiments the labelled material distribution along the nerve is characterized by (a) a significant amount of label at the injection site; (b) a region of gradual decrease of label with distance from the ganglion ("saddle area") and (c) a more distal radio-active peak or "front" of transported material. Ouabain 1 μM caused a partial blockade of FAXT as evidenced by the appearance of extra peaks behind the normal front. Higher concentrations cause a correspondingly greater inhibition, that is, a filling of the saddle area. Preliminary electron microscopy revealed in unmyelinated axons prominent "vacuoles", swelling of some mitochondria and signs of intraaxonal lysis; other axonal constituents such as microtubules and neurofilaments appeared intact. These axoplasmic alterations are more extensive with the high ouabain concentrations. Myelinated axons and glial cells appear less affected. The ionic imbalance induced by ouabain may disrupt the FAXT system by a general spatial disorganization of the cytoskeleton or possibly directly by a specific ionic effect. Supported in part by NICHHD-02528, U.S.P.H.S.

103 AXONAL TRANSPORT OF ^{35}S TAURINE ALONG NEONATAL AND YOUNG ADULT RAT OPTIC AXONS. Michael Politis and Nicholas Ingoglia. Dept. Physiol. and Neurosci., N.J. Med. School, Newark, N.J. 07103

Brain concentrations of taurine are highest in early development and decrease as a function of age. Studies in this laboratory have indicated that this sulfonic amino acid is axonally transported along goldfish optic nerves. In the present experiments the axonal transport of taurine has been examined in neonatal and young adult rat optic axons. The rat optic system was chosen because a large extent of development in this system occurs postnatally, the majority of synapses in the lateral geniculate bodies being formed between 5 and 12 days after birth.

^{35}S taurine was injected into the vitreous humor of right eyes of developing (1 to 15 day old) or young adult (40 day old) rats. At various times after injection ranging from 3 hrs. to 7 days, right retinae and left and right geniculates were removed and assayed for radioactivity. Since the rat optic system is predominately crossed, left minus right geniculate (L-RLG) radioactivity was used as an index of axonally transported ^{35}S taurine activity. Results indicated that taurine was rapidly transported along both neonatal and young adult optic axons. This is in contrast to other amino acids (i.e., leucine and proline) which are not axonally transported in this system. Peak L-RLG ^{35}S activity in both neonatals and adults was reached by 24 hrs. after injection. Significant developmental variations were seen in the levels of both L-RLG and right retinal ^{35}S taurine activity 24 hrs. after injection of 1,4,7,11,15 and 40 day old rats. Autoradiographic analysis of retinae following intraocular injection of ^{3}H taurine indicated that the proportion of total retinal radioactivity in the ganglion cell layer was approximately 15% in 5,11 and 40 day old rats. Thus, total right retinal ^{35}S activity was used as an index of ^{35}S taurine uptake by retinal ganglion cells. The levels of L-RLG ^{35}S taurine activity "corrected" for retinal uptake in animals injected at 1,4,7 and 11 days after birth (prior to and during the major period of synaptogenesis in the geniculates) were 4.5, 3.1, 2.3 and 2.6 times higher, respectively, than those in the young adults. In contrast, the amount of corrected L-RLG ^{35}S activity in animals injected 15 days after birth (after synaptogenesis) were not significantly different than those in the young adults.

These data show that taurine is transported along both neonatal and young adult optic axons and that the amount of taurine transported along neonatal axons prior to and during the development of synaptic connections is several fold higher than along adult axons. It is proposed that axonally transported taurine may be acting as a stabilizer of axonal membrane activity during the formation of synaptic connections.

104 SPECIFIC AND RAPID TRANSPORT OF FREE GLYCINE IN IDENTIFIED AXONS OF APLYSIA. C.H. Price, D.J. McAdoo, and W. Farr*. Marine Biomedical Inst., Univ. Texas Medical Branch, Galveston, TX 77550.

Neurons R3-R14 in the parietovisceral ganglion (PVG) of Aplysia may be glycinergic (Price, et al., and McAdoo, et al., 1978, Brain Res., in press). Their axons travel down the branchial nerve to peripheral terminals presumed to be near the junction of the heart and efferent vein from the gill. The 12 axons are easily identified in histological sections due to their large size, characteristic granules, and extensive invagination by glial cells. Using a double-chamber apparatus, the PVG was incubated in vitro, in media containing ^{3}H-glycine, and the branchial nerve was extended into a radioactivity-free, superfusion chamber. After incubations for several hours, the nerve was either frozen in place and sliced into sequential 1 mm pieces for liquid scintillation spectrometry or fixed with 3% glutaraldehyde for autoradiography. In light microscope autoradiographs of cross-sections taken at 4 mm from the PVG, 45% of the silver grains were localized in R3-R14 axons; these axons take up less than 10% of the entire nerve area. Electron microscope autoradiographs confirmed that the silver grains in R3-R14 were inside the axons and not in surrounding glial tissue. When other ^{3}H-amino acids were used instead of glycine, the axons of R3-R14 were labeled equally to other axons. At least 85% of transported radioactivity comigrated with free glycine in thin-layer chromatographic analyses of pieces of nerve from experiments in which ganglia were incubated in media with ^{3}H-glycine for 3-24 h. Free glycine was transported down the branchial nerve at a faster rate (65 mm/day) than other amino acids (20-48 mm/day) and in greater quantities (>6 times as much). In the left pleurovisceral connective (which contains no R3-R14 axons), glycine was transported at 25 mm/day. Transport of glycine down the branchial nerve was inhibited by mercuric ions ($HgCl_2$, 1 mM), by lowered calcium (oxalic acid, 20 mM), and by the microtubule agents vinblastine (0.1 mM) and Nocodazole (10 µg/ml) but was not affected by 2,4 DNP (2 mM), NaCN (1 mM), or high K^{+} (150 mM). Ligation stopped transport; no proximal accumulation of radioactivity was observed. Glycine is transported retrogradely at a rate comparable to orthograde transport but in quantities 9 times less. In autoradiographs of nerves from retrograde experiments, silver grains were localized almost exclusively to R3-R14 axons. We have demonstrated the fast and energy-dependent axonal transport of large quantities of free glycine in identified neurons R3-R14. This specific transport, which is directly dependent on the presence of calcium and may involve microtubules, strengthens the notion that there is a non-metabolic role for glycine in these neurons, perhaps as a neurochemical messenger. This work was supported by an NIH fellowship to CHP (#1F32NS 05856) and DHEW grant #11311 to DJM.

105 DIFFERENTIAL TURNOVER OF AXONALLY TRANSPORTED GLYCOPROTEINS. James A. Ripellino* and John S. Elam, Dept. Bio. Sci., Florida State Univ., Tallahassee, FL. 32306

It has previously been shown that axonally transported glycoproteins reach maximum accumulation in the goldfish optic tectum at 25-30 h after intraocular injection of ^{3}H- fucose (Forman et al, Br. Res. 48, p. 327 (1972); Monticone & Elam, Br. Res. 100, p. 61 (1975)). This label was found to undergo subsequent turnover with a half life approximately of 20-30 days. In the present study, the distribution and turnover of axonally transported glycoproteins was assessed in the membranous and soluble subfractions of goldfish tectum at various times after intraocular injection of ^{3}H fucose. The membranous fraction (sedimentable at 100,000 g) comprised 87% of the rapidly transported label 24 h postinjection. This fraction exhibited a half-life for the disappearance of radioactivity of 20 days. In contrast, the 100,000 g soluble fraction showed a more rapid turnover, with an apparent halflife of 7 days.

Axonally transported glycoproteins associated with the membranous and soluble fractions were converted to glycopeptides (by pronase digestion) and separated into dialyzable and non-dializable fractions. At 24 h post injection the membrane derived non-dialyzable glycopeptides produce a broad peak within the included volume of Sephadex G 50. At 20 days post injection, this distribution shows an apparent increase in molecular size, suggesting more rapid turnover of the lower molecular weight chains. There was no corresponding turnover-dependent change in the size of non-dialyzable glycopeptides associated with the soluble fraction.

The results suggest that soluble glycoproteins are utilized more rapidly than membranous glycoproteins in the nerve terminals. The various sized glycopeptides from the soluble fraction appear to have similar turnover rates while glycopeptides from membranous fraction show size dependent differences in turnover. These patterns support the concept of differential utilization of various classes of glycoproteins at the nerve terminal.

106 NEUROTOXIC HEXACARBONS INTERFERE WITH NERVE FIBER GLYCOLYSIS. Mohammad I. Sabri*, Cyril L. Moore*+ and Peter S. Spencer, Neurotoxicology Unit, Albert Einstein College of Medicine, Bronx, N.Y. 10461 and +the School of Medicine at Morehouse College, Atlanta, Georgia.

Prolonged, low-level exposure to neurotoxic carbon compounds such as methyl n-butyl ketone (MBK) or its metabolite, 2,5-hexanedione (2,5HD) initially causes axonally transported materials to accumulate and form swellings on the proximal side of nodes of Ranvier in the distal region of long and large PNS myelinated fibers, and, subsequently, fiber breakdown below an axonal swelling. Speculating that anterograde axonal transport blockade might first occur at nodes of Ranvier if decreased amounts of ATP were available to drive energy-dependent axonal transport and impulse conduction, investigations commenced to determine the possible effects of hexacarbons on metabolic pathways concerned with energy production. We have focused our studies on glyceraldehyde-3-phosphate dehydrogenase (GAPDH) and phosphofructokinase (PFK), major control steps in glycolysis. When crystalline GAPDH or PFK was pre-incubated with MBK or 2,5HD enzyme activity was inhibited as a function of the concentration of the toxin and the period of pre-incubation. Enzyme activity was preserved by dithiothreitol, suggesting that sulfhydryl groups were vulnerable to hexacarbons. A comparable response was found when these enzymes were assayed in both PNS and CNS tissue pre-incubated with MBK or 2,5HD in vitro. Double reciprocal plots of velocities against substrate concentration revealed that GAPDH was inhibited un-competitively by 2,5HD. By contrast, 1,6 hexanediol (a neurologically inactive hexacarbon compound) and acetone failed to inhibit crystalline GAPDH activity. The specificity of hexacarbon-induced GAPDH inhibition was shown by preservation of crystalline and tissue lactic dehydrogenase acticity, even after prolonged pre-incubation with 2,5HD or MBK in vitro.

These data demonstrate that neurotoxic hexacarbon compounds interfere with energy metabolism by inhibiting key glycolytic enzymes in peripheral nerves. Because GAPDH blockade is known to result in a failure of fast axonal transport, we suggest that this mechanism may be in part responsible for the abnormalities of axonal transport seen in hexacarbon neuropathy. Furthermore, these data provide the first evidence to support our hypothesis that hexacarbons are targeted directly against enzymes required for axonal integrity, the nerve cell body perhaps being unable to meet the presumed increased axonal demand, thereby causing distal regions to suffer first from a failure and undergo degeneration.

Supported by USPHS grants, OH00535 and NS 03355 and a grant from the American Petroleum Institute.

107 A MULTIWIRE PROPORTIONAL CHAMBER USED TO DETECT AXONAL TRANSPORT OF ^{35}S-METHIONINE AND ^{32}P-PHOSPHATE LABELLED MATERIAL.

R.E. Snyder*, T.R. Nichols* and R.S. Smith. Division of Biomedical Engineering and Applied Sciences, the Department of Physics and the Department of Surgery, University of Alberta, Edmonton, Canada.

A multiwire proportional chamber was used to detect axoplasmic transport in dorsal root ganglion/sciatic nerve preparations from *Xenopus laevis*. Nerve cell bodies exposed to ^{35}S-methionine were shielded from the detector by a lead-lined compartment; the sciatic nerve ran in an unshielded chamber over the detector. In experiments with ^{32}P, the effects of secondary X-rays were avoided by loading the label into the cell bodies for several hours in a separate bath; the dorsal root ganglia and adjacent nerve roots were then removed and the sciatic nerve alone was placed in a chamber over the detector. The detector collected radiation from a series of 6 mm segments of nerve for consecutive periods of 1/2 h for the duration of experiments lasting 18-22 h. Typically, in the ^{35}S-methionine experiments, the radioactivity of each nerve segment showed an initial plateau at background followed by a rise which was linear through time. Plots of the time at which the rise in radioactivity took place against the position of each segment of the nerve yielded transport velocities of about 6.2 mm/h. Cutting the nerve proximally showed that label left each segment of nerve at the same velocity. Material labelled with ^{32}P was also transported at a similar rapid velocity. An order of magnitude less label was transported if ^{32}P-phosphate was used in conjunction with phosphate-buffered saline than if the saline were HEPES-buffered and free of cold phosphate. With HEPES buffer, the amount of ^{32}P transported was about two orders of magnitude less than the amount of ^{35}S-methionine which was transported in similar preparations.

Supported by the Medical Research Council of Canada.

108 TRANSNEURONAL TRANSFER OF AXONALLY TRANSPORTED RADIOACTIVITY DURING POST-NATAL DEVELOPMENT OF THE HAMSTER VISUAL SYSTEM. Susan C. Specht* (SPON: W.C. De Mello). Dept. Pharmacol. UPR Sch. Med., San Juan, PR 00936.

Transneuronal transfer (TT) of axonally transported protein-bound radioactivity was examined in the visual system of neonatal and adult albino hamsters. Following intraocular injection of 3H-proline, radioactive protein is axonally transported to nerve endings in the lateral geniculate body (LGB) and superior colliculus (SC). Some of the transported radioactivity is transferred to LGB cells and subsequently transported to LGB nerve endings in layer IV of visual cortex where it can be detected by scintillation counting or autoradiography. Non-specific TT from SC to overlying retrosplenial cortex was also observed.

TT was evaluated both 1 and 11 days after intraocular injection of 3H-proline by scintillation counting of visual and non-visual cortex. Early TT (1 day) was greatly enhanced during the period of eye-opening (14-16 days post-natal) and then diminished in older animals. Labeling of LGB was not significantly different. Early TT was not detected against the cortical background radioactivity in 8 and 10 day animals. Late TT (11 days) was observed in all ages, but was significantly greater in young animals. Non-specific transfer to retrosplenial cortex followed essentially the same developmental pattern. These results demonstrate that the onset of functional visual activity in the optic nerve is accompanied by a large but transient increase in TT of rapidly (or intermediately) transported radioactivity. Increases in both specific and non-specific transfer suggest that the primary event is enhanced release from optic nerve endings and not a post-synaptic event, e.g., enhanced uptake or enhanced protein synthesis, although these may play a part. The fact that TT decreases in older animals with functional visual activity supports the conclusion of Grafstein and Laureno (Exp. Neurol. 39:44, 1973) that synaptic activity per se is neither a sufficient nor necessary condition for TT. The brief increase in TT at the time of eye-opening may be related to inductive events in visual system development. (Partly supported by grant CA-16598-02).

109 SIMILAR PROTEINS ARE RAPIDLY TRANSPORTED IN DORSAL ROOT SENSORY NEURONS AND VENTRAL HORN MOTONEURONS. George C. Stone and David L. Wilson, Dept. of Physiol. and Biophys., U. of Miami Sch. of Med., Miami, Fla. 33152.

Despite histochemical and enzymatic evidence suggesting the rapid axoplasmic transport of proteins unique to specific types of neurons, the majority of electrophoretic studies to date have found no differences in rapidly-transported proteins in various neuronal systems.

Two-dimensional gel electrophoresis has allowed a higher-resolution comparison of rapid transport in dorsal root sensory neurons with that in ventral horn motoneurons in sciatic nerve. Experiments were performed in vitro in frog as described previously (Stone et al., Brain Res. 144; 287-302). Dorsal root ganglia 8 and 9, or hemisected spinal cord were selectively exposed to ^{35}S-methionine for 6 hr, while the sciatic nerve was ligated 30 mm distal to the label site. After 24 hr at 18°C label which accumulated in a 3-mm segment proximal to the ligature was subjected to two-dimensional gel electrophoresis. Comparisons were made of fluorographic patterns from dried gels. Fifty independent species of protein, including all the more abundant ones were consistently common to both dorsal root and ventral horn neurons (see figure, closed symbols), while at most 4 minor protein species were possibly transported only in ventral horn neurons (open symbols). Less counts were transported in ventral horn neurons, so the determination of transported proteins unique to dorsal root neurons was not attempted.

The analysis suggests that approximately 50 of the most abundantly-transported, independent proteins are common to these two sets of neurons which subserve very different functions. This result verifies and extends the earlier observations of others made with lower-resolution electrophoretic techniques.

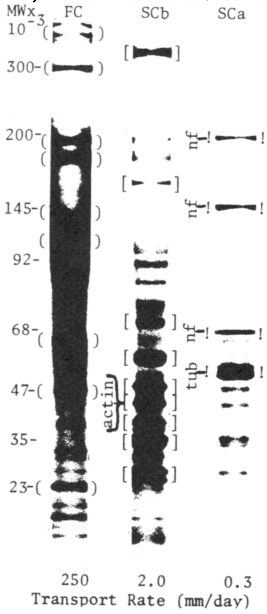
Supported by NIH grant NS12393 and a biomedical research support grant. GCS is a NIH postdoctoral trainee (NS07044).

110 COMPARISON OF FAST TRANSPORTED PROTEIN AND GLYCOPROTEIN DOWN-FLOW PATTERNS IN SENSORY AND MOTOR FIBERS OF MAMMALIAN SCIATIC NERVE. Daniel P. Stromska* and Sidney Ochs. Dept. Physiology, Indiana University School of Medicine, Indianapolis, IN 46202.

Glycoproteins and some polypeptides are considered to be carried in nerve fibers by fast axoplasmic transport, primarily to the axon terminals, while the bulk of the proteins synthesized by the soma are transported more slowly. We compared the outflow characteristics of fast transported ^{3}H-fucose and ^{3}H-glucosamine labeled glycoproteins with ^{3}H-leucine labeled proteins in the motor and sensory fibers of the cat sciatic after injecting the labeled precursors into the L7 dorsal root ganglion or L7 ventral cord. The resulting outflow patterns showed a higher amount of incorporated ^{3}H-leucine transported in the crest than of ^{3}H-fucose labeled components in the sensory fibers. The ganglion pool - nerve crest amplitude relationship (Ochs, J. Physiol. 255:249, 1976) was the same with either ^{3}H-fucose or ^{3}H-leucine as the precursor. The slope of the advancing front of ^{3}H-fucose labeled activity was shallower than that of the ^{3}H-leucine labeled proteins in the sensory fibers after 3 and 7 hours of downflow. A shallow front slope was also observed with ^{3}H-glucosamine labeled material in sensory fibers. The maintained shallow slope of the labeled fronts in the sensory fibers with distance of the ^{3}H-fucose labeled substances, suggests, that in contrast to ^{3}H-leucine labeled materials, fucose labeled glycoproteins have a different process of synthesis and export into the fibers. Glycoprotein synthesis requires transit through the Golgi apparatus, the shallower front slope found for the sensory fibers with ^{3}H-fucose compared to ^{3}H-leucine may be due to this process. The outflow patterns in the motor fibers generally show a somewhat higher amount of ^{3}H-fucose labeled material transported than ^{3}H-leucine labeled components, as judged by their crest amplitudes. In contrast to the sensory fibers, the slopes of the fronts of both ^{3}H-fucose labeled glycoproteins and ^{3}H-leucine labeled proteins were shallow in the motor fibers and this was seen after both 4 and 7 hours of downflow. This observation suggests that ^{3}H-leucine polypeptides are processed in motor neurons at a slower initial rate than in sensory neurons. The ^{3}H-leucine labeled polypeptides in the motoneurons may be more dependent on Golgi processes and/or slower polypeptide synthesis which occurs at a rate comparable to that of glycoproteins in sensory neurons. Supported in part by NIH grant PHS RO1 NS 8706-09 and NSF grant BNS 75-03868-A03.

111 AXONAL TRANSPORT IN GUINEA PIG OPTIC NEURONS: EACH COMPONENT CONSISTS OF A DISTINCT PATTERN OF PROTEINS. M. Tytell* and R. J. Lasek, Neurobiology Center and Anatomy Department, Case Western Reserve Univ., Cleveland, Ohio 44106.

When guinea pig optic neurons are pulse labeled, axonal protein transport appears as three major waves of radioactivity defined by their velocities: the fast component (FC), >250 mm/day; slow component b (SC_b), 2.0 mm/day; and slow component a (SC_a), 0.3 mm/day (Black & Lasek, Soc. Neurosci. 3:29, 1977). The hypothesis that each component contains a distinct class of proteins was tested by SDS-PAGE analysis. ^{3}H-lys and -pro were injected into the vitreous hymor of guinea pig eyes and the animals sacrificed after 6 hrs for FC, 6 days for SC_b, and 38 days for SC_a. For FC, the optic nerve was cut slightly anterior to the chiasm to cause the FC proteins to accumulate. The portion of nerve containing the wave of labeled proteins was homogenized in 8 M urea with 5% BME and 1% SDS, which solubilizes essentially all proteins. Following centrifugation at 140,000g-30 min, the labeled proteins in the supernatant were analyzed by SDS-PAGE on a 4-17.5 % gradient gel. In the Fig, the bands unique to each component are enclosed by () for FC, [] for SC_b, and !! for SC_a. The patterns are clearly different. None of the proteins are present in equal amounts in more than one component and most do not overlap at all. The few bands which appear similar in two components (80K, 92K, and 180K daltons for FC and SC_b and 35K, 43K, 50K, and 250 K daltons for SC_b and SC_a) are most likely different proteins with similar electrophoretic mobilities or small amounts of proteins trailing behind the wave. It is also possible that a few proteins are actively conveyed in more than one component. These possibilities are being explored. Since neurofilament proteins (nf) and tubulin (tub) are conveyed exclusively in SC_a, actin in SC_b and FC contains mainly membraneous proteins, each component of axonal transport appears to represent a specific set of structural and functional entities.



112 AXONAL TRANSPORT OF TRITIATED PROLINE IN THE CORTICOSPINAL TRACT OF THE RAT SPINAL CORD. H. Lee Vahlsing*, Earl R. Feringa and Ronald B. Hirschl*. Depts. Neurol. and Path., VA Hosp. and U. of Mich., Med. Ctr., Ann Arbor, MI 48105

Thirty-six female rats received injections of tritiated proline (100 µCi in 5 µl) into the sensory-motor cortex at eleven weeks of age. At time intervals of 1,2,4,6,8,16 and 24 hours and 2,4,7,14 and 21 days after injection, groups of three rats were sacrificed and formalin perfused. The spinal cords were completely removed and divided into sixteen 5 mm long segments beginning at the obex. Each segment was then analyzed for tritium content using scintillation counting technique. Radioactivity was detected in the spinal cord segments of rats sacrificed one hour after injection in amounts 5-10 times greater than that found in uninjected controls. Tritium label in segments from rats sacrificed two hours after injection showed similar low level background, but also exhibited the leading edge of a wave of tritium which passes down the spinal cord at the rate of 15-20 mm/hr. This wave, which was initially five to ten times the magnitude of background levels found at one hour, was approximately five cm in length and was skewed toward the leading edge. This wave left behind a residuum of tritium in each segment which was approximately proportional to the mass of that segment. Autoradiography on spinal cord segments revealed that most tritium was confined to the corticospinal tracts, but a minor amount was somewhat diffusely present in the dorsal and lateral horns of the gray matter. At four days after tritium injection, the leading edge of a second wave of tritium was apparent in the first few segments of spinal cord. Initially this peak was about 100 times greater than the background found in the one hour rats, but as it traveled at 3-4 mm/day, the peak decreased progressively leaving a residuum of tritium which labeled the corticospinal tracts lying ventrally in the dorsal white columns. Autoradiography revealed that this wave also frequently labeled a small tract adjacent to the ventral median fissure. This tract was most easily identified in the cervical regions. The label in the horns of the gray matter was less intense and more diffuse. Autoradiography after the injection of the sensory-motor cortex of only one cerebral hemisphere revealed only the contralateral dorsal corticospinal tract was labeled while the ventral tract was labeled only on the ipsilateral side of the cord.

113 RETROGRADE TRANSPORT OF FLUORESCENT SUBSTANCES IN THE RAT BRAIN. Derek van der Kooy, Henricus G.J.M. Kuypers[X], Coriene F. Catsman-Berrevoets[X] and Marina Bentivoglio[X]. Dept. Anat., Sch. Med., Frasmus Univ., Rotterdam, The Netherlands.

A search has been made for fluorescent substances that are retrogradely transported in axons. Evans Blue, which fluoresces red, and a mixture of Primuline and 4'-6-diamidino-2-phenylindol 2 HCL (DAPI), which fluoresces blue with golden granules, can both be shown to travel retrogradely from an injection area in the caudate-putamen back to cell bodies in the substantia nigra of the rat. Recently, Propidium Iodide, which fluoresces red- orange, has also been shown to undergo retrograde axonal transport in the nigro-striatal system. Two of these fluorescent compounds can be used to simply and effectively demonstrate double labelling of single cells. This has been shown in the mammillary bodies, after injection into two divergent axon collateral areas. Rats were injected unilaterally with 0.10-0.40 ul of 10% Evans Blue solution into the AV, AD, and AM thalamic areas, and with a similar quantity of 10% Primuline-2.5% DAPI solution into an area medial to the red nucleus where the descending mammillary body fibers travel. Many of the cells in the ipsilateral lateral mammillary nucleus and in the medial part of the ipsilateral medial mammillary nucleus were labelled both with Evans Blue and DAPI-Primuline. This double labelling technique has also been used to study the degree of collateralization of certain brainstem projections to the forebrain. After injections of Evans Blue into the frontal cortex- olfactory tubercle and DAPI-Primuline into the temporal cortex- amygdala, many double labelled cells were seen in the dorsal raphe nucleus. In contrast, separate, but intermixed, clusters of red and blue fluorescent cells were seen in the substantia nigra. Other experiments have demonstrated that a population of substantia nigra pars reticulata cells give collateral projections to both the thalamus and superior colliculus. A continuing search is in progress to find other fluorescent substances transported retrogradely in neurons, in order to improve further the double labelling methodology with the aim to investigate the axon collaterals of cells in other neural systems.

114 SUBCELLULAR LOCALIZATION OF PARTICLES INVOLVED IN THE TRANS-LOCALIZATION OF PROTEIN IN CEREBRAL TISSUE. Fredric P. White. Faculty of Medicine, Memorial University of Newfoundland, St. John's, Newfoundland, Canada. A1B 3V6

The translocation of newly synthesized protein from one subcellular site to another within brain cells has been investigated using cerebral cortex slices. In one experimental design vinblastine, an inhibitor of fast axoplasmic flow, was used in conjunction with a double label routine. In these experiments some slices were incubated with vinblastine [0.1µM], which does not inhibit protein synthesis in slices, and [^{3}H] leucine while other slices were incubated in ^{14}[C] leucine alone. The slices were homogenized together and fractionated by differential sedimentation and discontinuous sucrose gradient techniques. Comparisons of the ratios of $^{3}H/^{14}C$ for each fraction enables one to determine if any fraction is enriched for an export particle or import particle. An export particle is one in which vinblastine causes an accumulation of newly synthesized protein and an import particle is one in which vinblastine prohibits the accumulation of newly synthesized protein. This analysis has shown the presence of at least one export particle, $P_1 6$. This particle pellets in the crude nuclear fraction and has a density between 1.166 and 1.280. Light microscopy inspection of these fractions show the presence of nuclei, however, the particle of interest shows a skewed distribution towards the lighter portion of the gradient in comparison to DNA. The greatest enrichment for an import particle has been obtained from the crude mitochondrial pellet. It [$P_2 2$] has a density between 1.0592 and 1.1036, and is marked by the presence of both 5'AMPase and 2', 3' cyclic nucleotide 3'-phosphohydrolase [2',3'CNP]. Continuous sucrose gradients have shown that the 5'AMPase and 2',3'CNP activities can be separated and the import particle is skewed towards the 5'AMPase. It is believed, therefore, that 5'AMPase is a marker for this import particle. In other experiments using pulse-chase procedures $P_1 6$ was shown to decrease in specific activity during the chase period while $P_2 2$ increased in specific activity during the same period. Thus the conclusion drawn from the vinblastine experiments, that $P_1 6$ was an exporter of protein and $P_2 2$ an importer, were confirmed. Lowering the [Ca^{++}] of the incubation media inhibits the synthesis of protein by the slices, but transport is stopped only when the media is made up Ca^{++} free. It is concluded that subcellular particles can be isolated by ultra centrifugation techniques which are involved in the vinblastine and [Ca^{++}] sensitive transport of proteins. This research was supported by MRC Grant MA-5404.

BASAL GANGLIA

115 RESPONSES OF CAUDATE NEURONS IN AWAKE MONKEYS TO A VISUAL STIMULUS THAT INITIATES A MOTOR TASK. J. Wayne Aldridge, R.J. Anderson and J.T. Murphy. Dept.Physiol., Univ.of Toronto, Toronto, Ontario, Canada, M5S 1A8.

Monkeys were trained to perform a motor task involving wrist movements. The object of the task was to superimpose a square on a vertical target line displayed on a TV monitor. The monkeys achieved this through a manipulandum by flexion or extension of the wrist which corrected the horizontal position of the square. For this study experimental trials were designed to examine responses to the sudden appearance of the line and square on the TV screen, that is, to the visual cue initiating the task. Each trial consisted of a control period during which the display was blank followed by a period during which the monkey performed the task. Spikes from the caudate nucleus (Cd) were recorded with PtIr electrodes and spike times, angular velocity and angular position of the wrist were recorded by an on-line computer. Histological verification of cell locations was carried out.

Two hundred and sixteen Cd cells were examined for a visual cue response. Of this sample 100 neurons (45.6%) altered their cell firing with the appearance of the display. Fifty-two cells were inhibited, 56 were excited and 9 cells had both excitation and inhibition. The majority of the responses observed were phasic in nature. The mean latencies were 238($\pm$164) msec and 200($\pm$67) msec for excitations and inhibitions respectively. Ninety-two cells (92%) responded before the onset of movement. The mean latencies to movement were 200 msec and 261 msec for excitation and inhibition respectively.

These results demonstrate that a significant proportion of Cd neurons have responses correlated with a visual stimulus signifying the onset of a motor task. The anatomical position of the caudate may allow it to direct this information to other motor structures through the pallidal and thalamic pathways.

116 DEMONSTRATION OF RAT CAUDATE PROJECTION NEURONS BY INTRACELLULAR HORSERADISH PEROXIDASE TECHNIQUE. G.A. Bishop, R.J. Preston* and S.T. Kitai. Dept. Ant., Mich. State Univ., E. Lansing, MI 48824

The caudate (Cd) nucleus is composed of a variety of neuronal types differentiated on the basis of somatic size and dendritic morphology. While previous studies have attempted to identify which of these various neurons are projection cells, no conclusive evidence has been reported. In this study, therefore, we have combined intracellular recording and intracellular staining techniques to (1) identify Cd projection neurons and (2) examine the physiological responses of these projection cells to stimulation of the substantia nigra (SN). Male hooded rats (200-400 g) were anesthetized with urethane(120 mg/100g). SN stimuli (0.05-0.1 msec pulses) were applied through stereotaxically positioned insulated needles. Beveled microelectrodes filled with 4% HRP in 0.5 M KCl-tris buffer were used to record from and stain (positive DC pulses 5-20nA; 1-5 min; f=5/sec) single Cd cells. Following appropriate histological processing, neurons filled with HRP were serially reconstructed with the use of a drawing tube and identified as projection neurons by following their axons out of the CD nucleus. In these neurons, SN stimuli evoked monosynaptic EPSPs at an average latency of 4.3 msec. Often the EPSPs were followed by hyperpolarization lasting 100 msec or more. The injected neurons were located in various regions of the head of the Cd nucleus. Their somata had diameters of 14-24 µm, were either spherical or elliptical in shape and gave rise to 4-9 primary dendrites. These primary dendrites branched repeatedly into secondary and tertiary branches extending 250-400 µm anterposteriorly, 300-350 µm dorsoventrally and 150-200 µm mediolaterally. The somata and primary dendrites of the projection neurons were virtually spine free while the secondary and tertiary dendrites were heavily covered with both pedunculated and sessile spines. The axon arose either directly from the soma or from a primary dendrite and gave rise to 2-4 local collaterals which branched extensively to form a fine axonal plexus within, and to some extent beyond, the dendritic domain of the parent cell. Without branching further in the Cd, the parent axon coursed ventrally and caudally out of the nucleus and into globus pallidus (GP). Some axons appeared to terminate in GP while others, often after giving rise to a beaded collateral in this nucleus, continued into the internal capsule. Several of these latter axons were traced to a point near the entopeduncular nucleus; however, the precise area of termination of these axons has not yet been observed. This study has clearly demonstrated that at least one type of projection neuron in the Cd nucleus of the rat is a medium sized spiny neuron and that this neuron receives excitatory input from the SN. (This work was supported by NIH grant NS00405.)

117 EFFECTS OF VENTRAL MESENCEPHALIC TEGMENTAL LESIONS ON LOCOMOTOR ACTIVITY IN RATS. M.G. Boyeson, G.K. Hodge, and R.T. Linn. Dept. Psychology, U. of New Mexico, Albuquerque, NM 87131.

Recently, increasing concern has been focused on the systems underlying spontaneous locomotor activity in hopes of better understanding the motoric dysfunctions respondsible for hyperactive behavior exhibited by children. The exact neuroanatomical structures and neurophysiological functions respondsible for hyperactivity remain unclear. The integrity of monoaminergic pathways of the mesolimbic and nigro-neostriatal systems, however, appear essential in maintaining normal locomotor activity. Bilateral lesions in the ventral mesencephalic tegmentum, in particular, area A10, and pars compacta of the substantia nigra have resulted in increased locomotor activity (Le Moal et al., EXP NEUROL 50: 521, 1976; Hodge and Butcher, NEUROSCIENCE ABSTRACTS 1: 196, 1975). To further delineate the substrates of spontaneous hyperactivity, bilateral radiofrequency lesions were made in the ventral mesencephalic tegmentum of rats. Locomotor activity was assessed in an open field apparatus for 15 minutes on six days prior to, and twelve days following, the operations. The lesions resulted in a significant increase in locomotor activity. Subsequent histological evaluation revealed that hyperactivity was associated with damage to area A10; such lesions, however, also involved nucleus linearis centralis, believed to be comprised of serotonergic cell bodies. In fact, lesions of nucleus linearis centralis alone were found sufficient to elicit hyperactivity. These data suggest that serotonergic as well as dopaminergic systems may contribute to the increased activity produced by lesions of the ventral mesencephalic tegmentum. (Supported by U.N.M. Research Allocation grants 020-812-270 and 020-812-402.)

118 THE EFFECTS OF STIMULATION OF THE SUBSTANTIA NIGRA ON ENDOGENOUS AND DEUTERIUM-LABELLED ACETYLCHOLINE (ACh) IN THE CAUDATE NUCLEUS OF THE CAT. S.H. Butcher and E. Garcia-Rill, Mental Retardation Res. Ctr., Sch. Med. UCLA, Los Angeles, CA. 90024

The existence of an interaction between dopamine (DA) and ACh in the caudate nucleus has been accepted for many years. However, the exact nature of this interaction or modulation of ACh activity by DA, i.e. whether DA has an excitatory or inhibitory effect on ACh, remains a controversy. In an attempt to examine this interaction in the cat caudate nucleus we employed electrical stimulation of the nigrostriatal pathway as a means of stimulating the DA input to this region. A four-pronged stimulating comb was stereotaxically introduced unilaterally into the substantia nigra in locally-anesthetized, paralyzed cats. The cortex overlying the caudate nuclei was removed by suction allowing the removal of biopsies as described by Anchors and Garcia-Rill (Brain Res., 133:183, 1977). Throughout the experimental procedure animals were infused with deuterium-labelled choline ($^2H_9$-Ch, 1µmol/kg/min). Endogenous and labelled ACh and Ch were analyzed using the gas chromatographic-mass spectrometric method of Jenden et al (Anal. Biochem. 55:438]973). In an attempt to diminish post-mortem changes in ACh, tissue samples were withdrawn into a solution of 1N formic acid/acetone (15/85 v/v) within 1 sec and quenched in liquid nitrogen within 4 sec. In four cats, biopsies from both caudate nuclei were removed before and after 5 min of unilateral stimulation of the substantia nigra (15v, 20Hz, 0.2ms ea).

Stimulation of the nigrostriatal pathway produced a 74% decrease in deuterium-labelled ACh levels, as well as a decrease in the levels of endogenous ACh levels. This decrease in the specific activity of ACh (57%) implies that stimulation of the nigrostriatal pathway had an excitatory effect, (eg. increased ACh release) on ACh neurons in the caudate nucleus. This increased release in ACh probably represents release of ACh from the newly synthesized pool.

119 AN ELECTROPHYSIOLOGICAL STUDY OF CORTICO-CAUDATE CONNECTIONS: ROLE OF THE CENTER MEDIAN-PARAFASCICULAR NUCLEI OF THE THALAMUS. E. Cherubini*, M.S. Levine, N.A. Buchwald and C.D. Hull. Mental Retardation Research Center, Sch. Med., UCLA, Los Angeles CA 90024.

In cats, the pericruciate cortex (CX) projects heavily to the head of the caudate nucleus (CD). Electrical stimulation of CX produces an initially excitatory response in CD neurons. Some of the responses are monosynaptic but there are other routes by which stimulation of CX can influence CD neurons. For example, stimulation of CX can activate thalamic nuclei which project to the CD or may antidromically activate collaterals projecting from intralaminer thalamus to both CX and CD. There is anatomical evidence for each of these alternative routes. The present experiment was designed to determine the extent to which indirect activation of CD neurons occurs in response to CX stimulation. Extracellular spike potentials of CD neurons were evoked by electrical stimulation of precruciate CX in intact cats. Mean latencies to response and the distribution of these latencies were determined. Following these recordings electrolytic lesions of the center median-parafascicular complex of the thalamus (CM-PF), an important contributer of inputs to CD were produced in the same cats in order to interrupt some of the previously mentioned indirect CX-CD pathways. The responses of CD neurons to CX stimulation were then redetermined. Experiments were begun 1-2 hrs postlesion. Analysis of the data revealed a significant decrease in mean latencies to respond from 20 msec prelesion (6 cats, 86 units) to 12 msec postlesion (77 units). The distribution of latencies for individual units was also markedly changed. A shift from a peak latency of 20-25 msec (30% of the response) prelesion to a peak of 5-10 msec (30% of the response) postlesion occurred. In the lesioned cats less than 8% of the units responded with latencies of more than 25 msec while in intact animals more than 21% of the latencies were in this range. In addition to the shortening in latency, the postlesion responses were less variable. Average standard deviations (SD) decreased from 4 msec prelesion to 2.2 msec after the lesion. Similarly, there was a marked shift in the distribution of SDs. Before the lesion only about 10% of the response showed SDs less than 1 msec. After the lesion more than 40% of the responses were in this catagory. These results were not due to a non-specific effect of the lesions since additional control lesions in the entopeduncular nucles did not markedly alter response latencies. We conclude that in the intact cat many of the CX-CD responses may result from indirect activation of the CD through orthodromic or antidromic activation of thalamic inputs. Supported by USPHS grants MH-7097 and HD-05958.

120 THE SUBTHALAMIC NUCLEUS AND THE SUBSTANTIA NIGRA OF THE MONKEY. NEURONAL ACTIVITY IN RELATION TO MOVEMENT. Mahlon R. DeLong and Apostolos P. Georgopoulos, Dept. Physiology, The Johns Hopkins Sch. Med., Baltimore, MD 21205.

Single neurons in the subthalamic nucleus (STN) and substantia nigra pars reticulata (SNpr) and pars compacta (SNpc) were studied in the monkey during the performance of a step and a pursuit tracking task (see Georgopoulos,A.P. and DeLong,M.R., The globus pallidus of the monkey: Neuronal activity in relation to movement, this volume). 227 neurons were isolated in 32 histologically identified penetrations in two hemispheres: 123 from STN, 90 from SNpr and 24 from SNpc. Nearly all of the task-related units were activated in both the step and the pursuit tasks; detailed analysis of the relations of unit activity to the amplitude, velocity and acceleration of movement and to EMG activity is currently being done. Further observations were made by careful examination of the animal to specify the responses of the units to "passive" manipulations and to active movements that the animal made outside the context of the task. Most STN units exhibited a tonic, bursting pattern of spontaneous discharge. Many cells were strikingly modulated by active movements of individual contralateral limbs, or of the face, tongue or jaw. Most of the units related to the limbs discharged with proximal movements. Passive driving, when present, was usually weak and was related to deep structures in and around the region involved in the active movement. Movement related units were found largely in the lateral portion of STN, where units related to specific body parts were grouped together suggesting a somatotopic organization. Most units isolated from the medial part of STN were not clearly affected by movements. SNpc units had low spontaneous discharge rates and did not show clear modulation with active movements or passive manipulations. SNpr units had high spontaneous activity, similar to those of internal pallidal units. Many SNpr cells were modulated by chewing, licking or swallowing movements; only a few were related to limb movements, and a few were modulated by eye movements.

It appears that the pars reticulata of the substantia nigra and the internal segment of the globus pallidus (GPi) together form a functional entity which has been divided by the internal capsule. This is suggested by: (a) the striking similarities in the morphology of their neurons, neuropil and ultrastructure, as well as in their afferent and efferent connections, (b) the nearly identical patterns of spontaneous activity (high tonic discharge), and (c) the apparent continuation of the GPi body representation into the SNpr, with units related to licking and chewing movements located in the medial portion of GPi (Georgopoulos and DeLong, this volume) and in the lateral portion of SNpr, indicating further the arbitrariness of their separation by the internal capsule.

121 TWO FORMS OF CATALEPSY REVEALED IN DIFFERENTIAL EFFECTS OF MORPHINE VERSUS HALOPERIDOL ON POSTURAL SUPPORT MECHANISMS. Marc De Ryck*, Timothy Schallert*, and Philip Teitelbaum. Dept. Psych., Univ. of Illinois at Urbana-Champaign, Champaign, IL 61820.

Neuroleptics (e.g., haloperidol), which block dopaminergic receptors, and narcotic analgesics (e.g., morphine) produce catalepsy, i.e., active maintenance of passively imposed postures. The differences between neuroleptic and narcotic catalepsy are still poorly understood (Costall & Naylor, 1973). By electromyographic recordings from antagonistic flexor and extensor muscles in the frontpaw and hindpaw of 20 rats, we show that morphine and haloperidol have opposite effects on static support mechanisms. We analyzed an important feature of catalepsy, i.e., resistance to passively induced displacement ("negativism"). When haloperidol-treated rats (1, 5, 10 mg/kg) were pushed forward, backward, or sideways, they resisted passive displacement by enhanced bracing reactions in the limbs. Bracing was characterized by simultaneous tonic contractions in antagonistic flexor-extensor muscles of the frontpaw (biceps and triceps) and hindpaw (tibialis anterior and gastrocnemius). Synergistic activation of antagonistic limb muscles is a normal mechanism involved in static support (the positive supporting reaction of Magnus, PSR). In haloperidol-treated rats, the PSR appeared spontaneously, even in the absence of external challenges. Haloperidol-induced release of PSR was transient; it waned when haloperidol-treated rats were completely immobile in a stable posture. Thus, haloperidol causes a transient, synergistic rigidity in response to challenges to static equilibrium. Morphine (20, 30, 40 mg/kg) produced persistent rigidity in limb musculature normally antagonistic to a given limb position, i.e., extensor hypertonia during paw flexion and flexor hypertonia during paw extension. When subjected to challenges of body stabilization, morphine-treated rats failed to display bracing reactions and allowed themselves to be rolled over to their sides. Thus, morphine causes a free-running, steady-state, antagonistic rigidity insensitive to challenges to static equilibrium. In other words, whereas the PSR was released during haloperidol catalepsy, it was suppressed during morphine catalepsy. Like the PSR, cold-induced shivering in the limbs consists of synergistic contraction of antagonistic muscles. Haloperidol permitted limb shivering, but morphine abolished it. Haloperidol rats showed rapid contact or air righting from a supine position, whereas righting reflexes in morphine rats were slow or entirely inhibited. Tonic grasp was present in haloperidol rats, but absent in morphine rats. Thus, in haloperidol catalepsy, tonic postural mechanisms involved in securing and maintaining a normal stable equilibrium posture are released, whereas in morphine catalepsy these mechanisms are inhibited. Supported by NIH Grant #RO1 NS 11671.

122 ELECTRON MICROSCOPY OF GOLGI IMPREGNATED SPINY AND ASPINY NEURONS IN MONKEY NEOSTRIATUM. M. DiFiglia, P. Pasik and T. Pasik. Dept. of Neurol., Mount Sinai Sch. of Med., CUNY, New York, N.Y. 10029.

Most of the neurons in the monkey neostriatum are of medium size and, as shown in Golgi impregnations, include cells with spiny dendrites and long axons, and cells with aspiny, varicose dendrites and short axons (DiFiglia et al, 1976). Standard electron microscopic methods have provided data which permitted only a tentative correlation with the above findings (Pasik et al, 1976). Presently, however, positive identiffcation can be achieved by applying a gold-toning technique to Golgi impregnated material (Fairén et al, 1977). This procedure allows the examination of cytological detail of deimpregnated cells at the EM level. A modification of the latter method was used in the present study for the unequivocal identification of neostriatal Spiny I and Aspiny I neurons (DiFiglia et al, 1976). Golgi impregnated sections (175 μm) were gold-toned, and regions containing isolated neurons of the above types were microdissected and flat-embedded in Epon. Neurons were photographed or drawn with camera lucida, and then serial thin sections were cut and mounted on formvar-coated slot grids.

A comparison between these 2 neuronal types shows that Spiny I neurons have a relatively poorer content of perikaryal organelles. Axosomatic synapses are more numerous and are formed by various types of axon terminals, most of which contain pleomorphic vesicles and make symmetric contacts. Fewer synapses of similar nature are seen on proximal spineless portions of the dendrites. Distal branches are rich in synapses particularly on spines. Serial sections show that most axospinous complexes are surrounded by glial somata or their processes. Symmetric synapses are also present on the axon initial segment of these neurons. Aspiny I neurons are richer in most organelles: Golgi substance, mitochondria, lysosomes and rough endoplasmic reticulum. Some small stacks of the latter are also present. Axosomatic synapses are infrequent. In contrast, proximal and distal dendrites are contacted by numerous axon terminals with either small round vesicles and asymmetric junctions, or with pleomorphic vesicles and symmetric contacts. Synapses on the axon initial segment are only occasionally seen. Serial sections show that a single axon terminal can contact both a dendritic spine, most likely belonging to a spiny I neuron, and a dendrite of an aspiny I neuron. Such axonal endings can be of 2 categories: a frequently seen profile containing small round vesicles and making asymmetric contact, and another containing pleomorphic vesicles and making a symmetric contact.

These findings offer distinguishing features of the 2 most common medium size neostriatal neurons, and indicate a different distribution of inputs on these cells. Aided by NINCDS Grant NS11631.

123 THE LOCALIZATION OF ACETYLCHOLINESTERASE IN THE CORPUS STRIATUM AND SUBSTANTIA NIGRA OF THE RAT. H. C. Fibiger[1], John Lehmann[1] and L. L. Butcher[2] (SPON: J. Pinel). [1] Div. Neurological Sci., Dept. Psychiatry, University of British Columbia, Vancouver, B.C. Canada, and [2] Dept. Psychology, University of California, Los Angeles, California, U.S.A.

The distribution of acetylcholinesterase (AChE) in some extrapyramidal nuclei was examined by means of intrastriatal injections of kainic acid. Pharmacohistochemical experiments showed that AChE-containing neurons in the striatum were among those which were destroyed by kainic acid. In complementary biochemical studies, it was demonstrated that approximately 50% of the total AChE activity in the striatum was localized in these AChE-containing neurons. Intrastriatal injections of kainic acid produced a substantial decrease in the activity of the glutamic acid decarboxylase in the substantia nigra, thus demonstrating that neurons contributing to the striato- and/or pallido-nigral pathways had been lesioned. However, nigral AChE activity was not significantly reduced by the striatal kainic acid injections. Furthermore, stereotaxic injections of colchicine along the course of the striato-nigral projection failed to produce an accumulation of AChE in these fibres proximal to the injection. In contrast, injections of colchicine into the nigro-striatal projection led to a proximal accumulation of AChE in the fibres of this system, thus confirming the presence of AChE in these dopaminergic neurons. It is concluded that the striato- and pallido-nigral projections in the rat do not contain AChE. Furthermore, AChE-containing neurons in the striatum appear to be interneurons rather than the source of striatal efferents. It is suggested that these AChE-containing neurons may be striatal cholinergic interneurons.

	Corpus Striatum	
	% of control	Control value ± SEM
AChE	62.5% ± 6.0%*	43.4 ± 2.07 umole/mg prot-hr
CAT	27.5% ± 7.3%*	109.9 ± 4.01 nmole/mg prot-hr
GAD	23.3% ± 3.4%*	103.7 ± 3.71 nmole/mg prot-hr
TH	126.8% ± 5.5%*	7.88 ± .319 nmole/mg prot-hr

Table I. Neurotransmitter-related enzymes in corpus striatum and substantia nigra two weeks after injection of kainic acid (10 nmole) in the caudate putamen.

124 ALTERATIONS IN SPONTANEOUS NEURAL ACTIVITY IN THE CAUDATE NUCLEUS AFTER UNILATERAL NIGRO-STRIATAL LESIONS. E. Garcia-Rill, N. Buchwald, C.D. Hull, and E. Cherubini*. Mental Retardation Research Center, University of California, Los Angeles 90024.

We have shown previously, that unilateral electrolytic lesions intersecting the nigrostriatal bundle in the lateral hypothalamus (MFB lesions) of cats deplete dopamine by 90% in the ipsilateral caudate nucleus but have no statistically significant effect on spontaneous neuronal firing in that structure. In contrast, spontaneous neuronal firing in the contralateral caudate is slowed markedly by the unilateral lesions. In these earlier studies, the recordings of neuronal activity were made at least 2 weeks after the lesioning. It was possible, therefore, that significant but temporary alterations in caudate unit firing occurred earlier in the cat's post-lesion course. Accordingly, in a new series of cats, caudate neuronal firing rates and the extent of dopamine depletion were assessed at 3 and 7 days post-lesion. Statistically significant decreases (68%) in ipsilateral caudate dopamine levels occurred by 3 days. By 7 days the depletion averaged more than 90%. Spontaneous neuronal firing rates in ipsilateral and contralateral caudates were sampled simultaneously. Ipsilateral caudate firing slowed significantly at 3 days but returned to values similar to those measured in intact controls by seven days. Firing rates tended to be somewhat faster in cats tested at $\geq$ 2 weeks post-lesion but these values did not differ significantly from those tested at 7 days or from intact controls. In the caudate contralateral to the lesion, a gradual slowing of spontaneous firing occurred with post-lesion time. At 3 days post-lesion, spontaneous activity remained at intact levels, and it slowed significantly by 7 days and even more at $\geq$ 14 days. These data indicate that a long-term remodeling of spontaneous firing rates occurs following the MFB lesions. The net result of this remodeling is to produce a side-to-side asymmetry in the activity of caudate neurons. Previous studies have established 1) that an important factor in producing this asymmetry is interruption of caudate output fibers by the MFB lesion, and 2) that the asymmetry can be corrected by additional lesions of the thalamus.

125 CAUDATE UNIT ACTIVITY IN RESPONSE TO INPUT FROM NUCLEUS CENTRALIS MEDIALIS IN CATS. Edgar L. Gasteiger[1], Irma Zarco-Coronado* and Héctor Brust-Carmona. Depto. de Fisiología, Div. de Investigación, Fac. de Medicina, UNAM, México 20, D.F.

Ablation, neurotransmitter and field potential studies have shown that the ventral medial and lateral area of the head of the caudate nucleus (CN) is essential for the performance of motor conditioned responses. Stimulation-recording experiments in cats (Diez-Martinez et al., Physiol. Behav. 19: 269-276, 1977) revealed projection of the nucleus centralis medialis (NCM) to the CN. To further localize these projections we are characterizing and localizing unit activity in the head of CN (A16) in response to input from NCM in normal and in cats with sustantia nigral lesions produced by local injection of 6-hydroxydopamine. Extracellular recordings of unit discharges and their associated slow waves are recorded from stainless steel microelectrodes while stimulating NCM through concentric bipolar stainless steel electrodes. FM tape recordings are made and the activity then analyzed by use of an HP signal analyzer and a PDP 11/40 computer. Only spontaneously active units are being studied but attention is given to small "distant" units which can not be readily analyzed by computer. When using metal electrodes in flaxedilized cats free of general anesthesia, spontaneous unit activity is more plentiful than commonly reported. Preliminary findings indicate existence of a dorsal border strip of heightened activity composed of many small and a few medium unit discharges, and a second active area in the ventral medial caudate giving rise to small and medium unit discharges. Large unit activity has been recorded in the area bordering the internal capsule. Stimulation of NCM causes driving of some units in all three areas with the most common response consisting of a sequence of early firing (10-60 msec), inhibition (30-275 msec), and rebound discharge. A second frequent response is potentiation of discharge frequency which may last only during the initial period of tetanization (8-12/sec) or, in some cases, be prolonged after tetanization for more than a minute. During transient potentiation the positive slow waves show transient enhancement. With the exception of this transient effect our observations are consistent with those from intracellular studies of postsynaptic potentials in NC for other thalamic inputs (Buchwald et al., Exp. Neurol. 38: 311-323, 1973). These preliminary findings suggest a heterogeneous organization of the CN in contrast to the usual view of a homogeneous organization.

126 THE GLOBUS PALLIDUS OF THE MONKEY: NEURONAL ACTIVITY IN RELATION TO MOVEMENT. Apostolos P. Georgopoulos and Mahlon R. DeLong. Dept. Physiol., The Johns Hopkins Sch. Med., Baltimore, MD 21205.

Single neurons in the external (GPe) and the internal (GPi) segments of the globus pallidus of the monkey were studied in a step and a pursuit tracking task. The manipulandum was a light-weight handle which the monkey could grasp and move along a horizontal path with minimal friction. The display consisted of 2 rows of 128 lamps each (10/inch): the upper indicated the target position and the lower the position of the handle. After holding in a starting position for a variable period of time, step movements were elicited by suddenly jumping the target lamp to a new position, while pursuit movements of different but constant velocities were obtained by activating sequentially adjacent lamps. The monkey was rewarded with liquid for successful acquisition and maintenance of the target. Data for spike and behavioral events, and movement parameters (position, velocity and acceleration of the manipulandum) were collected for each movement. EMG activity from 16 arm, neck and paraspinal muscles was also collected durthe performance of the task.

236 units were isolated in 27 penetrations through a lateral approach: 151 from GPe and 85 from GPi. Nearly all of the task-related units were modulated in both the step and pursuit tasks; a detailed analysis of the relations of unit activity to the amplitude, velocity and acceleration of the movement and to EMG activity is currently being done. Further observations were made by careful examination of the animal to assess the functional properties of units in response to "passive" manipulations with the animal relaxed, and to active movements that the animal made outside the context of the task. The patterns of spontaneous activity in the two pallidal segments conformed to those described previously by DeLong. A majority of the cells were clearly modulated by active movements of individual contralateral limbs or by chewing, licking and facial movements. Passive driving, when present, was generally weak, and was related to deep structures in and around the region involved in the active movement. A few units did respond very sensitively to tapping of muscle tendons. Cutaneous driving was seen only rarely. Most of the movement-related cells were located in the ventroposterior 2/3 of the globus pallidus; units isolated from the dorsorostral 1/3 of the nucleus were not clearly related to the movements tested. Within the GPe, leg-related units were located most dorsally, those related to orofacial movements most ventrally, and arm-related units in between. Within the GPi, leg-related neurons were situated dorsal to arm-related neurons, whereas units related to chewing, licking and facial movements occupied the ventromedial portions.

127 PECKING AND CIRCLING IN PIGEONS FOLLOWING DESTRUCTION OF A TEGMENTOPALEOSTRIATAL PATHWAY, A POSSIBLE NIGROSTRIATAL HOMOLOGUE. Irving J. Goodman and Albert J. Azzaro*. Depts. of Psychology and Neurology, West Virginia University, Morgantown, WV 26506.

Apomorphine induced compulsive pecking may be significantly or totally blocked temporarily (3-14 days) with bilateral destruction of the pigeon's dopamine-rich paleostriatum augmentatum (PA), a homologue of the mammalian caudate-putamen. The present study explored the mechanisms of apomorphine induced stereotyped behavior by focusing on dopaminergic PA afferents, which originate in and around the nucleus tegmenti pedunculo-pontinus, pars compacta (TPc) and form the tegmentopaleostriatal (TPc - PA) pathway, a possible nigrostriatal homologue. Stereotaxic placement of unilateral electrolytic (DC, 2 mA/15 sec) or 6 hydroxydopamine (6-OHDA, 8 ug/2 ul saline) lesions were made in TPc or just rostral to it, in area ventralis (Tsai) (AVT). Apomorphine (2.0 - 3.5 mg/kg, i.p.)-produced wall, body, air or floor directed compulsive pecking, which tended not be biased toward the right or left side in presurgical baseline tests, deviated markedly toward the lesioned side after either type of lesion or placement. In most cases this was accompanied by circling with the same directional bias. Both effects were observed consistently from day 1 after surgery until 6 mo. later when testing was terminated. Histological and biochemical analyses confirmed lesion placements and dopamine depletion levels. An earlier study in our laboratory (Goodman & Stitzel, 1977) had noted similar directional biases in pecking following unilateral PA lesions, with circling a less frequent event. The anticipated outcome of the present study was that TPc/AVT lesions would favor pecking and circling away from the lesioned side, based upon findings in unilateral lesioned nigrostriatal rats and the accompanying explanation of supersensitivity of denervated caudate cells. Considering sensitivity changes as a means of explaining the above findings, we bilaterally lesioned TPc in other pigeons with the idea that if supersensitivity resulted from denervation in the pigeon, apomorphine induced pecking should increase in the bilateral preparation. In fact, animals showed a marked absence or reduction of apomorphine pecking for up to 30 days post-lesion, and recovery rarely reached baseline levels. If post-lesion sensitivity changes in PA cells is a correct explanation of the above experimental results, then, just the opposite, reduced sensitivity to apomorphine stimulation is suggested. No sooner have we begun to make a case for an avian homologue of the nigrostriatal pathway when we turn up, perhaps, an important behavioral exception.

128 STRIOSOMAL ORGANIZATION OF THE CAUDATE NUCLEUS: I. ACETYLCHOLINESTERASE HISTOCHEMISTRY OF THE STRIATUM IN THE CAT, RHESUS MONKEY AND HUMAN BEING. Ann M. Graybiel and Clifton W. Ragsdale, Jr.*, Dept. of Psychology, Mass. Institute of Technology, Cambridge, MA 02139.

A defining characteristic of the mammalian striatum is its high content of the enzyme, acetylcholinesterase. We have examined the distribution of acetylcholinesterase activity in the striatum of the adult cat, monkey and human using the histochemical staining methods of Geneser-Jensen & Blackstadt and Karnovsky & Roots.

In cross sections through the head of the caudate nucleus, marked local discontinuities in enzyme activity appear in all three species. These take the form of a variable number of circumscribed pale zones that lie embedded in a background of much denser staining. Even in single transverse sections, the individual zones of low enzyme activity are usually highly variable in shape, some being long and thin, others being rounded, still others being branched. The average transverse diameter of the zones is about 0.5mm in the cat, 0.5-0.8mm in the human. In the brains so far examined, these histochemical discontinuities were most prominent in the head of the caudate nucleus, especially its central sector, and faded in its dorsolateral quadrant. Comparable pale zones have been difficult to detect in the putamen. An observation that could have developmental implications is that, within the caudate nucleus, the pale zones often appeared to stretch away from the ventricular face.

Detailed study was made of uninterrupted sets of serial sections through part of the head of the caudate nucleus in the cat (80 50μm sections) and human (75 75μm sections). Important observations are first, that despite sometimes abrupt changes in their shapes from section to section, many of the profiles could be traced in continuity over several millimeters. Second, at least over the short distances so far analyzed in serial sections, many of the apparently unconnected pale zones in individual sections are also actually continuous with one another, forming elements of a highly branched three dimensional labyrinth.

The heterogeneity in staining described here provides support for the concept of a fundamental subdivision of the striatum in the human being, cat and monkey into at least partially segregated, histochemically distinct units. These units are here given the general name, striosomes. It is an unresolved problem how the cholinesterase-poor compartments described here relate to other inhomogeneities observed in the striatum, a particularly interesting instance being the "dopamine islands" observed by Tennyson et al.(1972) and Olson et al.(1972). Study of such relationships may be essential to understanding the significance of the compartmentalization here described.

129 QUANTIFICATION OF BEHAVIORAL AND NEUROCHEMICAL CHANGES FOLLOWING INTRASTRIATAL KAINIC ACID INJECTIONS. Robert D. Grubbs, Mary L. Michaelis, and Elias K. Michaelis. Dept. Human Development, U. of Kansas, Lawrence, KS 66045

The use of microinjections of kainic acid (KA) to induce neuronal degeneration has become an important tool for determining the neurochemical nature and interrelationships of cells within discrete brain areas. Within the striatum, there appears to be a strong correlation between the neurochemical and morphological changes induced by KA microinjections and the changes observed in postmortem striatal samples of Huntington's Disease patients. Furthermore, behavioral changes have been noted anecdotally following intrastriatal injections of KA. In the present study, an attempt was made to quantify these abnormal involuntary movements (AIMs) by means of a three class code in which the AIMs were operationally defined. The animals were intrastriatally injected with 2μg/μl of a KA solution while under ether anesthesia and videotaped beginning 2 hours after the injection for a period of 60 minutes. Two 15 minute segments of the videotape were then scored using the code. Glutamic acid decarboxylase (GAD) activity was measured 2 hours after injection to determine if a correlation existed between the AIMs and changes in GAD specific activity. GAD activity was also measured at 2 days post-injection. At 2 hours, no difference was observed in GAD activity between uninjected control caudate and KA injected caudate, while at 2 days, the KA injected caudate showed an average 27% decrease from control values. It was determined experimentally that the efficacy of the KA injection was largely dependent on the parameters of the injection procedure. Subsequently, a total volume of 1 μl of a 2μg/ μl solution of KA was administered intrastriatally by thereotaxic injection over a 5 minute period and the needle kept in place an additional 5 minutes. Using this injection procedure, a 58% decrease in GAD activity was observed 72 hours post-injection. In light of reported decreases in adenylate cyclase activity following KA administration, we looked for an effect on striatal cAMP-phosphodiesterase (PDE) activity following treatment. A 61% decrease in V_{max} for cAMP-PDE specific activity was observed, while essentially no change in K_m was seen. This decrease is comparable in mangitude with changes reported by others for ACh and GABA systems following KA injections.

130 DENDROAXONIC NEUROTRANSMISSION I: POSSIBLE SITES OF SYNTHESIS, STORAGE AND RELEASE OF DENDRITIC DOPAMINE AND ACETYLCHOLINE. T. Hattori, P.L. McGeer and E.G. McGeer. Kinsmen Lab. Neurol. Sci., Dept. Psych., University of B.C., Vancouver, B.C., Canada, V6T 1W5.

It has been known for some time that neurotransmitters such as dopamine exist in dendrites. In a companion paper (McGeer, McGeer and Innanen, Dendroaxonic Neurotransmission II), it has been shown by specific binding assays that receptors may exist on nerve endings for dendritically released dopamine in SN and acetylcholine in the neostriatum. This paper presents an ultrastructural evidence indicating possible sites of synthesis, storage and release of dopamine in SN dendrites and acetylcholine in neostriatal dendrites. Postsynaptic structures were carefully examined in the rat SN and striatum following post fixation with 4% unbuffered O_sO_4 and preembedding staining with 2% uranyl acetate. In the SN, round vesicle-like structures of 20 to 60 nm diameter were often seen attached to the inner surface of postsynaptic membranes. When the nigra was immunohistochemically stained for tyrosine hydroxylase (TH)[1], heavy staining was seen around vesicle-like structures. Microtubules were stained unevenly as if globules containing the enzyme were embedded in the tubules. These could be the precursors of the dendritic vesicles. When fixation was carried out following the administration of the false transmitter for dopamine, 5-hydroxydopamine (5-OHDA), it was found to be localized to smooth endoplasmic reticulum, where large vesicular structures approached the dendritic surface. In the striatum, round, vesicle-like structures of 20 to 60 nm diameter were also seen attached to or embedded in the postsynaptic thickenings of spines which received dopaminergic nerve endings as evidenced by 6-OHDA irduced degeneration. Immunohistochemically, these vesicles, as well as globules within the microtubules were heavily stained for choline acetyltransferase (CAT). In both nigral and striatal dendrites, the vesicle-like structures seemed to accumulate at postsynaptic sites and were rarely seen along other regions of the dendritic membrane. The origin of the vesicle-like dendritic structures is unclear. However, following the administration of horseradish peroxidase in vivo, the enzyme appears to be localized to similar structures following both anterograde and retrograde transport. Since the enzyme is also concentrated in the smooth endoplasmic reticulum, the possibility exists that these two intracellular structures are related. These morphological findings support biochemical data suggesting dendroaxonic transmission of dopamine and acetylcholine.

[1]We thank Dr. Menek Goldstein of the New York Medical Centre for supplying antibodies to TH.

131 NONDOPAMINERGIC AND DOPAMINERGIC NIGROSTRIATAL PATHWAYS IN RATS. John Hedreen. Dept. of Cell Biology and Anatomy, Johns Hopkins University School of Medicine, Baltimore, Md. 21205.

Rat brains stained by the Fink-Heimer method after electrolytic nigral lesions show no degenerating pathway in the ventral tegmental area, where the dopaminergic nigrostriatal axons travel. But a group of degenerating axons is seen which separates from the nigrothalamic path and proceeds rostrally in the zona incerta along the internal capsule. The axons pass through the entopeduncular nucleus in the network of cellular areas and transversely oriented fiber bundles, then pass principally through the ventral half of the globus pallidus and enter the neostriatum. Degenerating axons in the neostriatum are especially concentrated in the region lateral to the ventral half of the globus pallidus. The identification of this pathway as nondopaminergic, and of all or most of the dense terminal degeneration in the neostriatum in these cases as dopaminergic, is supported by the following experiments. Cases with nigral lesions and Fink-Heimer staining following long-term pretreatment with 6-hydroxydopamine show no change in this pathway or in the abundance and distribution of degenerating fibers in the neostriatum, while striatal terminal degeneration is much decreased. If the Fink-Heimer method is applied acutely after 6-hydroxydopamine the pathway described above is not seen; only a group of axons of entirely different staining characteristics is seen in the ventral tegmental area and zona incerta, and rarely also in the neostriatum. These are not seen in nigral lesion cases. Thus a limitation of the Fink-Heimer technique - its inability to stain degenerating dopaminergic axons after a nigral lesion - may be turned to advantage, allowing the demonstration of the nondopaminergic nigrostriatal pathway without interference from dopaminergic axons.

The dopaminergic nigrostriatal pathway, as described by Ungerstedt ('71), is revealed in autoradiography cases after nigral injections of tritiated amino acids. The axons in this path traverse the ventral tegmental area before entering the zona incerta. More rostrally, where they remain identifiable by their very strong labeling, they follow a partly different course from the nondopaminergic path, for example traversing the entopeduncular nucleus without favoring the cellular areas, and fanning out through the whole extent of the globus pallidus.

Clearly the two pathways provide a substrate for two kinds of nigral influences upon neurons of the neostriatum. The possibility that the nondopaminergic pathway consists of collaterals of nigrothalamic axons invites investigation.

132 LESIONS OF THE STRIATONIGRAL PATHWAY DO NOT REVERSE METHAMPHETAMINE-INDUCED TYROSINE HYDROXYLASE DEPRESSION. Adair Hotchkiss* and James W. Gibb*(SPON: L.W. Jarcho). Depts. Pharmacology, Univ. of Utah, Salt Lake City, UT 84132.

The apparent Vmax of neostriatal tyrosine hydroxylase (TH) is decreased by subacute administration of methamphetamine (METH) (Koda and Gibb, Pharmacologist 13:253, 1971). It was postulated that this depression is mediated through feedback inhibition of the nigral dopaminergic neurons via the striatonigral pathway (Buening and Gibb, Eur. J. Pharmacol. 26:39, 1974). This hypothesis was tested by evaluating the effect of subacute METH on striatal TH activity in rats with unilateral lesions of the striatonigral pathway produced by two different methods.

One type of lesion was produced by intrastriatal injection of kainic acid (2 µg in 1 µl/rat) in rats weighing 230 to 250 g. Ten days later METH was administered (10 mg/kg, s.c.) every 6 hrs for 5 injections. Thirty-six hrs after the first METH injection TH was depressed in both neostriata with no significant difference found between ipsilateral and contralateral neostriata or between sham- and kainic acid-injected animals. Concurrent administration of haloperidol (3 mg/kg, i.p.) prevented TH depression in both sides (Buening and Gibb, ibid); γ-acetylenic GABA (γAG, 20 mg/kg, i.p.) similarly prevented TH depression in both sides (Hotchkiss and Gibb, Fed. Proc. 37:510, 1978). A second group of animals was lesioned electrothermically in the crus cerebri just anterior to the substantia nigra as described by Gale et al. (Sci. 195:503, 1977). Preliminary data indicate equal TH depression in the paired neostriata after the METH regimen, 14 days following electrothermic lesion. With both lesion types, animals exhibited ipsilateral rotation following METH. In the kainic acid lesion model, rats receiving haloperidol and METH rotated in the contralateral direction, whereas rats receiving γAG and METH rotated in the ipsilateral direction.

These data suggest that inhibition of nigral dopaminergic cells by the striatonigral projection may not be responsible for the METH-induced TH depression. Likewise, reversal of TH depression by haloperidol and γAG does not require this pathway to be intact. The mechanism for the METH-induced depression of neostriatal TH is still uncertain and other possibilities such as presynaptic inhibition must be considered. Alternative hypotheses are being explored in an effort to explain the METH-induced depression of striatal TH activity. (Supported by USPHS grants GM 00153 and DA 00869.)

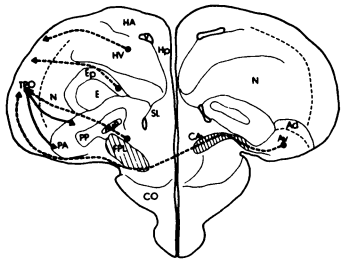
133 NEURAL CONNECTIONS OF THE AVIAN LATERAL CORTICOID AREAS. Cheryl A. Kitt & S. E. Brauth, Dept. Psychology, Univ. of Md. College Park.

In pigeons, HRP was injected into the tempero-parieto-occipital area (TPO) and area corticoidea dorsolateralis (CDL) of the telencephalon. Retrograde transport of HRP was observed to three ipsilateral cell fields: the hyperstriatum ventrale (Hv), periectostriatal belt (Ep) and to a region of neurons ventral to the paleostriatum primitivum (PP). TPO and CDL neurons also receive projections from cells in the contralateral ventral archistriatum (Av) via the anterior commissure. Other injections of HRP into the lateral neostriatum (N) and Av labelled cells in two different discrete fields of the frontal and caudal neostriatum and not cells within Ep, Hv or Av. Injections of HRP into the parahippocampal area (APH) labelled neurons ipsilaterally in the hippocampus (Hp) lateral septal area (SL) and in the diagonal band of Broca (FDB) In addition, cells in the nucleus superficialis parvocellularis (SPC)were labelled bilaterally in this case.

HRP injections were placed within the dorsal, central and lateral portions of TPO and CDL. No topography of the above described afferent projections was apparent, however virtually all retrogradely labelled cells observed in Ep were situated in the medial portions of this field.

Injections of 3H-leucine and 3H-proline into the TPO region revealed anterograde projections from these regions into the paleostriatum in aggreement with prior work (Brauth, Ferguson & Kitt, 1978). Fibers from TPO could be traced into PA, into the region ventral to PP, and as far medially as the ventromedial portion of the lobus parolfactorius. This latter projection was confirmed by means of HRP injections into LPO. The vast majority of TPO efferents terminate, however, in PA.

These results indicate that neurons in TPO and CDL receive unique projections from Ep, Hv, the region ventral to PP, and from the contralateral Av and project extensively upon the paleostriatum



This drawing represents a schematic of the major projections of the lateral corticoid areas in the pigeon telencephalon.

134 PROJECTIONS OF CENTRUM MEDIANUM TO CAUDATE NUCLEUS IN THE CAT AS DEMONSTRATED BY RETROGRADE TRANSPORT OF HORSERADISH PEROXIDASE. David C. Kuo*, Ernest S. Pile* and George M. Krauthamer. Dept. Anat., CMDNJ Rutgers Med. Schl. Piscataway, NJ 08854.

In order to determine more precisely the anatomical relationship between the medial thalamus and the head of the caudate nucleus (Cd), small, focal deposits of horseradish peroxidase were placed in Cd by electrophoresis. The brain sections were treated by a variation of the DeOlmos, Hardy & Heimer method, using tetramethyl benzidine.

Results showed a discrete input from centrum medianum (CM) which was clearly outlined by many labeled neurons in close proximity to each other. No other thalamic nuclei were labeled. Cell bodies, proximal dendrites and, presumably portions of axons were densely filled with granular reaction product. There were many apparent contacts between the processes of adjacent labeled neurons suggestive of a synaptic interrelation. In agreement with the present findings, a monosynaptic input from CM to Cd has been demonstrated (Kocsis et al.) and antidromic responses have been recorded in CM (Krauthamer et al.).

Other labeled neurons were seen in substantia nigra, pars compacta and lamina V of the corresponding cortical projection field. In contrast to the massive, densely labeled CM projection, these consisted of scattered and lightly labeled cells.

The results demonstrate that at least some regions of Cd receive their thalamic input from CM rather than n. centralis lateralis as commonly believed. Since CM, in turn, receives projections from the deep layers of superior colliculus and vestibular nuclei (McGuinness et al.), fairly direct access to Cd is provided for the polysensory activities related to orienting responses.

135 FUNCTIONAL ORGANIZATION OF NEURONS RELATED TO ARM MOVEMENT IN THE PUTAMEN. Samuel L. Liles. Dept. of Physiol., LSU Med. Ctr., 1100 Florida Ave., New Orleans, LA 70119.

Recent anatomical evidence suggests that motor cortex projects in a somatotopically organized manner to the putamen, such that axons arising in "leg", "arm" and "face" areas terminate in dorsolateral, intermediate and ventromedial regions, respectively, of the putamen (H. Künzle, Brain Res., 1975). The observations that arm movement-related (MR) units are found almost exclusively in intermediate regions of putamen (S. Liles, Fed. Proc., 1978) and units related to orofacial movements occur in ventromedial regions (Liles, unpublished observations) suggest, at least at the gross anatomical level, a possible relationship between afferent input and functional organization of neurons in the putamen. The present study concerns the fine anatomical distribution of arm MR units within intermediate regions of putamen.

Monkeys trained to push or pull a manipulandum to obtain a fruit juice reward (S. Liles, Fed. Proc., 1978) were prepared for single unit recording after the technique of Evarts (1968). Electrode penetrations were made at an angle of 36° from vertical. Unit response magnitudes were estimated from digitally integrated peri-response time histograms composed from 25 movement trials. About 80% of MR units showed activity during both push and pull movements, although most of these units were preferentially related to either the push or pull movement. Most MR units showed a tendency to occur in groups or clusters of 500 μm or less along recording tracks. During some electrode penetrations, seven or eight MR neurons were all encountered over an axial distance of only 400-500 μm; during other penetrations three or four such clusters of MR neurons were found. MR neurons within each cluster invariably showed similar activity patterns (viz., all units within a cluster were related preferentially to either push or pull movements). In seven instances it was possible to record the activity of two units simultaneously from the same site. Each of these pairs of units showed similar MR activity patterns.

These data suggest that arm MR neurons are not scattered randomly throughout the intermediate region of the putamen, but frequently occur in small neuronal colonies or clusters. The fact that neurons within these clusters show similar MR activities suggests that these colonies may represent functional groupings of neurons. Future studies utilizing more discrete conditioned movements (e.g., movements of wrist or digits) combined with microstimulation of motor cortex are needed to determine possible specific relations between afferent input from motor cortex and MR properties of neurons in putamen. (Supported by USPHS Grant NS-08907 and the E.G. Schleider Foundation).

136 NIGRO-NEOSTRIATO-NIGRAL NEUROANATOMY: TOPOGRAPHY, TRAJECTORIES, AND TARGET ELEMENTS. Raymond Marchand* and Larry L. Butcher. Dept. Psychol. and Brain Res. Inst., UCLA, Los Angeles, CA 90024.

Nigro-neostriato-nigral relationships were assessed by protein-incorporation autoradiography, horseradish peroxidase (HRP) histochemistry, and colchicine-induced build-up of dopamine (DA) and acetylcholinesterase (AChE) in the nigro-striatal pathway. To assess interconnections of (1) nigro-striatal neurons with AChE-containing neostriatal interneurons and (2) striato-nigral fibers with pars compacta dendrites projecting into pars reticulata, we used protein-incorporation autoradiography in combination with AChE histochemistry (see Butcher, 1978; in: Cholinergic Mechanisms and Psychopharmacology; Jenden, Ed.; Plenum Press, New York).

Nigro-striatal fibers—containing both AChE and DA and traveling in the ventromedial mesencephalic tegmentum, field H_2 of Forel and adjacent regions, and the internal capsule and globus pallidus—appeared to make contact with a small but definite proportion of neostriatal AChE neurons, primarily on the proximal portions of dendrites and/or somata of those target cells. Striato-nigral fibers, coursing prominently through the internal capsule, were observed to contact numerous AChE (DA)-containing dendrites of pars compacta neurons projecting into pars reticulata.

HRP injected dorsolaterally or dorsomedially in the rostral neostriatum (i.e., rostral to anterior commissure) resulted in accumulation of the enzyme in numerous cell bodies of the medial third of pars compacta throughout its entire rostro-caudal extent. Neurons of the more lateral segments of pars compacta showed little or no enzyme accumulation. HRP infusion into the caudate-putamen nucleus at the level of the decussation of the anterior commissure resulted in enzyme accumulation in pars compacta neurons in the lateral and intermediate segments of that structure; again, this accumulation was observed throughout the rostro-caudal extent of the cellular mass.

Since HRP is transported in anterograde as well as retrograde directions the neostriatal injections also disclosed a topographic, reciprocal relationship between the striato-nigral terminating fibers in the substantia nigra, pars reticulata and the HRP-containing somata of pars compacta apparently giving rise to the nigro-striatal AChE (DA)-containing pathway (see Butcher, 1977; Life Sci. 21, 1207-1226). 137 SENSORY INATTENTION PRODUCED BY 6-HYDROXYDOPAMINE INJECTIONS ALONG THE ASCENDING DOPAMINERGIC FIBERS: SPONTANEOUS RECOVERY AND PHARMACOLOGICAL CONTROL. John F. Marshall. Department of Psychobiology, University of California at Irvine, Irvine, CA 92717

Rats that received injections of 6-hydroxydopamine (6-OH-DA) into the area ventralis tegmenti displayed a syndrome of impaired orientation (inattention) to tactile, olfactory, and visual stimuli that was evident upon neurological examination. When the 6-OH-DA was injected unilaterally, these impairments were apparent only on the contralateral body side. Rats that received bilateral 6-OH-DA injections failed to attend to stimuli impinging on either side. When rats with bilateral 6-OH-DA injections were given small doses (0.05-0.20 mg/kg i.p.) of apomorphine 2-8 days postoperatively they showed a dramatic but short-lived restoration of orienting to touch, visual stimuli, and odors that was maximal in animals given 0.10 mg/kg apomorphine 3 days postoperatively. Lower doses of apomorphine had little obvious behavioral effect, while higher doses resulted in intense stereotyped sniffing, particularly on the 5th and 8th day postoperatively. The apomorphine-induced reversal of the sensory inattention was completely abolished by pretreatment with the dopamine receptor blocking agent haloperidol (0.05 mg/kg, i.p.), but not by its vehicle.

Further examination of the contralateral inattention to somatosensory stimuli in rats with unilateral 6-OH-DA injections revealed that many rats spontaneously recovered the ability to orient to touch of the affected body surface during the first postoperative month. This recovery occurred first to touch of rostral points of the body surface and only later to touch of progressively more caudal regions. When given i.p. alpha-methyl-para-tyrosine (70-100 mg/kg) or spiroperidol (0.05 mg/kg) 2-3 mo. postoperatively, these recovered rats showed a restitution of somatosensory inattention that was restricted to the contralateral body surface. After drug administration the somatosensory loss spread in a caudal to rostral direction. As the drug effects dissipated, orientation was restored rostrocaudally, recapitulating in brief the process of spontaneous recovery.

These findings suggest that the inattention syndrome seen after 6-OH-DA injection is related to a loss of dopamine receptor activity and that the spontaneous recovery of orientation depends critically upon dopaminergic mechanisms.

138 LOCALIZATION OF GLUTAMINASE IN THE RAT NEOSTRIATUM. E.G. McGeer and P.L. McGeer. Kinsmen Lab. Neurol. Sci., Dept. Psych., UBC, Vancouver, B.C., Canada V6T 1W5.

The subcellular concentration of glutaminase in the synaptosomal fraction of brain (Bradford and Ward, Brain Res. 110, 115 (1976)) suggests that it may play an important role in the maintenance of the transmitter pools of glutamate, GABA, or both. The rat striatum provides a system to test this hypothesis since the extensive glutamergic innervation from the cortical-striatal tract can be destroyed by cortical lesions without effect on the striatal GABAergic systems, while the latter can be extensively lesioned by local injections of kainic acid (KA) without adverse effect on the afferent glutamergic nerve endings. Thus, injections of 5 nmoles of KA cause a decrease in GAD activity to about 30% of control without effect on high affinity glutamate uptake, while cortical lesions cause a decrease in glutamate uptake to about 60% of control with no effect on GAD activity.

Using a radioactive assay for glutaminase, based on a coupled reaction with bacterial GAD, the activity was found to decrease significantly in the striatum following KA injections but not following cortical lesions.

The decrement in glutaminase in KA-lesioned striata correlated significantly with the decrement in GAD. The intercept on the x axis suggested that 60% of the glutaminase activity in the striatum is located in structures (presumably GABAergic neurons) destroyed by the KA-injections while 40% is in some unaffected compartment(s). Subcellular fractionation indicated some 60% of the glutaminase in control striata was in the P_2 fraction. These data suggest that about 60% of the activity in the striatum is probably in GABAergic structures with about 40% in glia. They do not support the hypothesis that the neurotransmitter pool of glutamate may be derived directly from glutamine in glutamergic nerve endings.

139 AN ALLELE OF DYSTONIA MUSCULORUM EXHIBITING LESIONS IN SOME AREAS OF THE EXTRAPYRAMIDAL SYSTEM. Anne Messer, Norman L. Strominger[+] and Lorraine Flaherty*. Div. of Labs and Research, NYS Dept. of Health and [+]Department of Anatomy, Albany Medical College, Albany, NY 12201 (12208).

An autosomal recessive mutation, characterized by severe motor deficits, arose spontaneously in the BALB/cByJ mouse stock maintained by Dr. Flaherty at the NYS Dept. of Health Labs. At about two weeks of age mutant animals show slight movement disorders and abnormal limb placements. The syndrome is steadily progressive to extreme ataxia with writhing side-to-side movements, and some shaking of the hind limb on first one side and then the other; there is almost no normal use of hind limbs. Front limbs exhibit stiff, flipper-like motions, and the entire body flexes into bizarre postures. The syndrome is fully developed by four weeks and coordination actually improves slightly after a few months. Although sometimes smaller than littermates, mutants can survive many months.

Because of a similarity in symptoms with the mutant dystonia musculorum, an allelism test was performed. Crosses between $+/dt^{J}$ and a known heterozygote from our colony revealed that the two mutations are allelic. Therefore the mutation found here will be called dt^{Alb}. The pathology of dt^{Alb} is now being compared to that of dt^{J}.

Duchen, Strich and Falconer (Brain 87, 367-378, 1964) reported that the major pathology seen in dystonics was "degeneration of nerve fibres in the peripheral nerves, in the sensory roots and ganglia of spinal and cranial nerves, and in the spinal cord and brain-stem." They found no obvious abnormalities in the basal ganglia or cerebellum but hypothesized that these may be functionally abnormal since a severe sensory ataxia may not account for the entire clinical syndrome. The dt^{Alb} shows clear abnormalities in the red nucleus and in part of the striatum, in addition to some of the pathological features described above. Formalin-fixed, paraffin-embedded serial sections (15 μ) stained with thionin show pathological changes in large coarse neurons with an overall reduction in number in the red nucleus. The striatum contains an abnormal number of small darkly staining cells when compared to controls. Notably, this pathology is asymmetric, although the clinical symptoms appear to be bilateral and equal within the limits of observation. Neurochemical correlates of these phenomena are being examined.

140 ELECTRICAL ACTIVITY IN THE IN VITRO CAUDATE PREPARATION. J.J. Miller, D.P. Rutherford* (SPON: T. Calvert), Dept. Physiology, University of British Columbia, Vancouver, B.C. V6T 1W5.

Recent reports have demonstrated the advantages of the in vitro slice preparation, particularly in the hippocampus, as a suitable model for studying synaptic transmission in the brain. In order to determine whether this technique may be applied to components of the basal ganglia, the present investigation was undertaken to examine the electrophysiological properties of the in vitro caudate slice preparation. Transverse sections of the rat caudate nucleus (500 μm in thickness) were maintained in a modified Ringer's solution at 34-36°C and superfused with 95% O_2-5% CO_2. Bipolar semi-micro stimulating electrodes were positioned at the confluence of the internal capsule or in the cellular zones between the radially oriented axon fascicles. Extracellular unit activity, recorded from the cellular regions consisted of spontaneous and orthodromically evoked single spikes at latencies of 2.5-4.0 msec. These responses followed stimulus frequencies of 10-20 Hz and were decreased or eliminated under conditions of anoxia. When the stimulus intensity was increased (2xT) a negative going population spike, on which single spikes were often superimposed, was evoked at similar latencies. When a Ca^{2+}-deficient medium was perfused, the evoked population response and unit activity were eliminated and both showed recovery upon replacement with the normal medium. Antidromically evoked cells and fiber responses were elicited at latencies of 1-2 msec. These responses followed high frequency stimulation (>100 Hz) and were resistant to the removal of Ca^{2+}. The activation of spontaneously discharging neurones was frequently followed by periods of inhibition lasting up to 50 msec. Paired pulse stimulation resulted in inhibition of the evoked response elicited by the test stimulus at C-T intervals up to 150 msec. In Cl^- deficient medium this inhibition was eliminated and a dramatic increase in the amplitude of the evoked population spike and background discharge rate was observed. Paired-pulse stimulation also resulted in an enhanced test response at intervals of 10-100 msec. Recovery of the control response was obtained when the Cl^- content in the media was restored. Although the cellular origins of the evoked responses have not been determined, these results provide preliminary evidence of the viability of the in vitro caudate slice and its suitability for studies of the pharmacological and ionic mechanism underlying synaptic transmission in this region.

141 STRIOSOMAL ORGANIZATION OF THE CAUDATE NUCLEUS: II. EVIDENCE THAT NEURONS IN THE STRIATUM ARE GROUPED IN HIGHLY BRANCHED MOSAICS. Sandra Moon Edley*, Ann M. Graybiel and Clifton W. Ragsdale, Jr.*, Dept. of Psychology, Mass. Institute of Technology, Cambridge, MA 02139. (SPON: W.J.H. Nauta).

The fiber projection from the caudate-putamen to the pallidum forms one of the two great efferent systems of the mammalian striatum. In order to study the distribution within the striatum of the cells giving rise to the strio-pallidal connection, we have injected the retrograde tracer, horseradish peroxidase (HRP), into the pallidum in the cat. Two points of technique were dictated by our attempts to obtain as nearly complete cell-labelling of the striatum as possible: first, we injected very large amounts of HRP; and second, we used the BDH and TMB histochemical techniques of Mesulam to detect labelled neurons. We report here on findings in 3 cats in which large pallidal deposits produced extremely dense labelling of striatal neurons.

The most striking finding in these cases is that, despite massive labelling of both small and large neurons in the caudate nucleus, the distribution of HRP-positive neurons was by no means uniform. Instead, in each case, a pattern of cell-labelling appeared in which large fields of labelled neurons were suddenly and repeatedly interrupted by variably shaped, roughly 0.5mm-wide zones containing relatively few and often scarcely any labelled neurons. These sparsely labelled zones were easily visible with the naked eye in cross-sections through the head of the caudate nucleus. Some of the zones were vermiform, long enough to cross nearly the full width of the caput (2-3mm), but others were rounded or of complex shape. By tracing individual zones from section to section it became clear that in many instances the profiles in serially adjoining sections were continuous with one another.

The enzyme deposits were in all cases large, involving not only both segments of the globus pallidus (GP) but also adjoining parts of the fundus striati and (2 cases) deep putamen rostrally, and the subthalamus caudally. In one case the substantia nigra (SN) itself was also included in the injection site, and in no case could the possibility be excluded of infiltration of perforant nigrostriatal fibers by the HRP. It is not yet clear, therefore, whether separate mosaics of striatal neurons give rise to the caudate's projection to GPe, GPi and SN, or whether the sparsely labelled zones here described represent neural populations with intrinsic striatal connections. Experiments are underway to study this problem and also to examine the relation between these neuronal compartments and the AchE-poor labyrinths described in the accompanying abstract. From the few intercalcated sections processed in the present experiments for AchE, it seems evident that the two striosomal patterns at least in part do overlap.

142 A DESCENDING PATHWAY INVOLVING NIGRAL-INDUCED HEAD TURNING MOVEMENTS. Fereshteh Motamedi and Donald H. York, Dept. of Physiology, University of Missouri, Columbia, Missouri 65212

Previous studies have shown that stimulation of various structures in the basal ganglia of the awake conscious rat, cat, or monkey will produce head turning movements to the contralateral side. The question of which precise neuronal output system from the basal ganglia results in these head turning movements is not resolved. The present study was undertaken to evaluate nigral-induced head turning movements in rats with ipsilateral brain transections just anterior to SN in order to eliminate the effects of striato-nigral or corticofugal fibers which may affect SN.

Experiments were carried out in Sprague-Dawley rats (350-450 gms) which were divided into two groups. Group I (control) were anesthetized and had a concentric bipolar electrode stereotaxically inserted into SN (pars reticulata, pr.) (A2.75, L2.3, $D^{-1.5}$) (Skinner, 1971). Group II rats were anesthetized and a transection of the mesencephalon (A4.25, L0.9 - 4.35, D-2.2) just anterior to SN was performed. A bipolar stimulating electrode was also inserted into SNpr ipsilateral to the lesion. A period of one week elapsed before behavior studies were undertaken.

Stimulation of SNpr (65-200μA, 0.1-0.2 msec, 50 Hz for 6 sec) produced consistent head turning to the contralateral side in both groups of animals. There was no significant difference in the threshold current required to produce head turning in these two groups. Haloperidol (0.5 mg/Kg) consistently elevated the stimulus threshold current required to produce head turning in the lesioned group (Group II). Higher doses of haloperidol (1 mg/Kg) abolished head turning. In the non-lesioned group, haloperidol also initially raised the threshold to induce turning in some animals, but was found to lower threshold in others. The lowering of stimulus threshold was never observed in the lesioned group.

Recent neuroanatomical findings have defined a pathway from SNpr to the superior colliculus and midbrain tegmentum. In order to discover if this pathway was responsible for head turning movements, animals of Group II were given a further lesion involving the ipsilateral superior colliculus (A0.85, L1.5, D1.5). A week was allowed before further testing commenced. Stimulation of SNpr did not consistently produce a contralateral head turning. There was either no effect or an equal tendency to turn left or right in these animals.

These results suggest that there is a dopamine link in the output pathway from SNpr to cervical spinal cord motoneurons. The superior colliculus may also play a role in the nigral output pathway involved with head turning movements.

143 ELECTROPHYSIOLOGICAL DEVELOPMENT OF THE GLOBUS PALLIDUS IN KITTENS. G.D. Novack, M.S. Levine, E. Cherubini*, C.D. Hull and N.A. Buchwald. Ment. Retard. Res. Ctr., Sch. Med., UCLA, Los Angeles CA 90024

These experiments are part of a series of studies assessing the maturation of connections of the caudate nucleus (CD) and globus pallidus (GP) in the kitten. We showed previously that inputs to the CD from cortex (CX), thalamus and nigra are functional in the first few days of life. Stimulation of any of these structures evoked action potentials from extracellularly recorded CD neurons in 1 or 2 day old kittens. Extracellular records were adequate to demonstrate the excitatory connections to the CD. To demonstrate the development of inhibitory potentials we were forced to record intracellularly from neonatal CD neurons. In adult animals, the typical response of CD cells to stimulation of their afferents is an excitation followed by an inhibition (EPSP-IPSP sequence). In kittens we found that the IPSP developed very slowly and did not reach adult levels in terms of frequency of occurrence, duration, and amplitude until over 40 days of age. The present experiments concern development of caudate outputs to the globus pallidus. Extracellular spike responses were evoked in GP neurons by stimulation of CD or CX. CD stimulation was used to assess development of striopallidal connections directly. Responses to CX stimulation assessed the ability of the CD to relay information to the GP. There is little evidence for a direct CX-GP pathway. Results of this study showed that CD-GP connections exist as early as 2 days of age. Latency of the CD evoked spike decreased with increasing age from a mean of 40 ms in the 1-10 day range to 20 ms at 60 days. For CX stimulation, the latency to response decreased from 50 to 40 ms at the same ages. Concomitantly, the percent of units responding to CD increased from 70% to 90%, while the percent of units responding to CX stimulation remained constant (60%). The majority of responses to both CD and CX stimulation in younger kittens were excitatory. In older kittens, the majority of responses were either purely inhibitory or involved excitatory-inhibitory sequences. About 40%-50% of the units responded to stimulation of both sites regardless of age. Of these, the percent responding with the same type of response decreased with age from about 73% to 45%. These experiments show that the majority of excitatory input connections to both the CD nucleus and GP are well developed at birth. In contrast, inhibitory connections in both these nuclei develop more slowly. The results also suggest that the CD, early in postnatal development, probably serves as a passive relay rather than as a complex processor of incoming information. Supported by USPHS grants HD-05958, MH-7097 and NS-12324.

144 PAW USAGE IN ACAUDATE AND AFRONTAL CATS. Ch. E. Olmstead and J.R. Villablanca. Depts. Psychiat., Anat., and MRRC, UCLA, CA 90024.

A modified Wisconsin General Test Apparatus was used to evaluate and compare the paw usage of 50 adult cats distributed as follows: 26 intact[14 colony-reared(CI)and 12 pound-derived(PI); 15 with bilateral aspiration lesions of the caudate nuclei [7 operated as kittens(KBAc)and 8 as adults(BAc)];6 with unilateral caudate removals(UAc-all adult);12 with bilateral frontal cortical removal [9 as kittens(KBFr)and 3 as adults(BFr)];and 6 sham[all as kittens(ShO)]. Many of the adult operated were evaluated both pre- and post-operatively.The ability and accuracy in retrieving chunks of meat through a narrow opening were evaluated for 10 trials on each of 5 days. Paw attitude was scored on a 5-point scale and the number of swipes per trial was counted.In all intact and ShO animals, the dominant movement was a sweeping forward, lateral and medial thrust of the paw to envelop or hook the food.More of the PIs showed a definite handedness(left)than did the CIs or ShOs.All of the lesion groups showed changes in both paw attitude and the number of swipes to obtain meat.Most severely affected were the BAc and KBAc groups where only the adult animal with the smallest lesion showed any normal performance.The dominant attitude for both groups was a straight clubfooted movement that was inaccurate.Successful retrievals were usually followed by perseverative responding at that site despite a new meat position.Differences between the BAc and the KBAc were that the BAc tended to use their claws more often and that none of the KBAc ever showed the normal swipe.Although the KBAc generally took more swipes per trial than the BAc, the difference was not statistically significant.Neither group showed a significant change in either attitude or accuracy with continued training.In the BAc group, there were no changes in handedness from that seen preoperatively.The UAc group showed bilaterally many of the changes seen in the BAc group but all improved with training.There were no changes in handedness despite the fact that the paw contralateral to the lesion was significantly($p<.02$)less accurate than the one ipsilateral.The most striking difference between the adult and the kitten lesioned animals appeared in the BFr and KBFr groups where a)the BFrs were extremely inconsistent in their behavior and when they retrieved showed only a random mixture of normal swipes and dismetric jabs while the KBFr showed fairly consistent, albeit dismetric, approximations to the normal paw movements;b)what dismetria there was in the KBFr improved with training while the BFr showed none.These data suggest that a)the caudate nuclei have a role in postural adjustments for paw usage;b)these defects probably contribute to the deficits in bar pressing previously reported for both BAc and KBAc;c)the slowness in the KBFr and BFr cats was probably due to inconsistent behavior and dismetria (USPHS Grants HD-05958, MH-07097, and HD-94612).

145 IS THERE A PALLIDOHABENULAR PATHWAY IN MONKEYS? A. Parent and R. Boucher, Lab. Neurobiol., Fac. Méd., Univ. Laval, Québec, Canada.

In the rat, the entopeduncular nucleus (EN)(the equivalent of the internal pallidum of primates) has been shown to be the major source of forebrain afferents to the lateral habenula (LH) with the horseradish peroxidase (HRP) method (Herkenham and Nauta, J. Comp. Neur., 173: 123, 1977). In the cat, however, we have shown by means of the same procedure that the largest collection of forebrain neurons projecting to the LH occurs along the ventromedial aspect of the EN but not in the EN itself (Gravel et al., Neurosc. Abstr., 3: 198, 1977).

In order to see if the latter condition is peculiar to cats or if it may also be found in other non-rodent mammals, single injections of HRP (30% sol'n, 0,15-0,25 µl) were made in the habenula of 6 squirrel monkeys (Saimiri sciureus). Retrogradelly labelled cells were visualized after a survival period of 24 to 48 hrs by means of the original LaVail method. In 3 monkeys, the injection sites were mainly confined to the LH and only slightly involved the medial habenula or the dorsomedial thalamic nucleus. In such cases, the largest number of labelled neurons are found along the ventromedial border of the rostral third of the internal pallidum (IP). Many of these numerous and strongly positive cells are intermingled with the fibers of the inferior thalamic peduncle and of the ansa lenticularis. A small number of labelled neurons also occurs along the lateral border of the IP, i.e. within the internal medullary laminae, and along the dorsal aspect of the IP, beneath the internal capsule. No HRP-positive cells are found in the viscinity of the caudal two-third of the IP. Although the rostral IP appears nearly completely surrounded by labelled cells, only a few HRP-filled neurons are present within the IP itself. In another monkey, the HRP injection site involved mainly the dorsomedial nucleus and diffused only slightly into the LH. In such a case, the number of HRP-positive cells was greater in the internal medullary laminae but much lesser along the ventromedial border of the IP than after LH injection.

Therefore, in monkeys as in cats, the main source of forebrain afferents to the LH appears to be the peripallidal cells, especially those lying along the ventromedial edge of the IP. These peripallidal neurons may well be part of certain limbic structures intimately surrounding the pallidum, such as the substantia innominata and the lateral hypothalamus.

146 LEARNING IMPAIRMENTS IN RATS WITH EXPERIMENTAL DEGENERATION OF THE NEOSTRIATAL NEUROPIL. Michele Pisa, Paul R. Sanberg and Hans C. Fibiger. Div. Neurol. Sci., Dept. Psychiatry, Univ. of B.C., Vancouver, B.C., Canada, V6T 1W5.

In contrast to conventional methods of lesions, injections of kainic acid (KA) in the caudate-putamen result in a relatively selective degeneration of neostriatal neurons with apparently little damage to both afferents terminals and axons in transit. The neurotoxic lesion therefore appears to afford a more specific attribution of the resulting behavioral disorders to neostriatal dysfunction. Three nmoles of KA in 0.5 µl of phosphate buffered saline were injected in the rostral neostriatum of male Wistar rats. The control rats received injections of the vehicle solution only. In the first experiment KA treated rats showed retarded acquisition, normal retention, increased resistance to extinction, normal reacquisition of a 1-way active avoidance response and impaired acquisition on subsequent training of a passive avoidance response using the shock-shock conflict procedure. In a second experiment all KA treated rats, in contrast to the controls, failed to learn a food-reinforced spatial alternation task in a T maze. Similar effects have been documented in earlier studies in which both the neostriatal neuropil and neocortical connections in transit were damaged. The present findings indicate that impairments of associative processes can also result from lesions mostly limited to neostriatal tissue. The results suggest that the neostriatal degeneration of patients with Huntington's disease may account, at least in part, for the associated cognitive impairments.

147 ANTIDROMIC AND SYNAPTIC ACTIVATION OF HRP IDENTIFIED SUBSTANTIA NIGRA AND RETRORUBRAL NEURONS IN THE CAT: ANATOMICAL AND ELECTROPHYSIOLOGICAL STUDY. R.J. Preston*, R. A. McCrea, H. Chang* and S. T. Kitai (SPON: M.H. Cooper). Dept. of Anatomy, Mich. State Univ., E. Lansing, MI 48824.

The nigro-striatal system was investigated by recording the intracellular responses of horseradish peroxidase (HRP) identified substantia nigra (SN) and retrorubral (RR) neurons. These neurons were activated by stimulation of the caudate (Cd) nucleus or the internal capsule (IC) and medial forebrain bundle (MFB). Cats were anesthetized with surital (35 mg/kg) and α-chloralose (80 mg/kg). Stimulating electrodes were positioned stereotaxically in the head of the Cd nucleus and in the IC-MFB (A. 10, Reinoso-Suàrez). Recording microelectrodes were filled with 2M KCl (30-50 megohms) or with 4% HRP in 0.2 M KCl-tris buffer (pH 7.6). Cd nucleus stimulation evoked IPSPs with latencies of 3-15 msec ($\bar{x}$=7.9). IC stimulation produced mostly IPSPs (1.0-9.0 msec; $\bar{x}$=3.5) but occasionally these IPSPs were preceded by depolarizing potentials with latencies of 1.2 - 6.0 msec ($\bar{x}$=2.9 msec). Both MFB and Cd stimuli evoked antidromic potentials with mean latencies of 4.0 and 9.3 msec, respectively. Conduction velocity for SN and RR axons ranged from 1 - 3 m/sec. Neurons identified by intracellular injections of HRP were located in pars compacta of SN or in the RR nucleus. Their spine free pyramidal or fusiform somata ranged in size from 15 - 29 µm. Three to six spine free primary dendrites branched sparsely into spine laden secondary and tertiary dendrites which coursed without branching until terminating in complex thickets at radial distances of 240-860 µm. Axons arose mainly from primary dendrites. For some neurons, the axon coursed rostrally without collateralizing while for others, the axon coursed caudally and gave off 2-5 collaterals which appeared to terminate locally. These data indicate that neurons of both SN and RR send axons to the Cd nucleus and in turn receive mainly inhibitory input from the caudato-nigral pathway. (This work was supported by NIH Grant NS00405.)

148 EVIDENCE FOR A MIDBRAIN RETICULAR - ZONA INCERTA LOOP. N.Ropert*, A. Kitsikis*, A. Parent and M. Steriade. Lab. Neurophysiol. and Lab. Neurobiol., Faculty of Medicine, Laval University, Quebec, Canada.

Ascending influences of the brain-stem reticular formation are thought to distribute mainly through medial-intralaminar thalamic nuclei and subthalamic areas. This view stemmed from experimental approaches which could not circumvent difficulties resulting from the presence of a great number of *en passage* fibers in these regions, especially in the subthalamus. To test the hypothesis that the upper reticular formation and related subsystems play a role in forebrain activation processes, we first decided to identify the target structures of rostrally projecting cells in the mesencephalic central tegmental field (FTC) and to disclose some control circuits involving the FTC. Both electrophysiologic and morphologic methods were used and their results were concordant. Within the frame of the physiologic investigation, extracellular unit recordings of FTC, zona incerta (ZI) and medial-intralaminar thalamic neurons were performed in chronically implanted, behaving cats while stimulating various brain-stem, thalamic, anterior hypothalamic and neocortical areas. Fiber recordings were rejected. Here only the FTC-ZI interrelationships will be reported. Antidromic invasion of FTC neurons following stimulation in the ipsilateral ZI region occurred within a latency range of 0.5 ms to 5.0 ms. The question whether the testing stimulus affected FTC terminals ending in ZI was positively answered in parallel experiments when unit discharges belonging to ZI cell bodies were monosynaptically elicited (1-3 ms) following focal stimulation in FTC. This midbrain reticular→ZI projection is supported by autoradiographic studies of Edwards and de Olmos (J. Comp. Neurol., 165: 417, 1976). On the other hand, backfiring of ZI cells was elicited at 0.5-1.5 ms latencies, following stimulation of one or several foci in the ipsilateral FTC. That fibers arising in ZI terminate in the FTC was corroborated by recording monosynaptic discharges of FTC cells following ZI stimulation. In order to substantiate the electrophysiologic findings, the retrograde transport of horseradish peroxidase was studied with the diamino-benzidine method and the improved, tetrametyl-benzidine procedure of Mesulam (J. Histochem. Cytochem., 26: 106, 1978). Labelled neurons were found in large number in both medial and lateral parts of ZI after injections in the midbrain tegmentum, whereas only a few positive cells occurred in the adjacent hypothalamic areas. The significance of these reciprocal pathways between FTC and ZI for activation-deactivation processes is now being investigated by recording spontaneous firing and evoked activities of physiologically identified cells at various levels of alertness. (Supported by MRC grants MT-3689 and MT-5781).

149 LOCOMOTOR ACTIVITY, EXPLORATION AND NEOPHOBIA IN RATS WITH KAINIC ACID-INDUCED DEGENERATION OF THE NEOSTRIATUM. Paul R. Sanberg, Michele Pisa and Hans C. Fibiger. Div. Neurol. Sci., Dept. Psychiatry, Univ. of British Columbia, Vancouver, B.C., Canada, V6T 1W5.

Locomotor, exploratory and neophobic behaviors were assessed in male Wistar rats with neurotoxic degeneration of the neostriatal neuropil. Kainic acid (KA; 3 nmoles in 0.5 µl of phosphate-buffered saline) was bilaterally injected into each caudate-putamen of the experimental rats. The controls received injections of the vehicle only. No differences between groups were found in daytime locomotor activity in photocell activity cages. Exploration of the arms of a T-maze was assessed in 5 daily sessions, each 5 min long. The experimental rats explored less than the controls in the first and the last two sessions, as reflected by the significant interaction of lesion treatment with sessions. The experimental rats also tended to ambulate less then the controls at the onset of each session. This was especially evident in the subsequent spontaneous alternation test in the T-maze, in which the experimental rats failed to leave the start box or to complete the trials significantly more frequently than the control rats. Although the KA treated rats alternated less than the controls on the average, the difference was not significant, owing to great variability in their behavior. There were no differences between groups on locomotion and rearing in an open field. The rats with lesions, however, showed significantly less thigmotaxic, i.e. wall hugging, behavior. Activity was finally measured in a maze with 7 parallel alleys joining a start box and a goal box. The KA treated rats showed significantly longer latencies both to leave the start box and to eat the first food pellet in the goal box. Their locomotor activity in the alleys did not differ from that of the controls, however.

These results suggest that neostriatal lesions may not affect gross daytime locomotor activity, expecially if it is measured in homogenous environments. On the other hand, in conditions involving locomotion from one place to another, neostriatal lesions appear to result in decreased activity, presumably on account of an increased fear of novelty. These finding indicate a role of the neostriatum in the control of emotional reactions. It is of interest that patients with Huntington's disease, which involves gross neostriatal degeneration, also suffer intense emotional disorders.

150 EFFECTS OF INTRASTRIATAL KAINIC ACID ON MOTOR BEHAVIOR IN RATS. E.K.Silbergeld, R.E.Hruska, J.R.Walters, S.Kennedy*, N.Eng* & S. deSantis* (SPON: T.N. Chase). Experimental Therapeutics Branch, NINCDS, NIH, Bethesda, MD 20014.

Kainic acid (KA) injected intrastriatally has been reported to produce relatively specific neurotoxic sequelae involving cholinergic and GABAergic neurons in the striatum. KA-treated rats have been proposed as models for Huntington's disease by Coyle & Schwarcz (Nature 263:244, 1976). However, this analogy has not been supported by studies of the effects of KA on motor behavior.

Rats (250-300 gm) were injected stereotactically into the striatum with 1 µg KA dissolved in 0.5 µl 0.1 M NaH_2PO_4 buffer, pH 7.4. For behavioral studies, injections were bilateral, at these coordinates (Koenig & Klippel): 7.9 mm anterior, 2.6 mm lateral, and 5.7 mm below skull surface. Biochemical changes were measured in striata and nigras of rats, injected unilaterally with the same dose, 7 and 14 days after injection. In KA-injected striata, high affinity choline uptake was 30% (7 days) and 27% (14 days) of control striata (non-injected side); glutamic acid decarboxylase (GAD) activity was 18% (7 days) and 16% (14 days) of controls; striatal dopamine levels were not significantly changed, nor was the accumulation of DOPA after inhibition of DOPA decarboxylase. In nigras ipsilateral to KA injected striata, GAD activity was also lower: 30% (7 days) and 35% (14 days) of contralateral nigras.

Motor behavior was assessed 7 and 14 days after bilateral injections. Rats were intubated for 4 days after injections; but survivors lost 25-40% body weight. Gait was studied quantitatively by recording footprints of rats freely walking on an enclosed, inclined runway. Length of stride, placement of hind and forefeet, and angles between contralateral footfalls were found to be consistent among control rats. Motor behavior was also studied by videotaping freely moving rats and analyzing dynamic records as to duration of stride, swing time for each limb, and footfall sequence. KA rats were found to be significantly different from controls in: variability of stride length, lack of superimposition of hind over forefootfall, distance covered per stride, duration of stride, and swing time. In addition, observation of nonquantifiable aspects of motor behavior indicated abnormal posture and problems in controlling nonlocomotive forefoot movements in KA rats. These changes were not seen in rats having lost comparable body weight through food restriction, or in rats injected bilaterally with buffer.

151 STRIATAL CYSTEINESULFINIC ACID DECARBOXYLASE. Wm. A. Staines*, A.M. Benjamin* and E. G. McGeer (SPON: A. Jakubovic). Div. Neurological Sciences, University of British Columbia, Vancouver, B.C. V6T 1W5, Canada.

Cysteinesulfinic acid decarboxylase (CSAD), the enzyme catalyzing the penultimate step in the major route of taurine synthesis, is reported to be predominantly synaptosomal and may thus serve as a marker for taurine-containing neurons if such exist. The acute and long term effects of kainic acid (KA)-induced lesions on CSAD activity in rat striatum and substantia nigra were studied using a modification of the assay of Pasantes-Morales et al (Brain Res., 1976, 107, 575-589). In some cases taurine levels were measured on an amino acid analyzer. Activities of CSAD in control tissue were 85 µmoles/hr/mg protein in striatum and 162 µmoles/hr/mg protein in substantia nigra (SN). The Km determined for striatal tissue was 5.56 mM. Control taurine level in striatum was 8.63 µmoles/gm initial weight.

Previous work indicates that injections of KA under the conditions used here destroy striatal neurons but leave intact nerve endings and fibres of passage. One week after unilateral striatal injections of 3 nmoles of KA the CSAD activity (like those of choline acetyltransferase and glutamic acid decarboxylase) were reduced to approximately 50% of control. Similar injections of vehicle, 5 nmoles KA and 10 nmoles KA reduced CSAD activity in the striatum to 94%, 38% and 27% respectively. Taurine levels in the striatum showed a significant reduction to 64% of control levels after an injection of 5 nmoles of KA. A smaller but dose-dependant reduction in CSAD activity was also seen in the ipsilateral SN after intrastriatal KA injections.

Six to eight weeks after striatal injections both CSAD activities and taurine levels seemed to be reduced to a lesser extent than in the more acute experiments.

In as much as KA is believed to be a neuron-specific toxin, the loss following its injection give some further support to a neuronal localization for CSAD activity. The long term recovery in both taurine levels and CSAD activity may be due to a compensatory increase in glia. Intrastriatal injections of KA have been suggested as an animal model of Huntington's chorea. Reports of amino acid levels in this disease indicate no abnormalities with respect to taurine so that our data on animals acutely lesioned indicate a difference from the diseased state. The long term effects of small doses may still, however, cause insignificant changes in the taurine system as seen in chorea.

This work was supported by the Huntington Chorea and the Garfield Western Foundations.

152 ELECTROPHYSIOLOGICAL ANALYSIS OF EXTRINSIC INPUTS TO RAT CAUDOPUTAMEN. Cam P. VanderMaelen*, Anthony C. Bonduki*, and S.T. Kitai (SPON: J. A. Rafols.) Dept. Psychol., Wayne State Univ. Detroit, MI, and Dept. Anat., Michigan State University, E. Lansing, MI 48824.

Intracellular recordings were obtained from neurons in the caudoputamen of hooded rats. Animals were anesthetized with urethane, placed in a stereotaxic holder, and a craniotomy performed to allow for the placement of stimulating and recording electrodes. Stimulating electrodes were placed in the cerebral neocortex (CX), centromedian-parafascicular area (CMP) of the thalamus, and the substantia nigra (SN). Recording electrodes consisted of glass micropipettes filled with 2M KCl or K-citrate with DC resistances of 30-70 Megohm. Electrical stimulation of CX, CMP, or SN elicited monosynaptic EPSPs in caudoputamen neurons. Response latencies ranged from about 1.7-4.5 msec (Median=3.0) for CX stimulation; 2.6-3.6 msec (Median=3.2) for CMP; and 2.3-5.5 msec (Median=3.5) for SN. Convergence of monosynaptic inputs from stimulation of all three areas was demonstrated. Such monosynaptic convergence was also recently reported in the cat caudate nucleus (Kocsis et al., Brain Res., 124, 1977, 403-413). Most neurons exhibited a hyperpolarizing potential following the initial EPSP, which was sometimes followed by rebound excitation with action potentials. EPSP amplitude was increased by injecting hyperpolarizing current through the recording electrode, and was decreased by the passage of depolarizing current.

Double stimulation of SN or CMP with an appropriate interstimulus interval (e.g. 40 msec) resulted in 50-100% reduction in the test EPSP amplitude. But double stimulation of CX at various interstimulus intervals resulted in little or no reduction in test EPSP amplitude. Similarly, test EPSPs from CX stimulation were not substantially reduced by conditioning stimulation to CMP or SN. However, test EPSPs from SN or CMP were reduced by conditioning CX stimulation. This finding in the rat of "prepotency" of the cortical input to the striatum is in agreement with results reported for the cat (Hull et al., Exp. Neurol., 38, 1973, 324-336). (This research was supported by NIH grants NS00405 and NS05576.)

153 KAINIC ACID AND $[^3H]$-GLUTAMATE BINDING IN RAT STRIATUM. Steven R. Vincent and Edith G. McGeer. Kinsmen Laboratory of Neurological Research, Dept. of Psychiatry, Univ. of British Columbia, Vancouver, B.C., V6T 1W5, Canada.

Kainic acid is a neurotoxic amino acid which has been suggested to act via glutamate receptors in the central nervous system to exert both its neurotoxic and neuroexcitatory actions. In the present study we have examined the effects of kainic acid on the specific binding of $[^3H]$-glutamate to rat striatal membranes. The specific binding of $[^3H]$-glutamate (defined as that displaceable with 5 mM unlabelled glutamate) was found to be sodium-dependent and saturable. Kinetic studies revealed a dissociation constant (Kd) of 2.1 µM and the maximum number of binding sites (Bmax) was 1.1 nmoles per mg. protein. Kainic acid inhibited the Na^+-dependent $[^3H]$-glutamate binding, however, the slope of the displacement curve was less than that found for glutamate, suggesting that kainic acid was acting at a different site than glutamate. This was confirmed in kinetic studies, where kainate was found to inhibit non-competitively the $[^3H]$-glutamate binding with a Ki of 0.54 mM.

It has been suggested that Na-dependent glutamate binding represents binding to a glutamate uptake site. However, drugs such as glutamic acid diethyl ester and ibotenic acid which have no effect on high affinity uptake were found to inhibit Na-dependent $[^3H]$-glutamate binding, while oubain was without effect. Also, lesions of the striatum with kainic acid did not reduce Na-dependent, high affinity glutamate uptake, but did result in a 50% reduction in the density of Na-dependent $[^3H]$-glutamate binding sites, without affecting their affinity. Thus it appears that kainic acid can inhibit the sodium-dependent binding of glutamate to neuronal membranes by acting at a site distinct from the glutamate receptor.

154 NEUROLEPTICS AND NIGROSTRIATAL DOPAMINERGIC NEURONS. Suzanne M. Wuerthele and Kenneth E. Moore. Department of Pharmacology and Toxicology, Michigan State University, East Lansing, MI 48824.

Increased activity of nigrostriatal dopaminergic neurons is associated with increased concentrations of 3,4-dihydroxyphenylacetic acid (DOPAC) in the striatum (Roth et al., Eur. J. Pharm. (1976) 36: 163-172). In the present study a radioenzymatic procedure was employed to measure the concentrations of dopamine and DOPAC in the striatum and substantia nigra of rats treated with drugs reported to increase or decrease nigrostriatal nerve activity. Systemic administration of haloperidol (0.1 mg/kg, i.p.) increased the concentrations of DOPAC in the striatum and substantia nigra to 270% and 140% of control, respectively, but failed to alter dopamine concentrations in either region. Several days after a unilateral injection of kainic acid (2.5 µg in 2 µl), which destroys cholinergic and GABAergic neurons in the striatonigral feedback loop, the concentration of dopamine was unaltered while the concentration of DOPAC was increased in the ipsilateral striatum. Systemic administration of haloperidol caused a further increase in the DOPAC concentration in the kainic-acid lesioned striatum, suggesting that the neuronal feedback loop is not essential for this action. To determine if blockade of putative autoreceptors located on nigrostriatal cell bodies are involved in the DOPAC-elevating actions of neuroleptics, haloperidol (0.1, 0.5, 1 µg in 2 µl) was injected unilaterally into the substantia nigra of conscious rats through chronically implanted cannulae. Thirty minutes after intranigral injections of haloperidol the concentration of dopamine and DOPAC in the striatum and substantia nigra were unaltered. On the other hand 30 minutes after intranigral injections of baclofen (2.5 µg in 2 µl) the concentration of dopamine was increased and the concentration of DOPAC was decreased in the striatum. Baclofen also decreased DOPAC concentrations in substantia nigra. A lower dose of baclofen (0.1 µg) which was without effect on striatal DOPAC concentrations per se prevented the haloperidol-induced increase of striatal DOPAC. These data suggest that although nigrostriatal activity can be influenced by intranigral baclofen, haloperidol-induced increases in nigrostriatal activity may not be mediated through an action on dendritic receptors located in the substantia nigra. (Supported by USPHS Grant MH13174)

155 ALTERED CAUDATE NUCLEUS FIELD POTENTIALS FOLLOWING SUSTAINED STIMULATION TO DIFFERENT SUBSTANTIA NIGRA REGIONS. R.R. Yeoman*, B.M. Rigor*, N. Dafny, (Spon: Richard Wiggins). Department of Neurobiology and Anatomy, The University of Texas Medical School at Houston, Houston, Texas 77025.

It has been demonstrated neuropharmacologically that electrical stimulation of central pathways causes changes in terminal area transmitter concentrations. The present experiments were initiated to confirm electrophysiologically if field potentials from the head of the caudate nucleus are also changed subsequent to sustained stimulation of the substantia nigra pars compacta and pars reticularis. Urethane anesthetized male rats were stereotaxically implanted with bipolar concentric recording electrodes localized in the caudate nucleus. In experiment one, the pars compacta-medial lemniscus area was stimulated through bipolar concentric electrodes with square wave 0.1 msec pulses at 1/3 sec for a control recording. After the responses from eight test stimuli were recorded and averaged, a single five minute train of 0.2 msec biphasic square pulses at 50 cycles per second were given. Immediately after the train, 8 test stimuli were again given and the responses recorded and averaged for comparison to pre-burst activity. Responses stimulated from pars compacta were characterized by two fast spikes followed by a wave, P_3-N_3. This wave was markedly increased in amplitude immediately after the stimulation train, yet returned to control level within five minutes. In experiment two, the pars reticularis was similarly stimulated and tested. The characteristic waveform from this area consisted of a biphasic spike followed by a wave, P_2-N_2-P_3. The P_2 peak was consistently decreased after a burst in this area yet it also returned to control within five minutes. The burst affected peak had similar latencies of 10-15 msec in both experiments. Histological verification of the stimulus site was done in all animals. The apparent substantia nigra stimulus localization effect on caudate nucleus field potentials suggests different transmitter pathways may be involved and modified by the electrical stimulation train.

BRAIN METABOLISM AND NUTRITION

156 EFFECTS OF CARBIDOPA OR PRECURSOR (TYROSINE) LOADING ON URINARY CATECHOLAMINE LEVELS IN RATS. R. Alonso*, J. Agharanya* and R. J. Wurtman. Dept. Nutrition & Food Sci., MIT, Cambridge, MA 02139.

We have used urinary norepinephrine (NE) and epinephrine (E) levels to examine the effects of carbidopa or tyrosine (Tyr) administration on NE and E release from peripheral sympathetic nerves and adrenal medulla of rats. We previously showed that carbidopa, a peripheral inhibitor of aromatic amino acid decarboxylase, suppresses the decarboxylation of endogenous ^{3}H-dopa formed from ^{3}H-tyrosine in cardiac sympathetic nerves (Nature 265: 79, 1977). Tyr is the circulating precursor for NE, and its administration enhances NE synthesis in (Science 185: 183, 1974) and release from (Gibson & Wurtman, Life Sci., in press) CNS noradrenergic neurons. The present results show that carbidopa (100 mg/kg i.p.) decreased urinary NE of male rats and completely blocked the rise in NE excretion caused by cold exposure (Table). The carbidopa-induced decrease in urinary NE was associated with a reduction in cardiac NE content (from 333.3 ± 21.7 ng/g to 136.0 ± 18.9 ng/g), but no change in brain NE. Hence, carbidopa reduces the NE content of rat urine by inhibiting its synthesis in peripheral sympathetic nerves, without affecting brain NE neurons. These data provide an additional basis for clinical trials of high doses of carbidopa when it is desired to decrease peripheral sympathetic activity without affecting brain function. In studies on Tyr, male rats fasted overnight and placed in a cold (4°C) environment were injected with Tyr (100, 200, or 400 mg/kg i.p.) or its diluent and given water (5 ml) by stomach tube. The excretion of both catecholamines during the following 3 hr increased in rats treated with 200 or 400 mg/kg Tyr, and the effect was linearly dose-related in the case of E. These observations suggest that catecholamine synthesis in, and release from, peripheral tissues, as in rat brain, can be precursor-dependent. It remains to be determined whether the amounts of Tyr available for peripheral NE and E synthesis depend solely on plasma Tyr levels, or also on plasma concentrations of other neutral amino acids. Perhaps induced changes in plasma amino acid levels may be useful in treating disorders of sympathetic nervous function.

157 CORTICAL OXIDATIVE METABOLISM IN NORMAL AND MILDLY ISCHEMIC BRAIN. George Austin, Britton Chance, Clyde Barlow, and Ronald Jutzy*. Sect. of Neuros., Loma Linda Univ., Loma Linda, CA., 92350 and Johnson Research Foundation, Univ. of Penns., Phila., PA. 19174

In an area of normal cortex or an area of relative brain ischemia, where considerable function still exists in the cortical network, it is possible to increase relative brain O_2 tension, (bPO_2) by: 1) increasing the mean B.P., 2) increasing the FiO_2 at least up to 60%, and 3) increasing the CBF by additional CO_2 inhalation. These studies were carried out in a series of cats under N_2O/O_2 anesthesia, in a 2/1 ratio. They were based on the use of 25 μ teflon coated platinum electrode inserted 1 - 2 mm in the prefrontal cortex to record bPO_2. In all cats it was necessary to exceed autoregulation of flow or of bPO_2 by increasing the mean B.P. or FiO_2 by a degree beyond that which allows the autoregulatory mechanisms to effectively perform. In a follow-up group of normal and mildly ischemic cats the results of a significant rise in bPO_2 on cortical oxidative metabolism were investigated by the use of non-invasive optical techniques to measure the relative redox level of some members of the mitochondrial electron transport system. These included Cyt. a,a_3 (by dual beam, dual wavelength spectrophotometer), flavoprotein (by flying-spot fluorometer), and NADH (by fluorometer). The results of these studies show that cortical oxidative metabolism can be increased, at least in some areas of the brain, by driving up the bPO_2. The results of these ongoing animal studies form the basis for intraoperative monitoring of cortical oxidative metabolism in patients undergoing microanastomosis. They support the conclusion that the increase in bPO_2 and increase in oxidized state of members of the electron transport chain, offer a reasonable explanation for the acute improvement following microanastomosis.

158 NEW APPROACH TO EARLY TREATMENT OF PHENYLKETONURIA (PKU). Helen K. Berry, Mary K. Bofinger*, and Richard E. Butcher*. Dept. Pediatrics, Univ. Cincinnati. Sch. Med. Cincinnati, OH 45229.

We have shown that phenylalanine levels in brains of PKU rats treated with valine, isoleucine, and leucine (VIL) were lower than in untreated PKU rats. We also demonstrated reduction in CSF phenylalanine (Phe) in an adult woman with untreated PKU after administration of VIL, although serum Phe levels were unchanged. It seemed logical to test the effect of VIL on treatment of infants with PKU.

An infant recognized to have PKU as a result of newborn screening was treated with VIL to determine if transport of Phe into CSF could be inhibited. Newborn screening for Phe was positive at 4 days of age. Serum Phe measured at 18 days was 55 mg% (normal<1). Tyrosine was 1.2 mg% (normal<2). Phenylpyruvic acid excretion by Phenistix was 15 mg%. Following confirmation of the diagnosis the infant was hospitalized for treatment. Prior to beginning the low-phenylalanine diet baseline studies were carried out to determine the effect of treatment with VIL on cerebral Phe transport. Blood and cerebrospinal fluid were collected while the infant was fed with Similac (24 oz/day). The infant was then fed with Similac supplemented with valine, 135 mg/kg; isoleucine, 129 mg/kg; and leucine, 241 mg/kg. At the end of 48 hours blood and CSF were collected; VIL treatment was discontinued and a low Phe formula was begun. During the 48 hour period on VIL serum Phe remained unchanged at 3174 uM, while CSF Phe decreased from 1049 to 882 uM.

Similar studies were carried out in two additional infants with comparable results. Trials of VIL combined with low Phe diet are now being undertaken to determine if CSF Phe levels can be reduced to a greater degree than by diet alone.

159 EXTRACELLULAR POTASSIUM CHANGES IN NORMAL AND GLIOTIC CEREBRAL CORTEX DURING ISCHEMIA. William F. Blank. Dept. Pathology, Washington U. Medical School, St. Louis, Mo 63110.

Extracellular potassium concentration (K_o) was measured continuously in gerbil cortex during ischemic insults caused by occluding one or both carotid arteries. The gerbils were anesthesized with 30 mg/kg pentobarbital and body temperature kept constant at 37°C. Portions of the cortex were frozen for 15 seconds with a dry ice/acetone slurry in order to produce astrocytosis.

The control K_o before the insult averaged 2.7 mM in normal cortex and 4.8 mM in gliotic cortex. After the carotid arteries were clamped the K_o increased. In normal cortex the K_o rise was a complex exponential and resembled spreading depression. The maximum rate of rise averaged 4.75 mM/sec and the K_o reached a mean of 99 mM/L. The K_o rise in gliotic cortex was linear and averaged 3.1 mM/min. The maximum K_o reached 26 mM before reversal of the insult.

The insults were reversed by unclamping the carotids. The K_o fall was described by a single exponential function in both normal and gliotic cortex. The rate constant averaged -.025/sec in normal cortex and -.004/sec in gliotic cortex. Undershoots of K_o below control levels of up to 1.2 mM (mean .65 mM) occurred in normal cortex but were not seen in gliotic cortex.

Since neurons and axons are absent in the gliotic cortex, it is postulated that the presence of neurons and axons are necessary for the occurrence of the exponential, spreading depression-like rise and the undershoot of K_o following reversal of the insult. The exponential rise probably occurs during ischemia (energy depletion) because of increased neuronal permeability due to massive transmitter release from synaptic endings. The linear rise in gliotic cortex is probably due to inhibition of $Na^+ - K^+$ ATPase of the astrocytes and diffusion of K^+ from the normal (though ischemic) surround. (See Blank, W.F. and Kirshner, H.S.: Brain Research 123:113-124, 1977).

160 ROLE OF ASPARTIC AND GLUTAMIC ACIDS IN THE ATAXIA PRODUCED BY THIAMINE DEFICIENCY. Roger F. Butterworth, Edith Hamel* and André Barbeau. Dept. Neurobiology, Clinical Research Institute of Montreal, Montreal, Quebec, Canada.

Thiamine deficiency is considered to produce its effect on the central nervous system by one (or more) of the following mechanisms: (i) inhibition of brain transketolase (ii) inhibition of brain pyruvate and α-ketoglutarate dehydrogenases (iii) by a direct action on the neuronal membrane.

Pyrithiamine, a central thiamine antagonist, when administered to rats in doses of 0.5 mg per kg per day, produces within 18 days, neurological symptoms of thiamine deficiency including ataxia. Brain levels of the amino acids glycine, GABA, glutamine, aspartic acid, glutamic acid and taurine were measured by a double-labelling dansyl microassay (Anal. Biochem., 64, 389 (1975)) in whole brain, retina, dorsal root ganglion and in the following discrete brain regions of affected animals: cerebellum, medulla oblongata, cortex, hypothalamus, hippocampus, midbrain, caudate nucleus and olfactory bulbs. In cerebellum, medulla oblongata and midbrain, regions of the brain most affected pathologically in thiamine deficiency, aspartic and glutamic acids were decreased by 47% and 26% respectively ($p < 0.01$).

In a separate series of experiments, rats were maintained on a thiamine-deficient diet for up to 7 weeks, at which time signs of deficiency (loss of righting reflex, ataxia) were present. Significant decreases in glutamic and aspartic acids were again observed in medulla oblongata, cerebellum and midbrain of affected animals when compared to pair-fed controls, suggesting that the amino acid changes were not secondary to the anorexia associated with thiamine deficiency. These results suggest that the putative excitatory amino acids, glutamic and aspartic acids may play a key role in the production of the neurological symptoms of thiamine deficiency. Mechanisms implicating either inhibition of pyruvate (and α-ketoglutarate) dehydrogenase(s) or a direct role for thiamine in membrane excitability will be discussed.

Supported by grants from Université de Montréal CAFIR and The Association Canadienne de l'Ataxie de Friedreich.

161 PROPAGATION OF FOCAL MOTOR SEIZURES IN THE MONKEY William F. Caveness, Motohiro Kato*, Shinichi Hosokawa*, Barbara L. Malamut*, Shinichiro Wakisaka*, and Raymond R. O'Neill*, NINCDS, National Institutes of Health, Bethesda, Maryland 20014

Focal seizures were induced in 3.5 Kg. Macaca mulatta by injecting 25,000 units of Penicillin in 0.25 m. water into the face-hand area of the right cerebral motor cortex. The paroxysmal activity was monitored by electroencephalography and electromyography. After thirty minutes each head was removed, frozen and serially sectioned. The cortical and subcortical metabolic activity was then determined by the Sokoloff Method: 2-deoxy-D[^{14}C]glucose, injected by vein at the beginning of the seizure, competes with glucose for transport across the blood brain barrier and for the enzyme hexokinase. While glucose completes its metabolic cycle, the deoxyglucose is trapped in brain tissue at the phosphorylated phase where its [^{14}C] label may be quantitatively measured by autoradiography. Using these measurements with those of the isotope in arterial blood, the actual rate of local glucose utilization may then be calculated in mg per 100 grams of brain per minute.

The pattern of glucose utilization in four control monkeys was bilaterally symmetrical with a range in individual brain components from 8-9 mg/100/gm/min to 2-3 mg/100 gm/min. The right-left difference, % (R-L)/L, was negligible. With contralateral face seizures, in four monkeys, there was a distinct though uneven increase in activity with a right-left difference of 90-100% in the lateral globus pallidus, VPM of the thalamus, and motor cortex, with somewhat less difference in VPL, VL and medial globus pallidus. With extension to contralateral face and hand seizures, in four monkeys, there was a dramatic change in pattern, predominantly unilateral, with values as high as 22-28 mg/100 gm/min. The right-left difference was 400% in medial, and 340% in lateral globus pallidus, twice that of any other structure; 120-160% in the motor and sensory cerebral cortex; 90-120% in VL, VPL and VPM; and a left-right difference of 50-60% in the cerebellar cortex.

These data provide fresh insight into the location and extent of increased neuronal activity in focal motor seizures, that must be accommodated when considering basic mechanisms. Further, they should be considered in the search for new modes of therapy.

162 SYNTHESIS OF MYELIN-ASSOCIATED GLYCOPROTEINS IN PROTEIN-DEFICIENT RATS. Mary J. Druse-Manteuffel and Nancy L. Krett*. Department of Biochemistry and Biophysics, Loyola University Medical Center, Maywood, Il. 60153.

The synthesis of fucosylated glycoproteins was studied in the 15-, 20- and 27-day-old offspring (control and protein-deficient pups) of female Sprague-Dawley rats that were maintained on normal laboratory chow or a protein-deficient diet (8% protein) during the first twenty days after parturition. A double-label isotope technique was used whereby a control rat was given an intraventricular injection of ^{3}H- or ^{14}C-fucose 18 hours prior to sacrifice and a protein-deficient rat was given fucose labeled with the other isotope. Brain homogenates from a control and protein-deficient pup were combined. Purified myelin (JNC 21: 749, 1973) was subfractionated (BBA 329: 305, 1973) into light, medium and heavy myelin. ^{3}H and ^{14}C radioactivity was determined in separated myelin subfraction proteins.

These experiments provide evidence that the major myelin-associated glycoprotein in young protein-deficient pups has a higher apparent molecular weight than that from the myelin subfractions from age-matched control pups. These results may be explained by the presence of a new, abnormal glycoprotein in the protein-deficient rats. Alternatively, the developmental shift to a lower apparent molecular weight glycoprotein which has been seen in normal rats (Brain Res. 58: 506, 1973) may have been delayed in the protein-deficient rats.

This research was supported by a Basil O'Connor Starter Research Grant from The National Foundation-March of Dimes. Dr. Mary Druse Manteuffel is the recipient of a Schweppe Foundation Career Development Award.

163 EFFFCT OF CHRONIC PROTEIN MALNUTRITION ON PENTYLENETETRAZOL-INDUCED AND KINDLED MOTOR SEIZURES IN THE RAT. W.B. Forbes, C.A. Tracy*, W.C. Stern, P.J. Morgane, and O. Resnick. Worcester Foundation for Exptl. Biology, Shrewsbury, MA 01545.

In a previous study (Brain Res., 79:375-384, 1974) we found that rats malnourished during lactation exhibit, at adulthood, greater susceptibility to electroconvulsive shock applied via ear-clip electrodes. In order to evaluate the generality of that finding, we tested the susceptibility of malnourished and normal rats to pentylenetetrazol (PTZ) induced and kindled motor seizures.

Female rats were fed one of two isocaloric diets, differing only in percent casein content (8% or 25%), for five weeks prior to mating, throughout gestation and lactation. Following weaning, pups were fed the same diet as their mothers, ad lib., either the high (group HH) or low (group LL) casein diet. For the study of kindled motor seizures, two additional groups of animals were switched to the opposite diet at weaning (groups HL and LH). Testing of the pups was performed at adulthood, i.e., 60 - 120 days.

Susceptibility to PTZ-induced seizures was evaluated by administering repeated doses of the drug (15 mg/kg, i.p.) at 15 min. intervals and measuring the latency from the first injection to the occurrence of a convulsion. No difference between dietary treatment groups in latency to convulse was seen. Kindled motor seizures were induced by daily elicitation of amygdaloid after-discharges. Electrical stimulation at threshold levels was applied daily until full motor convulsions were observed. In comparison with group HH, group LL exhibited after-discharges of shorter duration early in the experiment (HH=18±7 sec, LL=10±7 sec) but when full motor convulsions developed, did not differ significantly from group HH in this respect. Group LL required significantly more stimulations for the elicitation of a full motor seizure than group HH (LL=15±3; HH=10±2). Only the HL dietary treatment group differed significantly from group HH in threshold for after-discharge elicitation (HL=333±78μA; HH=184±65μA).

These data do not support the generality of the previous observation that chronic malnutrition enhances seizure susceptibility. It appears that the effect of malnutrition on this aspect of brain functioning is situation dependent. The present findings of decreased amygdaloid after-discharge duration and slower kindling of motor seizures in group LL are in keeping with our previous observation of higher brain levels of serotonin and norepinephrine in chronically malnourished rats (Exp. Neurol., 49:314-326, 1975). However no general conclusion regarding the effect of chronic malnutrition on seizure susceptibility is possible at this time. (Supported by NICHHD Grant HD06364.)

164 PIAL ARTERY PRESSURE IN THE DOG: EVIDENCE THAT AUTONOMIC INNERVATION DOES NOT AFFECT SURFACE BRAIN ARTERIES.
Patricia A. Grady, Otis R. Blaumanis* and Erland Nelson. Univ. of Md. Sch. Med., Dept. Neurol. Balt., Md. 21201

Among the most controversial aspects of the physiology of the cerebrovascular system is the functional role, if any, of the innervation of cerebral blood vessels. Numerous investigators have argued on the basis of morphological and physiological observations that the autonomic nerves which accompany the pial arteries exert a significant influence on cerebral blood flow (CBF). In recent years attention has been focused on the possible role of the central adrenergic system which appears to innervate the cerebral microcirculation and originates within the central nervous system itself. It has been suggested that either or both of these systems is involved in the neurogenic component of the autoregulation of CBF. Whether or not the nervous system influences CBF by some direct action remains unknown. Several investigators have found that the larger pial arteries are the sites of a significant proportion of the total cerebrovascular resistance. Others have found that this segment of the cerebrovascular system is richly endowed with autonomic nerves. Numerous technical problems have impeded a resolution of the question of whether perivascular innervation has a significant effect on the caliber of the pial arteries.

The present study was carried out using mongrel dogs anesthetized with Pentobarbital. Aortic and middle cerebral artery pressures were measured. We hypothesized that if the pial arteries, known to contribute substantial resistance to overall CBF, were involved in autoregulation, downstream pressures in small arteries should remain relatively constant as systemic arterial pressure varied. Direct cannulation of vessels as small as 200μ showed that this was not the case. When mean aortic pressure was decreased from 200 to 20 mmHg by reducing blood volume, pial artery pressures followed in a linear relationship. Pial artery pressures were always less than those in the aorta, but the difference between the two was constant. The mean arterial pressure in these experiments was varied over the entire range of the cerebral autoregulatory curve. The pial artery pressures varied accordingly. These relationships were not altered after blockade of the sympathetic nervous system by phenoxybenzamine (5mg/kg) administered 30-60 minutes before decreasing the blood pressure.

These data suggest that the well innervated cerebral arteries do not participate to any significant degree in the overall autoregulatory mechanism of the cerebral circulation. These findings suggest that the microcirculation of the brain is the major site of regulation of cerebral blood flow.

165 ULTRASTRUCTURAL CHANGES IN PURKINJE CELLS DUE TO PERINATAL UNDERNUTRITION.
D.E. Hillman and S. Chen. N.Y. Univ. Med. Ctr., Dept. Physiol. & Biophys., 550 First Avenue, New York 10016

Protein deficiency during perinatal development results in decreased body and brain weight. Reduced number of some neuronal and glial cell types as well as cell size, are believed to be responsible for the decreased nervous tissue mass. Though quantitative alterations have been described, qualitative changes which are indicative of a deprived nutritional status during development have not been reported. In studies using a rat model to determine the impact of 8% protein diets, with normal calories, on the development of the nervous system, characteristic ultrastructural changes in dendritic cytoplasmic constituents of Purkinje cells were observed. Endoplasmic reticulum (ER) formed stacked arrays in about 30% of the offspring which were reared from mothers deprived of normal amounts of protein both pre- and postnatally. These arrays consisted of 2-6 cisternae which were adjoined to each other by dense particles between the cytoplasmic surfaces of these adjacent membranes. The ER of the soma appeared normal, while in dendrites, the arrays lined the plasma membrane of large processes and were found throughout smaller dendrites. Quantitative measurement showed that stacking was accompanied by a 30% increases in the perimeter of the ER profiles per unit area of dendritic section.

In a small percentage of the animals with the ER changes, giant spines were found on the spiny branchlets of Purkinje cells. These dendritic profiles had even greater amounts of ER. The diameter of the giant spines was 2-3 times larger than normal and displayed equally elongated synaptic contacts. About 30% of the spines in these animals were giant spines.

This alteration in the ultrastructure of Purkinje cells may be due to factors extrinsic to the Purkinje cell such as fewer granule cells and a reduction of presynaptic sites. A second possibility is that the deficiency may act intrinsically by interfering with the Purkinje cells' ability to produce a cytoskeleton of tubules and filaments which are necessary to obtain a full sized neuron. In either case, the excess ER may result since the dendritic trees are small. (Supported by the USPHS Grant HD-10934).

166 **A TEST OF AUTO-OXIDATION OF PARTIALLY DISRUPTED BRAIN TISSUE IN VITRO.**
Kyuya Kogure, Hiroshi Morooka*, Raul Busto* and Elena Martinez*. Cerebral Vascular Disease Research Center, Univ. of Miami, Miami, FL 33152.

Mincing of the brain starts the process of autolysis because of: 1) mechanical damage of cell membranes and 2) ischemic disorder of metabolic activity. A hypothesis tested here was that after the electron transport chain is injured by ischemic insult, restoration of oxygen may facilitate lipid peroxide production and catabolic subcellular components. Three groups of minced brains were incubated at 37°C with bubbling of 1) room air, 2) 100% nitrogen and 3) 100% oxygen, respectively; and frozen by liquid nitrogen 5, 15, 30 and 60 minutes after the beginning of incubation. The frozen samples were then assayed for energy metabolites, and the free radical reaction indices, malonyl dialdehyde (MDA), oxidized form of glutathione (GSSG), and the reduced form (GSH). Brain tissue incubated with 100% oxygen had the highest amount of ATP and PCr, but also demonstrated the highest values of MDA and GSSG/GSH ratio. The anoxic incubation resulted in the lowest energy reserve, and the lowest values in free radical indices. The earliest liquefaction of the incubated media was seen in the oxygenated group. These results strongly suggest that: 1) the level of energy metabolites does not necessarily represent the ability of the tissue to maintain structural integrity, and that 2) excess oxygen to the injured brain cell initiates free radical reactions.

167 ROLE OF ERYTHROCYTE CARBONIC ANHYDRASE IN OXYGEN DELIVERY TO BRAIN.
Brian E. Laux* and Marcus E. Raichle. Dept. Radiol., Neurol., Sch. Med., Washington University, St. Louis, MO 63110.

The brain is critically dependent for its moment to moment function and survival on an adequate supply of oxygen. This supply of oxygen is in turn dependent on a precise spatial temporal relationship between the unloading of oxygen from hemoglobin in the capillaries and the acidification of blood by carbon dioxide from the tissue. Since an erythrocyte spends only about 0.6 seconds in the capillary, the reaction time required for the hydration of CO_2 becomes crucial. The enzyme carbonic anhydrase (CA) (EC 4.2.1.1) may play an important role in oxygen delivery to brain tissue by facilitating the hydration of metabolically produced CO_2 in erythrocytes in brain capillaries, thus permitting the Bohr effect to occur while the erythrocyte is still in the capillary. We have tested this hypothesis by examining the effect of IV acetazolamide (30 mg/kg), a potent inhibitor of carbonic anhydrase, upon cerebral oxygen consumption ($CMRO_2$) in lightly anesthetized, passively ventilated rhesus monkeys. Cerebral blood flow (CBF) and $CMRO_2$ were measured with oxygen-15 labeled water and oxygen-15 labeled oxyhemoglobin, respectively, injected into the internal carotid artery and monitored externally. Acetazolamide produced an immediate and significant increase in CBF (64.7 to 83.8 ml/min/100g), an increase in arterial carbon dioxide tension (40.7 to 47.5 torr), and, most importantly, a 32% decrease in $CMRO_2$ (from 4.16 to 2.82 ml/min/100g). Because the change in $CMRO_2$ occurred within minutes of the administration of acetazolamide, this effect probably was due to an interference with oxygen unloading in the brain, and not a direct effect on brain cells containing CA (e.g., glia). The critical nature of the spatial temporal relationships critical to oxygen delivery to the brain is further emphasized by companion studies involving the addition of CA to plasma. CA normally resides only in red cells, thus potentially delaying CO_2 hydration by the time necessary to diffuse through plasma. We tested this hypothesis by the addition of bovine CA to plasma. This caused a significant increase in $CMRO_2$.

These results demonstrate the delicate balance between oxygen delivery and consumption by the brain and point out, for the first time, the important role played by erythrocyte CA in this process.

168 PRENATAL INFLUENCE OF PROTEIN MALNUTRITION IN RATS. Maravene Miller*, Oscar Resnick*, J. Patrick Leahy* and Peter J. Morgane. Worcester Foundation for Experimental Biology, Shrewsbury, Ma. 01545.

Our group has reported marked increases in brain serotonin (5-HT) levels from birth through adulthood in rats whose dams received a low protein diet (8% casein) starting 5 weeks prior to conception as compared to rats whose dams received a normal diet (25% casein). These alterations were correlated with increases in tryptophan (Trp) availability to the brain due to changes in plasma albumin (Alb) and fatty acid (NEFA) levels (Exp. Neur. 57: 142, 1977). To determine which of these changes were the result of prenatal deficiencies and which could be caused by lactational deficiencies, pups born to dams fed 25% or 8% protein diets were cross-fostered at birth to dams of the opposite diet, i.e., pups from 8% dams were fostered on 25% dams; 25% pups were fostered on 8% dams. At 21 days of age these rats were compared to unswitched rats of each diet. These results (table below) show that while some parameters can be induced as a result of lactational deficiencies, most parameters could not be completely rehabilitated by an adequate diet during lactation. As a result, protein inadequacies during gestation appear to cause long lasting metabolic changes in offspring of rats. While the mechanism(s) responsible for these changes are unknown, these results demonstrate for the first time that prenatal protein malnutrition alone can importantly influence brain indole metabolism in the postnatal period.

169 EFFECT OF TIMING ON MANNITOL ADMINISTRATION ON BRAIN DENSITY. Michael E. Miner, Steve H. Graham*, and Gerald Wantz*. Department of Surgery (Neurosurgery), University of Texas Medical School at Houston, 77030.

Osmotic agents such as mannitol are used to treat human cerebral edema of a wide variety of etiologies. However, a paradoxical increase in white matter edema has been noted by some investigators when these agents are used. We investigated the timing of mannitol administration after producing a brain lesion known to result in cerebral edema.

Utilizing a density gradient column of bromobenzine and kerosine white matter density was measured in rats. In 20 control animals the specific gravity was 1.0425 ± .0003. Intravenous mannitol (2 gm/kg) was given to a series of animals. After two hours the specific gravity rose to 1.437 ± .001 but at 6 and 24 hours was within the control range. A liquid nitrogen cold lesion resulted in an ipsilateral decrease in specific gravity most pronounced at six hours (1.0402 ± .0005). The contralateral white matter density decreased slightly less. Intravenous mannitol (2 gm/kg) was then given to a series of rats one hour after making the cold lesion. The white matter density was increased at two hours (1.0432 ± .0003) similar to the series given only mannitol with no lesion, and was only slightly less than control values at 6 and 24 hours. However, a fourth series of animals was given intravenous mannitol (2 gm/kg) 10 minutes after making the same cold lesion and the ipsilateral white matter density was indistinguishable at 6 hours (1.0398 ± .0004) and 24 hours from rats with the cold lesion alone. The contralateral white matter increased in density at 2 and 6 hours, but was of less density at 24 hours than any other group.

This data demonstrates that mannitol given very soon after a cold lesion does not significantly dehydrate the brain and at six and 24 hours the density is no different than animals who only have the cold lesion and no mannitol. However, when mannitol was given one hour after the cold lesion a significant increase in density was observed and at six hours there was a marked reduction of the decrease in brain density compared to creating only the lesion. This data implies that mannitol may at least partially cross the blood brain barrier early after a cold lesion. This may be dependent on lesion size and when the mannitol is presented. This "rebound" effect did not occur when the drug was given an hour post-lesion. This data has implications in treating human cerebral edema and may help to explain the absence of the rebound phenomenon seen in the patients treated with mannitol.

170 TRANSPORT OF THYROID HORMONES ACROSS THE BLOOD-BRAIN BARRIER. William M. Pardridge. UCLA School of Medicine, Los Angeles, CA 90024.

The transport of ^{125}I-triiodothyronine (T_3) across the brain capillary wall, i.e., the blood-brain barrier (BBB), was investigated with a tissue sampling-single injection technique. Approximately 0.15 ml of buffered Ringers solution containing 1.25 µCi/ml of ^{125}I-T_3 and 25 µCi/ml of ^{3}H-water, a highly diffusable internal reference, was rapidly injected via the common carotid artery in barbiturate-anesthetized rats with decapitation 15 sec later. High affinity binding of labeled T_3 to glass vials and plastic syringes was prevented by the addition of 0.1% albumin to all injection solutions. The clearance of T_3 by brain was estimated by calculating the brain uptake index (BUI), i.e. the ratio of ^{125}I/^{3}H DPM in brain divided by the same ratio in the injection solution (x100). The ratio of ^{125}I/^{3}H was determined by double isotope liquid scintillation counting. The BUI for a tracer concentration (2 nM) of T_3 was 32.1 ±1.5% for whole brain analyses. Since albumin is known to avidly bind thyroid hormones, the effect of varying doses of this compound on the BUI of T_3 was studied; increasing the albumin concentration from 0.001%, an albumin level that should bind only 5% of T_3 (based on the affinity constant of albumin for T_3), to 0.1%, a dose that should bind 80% of T_3, resulted in no change in the BUI for T_3, suggesting both free and bound hormones are transported into brain. The addition of increasing concentrations of unlabeled T_3 or thyroxine (T_4) decreased the BUI of labeled T_3; double reciprocal plots of the saturation data were linear (r=0.92) and provided estimates of the kinetic constants of thyroid hormone transport: K_m=2.7 µM and V_{max}= 0.2 nmol/min/g for T_3 and K_i=2.5 µM for T_4. Transport showed little stereospecificity as D-T_3 competed actively for transport with labeled L-T_3. Tyrosine, leucine, and potassium iodide at levels of 1000 µM had negligible effects on T_3 transport. Conclusions: (1) The major route of entry of thyroid hormones into the CNS is transport through the BBB via a carrier system specific for thyroid hormones. (2) The affinity of the BBB transport system for T_3 exceeds the affinity of albumin for T_3 (K_d= 4 µM); therefore, albumin-bound T_3, which comprises 20% of the circulating pool of this hormone, may be stripped off the plasma protein by the BBB thyroid hormone transport system.

171 METABOLIC MAPPING OF FUNCTIONAL NEURAL PATHWAYS IN MAN WITH ^{18}F-FLUORODEOXYGLUCOSE. M. Reivich, A. Alavi*, J. Greenberg*, J. Fowler*, D. Christman*, A. Wolf*, A. Rosenquist*, P. Hand and R. Tusa*. Cerebrovascular Res. Center of Dept. of Neurology and Depts. of Anatomy and Animal Biology, Schls. of Med. and Vet. Med., Univ. of Penna., Phila., PA 19104

The ^{18}F-fluorodeoxyglucose method for measuring local cerebral glucose consumption (Reivich, et al Acta Neurol. Scand. 56: suppl 64, 190, 1977) has been used to map functional neural pathways in man. Alterations in functional activity change the metabolic rate of the involved regions of the brain which can be detected with a positron emission tomographic scanning system. The effect of visual and somatosensory stimuli have been investigated. Four visual system studies have been carried out in 3 normal male volunteers. One subject was tested twice, first with both eyes open and second with both eyes blindfolded. The occipital cortex was symmetrically labeled bilaterally in both tests, but in the blindfolded condition there was a 23% decrease in glucose utilization in both left and right occipital cortices from a value of 11.2 to 8.6 mg/100 gm/min. Two other subjects were required to look into a clear plastic hemisphere and fixate upon a small light located at its center. This light randomly dimmed so slightly as to be detectable only by foveal vision. Reports of dimming events indicated a greater than 95% accuracy in both subject's fixation. The right visual field was blackened and received little or no patterned visual stimulation during the test. The left visual field was stimulated with high contrast black and white line and dot stimuli during the test. In both subjects a clear asymmetry was seen in the occipital pole with the right pole showing greater glucose utilization than the left, presumably due to visual stimulation of the left visual field. In the somatosensory study, rapid brush stroking of the fingers and hand of the right arm of two right-handed subjects produced a dramatic increase in the metabolic rate for glucose in the left postcentral gyrus at tomographic levels OM+8 cm and OM+9 cm. This cortical region corresponds to the finger and hand area as described by Penfield and Rasmussen (1950). This asymmetry was not seen in control subjects without somatosensory stimulation. These studies demonstrate that ^{18}F-fluorodeoxyglucose can be used to map the regions of the brain with altered metabolic activity in response to alterations in local functional activity in man. (Supported by USPHS Grant NS 10939-06)

172 MITOCHONDRIAL VULNERABILITY TO ISCHEMIC INJURY: STIMULUS-EVOKED RESPONSES OF METABOLISM DURING AND FOLLOWING ISCHEMIA IN CAT CEREBRAL CORTEX IN SITU.

Myron Rosenthal and David L. Martel, Depts. Neurol. & Physiol/Biophys., Univ.Miami Med.Sch., Miami,Fla 33156

Examination was made of reduction/oxidation ratio changes of nicotinamide adenine dinucleotide (NADH/NAD^+), the initial co-enzyme of the mitochondrial respiratory chain, during and following incomplete and complete ischemic episodes in cat cerebral cortex. These measurements were made noninvasively by monitoring the fluorescence at 460 nm when the tissue was presented with excitation light at 366 nm (NADH fluoresces, NAD^+ does not). Ischemia was produced by various combinations of ligation and/or clamping left subclavian, left and right common carotids and left innominate arteries after previous ligation of other possible ascending pathways in cerveau isolé cat preparations. Incomplete ischemia was accompanied by increased levels of reduced NAD which returned toward baseline during arterial clamping. Complete ischemia was accompanied by complete reduction of NAD. The rates of return of NADH to baseline after successive 1 min periods of complete ischemia were faster in each successive case. Blood volume, however, returned at a constant rate and hemoglobin oxygenation, measured by reflection spectrophotometry, returned more slowly in successive insults, indicating an uncoupled mitochondrial system. When stimulus pulses were presented to the cortical surface at intensities sufficient to evoke small shifts of the steady potential, incomplete ischemia resulted in a decrease in the amplitude of the transient NADH oxidation. Complete ischemia produced an amplitude decrease but also initially increased and then decreased the rate of NAD^+ re-reduction. Stimulation sufficient to provoke spreading cortical depression (SD) resulted in accentuation of these ischemia-related metabolic changes. There appears to be a critical level of perfusion at which no change in SD kinetics occurs when perfusion is adequate for normal NADH/NAD^+ regulation. Decreased perfusion results in marked changes in excitability and a slowing of the NAD re-reduction rate. These findings confirm that short ischemic periods can produce alterations in oxidative metabolic capabilities indicative of uncoupling, resulting in decreased excitability and decreased capacity to respond to increased metabolic demand. (Supported by PHS grants NS 14319 & NS 14325).

CEREBELLUM

173 TOPOGRAPHY OF AFFERENT BRAIN STEM PROJECTIONS TO POSTERIOR VERMAL CEREBELLUM OF THE RAT. S. Ausim Azizi*, Richard A. Burne and Donald J. Woodward (SPON: J. Kirkpatrick). Dept. of Physiology, Univ. TX Health Sci. Ctr., Dallas, Texas 75235.

This study was undertaken to determine the origin of the afferent projections to the auditory and visual zones of the posterior vermis of the rat cerebellum. We describe here the topographical organization of the projections from the pontine gray (PG), inferior olive (IO), and the brain stem reticular nuclei to the vermal regions of lobules V-IX and their relation to the descending cortical and tectal projections to the brain stem. The midline cerebellar zones of thirty five rats (200-300 g.) were hydraulically injected with 0.06-0.12 µl of horseradish peroxidase in H_2O solution to localize the origins of afferent projections.

With injections localized to the midline, all resulting HRP labeled cells were observed bilaterally within the PG, IO and reticular nuclei. The basic trend of projections noted was: Lobules V and VIa-b receive a sparse and non-focal projection from the PG, but a substantial input from the medial accessory olive (MAO), lateral reticular nuclei (LRN) and caudal principal olive (PO). Lobules VIc and VIIa receive projections from rostral PG, whereas lobules VIIb, VIII and IX receive primarily from paramedial and lateral zones in the caudal PG. With respect to olivocerebellar projections, the posterior vermis (lobules VIc-IX) receive primarily from the medial aspect of MAO, whereas lobules V, VIa and b receive from the lateral MAO. All the midvermal lobules studied receive a projection from the caudal PO, with the exception of lobule VIIb, which receives solely from the MAO. In addition the studied lobules receive from paramedian reticular nuclei and/or LRN.

We conclude that pontine projections to the lobules VIc and VIIa originate from areas receiving descending input from the visual (VC) and auditory cortices (AC). Pontine areas projecting to lobules VIII and IX receive input from the somatosensory cortex (SC), as revealed by other studies in this laboratory. With respect to lobules V and VIa-b, the sparse pontine innervation noted does not appear to correspond with the known descending projections from the VC, AC, SC or tectal regions. In addition, the MAO regions which receive visual projections from the tectum, project to lobules VI-IX supporting a visual climbing fiber input to the midvermal region. Such results support the electrophysiological evidence for visual and auditory input to posterior vermis (Lobules VIc-IX) in the rat and cat cerebellum. A general result is that each sublobule in posterior vermis receives a highly discrete set of afferents. These can be expected to mediate diverse functions in visual and auditory aspects of sensori-motor integration. (Supported by NSF BNS 77-01140 to D.J. Woodward)

174 UPTAKE AND TRANSPORT OF ^{3}H-GABA INJECTED EXTRACELLULARLY IN THE CAT DENTATE NUCLEUS. H. Bantli and D.L. Tolbert. Dept. Neurosurg., Minn. Med. Sch., Minneapolis, Minn. 55455

Recently small neurons in the dentate nuclei of the rat have been shown to accumulate extracellularly injected tritiated gamma amino butyric acid ^{3}H-GABA, (Chan-Palay, Cerebellar Dentate Nucleus, Springer-Verlag, N.Y., 1977). On the basis of these observations, it was proposed that some of the small neurons in the dentate nucleus are inhibitory local circuit neurons. However, results obtained following multiple injections of horseradish peroxidase in the cat brainstem (McCrea, et al, 1978, J. Comp. Neurol.) indicated that probably all neurons in the cerebellar nuclei project to extracerebellar structures. Based on these findings, it may be inferred that neurons which accumulate ^{3}H-GABA also project to extracerebellar nuclei. To test this hypothesis, ^{3}H-GABA was injected into the dentate nuclei in four cats. As a control, ^{3}H-GABA was also injected in the cerebellar cortex, since it is well known that all cortical neurons except granule cells accumulate ^{3}H-GABA to varying degrees. The results obtained from these four animals suggested that if neurons in the cerebellar cortext were labelled with ^{3}H-GABA, thereby indicating a successful experiment, then labelled fibers could also be observed to course from the dentate nucleus towards the lateral folia of Crus I and dorsomedial folia of Crus II and from the ventrolateral aspect of the nucleus to the white matter of the dorsal parafloccu-lus. Because of the short survival period, these fibers could only be followed for approximately 4 mm from the injection site. In the same animals, other labelled fibers were observed leaving the dentate nucleus from its ventromedial aspect and projecting into the brachium conjunctivum. When these labelled fibers were present, dense accumulations of silver grains could also be observed overlying nissl-stained cells in the dentate nucleus, indicating that these cells had taken up the ^{3}H-GABA. These findings suggest that neurons in the cerebellar dentate nucleus, which accumulate ^{3}H-GABA, also appear to orthogradely transport labelled GABA to extracerebellar sites. The labelled fibers directed to the cerebellar cortex could have resulted from the uptake of ^{3}H-GABA by Purkinje cell axon terminals and the subsequent retrograde transport of this compound. Alternatively, the uptake of ^{3}H-GABA by dentate neurons which resulted in the labelling of axons in the brachium conjunctivum may have also orthogradely labelled fibers in the nucleocortical pathway since at least some of these fibers are collaterals of cerebellar efferent projections. The significance of these observations as to the possible use of GABA by extracerebellar projecting neurons can only be speculative on the basis of our data. NIH contract # N54-2332 and Fellowship # NS-05577.

175 CEREBRO-CEREBELLAR MICROCIRCUITS: MICROMAPPING THE FINE-GRAINED PROJECTIONS BETWEEN TACTILE AREAS IN CEREBRAL (SI) AND CEREBELLAR (GRANULE CELL) TACTILE AREAS OF RATS. Donald H. Beermann, John M. Gibson, James M. Bower, Georgia M. Shambes and Wally I. Welker, Dept. of Neurophysiology, University of Wisconsin, Madison, WI 53706

We found highly specific patterns of connections between the somatotopically organized tactile areas in the hemispheres of cerebral and cerebellar cortex. These cerebro-cerebellar projections originate in SI and terminate in granule cell (GC) layer of cerebellar cortex.

Two independent, monopolar, ball-tip, tungsten microelectrodes were used to record multiple unit responses from homologous tactile areas in SI and GC cortex. The receptive fields (RF's) in both areas were defined by threshold mechanical stimulation of cutaneous tissues. In-depth microstimulation (single, biphasic pulses; 5-10µA, 5/sec.) through the SI electrode evoked responses in the GC cortex. Two sampling strategies were employed for micromapping the cerebro-cerebellar projections. (1) The SI electrode remained stationary after the approximate best activating depth was located; then the cerebellar electrode was used to map the areal extent of the GC cortex which was activated from the stimulating SI locus. In each successive cerebellar puncture the peripheral RF was also determined. These strategies yielded recording maps. (2) In other experiments the SI stimulating electrode was used as the mapping electrode while the cerebellar recording electrode remained stationary. These strategies yielded stimulating maps. In this case RF's were defined for each puncture in SI cortex before it was stimulated electrically. Sampling densities of up to 75 punctures/mm^2 were required to fully delineate the fine-grained spatial pattern of these projections. The borders and areal extents of the interconnected focal areas were defined by these two mapping strategies.

Major results are: (1) the SI sources and the GC destinations of the cerebro-cerebellar circuit are small, less than 1mm^2; (2) the interconnected SI and GC foci were located within portions of the two tactile areas which have the same peripheral RF's (e.g., SI upper lip focus projected to GC upper lip patch); (3) each SI source projects only within the confines of a homotypical GC columnar patch in the mosaic of the cerebellar tactile area defined by Shambes et al. (Neuroscience Abstr., 2: 117, 1976); (4) the foci of optimal responsiveness in GC columns to SI and peripheral stimulation were congruent; (5) however, the SI source is located just below layer IV (cells in layer IV respond best to peripheral RF stimulation); (6) minimal latencies of SI-GC evoked activity were 3-4 msec. (Supported by NSF grants BNS #'s 75-08124 and 77-16230 and by USPHS grants NS06225 and NS07026).

176 THE ORGANIZATION OF DESCENDING PROJECTIONS FROM THE BRAIN STEM ACTIVATED BY THE OUTPUT OF THE DENTATE NUCLEUS. J.R. Bloedel, E. G. Hames*, H. Bantli, and J.F. Rowlands*. Depts. Neurosurg. & Physiol., Minn. Sch. Med., Minneapolis, Minn., 55455.

Experiments were performed in unanesthetized decerebrate cats and cats anesthetized with alpha choloralse to determine: 1) the organization of descending systems from the brain stem activated by the output of the dentate nucleus and 2) the effects of these systems on segmental interactions occurring in the spinal cord. In addition to our previous demonstration of the dentato-reticulospinal system, evidence was also obtained for the existance of a dentatorubrospinal system projection. The latter was demonstrated in a series of electrophysiological studies in which the effects of various lesions on the responses evoked in the cervical spinal cord following dentate stimulation were assessed. It was shown that the response presumably evoked via the dentatorubrospinal projection could be eliminated by lesions in the lateral brachium conjunctivum as well as in the contralateral red nucleus. In addition, this response was present in decerebrate animals. The possibility that this response was evoked via spread of the stimulus current to the interposed nucleus was ruled out by showing that the response was unaffected by electrolytic lesions in this structure adjacent to the position of the stimulating electrode in the dentate nucleus. The segmental effect of these dentatoreticulospinal and dentatorubrospinal projections was found to produce marked changes on interneurons as well as on reflexes activated by cutaneous afferent fibers. In addition to demonstrating that dentate stimuli produced marked changes in the excitability of certain spinal interneurons impinged upon by low threshold cutaneous afferents, the results indicated that the reflexes evoked in motoneurons by the same afferents were also affected. These data indicate that the output of the dentate nucleus activates at least two descending projections from the brain stem to the lumbar region of the spinal cord and that the activation of these projections affects the excitability of neurons and reflexes activated by low threshold cutaneous afferent fibers. This was supported by Grant# NS 09447.

177 VISUAL INPUT TO THE PARAFLOCCULUS: AN ELECTROPHYSIOLOGICAL STUDY. Richard A. Burne and Donald J. Woodward. Dept. Cell Bio., Univ. Tx. Health Sci. Ctr., Dallas, Tx 75235

Previously we presented anatomical evidence suggesting that the paraflocculus is a cerebellar target zone for visual cortical and tectal input. The present study was undertaken with the general aim of determining the electrophysiological properties of the visual sensitive Purkinje cells within the paraflocculus of the rat cerebellum as determined by 1) electrical stimulation of regions within the visual cortex and superior colliculus, or 2) presentation of controlled optical images in the visual field of the rat.

Single unit recordings of Purkinje cell activity in halothane anesthetized rats and post-stimulus-time-histogram (PSTH) analysis were employed to determine the response characteristics following cortical and tectal stimulation with monopolar and bipolar concentric electrodes, respectively (0.1 ms, 0.1-0.6 ma, 1-10 Hz). Of 58 identified Purkinje cells in the paraflocculus, PSTHs of 49 cells (84%) showed evidence of a mixed excitatory-inhibitory mossy fiber input (42 cells, 86%), or a pure inhibitory (5, 10%) or excitatory (2, 4%) input following cortical stimulation. Following tectal stimulation, 33 cells (80%) responded to either a mixed excitatory-inhibitory mossy fiber input (24 cells, 59%), or a pure inhibitory (7, 17%) or excitatory (2, 4%) input. The mean latencies to onset of excitation were 10.3 ± 0.5 msec and 7.7 ± 0.53 msec, and to onset of inhibition, 13.7 ± 2 msec and 11.8 ± 1 msec for cortex and tectum, respectively. Sixty-eight percent of the Purkinje cells tested responded to both cortical and tectal stimulation. In addition, complex spike responses (via climbing fibers) were elicited at a latency of 22 ± 1.7 msec and 17 ± 2 msec following cortical and tectal stimulation, respectively.

Single unit recordings of an additional 7 paraflocular Purkinje cells in unanesthetized, immobilized rats showed evidence, through PSTH analysis, for mixed excitatory-inhibitory mossy and climbing fiber input following visual field stimulation. Single and complex spike responses were primarily elicited from light spots or bars projected against a dark background and moving in the nasal or temporal direction at velocities of 0.93-18 m/sec. In addition, on-off complex spike responses were elicited by 400 msec pulsed (at 1 Hz) stationary spots of light (10° dia.) when projected upon different quadrants of the visual field.

These results confirm our previous anatomical work suggesting a strong visual input to the paraflocculus, and also indicate that a significant input from visual cortex and superior colliculus converges upon paraflocular Purkinje cells. Our hypothesis is that the paraflocculus may serve as a strong link in visual sensori-motor integration. (Support by NSF BNS77-01174 to DJW).

178 ISOLATION OF OLIGODENDROCYTES FROM MOUSE CEREBELLUM USING MAGNETIC MICROSPHERES. Graham LeM. Campbell*, Oded Abramsky,* and Donald H. Silberberg, Franklin Inst. Res. Labs.and Dept. of Physiology, Temple University Med. School, Phila., Pa. and Dept. of Neurology University of Pennsylvania School of Medicine, Phila., Pa. 19104

Isolation and separation of highly enriched populations of oligodendrocytes from brain regions not enriched in white matter using density gradient techniques is inherently difficult. Techniques for cell separation based on differential binding of ligands to cell surface moieties provides an alternative methodology. The development of magnetic microspheres to which ligands may be conjugated provides a facile and effective technique for the separation of oligodendrocytes from the cerebellum of 10 day old mice.

Cerebellar cells were isolated and glial cell enriched population prepared as described previously (Campbell et al, Brain Res. 127: 68-86, 1977). Glial cell enriched population was incubated with rabbit anti-bovine oligodendrocyte anti-serum, washed and then incubated with magnetic microspheres conjugated with goat anti-rabbit IgG. The resultant mixture was washed and introduced into a magnetic field. Cells to which the microspheres adhered were retained, whereas the remaining cells passed through the magnetic field. After the magnetic field is removed, the cells with adherent microspheres were released and collected. This retained population yielded 1-2% of the total isolated cerebellar cell bodies and represents approximately $0.5x1.0x10^5$ cells/cerebellum.

Observations using SEM and TEM indicate that over 90% of the cells examined were morphologically similar to cells isolated by bulk preparative techniques. The size range is 5-8 u with a high nuclear to cytoplasmic ratio. Occasional cells (less than 5%) were seen to have myelin fragments. In addition, these cells extend processes in vitro on polylysine coated coverslips within 1 hr. incubation at 37°C. Further characterization of these cells by measuring the enzyme 2'3' cyclic nucleotide phosphohydrolase and the uptake of S^{35} into sulfatide will also be presented.

179 INCREASED SPINOVESTIBULAR PROJECTIONS AFTER NEONATAL HEMICEREBELLECTOMY IN RATS. Anthony J. Castro and Diane E. Smith, Depts. Anatomy, Loyola Univ. of Chgo., Stritch Sch. Med., Maywood, Ill., 60153 and Louisiana State Univ., Sch. Med., New Orleans, La., 70112.

In light of recent reports of aberrant cerebellar efferent projections that develop after neonatal hemicerebellectomy, this study was undertaken to examine possible changes in afferent spinal-cerebellar pathways after similar neonatal lesions. Under hypothermic anesthesia, hemicerebellectomy lesions were made by aspiration with small pipettes in 2-3 day old rat pups. Two to 12 months later these same animals under sodium pentobarbital anesthesia sustained spinal cord lesions at mid-thoracic levels on the side ipsilateral to the neonatal hemicerebellectomy. Control animals received only spinal cord lesions. Animals were sacrificed 4-10 days after spinal cord lesions, and their brains were processed using the Fink-Heimer method. Lesion sites and brainstem cytoarchitecture were examined with Nissl stains.

In control animals, spinocerebellar fibers were observed to enter the cerebellum ipsilaterally and cross within the cerebellum to project bilaterally to the fastigial nuclei as well as specific cortical areas of the anterior and posterior lobes. Control spinobulbar fibers projected to several brainstem areas. Of particular interest to this study are the ipsilateral projections to the vestibular nuclear complex.

After hemicerebellectomy, few spinal afferents were observed within the spared side of the cerebellum indicating a lack of neuroanatomical rerouting of spinocerebellar projections to the contralateral side. However, analysis of ipsilateral projections revealed an increase of spinovestibular projections to the lateral vestibular nucleus in comparison to the relatively small input found in control animals. The increase of ipsilateral projections to the lateral vestibular nucleus would appear to be a plausible alternative locus for remodelling considering the functional interrelationship between the vestibular and fastigial nuclei.

180 TWO MODES OF INTEGRATION OCCURRING IN THE CEREBELLAR CORTEX. T.J. Ebner* and J.R. Bloedel. Depts. of Neurosurg. & Physiol., Univ. of Minn. Sch. of Med., Minneapolis, Minn. 55455.

Experiments were performed in decerebrate, unanesthetized cats to determine the effects of natural stimuli on the temporal correlations between the stimultaneously-recorded discharge of two to three Purkinje cells. Alterations in temporal correlation were compared to the excitability changes evoked in Purkinje cells by a natural stimulus. The pairs and triplets of Purkinje cells were located on surface folia either parallel or perpendicular to the orientation of parallel fibers. Purkinje cells were identified by the presence of spontaneous climbing fiber responses The natural stimuli consisted of stretch of the ipsilateral gastrocnemius-soleus muscle, with or without a plate in contact with the planter aspect of the hindfoot. The cross correlation between the discharge of pairs of Purkinje cells was computed during spontaneous firing and during the application of the natural stimulus. The excitability changes evoked by the stimulus were determined by constructing PST histograms. The results suggested that there are two types of integrative processes occurring in the cerebellar cortex which may be relatively independent. Stimuli, in addition to evoking the well documented modulation in Purkinje cell excitability, also resulted in changes in the cross correlation between pairs of cells. On some occasions an increase in excitability was associated with an increase in the temporal correlation. In other cases, although each cell in the pair responded to the stimulus, there was no alteration in the temporal correlation. Also, in many pairs the duration of the responses in the PSTH were different than the time course of the changes observed in the cross correlation. Furthermore, in certain pairs of cells the addition of the cutaneous stimulus during muscle stretch produced marked alteration in the structure of the cross correlation, but only minor alterations in the PSTH. These findings imply that peripheral inputs may result not only in excitability changes, but also in changes in the temporal correlation between Purkinje cell discharge, and that these two processes may be independent. This research was supported by Grant # NS 09447. Timothy Ebner is a Life Insurance Medical Scientist Scholar.

181 THE PONTO-CEREBELLAR PROJECTION IN THE RAT: DIFFERENTIAL PROJECTION TO SUBDIVISIONS OF THE UVULA. Leonard M. Eisenman. Dept. Anat., Thomas Jefferson Univ., Philadelphia, PA 19107.

Microinjections of 5 to 10% solutions of horseradish peroxidase (HRP) were made in different subdivisions of the uvula cerebellar vermal cortex (lobule IX of Larsell, '52). These injections resulted in retrograde labeling of cells located in the pontine nuclei, in addition to cells in other brainstem nuclei e.g. the vestibular nuclei and inferior olive. Those experiments in which the injected HRP labeled only sublobules IX, a, b or c of the uvula, revealed that two columns of cells in the candal half of the pontine nuclei project to this part of the cerebellar cortex. The most ventral lobule of the uvula (IX c) receives a projection from both pontine columns, one medial and one ventrolateral. The intermediate uvular lobule, IX b receives a projection from similarly placed columns but there is evidence that the columns are more extensive in dorsoventral extent. Finally the most dorsal of the uvular sublobules, IX a, appears to receive a different input from only one pontine columns of cells. This column is in the lateral portion of the pontine nuclei but more dorsal to the column projecting to sublobules IX b and c.

These differential projections from the pontine to subdivisions of the uvula, especially sublobule IX a as compared to sublobules b and c suggest that there may be functional differences between these parts of the uvular portion of the vermis. Although injections were placed in medial and lateral parts of the lobules no clear distinction in labeled pontine cells is evident which may suggest a sagittal organization in this projection system.

182 LENGTH OF PARALLEL FIBERS IN CAT CEREBELLAR CORTEX: STEREOLOGICAL DETERMINATION. V.L.Friedrich,Jr. Department of Biobehavioral Sci., Univ. Connecticut, Storrs, CT. 06268.

Parallel fiber degeneration extends for lengths of 5 to 7 mm from knife cut lesions of cerebellar cortex (Brand et al., Exp. Brain Res. 26:39). This finding is in conflict with previous estimates of parallel fiber length based on other methods. I here report a preliminary estimate of the length of parallel fibers, based on a stereological analysis of the molecular layer. The result is consistent with the degeneration data.

In sections transverse to folia (and thus to the parallel fibers), the expected areal density of parallel fiber profiles in the molecular layer (N_A) is related to the average length of parallel fibers (L) and the number of parallel fibers per unit volume of molecular layer (N_V^{pf}) by $N_A=LN_V^{pf}$. Since each parallel fiber is associated with one granule cell, $N_V^{pf}=N_V^{gc}V^{gl}/V^{ml}$, N_V^{gc} the density of granule cells in the granular layer and V^{gl} and V^{ml} the volumes of granular and molecular layers, respectively. Thus, $L=(N_A/N_V^{gc})\ (V^{ml}/V^{gl})$.

Parasagittal slices of vermis used previously to determine N_V^{gc} and V^{ml}/V^{gl} (Anat. Rec. 190:398) were trimmed to well fixed regions and sectioned for electron microscopy. The fields photographed were selected by a calculator programmed to generate random stage coordinates positioned within the molecular layer; this procedure eliminated operator bias in the selection of fields.

The fractional area of parallel fibers in the micrographs (A_A) was determined by point hit counting, the average area per profile (a) by planimetry and the areal density by $N_A=A_A/a$; the results were $A_A=0.44$, $a=0.07\ um^2$, $N_A=6.3\ um^{-2}$ and L=5.4 mm.

My preliminary estimate of 5.4 mm , which represents the average length of parallel fibers, is in good agreement with the maximal length of 5 to 7 mm as estimated by the degeneration method. This agreement is compelling evidence for the validity of both values. Evidently, previous estimates in the range of 2 mm are in error. The lateral spread of parallel fibers and their maximal conduction time are thus greater than thought previously.

183 PURKINJE CELL ACTIVITIES DURING THALAMOCORTICAL EPILEPTOGENESIS (PENICILLIN FOCUS;CAT). T.L.Frigyesi, W.B.Jarzembski* and J.B. Lombardini*. Depts. Physiology, Biomedical Engineering, and Pharmacology, Texas Tech U. Sch. Med., Lubbock, Texas 79409.

Motor cortical penicillin epilepsy is, for the most part, the function of thalamic multisynaptic machinery that is also governed by cerebellar activities. Hence, the behavior of Purkinje cells is germaine to thalamocortical epileptogenesis. An acute penicillin focus was established in the motor cortex of 20 encèphalé isolé cats; simultaneous recordings were obtained from the motor cortical surface, and unit and focal potentials from the thalamic ventrolateral nucleus (VL) ipsilaterally, and from cerebellar Purkinje cells, contralaterally. In all animals, interictal spike relations at these three recording sites were 1:1:1 (save for the initial 10-15 minutes when Purkinje cells failed to fire). In 12/20 cats, the VL potentials preceeded and the Purkinje potentials followed the cortical interictal spikes. This sequential order of interictal spikes could be modified by 1) i.v. taurine: an additional focal negativity developed in the Purkinje layer, the onset of which was either coincident with or preceeding the onset of the VL interictal spikes; i.v. DPH abolished the early Purkinje firing and restored the sequential firing order of the control; i.v. barbiturate abolished the focal potentials in the Purkinje layer but failed to alter the control time relation of VL-motor cortical firing; 2) following severance of the climbing fibers, Purkinje focal negativities occurred later; 3) following severance of the ipsilateral brachium conjunctivum, the Purkinje focal negativities occurred prior to the cortical interictal spikes. Purkinje unit discharges were as frequently observed before or concomitant to as following the thalamocortical interictal complexes. High doses of DPH i.v. induced prolonged Purkinje unit discharges with coincident abolition of all thalamocortical epileptic activities. However, topical DPH onto the neocerebellum induced sustained Purkinje discharges with exacerbation of thalamocortical interictal and ictal activities. Topical DPH onto the motor cortex attenuated the cortical and abolished the Purkinje interictal spikes. During fully developed icti, Purkinje cell activities were enhanced; however, in 6 animals, Purkinje activities were suppressed during the tonic phases. Purkinje burst activities were only occasionally encountered at the termination of thalamocortical bursts. Topical DPH onto the neocerebellum increased Purkinje cell activities with resultant increases in thalamocortical seizures. These and other data indicate that Purkinje cells are momentously involved in thalamocortical penicillin epileptogenesis. However, the cerebellar suppression of thalamocortical paroxysms involves mechanisms other than the Purkinje cell induced disfacilitation of thalamocortical projection activities.

184 EVIDENCE FOR A NEW SPINOCEREBELLAR PROJECTION FROM THE NUCLEUS DORSALIS (CLARKE'S COLUMN) IN THE CAT. E.G. Hames*, D.L. Tolbert, J.R. Bloedel. Depts. of Neurosurg. & Physiology, Univ. of Minn. Med. Sch., Minneapolis, Minn. 55455.

The origin of spinocerebellar pathways from the nucleus dorsalis in spinal segments T-1 through L-4 was examined following injections of horseradish peroxidase (HRP) into the anterior lobe. A series of experiments were performed to determine if a spinocerebellar projection in addition to the dorsal spinocerebellar tract (DSCT) originates from this nucleus. Unilateral injections of HRP into the anterior lobe in a cat with bilateral lesions of the superior cerebellar peduncles confirmed the projection of DSCT as ipsilateral to the cerebellum and as principally originating from the nucleus dorsalis, at least at these spinal segments. These experiments also defined the region of the nucleus dorsalis at these spinal segments as an area whose cell bodies are primarily located immediately dorsal and lateral to the central canal. In another set of experiments in which unilateral anterior lobe injections were made in animals with a lesion of the ipsilateral inferior cerebellar peduncle, the labelled neurons were distributed bilaterally in the nucleus dorsalis. The number of neurons on each side of the cord appeared qualitatively similar. This finding suggests that a projection other than the DSCT originates in the nucleus dorsalis. To examine the spinal course of this spinocerebellar projection from the nucleus dorsalis through the superior cerebellar peduncle, a unilateral anterior lobe injection in an animal with an ipsilateral lesion including the dorsal column and the entire lateral funiculus was performed at T-9. This lesion should eliminate the labelling of DSCT neurons ipsilaterally. Again, a qualitatively similar distribution of labelled cells was found bilaterally in the nucleus dorsalis. After a bilateral injection of the anterior cerebellar lobe following a lesion of the dorsolateral fasciculus at T-9, labelled neurons in the contralteral nucleus dorsalis resulted from uptake both by ipsilateral DSCT terminals as well as by the terminals of bilateral projections into the cerebellum via the superior peduncles. The nucleus dorsalis located ipsilaterally below the lesion contained only HRP positive neurons retrogradely labelled through the bilateral projection coursing through the superior cerebellar peduncles. This evidence suggests that spinocerebellar projections other than the DSCT originate in the nucleus dorsalis and project bilaterally to the cerebellar anterior lobe through the superior cerebellar penduncles. This research was supported by NIH Grant # NS 09447. Dr. Tolbert was supported by NIH Fellowship # NS 05577.

185 THE TOPOGRAPHICAL ORGANIZATION OF THE CEREBELLO-OLIVARY PROJECTION IN THE RAT. Alan J. Haroian, Leo C. Massopust, Paul A. Young, and Michael G. Murphy. Depts. of Anat. and Surg., St. Louis Univ. Sch. Med., St. Louis, MO 63104.

Topographical projections of the deep cerebellar nuclei to the inferior olivary nucleus have been well documented in the monkey, cat, and opossum. Faull and Carman (1978) observed cerebello-olivary fibers in the descending limb of the brachium conjunctivum after ablating the superior cerebellar peduncle in the rat. Chan-Palay (1977) has shown autoradiographically that the rat dentate nucleus projected primarily to the contralateral principal nucleus. At the level of the olive, some fibers recrossed the midline to terminate ipsilaterally. The purpose of the present investigation was to determine the cerebello-olivary projection from each of the deep nuclei in the rat.

Following injections of 3H-leucine in the deep cerebellar nuclei, the rostral two-thirds of the contralateral inferior olivary complex was heavily labelled and the ipsilateral olive lightly labelled. The nucleus interpositus anterior (NIA) projected primarily to the rostral three-quarters of the dorsal accessory olive (DAO), the nucleus interpositus posterior (NIP) to the rostral two-thirds of the medial accessory olive (MAO), and the dentate nucleus (DN) to both the dorsal and ventral lamellae of the principal olive (PO). No fastigial projections to the inferior olive were observed. Preliminary results from micro-injections of 3H-leucine into parts of the individual nuclei revealed that a much more complex topographical organization exists. The central part of the middle third of the NIA projected to a similar zone in the DAO, the medial part of the caudal NIP to the lateral part of the middle third of the MAO, and the dorsal part of the middle third of the DN to the lateral half of the dorsal lamella of the PO. The basic mammalian pattern reported for the monkey, cat, and opossum was also observed in the rat; however, the topographical organization from parts of the individual cerebellar nuclei to their respective counterparts in the olive differs from species to species.

186 FETAL ALCOHOL INTOXICATION AND CEREBELLAR DEVELOPMENT. S.E. Kornguth, E. Sunderland*, U. Juhl*, F. Siegel, and I. Carlson*. Wis. Univ. Med. Ctr., Madison, WI 53706.

Albino rats were placed on a liquid diet (Ensure) containing either 9% or 5% ethanol during the second to twentieth day of pregnancy. Each animal was matched with a pair fed control. The control diet contained an amount of sucrose equivalent calorically to the ethanol ingested by the experimental animal of the pair. The offspring of these animals were sacrificed on days 7, 11, 14, and 21 after birth and the following parameters analyzed: body weight; brain weight; cerebellar weight; cerebral and cerebellar activities of ornithine decarboxylase (ODC), aspartyl amino transferase (AAT), and malic dehydrogenase (MDH); sera levels of thyroxine (T_4); histological development of the cerebellum revealed by the Golgi silver and Nissl stains.

The 5% rats drank the maximal amount of food presented (100 ml per day of a 70% Ensure diet). In some cases the amount of alcohol ingested by rats on the 5% diet was equivalent to that ingested by animals on the 9% diet since the latter group had decreased total food intake (40-50 ml per day). The pups of mothers that ingested more alcohol during pregnancy (greater than 6 ml absolute ethanol per day) were significantly smaller by day 14 after birth than pair fed controls or pups of mothers that drank less than 4 ml alcohol per day. The cerebellar ornithine decarboxylase activities of pups from mothers on the 5% ethanol diet were elevated even at day 14 (1.3 picomoles CO_2/min/mg protein) compared with pair fed controls (0.3 pM/min/mg protein). Pups from the 9% experiment and control groups had slightly elevated ODC activities at day 14 which may reflect the reduced total food intake in this group. The T_4 levels at 11 days postnatum of pups exposed to the 9% ethanol were reduced (2 µg/dl) compared with their pair fed controls (4 µg/dl) or with the 5% group (3-5 µg/dl). The cerebellar AAT and MDH activities of pups exposed to ethanol were similar to their pair fed controls at each stage of development studied. Histologically, the development of cerebellums was impeded at day 7 postnatum in pups exposed to either 5 or 9% alcohol. The Purkinje cells of pair fed controls were in a single lamina at this time whereas those exposed to alcohol were still clustered. The experimental cerebellums also had a decreased molecular layer width compared with controls. These data indicate that the exposure of rats during embryonic and fetal life to alcohol, affects both cerebellar development and serumthyroxine levels. Alcohol may impede cerebellar development either directly or indirectly; in the latter case hypothyroidism may be one cause.

187 SODIUM AND CHLORIDE CHANGES DURING SPREADING DEPRESSION AND ANOXIA IN RAT CEREBELLUM. R.P. Kraig, C. Nicholson & J.M. Phillips*. Dept. Physiol. & Biophys., N.Y. Univ. Med. Ctr., 550 First Avenue, New York, NY 10016

Spreading depression (SD) and anoxia are two related phenomena. In the teleost fish cerebellum large decreases in $[Na^+]_0$ and $[Cl^-]_0$ are observed during SD (Kraig and Nicholson, Neuroscience, in press). We have now examined changes in these ions in a mammalian preparation, the rat cerebellum, and also compared them with anoxic changes.

Rats were anesthetized with urethane and the exposed cerebellum was superfused with Ringer solution. By using hypotonic Ringer solution (100m Osm.; $[Na^+]$: 46mM, $[Cl^-]$: 30mM, other constituents as Feldberg and Fleischhauer, J. Physiol. 150: 451, 1960) SD could be readily induced with 20 Hz local surface stimulation. Anoxia was induced with N_2 breathing under normal Ringer superfusion. $[Na^+]_0$ was measured with theta-micropipettes containing monensin-based ion-exchanger (Kraig and Nicholson, Science 194: 725, 1976) or neutral carrier ligand (Güggi et al, Helv. Chim. Acta 59: 2417, 1976). $[Cl^-]_0$ was measured with micropipettes containing Corning exchanger 477315. $[K^+]_0$ and $[Ca^{2+}]_0$ were also monitored for comparison.

The reduced NaCl Ringer lowered ambient $[NaCl]_0$ cerebellar molecular layer to between 50 and 70 mM below normal baseline values. When SD occurred, a further, transient, fall in both $[Na^+]_0$ and $[Cl^-]_0$ took place to levels approximately 1/3 of those in the cerebellum before superfusion with hypotonic Ringer. During anoxia, with normal Ringer superfusion, both $[Na^+]_0$ and $[Cl^-]_0$ fell to levels similar to those seen at the peak of SD, but no recovery took place during the anoxic period. $[K^+]_0$ and $[Ca^{2+}]_0$ changes during both SD and anoxia resembled those reported previously (Nicholson et al, Proc. Natl. Acad. Sci. USA, 74: 1287, 1977).

The falls in $[Na^+]_0$ and $[Cl^-]_0$ during SD and anoxia in the rat cerebellum are similar, in both magnitude and proportion of normal baseline values, to those seen during SD in the fish (Kraig and Nicholson, Neuroscience, in press). These results show that $[Na^+]_0$ and $[Cl^-]_0$ fall to relatively invariant levels during SD and anoxia in diverse species and under different initial NaCl concentrations. This suggests that these ionic changes are a manifestation of a fundamental ionic mechanism of the brain. (Supported by Public Health Service, Grant NS-13742).

188 DENDRITIC CALCIUM SPIKING IN MAMMALIAN PURKINJE CELLS: IN VITRO STUDY OF ITS FUNCTION AND DEVELOPMENT. R. Llinás and M. Sugimori*, Dept. Physiology & Biophysics, New York Univ. Med. Ctr., 550 First Ave., New York 10016.

Intracellular recordings from soma and dendrites of rat Purkinje cells were obtained from cerebellar slices kept in vitro by perfusing with an oxygenated Krebs solution. Sodium conductance blockage by TTX (10^{-5}) demonstrated calcium action potentials followed by prolonged potassium-dependent after-hyperpolarizations. It was shown that this calcium-potassium system is capable of changing the effective time constant of the cell and of producing long-lasting modulation of membrane potential. Intradendritic recording, under direct vision, further indicated that this voltage-dependent conductance change is especially prominent at the mid-dendritic level. Under normal conditions, in vitro Purkinje cells fire repetitively in a spontaneous manner, quite similarly to the burster neurons in invertebrates. This bursting property is underlayed by slow modulation of the membrane potential which remains unchanged following sodium conductance blockage. In the absence of calcium current (after blockage by 1 mM cadmium), Purkinje cells ceased to show rhythmic bursting. If cadmium is applied without blockage of the sodium current, high frequency sodium-dependent spikes (up to 1500/sec) may be observed during direct depolarization, indicating that in this cell sodium conductance behaves mainly as a booster, membrane excitability being apparently governed by the calcium-potassium system. A second set of in vitro experiments in newborn rats has shown that prior to the development of the main dendritic tree (5th to 6th days after birth) only sodium-dependent spikes can be obtained. At the 5th or 6th day after birth, development of the main dendritic tree begins, accompanied by climbing fiber activation and by the presence of vigorous calcium spikes. It is proposed that calcium is necessary for normal integration and for the growth of Purkinje cells. (Supported by USPHS grant NS-13742 from NINCDS)

189 BIOCHEMICAL AND MORPHOLOGICAL CHANGES IN THE MOUSE CEREBELLUM FOLLOWING NEONATAL ADMINISTRATION OF METHYLAZOXYMETHANOL ACETATE. K. L. Lovell and M. Z. Jones, Dept. Pathology, Mich. State Univ., E. Lansing, MI 48824.

Methylazoxymethanol acetate (MAM), when injected subcutaneously into neonatal mice, destroys dividing neurons of the external differentiating cell layer resulting in a deficit of cerebellar interneurons and aberrant development of the remaining cells. To assess the effects of MAM-induced cell depletion and disruption of cytoarchitecture on the norepinephrine (NE) and gamma-aminobutyric acid (GABA) transmitter systems, biochemical assays of cerebellar NE concentration and glutamic acid decarboxylase (GAD) activity were conducted at several ages. In these experiments 0.045 µl MAM/gm body weight, or an equivalent amount of saline solution, was injected into mice within 24 hr of birth. As in previous studies, animals that received MAM showed decreases in body and cerebellar weights, delayed development of the external differentiating cell layer, depletion of interneurons (granule, basket and stellate cells), and misalignment of Purkinje cells. NE was measured fluorometrically and GAD activity was assayed by the $^{14}CO_2$ trapping method (Kanazawa, I., et al., J. Neurochem., 27: 1267, 1976). The amount of NE per gram of tissue was increased in MAM-injected animals, while the amount per cerebellum was not significantly different from control animals. This suggests that the total number of NE terminals (present in the cerebellum before birth) is unchanged by MAM treatment. The GAD activity per gram of tissue was higher in MAM-injected animals compared to saline-injected controls, while the total cerebellar GAD activity was decreased. A loss of some GABA containing neurons (mainly basket and stellate cells) could explain the decrease in activity per cerebellum while an increased density of remaining GABA-containing cells (e.g. Purkinje cells or neuroglia) in a smaller cerebellum might account for the increase in GAD activity per gram of tissue. Thus these studies provide correlations between aberrant cerebellar development and neurotransmitter biochemistry.

This research was supported by a NIH postdoctoral fellowship to K.L.L.

190 DEVELOPMENT OF THE INFERIOR OLIVARY NUCLEUS IN THE AMERICAN OPOSSUM: A LIGHT AND ELECTRON MICROSCOPIC STUDY. Bruce E. Maley* and James S. King, Department of Anatomy, The Ohio State University, Columbus, Ohio, 43210.

In order to study the development of the inferior olivary nucleus (ION) a series of young opossums at different snout-rump (SR) lengths were removed from their mothers' pouches and processed for light and electron microscopic analysis. The ION is not present as a discernable nuclear group at birth (12-13 days post conception), but it is apparent by the 4th-5th day (23mm) in the pouch. At this SR length the ION is a homogenous mass of cells with no apparent nuclear subdivisions. Separate principal and accessory nuclei cannot be identified until the animals attain a SR length of approximately 50mm. During this period of time (SR 23mm to SR 50mm) the ION increases in length from 650µm to 920µm. Analysis of Nissl and Golgi preparations reveals that olivary neurons are 5-10µm in diameter and exhibit relatively short dendrites with infrequent sessile spines. By the 50-55mm stage comparable neurons have increased in size to 10-15µm with varicose dendrites which have spines and spiny appendages. Often the tips of these dendrites end in a moniliform appearance. It is not until animals attain a length of over 90mm that the neurons resemble those seen in the adult (Bowman and King, 1973, J.C.N., 148: 491).

Examination with the light as well as the electron microscope discloses, at the 23mm stage, that the neurons within the developing ION are densely packed with scant neuropil. At this SR length all neurites are unmyelinated with only an occasional synaptic contact observed. Synaptic vesicles encountered were either of the clear, spherical type or the large granular variety. By the 50-55mm SR length the olivary neurons are surrounded by more neuropil which also includes profiles described as growth cones (Skoff and Hamburger, 1974, J.C.N., 153: 107), as well as processes that could be the ultrastructural correlates of varicose dendrites. There is an apparent increase in synaptic vesicles within the individual neurites as well as the total number of synaptic contacts. Most synaptic contacts in both the 23mm and 50mm stages are on neurites, however on a rare occasion a somatic synapse has been observed. In the 50mm stage, the synaptic vesicles are either clear, spherical or large, granular. Neuroglia are present in both the 23mm and 50mm stage, but no glial enclosed synaptic clusters, as seen in the adult ION, are present (King, 1976, J.C.N., 165: 387).

191 PURKINJE CELL ACTIVITY IN THE INTERMEDIATE CEREBELLAR CORTEX DURING A VARIABLE BALLISTIC MOTOR TASK. James McElligott, Eric Hansen*, and Robert Kester*, Dept. of Pharmacology, Temple University School of Medicine, Philadelphia, Pa. 19140.

The intermediate area of the cerebellar cortex has been considered to regulate the details of on-going movements in contrast with the lateral area which is involved with preprogramming a movement (Allan & Tsukhara, 1974). Previous work (Thach,1968,1970) showed that intermediate zone Purkinje cells modulate their firing patterns during discrete phases of a stereotyped wrist movement. The object of this study was to investigate Purkinje cell activity in the intermediate cerebellar cortex during a variable ballistic motor task and to determine if alterations in the motor task are reflected by changes in Purkinje cell firing patterns. We were also interested in observing the types of sensory input that influence these cells.

Four female cats were prepared for chronic extracellular single unit recording from the cerebellar cortex. They were habituated to a head restraining apparatus and trained to make a ballistic forelimb response. This response consisted of lifting the forelimb from a predetermined position and rapidly extending it to cover a spot of light presented at various positions on a large screen oscilloscope mounted in front of the animal.

Eighty percent of the recorded Purkinje cells (n=60) modulated their activity before as well as after the initiation of the forelimb response. Increases (54%), decreases (26%) and biphasic (20%) responses were observed. The modulation of the firing pattern for an individual cell was qualitatively similar for each trajectory. However, a variation in trajectory was generally accompanied by a change in latency, duration or firing rate modulation. For adjacent locations of the target light, the changes in the neuronal response appeared to be on a continuum. In no instance was there an abrupt change, e.g., from strong excitation to no excitation or to inhibition.

A number of the Purkinje cells (30%) related to the forelimb response also responded to a tone which initiated each trial. This response was usually a short latency (<30 msec) excitation of brief duration (<50 msec) that occurred independently of the forelimb response. No cells were found that responded to the presentation of the target light.

These results provide evidence that Purkinje cells in the intermediate cerebellar cortex can regulate and reflect details of specific motor responses. The short latency response to auditory input may prepare the motor system for action and may be similar to that observed by Mortimer (1975) during an acoustically elicited startle reflex.

192 CEREBELLAR STIMULATION IN MAN; CHANGES IN JOINT COMPLIANCE AND MUSCLE COACTIVATION. Barbara Miller*, Richard D. Penn, Gerald Gottlieb, Gyan C. Agarwal* (SPON: R. D. Penn). Dept. Neurosurg., Rush Medical College, Chicago, IL 60612.

Chronic electrical stimulation of the superior surface of the cerebellum is now being used to alleviate the motor problems of cerebral palsy patients. This operation provides, for the first time, an opportunity to study the physiological changes that occur due to cerebellar stimulation in man. To quantitate the motor effects, tests of ankle joint compliance and stretch reflexes of the leg were performed on 10 cerebral palsy patients with and without stimulation. The seated subjects have one foot strapped to a footplate which rotates about a horizontal axis through the medial malleolus. Surface EMG electrodes are placed over the anterior tibial (AT) and gastrocnemius-soleus (GS) muscles. The footplate is rotated by a d.c. torque motor. A computer generates the motor-drive voltage and digitizes the data. The applied torque, angular rotation, and GS and AT EMGs are stored on digital magnetic tape. Two separate series of experiments are conducted. First, the computer directs a series of sinusoidal oscillations to the foot. Recordings are made for 10 seconds with frequencies of oscillation from 3 to 30 Hz. The joint compliance is determined from the angular rotation and the constant torque level at each drive frequency. Second, the myotatic (stretch) reflex is evoked by sudden step-like dorsiflexions and plantarflexions of the ankle given in a random series directed by the computer. In both studies the magnitude and latency of EMG activity is measured with respect to the onset of stretch. Simultaneous increases in AT and GS activity represent coactivation of agonist and antagonist muscles.

In those cerebral palsy patients who are clinically diagnosed as spastic, sinusoidal oscillation of the ankle reveals a low ankle compliance (which is characteristic of a "stiff" joint) and coactivation of GS and AT muscles during the dorsiflexion phase of the cycle. Quick stretch of the ankle results in simultaneous responses of AT and GS at the latency of the stretch reflex, regardless of the direction of stretch; this activity is never seen in normal subjects. Some patients who received regular cerebellar stimulation showed increases in joint compliance and reduction in muscle coactivation, but the degree and time course of change varied enormously. At one extreme a 50% increase in compliance was found within 5 minutes of stimulation, at the other extreme no significant change was found after 6 months. The prestimulation tests suggest that these cerebral palsy patients have abnormally active stretch reflexes as well as deranged spinal connections which result in coactivation. Stimulation decreases these abnormalities in some cases.

193 PROXIMAL LIMB MOVEMENTS ELICITED BY MICROSTIMULATION OF CEREBELLAR NUCLEI IN MONKEY. E.B. Montgomery*, W. Schultz*, R. Marini*, and G.I. Allen. Lab. Neurobiology, Dept. Physiol., State Univ. of New York, Buffalo, New York 14214.

The dentate and interpositus nuclei of the primate cerebellum have been assumed to play an important role in the initiation and control of skilled movements. Recently, it has been observed that the lateral cerebellum exerts a direct descending influence upon the spinal cord and this may mediate a postural mechanism. In order to clarify this problem, movements elicited by microstimulation of dentate and interpositus nuclei were studied in nine adult monkeys (Cebus apella) under light thiopental anesthesia. Microstimulation of dentate and interpositus nuclei and the areas of efferent fibers anterior to them elicited a response consisting of a combination of the following five movements regardless of the site of stimulation: flexion of the elbow, and elevation of the shoulder in the forelimb. and hip flexion, knee flexion and dorsiflexion of the ankle in the hindlimb. Thresholds were as low as 5 μA. No movement was accepted where threshold exceeded 100 μA. A response consisting of at least one forelimb and one hindlimb flexion with current up to 100 μA was elicited from 42% of all effective stimulus sites. Four out of these five movements could be elicited by stimulus strengths of 100 μA at 22% of all effective stimulus sites. Movements of the fingers or toes were seen only at 7 of 281 sites. Ipsilateral facial movements were seen at 25% of effective stimulus sites. These stereotyped proximal flexion movements were not dependent on the motor cortex or red nucleus as demonstrated by continued response to stimuli following ablation of the contralateral motor cortex or intercollicular brain stem transection. These responses were eliminated only with transection of the brachium conjunctivum caudal to its decussation. The stereotyped forelimb and hindlimb proximal flexion without apparent somatotopy suggests activation of descending postural mechanisms independent of structures rostral to and including the red nucleus. This is not inconsistent with a role of the lateral cerebellum in skilled distal movements via motor cortex. The dentate and interpositus nuclei may affect the posture of the proximal musculature in preparation for skilled distal movement which is then superimposed.

194 A FORMAL THEORY FOR CEREBELLAR FUNCTION: THE PREDICTIVE DISTRIBUTED PROPERTY OF THE CORTICO-NUCLEAR CEREBELLAR SYSTEM AS DESCRIBED BY TENSOR NETWORK THEORY AND COMPUTER SIMULATION. A. Pellionisz and R. Llinás, Dept. Physiology & Biophysics, New York Univ. Med. Ctr., 550 First Ave., New York 10016.

It is difficult to describe in abstract terms the properties of a neuronal network in which inputs are distributed over a large cortical area, carrying information in a parallel manner. Generally these networks are treated as "loops" of a few individual neurons, or the system is simply deemed redundant. This spatially distributed parallel organization, being characteristic for the brain in general and for the cerebellum in particular, has compelled us to devise a new set of premises for the analysis of such systems. Using computer simulation methods, two features of a new theory of cerebellar function (Pellionisz and Llinás, *Neuroscience*: in press) will be demonstrated. At the single cell level the theory identifies the function of individual Purkinje cells as taking different order time-derivatives of the parallel fiber input. *The first tenet of the theory holds that the activity of individual cells over a cortical area may be represented by a spatially distributed, finite, series expansion of a time-function, which is then reconstructed on a set of nuclear neurons.* For the cerebellum, given a proper ratio of Purkinje cells taking 0,1,2,3.... order derivatives, these cellular activities can be treated as a Taylor expansion such that the reconstruction of the time function on the nuclear neurons can provide a running tally which predicts (by extrapolation from the past neuronal activities) a future value at a delta look-ahead time. While it is intuitively obvious that prediction is essential for coordination of time functions, our theory embeds the above assumption into a second tenet in order to formulate a general theory for the cerebellar coordination. *Neuronal networks are considered as tensors (in full generality), each identifying a scalar valued function of a number of vector variables which is linear in each variable.* Rather than conceptually oversimplifying neuronal networks into "loops" or "reflexes", we regard these entities as tensors; thus the function of the cerebellum may be explained by the available tensor theory. For example, the Purkinje cell network becomes a tensor of rank two, which assigns to a given mossy fiber vector (curve-point in m-space at t) a Purkinje cell vector (curve-point in n-space at time t + delta) by virtue of the connectivity matrix. The application of these principles will be demonstrated by computer simulation. In addition to providing a theory for cerebellar coordination, the model demonstrates the principle of distributed organization of a system which is, by its nature, quite impervious to diffuse lesions. (Supported by USPHS grant NS-13742 from NINCDS)

195 LOW THRESHOLD CLIMBING FIBER PROJECTIONS FROM FORELIMB TO CEREBELLAR CORTEX IN THE CAT. D. S. Rushmer, L. T. Robertson, K. D. Laxer*, M. H. Woollacott. Neurological Sciences Institute, Good Samaritan Hospital & Medical Center, Portland, Oregon.

The olivocerebellar projection has been shown by a number of electrophysiological and anatomical investigations to have a parasagittal orientation. Previous work reported by this group described a parasagittally oriented strip of Purkinje cells receiving climbing fiber projections in lobules Vb and Vc of the cerebellar intermediate cortex that were highly responsive to small displacements of the forepaw. The present work elaborates on these findings and describes a second more laterally located climbing fiber strip that is responsive to natural stimulation of receptors in the dorsal forepaw and forearm. Extracellular single unit responses of Purkinje cells to natural stimulation of the forelimb were recorded in cats anesthetized with pentobarbital. Peristimulus histogram techniques were utilized to compute characteristics of climbing fiber responses (CFRs) and simple spikes. The stereotaxic location of all units was recorded and the final electrode penetration was verified histologically.

The center of the medial strip was located 4 mm from the midline, was 700-900 μm wide and extended rostrocaudally 13 mm. The CFRs in this strip were highly responsive to small displacements of the forepaw or low threshold stimulation of the paw pads. Lateral to the medial strip was a 2 mm wide unresponsive zone in which the spontaneous CFRs were identified, but were not correlated with any form of natural stimulation of the ipsilateral or contralateral fore- or hindlimbs. Beyond the unresponsive zone was a 1.5 mm wide lateral strip that was sensitive to natural stimulation of the dorsal surface of the forepaw and forearm. The rostrocaudal extent of this strip appeared to be approximately the same as the medial strip.

Many of the CFRs within the lateral strip could be elicited by pulsatile forces as small as 10 gm, had an average latency of 18 msec, and followed stimulus frequencies of 10/sec. The lateral strip was topographically organized. The more medial portion was responsive to forces applied the dorsal surface of the forepaw between the wrist joint and the distal phalanx. Cells in the lateral aspect of the strip were responsive to stimulation of the dorsum of the forearm between the elbow and wrist joints.

196 TOPOGRAPHY OF DESCENDING PROJECTIONS TO THE INFERIOR OLIVE FROM THE PARAFASCICULAR REGION, MESENCEPHALON AND SUPERIOR COLLICULUS IN THE CAT. J.A. Saint-Cyr and J. Courville. Centre de Recherche en Sciences Neurologiques, Département de physiologie, Université de Montréal, Montréal, Québec.

Experiments on 20 cats utilizing the retrograde transport of horseradish peroxidase (HRP) revealed the sources of descending projections to the inferior olive from the upper brainstem. The cells of origin lie ventrolateral to the central gray and are continuously distributed from the vicinity of the fasciculus retroflexus to the rostral pole of the red nucleus. These cells are located in regions which include the following structures: nuclei parafascicularis and subparafascicularis, nucleus of Darkschewitsch (ND), interstitial nucleus of Cajal (INC) and parvocellular red nucleus. HRP-labeled neurons were also found in the deep layers of the superior colliculus. The topography of projections from these sites to the inferior olive were evaluated with the anterograde transport of ^{3}H-L-leucine (0.3-0.4 μl, 150-170 μCi/μl) in 12 cats. Injections in the superior colliculus resulted in a dense distribution of silver grains in the caudal part of the contralateral medial accessory olive (MAO) with a similar but lighter ipsilateral deposit. After injections in the rostral part of the continuous cell distribution revealed with the HRP method, dense ipsilateral deposits were observed in the rostral MAO and in the rostro-medial portion of the principal olive. Cases with more caudal injections which included the ND and INC showed dense label in the rostro-medial MAO and light deposits in the rostro-lateral MAO ipsilaterally. In addition, there were accumulations of silver grains in the rostro-medial part of the principal olive and in the caudal part of the dorsal lamella of the principal olive again ipsilaterally. Injections which were centered in the rostral pole of the red nucleus and adjacent INC resulted in the labeling of the dorsomedial cell column bilaterally in addition to the rostral MAO distribution indicated in the previous case. In addition, in these cases, most of the caudal MAO, the two lamellae of the principal olive, and the medial portion of the caudal third of the dorsal accessory olive were labeled ipsilaterally. Animals with injections centered in the magnocellular red nucleus and extending to the rostral pole of that structure showed partial ipsilateral labeling of the dorsal lamella. These results indicate that the upper brainstem sites of origin as well as the areas of distribution of the projections to the olive are more extensive than hitherto demonstrated and present a topographic arrangement.

197 **TOPOGRAPHICAL ORGANIZATION OF THE CEREBELLOTHALAMOCORTICAL PATHWAY IN CAT AND DOG.** **G. B. Stanton* (SPON: D. L. Robinson). Department of Anatomy, College of Medicine, Howard University, Washington, D.C. 20059.**

Results from isotope labeling and/or anterograde degeneration studies in the cat and dog indicate that projections from localized parts of the deep cerebellar nuclei terminate in patches in the ventrolateral nucleus of the thalamus (VL) which are distributed in a gross topographical organization. Retrograde labeling experiments with peroxidase (HRP) indicate a similar gross organization of the distribution of VL thalamocortical cells. Caudal parts of the fastigial nucleus terminate in ventromedial parts of VL and overlap to some extent with the terminals from dorsal parts of the dentate nucleus. In the cat, cells in this thalamic area were labeled from HRP injections in area 6 in the medial or rostrolateral precruciate gyrus. Monopolar stimulation in both areas produced muscle contractions of the contralateral face. Projections from ventral parts of the dentate nucleus terminate in the dorsal and medial parts of VL where labeled cells were found from HRP injections in hidden parts of the medial precruciate gyrus. Dentate projections to paralaminar portions of the mediodorsal nucleus were found which coincided with the distribution of HRP-labeled cells from injections in widespread parts of the pre- or postcruciate gyrus. Projections from the interpositus posterior terminated in fewer, more closely spaced patches in mid-ventral VL. This area contained cells labeled by HRP injections at the lateral end of the cruciate sulcus. No projections to paralaminar mediodorsal nucleus were seen following an isotope injection in the interpositus posterior. Peroxidase injections in several sites in the postcruciate gyrus produced labeled cells in ventrolateral VL, but no cerebellar projections to this area have been confirmed as of this writing. Comparison of these results with recent physiological maps of the cat motor cortex suggest there is a somatotopical organization of the cerebellothalamocortical pathway in which the face, trunk, and proximal forelimb are represented in the dentate nucleus; face and trunk are represented in the fastigial nucleus; and the distal forelimb is represented in the interpositus posterior.

This investigation was supported by the General Research Support Grant #5 SO1 RR 05361 of the General Research Support Branch, National Institutes of Health.

198 RECIPROCAL MODULATORY EFFECTS OF LOCUS COERULEUS AND RAPHE ON CEREBELLUM. Jean C. Strahlendorf and Charles D. Barnes. Dept. Physiology, Texas Tech Univ. Sch. of Med., Lubbock, TX 79409.

Previous work in our laboratory revealed that discrete stimulation (1-3 shocks, 25-500 μA, 0.1-0.2 msec) of raphe nuclei (pontis, centralis superior and inferior) (R) elicit an initial bursting or entrainment within 4-20 msec, followed by prolonged inhibition lasting 500 msec, and sometimes as long as 1600 msec in cerebellar cortex and fastigial nucleus. Consonant with raphe, locus coeruleus (LC) activation (3 shocks, 25-500 μA, 0.1-0.2 msec) produced excitation with subsequent inhibition in the cerebellum. Furthermore, conditioning stimuli to either LC or R 50-300 msec preceding test shocks to the other nucleus, suppressed characteristic cerebellar responses. C-T paradigm studies suggested at least 2 possibilities: that the interaction may occur between the 2 nuclei in the brain stem region, both inhibiting the firing pattern of the other or direct interaction on cortex and fastigial N. since R and LC terminate in Purkinje, molecular and granule cell layers. The purpose of this investigation was to electrophysiologically study the first premise, an interplay of 5HT and NE neurotransmitter systems within the brain stem region. Anatomical findings have revealed that the raphe dorsalis, CS and CI project to the ventrolateral part of LC, while projections between LC and raphe have recently been demonstrated, suggestive of a reciprocal innervation.

Raphe N. and LC were initially stereotaxically identified and verified by presence of characteristic pressor responses upon stimulation, in cats anesthetized with α choralose or decerebrated at precollicular level. Raphe stimulation (1 shock, 50-500 μA, -pulse, 0.1-0.2 msec) evoked transsynaptic spike activity within 6-10 msec in the locus coeruleus. Antidromic spikes identified by fixed latency and ability to follow up to 100-300 cycles/sec were recorded in LC following raphe activation. R stimulation (1 shock, 50-500 μA, 0.1-0.2 msec) produced transsynaptic spikes in LC nuclei 3-10 msec after introduction of the stimulus. Antidromic spikes were also elicited in LC 1-1.75 msec after raphe excitation. Mean conduction velocities were calculated for both areas. In addition, LC and raphe stimulation inhibited the firing pattern of spontaneously firing cells of the other for up to 350-400 msec, followed by rebound excitation. The data electrophysiologically verify the anatomical findings for a reciprocal innervation between these two areas and provide evidence of a means in which they may modulate each other's effect on the cerebellum. (Supported in part by NIH Grant HL 7289).

199 SPINOBULBAR AND SPINOCEREBELLAR PROJECTIONS IN THE RAT. Rand S. Swenson* and Anthony J. Castro, (SPON: Charles L. Webber, Jr.) Depts. Anat., National College of Chiropractic, Lombard, Ill., 60148 and Loyola Univ. of Chgo., Stritch Sch. Med., Maywood, Ill., 60153.

The normal distribution of spinobulbar projections was determined in adult Long-Evans, black-hooded rats using the Fink-Heimer staining technique. Various lesions of the spinal cord were placed at mid-thoracic levels. Animals were sacrificed 4 to 10 days postoperatively, and the brainstem and cerebellum were examined for axonal and preterminal degeneration. The major tract degeneration was found in the dorsal columns and in the ventrolateral portions of the brainstem. The ventrolateral tract gave rise to preterminal degeneration in the lateral part of the dorsal accessory olive, the subnucleus a of the medial accessory olive, the lateral reticular nucleus (particularly its rostral portions), and the nucleus reticularis ventralis, gigantocellularis and pontis caudalis. Degenerating fibers could be traced diverging from this bundle into the restiform body from which they were primarily distributed to the cerebellum with small inputs to the lateral vestibular nucleus and the subnucleus x of the vestibular complex.

At levels immediately caudal to the chief nucleus of V many degenerating fibers were seen to leave the ventrolateral region and arc dorsalward giving off fibers to the nucleus reticularis pontis oralis. This pathway forms the ventral spinocerebellar tract and occupies a position dorsal to the brachium conjunctivum where it proceeds caudally into the cerebellum. Ventrolateral fibers were also observed to project to the pontine gray, to the deep layers of the inferior colliculus bilaterally (crossing in the commissure of the inferior colliculus), and finally, the few remaining fibers at mesencephalic levels could be seen to join with the medial lemniscus.

Fiber degeneration was observed within the fasciculus and nucleus gracilis, and a few fibers could be traced leaving this region and coursing laterally, just beneath the dorsal surface of the brainstem. These fibers were traced to the external cuneate nucleus and the subnuclei x and z of the vestibular complex.

Degeneration within the cerebellar nuclei was heaviest within the fastigial nucleus with little observed within the interpositus and dentate. Considerable amounts of degeneration was found in the cortex of the anterior lobe and the posterior portion of the posterior lobe. Other areas receiving trace degeneration included the locus ceruleus, substantia nigra, periaqueductal gray, superior olive and the nucleus commissuralis. Differences resulting from lesion variances will be discussed.
(Supported by NIH Grant NS 13230.)

200 A POSSIBLE EXPLANATION FOR CEREBELLAR TREMOR. T. Vilis and J. Hore. Dept. of Physiology and Dept. of Ophthalmology, University of Western Ontario, London, Canada.

Trained Cebus monkeys can return their forearm, which has been displaced by a perturbation applied to a handle, back to the original position with little or no overshoot. However, if the function of the ipsilateral dentate and interpositus nuclei is impaired by reversible cryoprobe lesions, the same displacement triggers a prolonged series of oscillations at 3 to 4 Hz. We found, in three monkeys that the number, amplitude, and period of the oscillations was directly related to the degree of cerebellar cooling. Normally the return of the arm was initiated in part by short latency (15-25 msec) and long latency (30-80 msec) reflex responses in the agonist muscle. The return was usually actively terminated by EMG activity in the antagonist occurring 150 to 200 msec after the torque pulse. As the temperature of the cryoprobes was progressively lowered, the onset of this antagonist activity was progressively delayed causing the correction to overshoot by increasing amounts. This activity was also prolonged thus initiating a second cycle of oscillations.

Could these oscillations result from impaired stability of a servo mechanism through motor cortex? To answer this the activity of 74 precentral neurons, which responded to displacement of the arm were compared before, during and after cooling of the cerebellar nuclei. In 24 neurons an early excitation (onset 30 to 40 msec) was followed by a later inhibition (70 to 80 msec) for a perturbation in one direction, and early inhibition followed by late excitation for a perturbation in the opposite direction. Normally this late excitation appeared in advance of the EMG activity in the antagonist which acted to terminate the corrective movement. During cooling this response, in 17 of these 24 neurons, was delayed in this and subsequent oscillations so as to occur after the onset of EMG activity. The onset of this neural response occurred after the start of muscle stretch whereas in normal movement it was predictive i.e. it occurred prior to the start of muscle stretch.

A possible interpretation of these results is that after an arm perturbation an initial correction is initiated by segmental and suprasegmental stretch reflexes. The motor cortex, in advance of this movement correction generates a command to terminate this correction on the basis of predictive information provided by the cerebellum (the 70 msec cortical response). When this information is lacking, servo control through the motor cortex must rely on afferent information. This results in a descending command which comes too late in the movement thus causing overcorrection and subsequent tremor.

201 THE ROLE OF CEREBELLAR AND BRAIN STEM NUCLEI IN VESTIBULAR COMPENSATION IN RATS: A 2-DEOXY-D-GLUCOSE STUDY. K. Walton and R. Llinás, Dept. Physiology & Biophysics, New York Univ. Med. Ctr., 550 First Ave., New York 10016.

Recovery from hemilabyrinthectomy in the rat has been used to investigate the role of the cerebellar system in motor learning. This vestibular compensation (VC), as indicated by the return of postural symmetry, the cessation of spontaneous nystagmus, and the return of normal eye position, occurs within 24 to 36 hours in normal animals. Compensation is irreversibly absent in animals in which the inferior olive (IO) has been chemically lesioned by the administration of 3-acetylpyridine (3-AP) and harmaline followed by niacinamide (see Llinás et al., Science 190: 1230, 1975) and is markedly delayed in animals with partial IO lesion. VC is lost if the IO is lesioned following compensation. In contrast, removal of the cerebellar cortex slightly retards, but neither prevents nor leads to, the loss of compensation. Thus, the olivo-cerebellar system, but not the cerebellar cortex, plays an essential role in both the acquisition and retention of vestibular compensation.

In order to obtain a global picture of the changes in neuronal activity underlying this learning process at brain stem and cerebellar nuclear levels, 2-deoxy-D-glucose was used to determine the distribution of glucose uptake at these sites in normal, uncompensated, compensated, and 3AP-decompensated animals. These studies showed that the asymmetries following hemilabyrinthectomy reflect an imbalance in the activity of the vestibular nuclei (VN) and that compensation results from the restoration of balance. In uncompensated and decompensated animals the VN ipsilateral to the lesion were significantly less active than the contralateral VN. In compensated animals, VN activity was the same on both sides, the level being close to or higher than normal. Thus, VC is accompanied by an increase in activity in the ipsilateral VN. This is mediated by several structures, as indicated by an elevation of their function above normal levels. For example, in addition to enhanced activity in the granular layer of the nodulus and uvula, compensated animals show enhancement in the ipsilateral cerebellar nuclei, the lateral reticular nucleus and in the contralateral IO, particularly the medial accessory subnucleus.

The present study demonstrates that the brain is capable of re-organizing its activity to recreate, by internal means, a meaningful equivalent of normal vestibular input. The actual distribution of this "engram" is reflected in the spatial distribution of radioactivity. (Supported by USPHS research grant NS-13742 from NINCDS)

CEREBRAL CORTEX

202 THALAMIC AND NON-THALAMIC SUBCORTICAL PROJECTIONS TO CAT'S FRONTAL EYE FIELD. C. Avendaño*, A. Llamas* and F. Reinoso-Suárez. Dept. Morfología, Inst. Invest. Oftalmol. Castroviejo, Fac. Medicina, Univ. Autónoma, Madrid 34, Spain.

Using minimal electrical stimulation, Schlag and Schlag-Rey (1971) identified regions in the frontal cortex of the cat from which oculomotor responses could be elicited. These regions corresponded to both the dorsal sector of the medial wall of the prefrontal cortex and to the depth of the praesylvian sulcus. Classical neuroanatomical procedures have not yielded conclusive results as to the subcortical projections to these areas. On the other hand, electrophysiological findings uphold the existence of reciprocal connections between them and the thalamic nucleus centralis lateralis (CL), the claimed thalamic locus for oculomotor control.

As a part of a broader study of the frontal cortex of the cat, we have explored the thalamic and non-thalamic subcortical projections to the frontal cortical areas of ocular movements by means of the retrograde transport of HRP technique. Small amounts (.1 to .3 µl) of a solution of HRP were injected in various portions of these areas in adult cats. After survival times of 44-46 hr. animals were perfused and brains processed to reveal HRP in the CNS.

Injections remained limited within the gray matter sparing the subcortical white matter, thus impregnating terminals only in restrained portions of the cortex. In all cases labelled neurons were found in the thalamic nuclei medialis dorsalis (MD), ventralis anterior (VA) and ventralis medialis (VM). Most injections gave rise also to labelling of neurons in the middle or two posterior thirds of the centralis medialis (CeM). In contrast with the above mentioned electrophysiological data, no labelled neurons could be observed in CL. Labelling in MD was topographically organized: injections in the medial wall of the hemisphere produced labelled cells dorsally in its lateral sector, whereas injections in the bottom of the praesylvian sulcus gave rise to HRP-cells also in the lateral sector, but ventrally and posteriorly.

Labelled neurons were also found in other subcortical regions. Conspicuously in the ipsilateral dorsal claustrum and basal magnocellular amygdaloid nucleus, occupying in these nuclei an intermediate position between those of neurons projecting to the motor cortex and of neurons projecting to the remaining prefrontal cortex. A few HRP-cells distributed sparsely in the medial hypothalamus and in the locus coeruleus complex.

These findings suggest that thalamic projections to the frontal area of ocular movements in cat organize topographically, similarly to those in monkey, and that projections to the same area from other subcortical levels resemble those reaching the remaining prefrontal cortex, although varying somewhat in their topography.

Supp. by Grant N° 78/77 from FDC-INP.

203 NEUROANATOMICAL BASES OF SHORT-TERM SPATIAL MEMORY IN THE RAT. James Becker*, John A. Walker*, David S. Olton, and Barbara G. O'Connell*. Dept. Of Psych., Johns Hopkins Univ., Baltimore, Md.

The frontal cortex and limbic systems have been implicated in spatial short-term memory. In order to dissociate between the roles played by these areas in spatial memory, post-operative retention of an eight arm radial maze task was measured in groups of rats with either frontal or limbic system lesions.

Prior to surgery all of the rats demonstrated good maze performance, choosing a mean of at least seven correct arms in the first eight trials. Rats were randomly assigned to groups and lesions were made in medial frontal cortex (MF), sulcal frontal cortex (SF), caudate nucleus (CN), dorsal medial nucleus of the thalamus (DMT), or the fornix (FX). Testing was resumed following one week of recovery.

After surgery, the normal and operated control animals showed good retention of the task. Immediately after surgery they were performing as well as they had pre-operatively. This high level of performance was maintained for the duration of the 20 sessions.

In marked contrast to the control group, the FX group had an immediate and severe deficit in performance. Choice accuracy dropped to the level expected by chance in the first five tests and never rose above this level for 50 post-operative sessions.

The groups of rats with damage to the frontal cortex system (MF, SF, CN, DMT) showed an immediate and severe deficit in performance. Choice accuracy decreased to chance level in the first five post-operative sessions. Performance subsequently recovered to normal levels in the second block of five tests. This behavior was maintained for the remainder of the 20 test sessions.

The recovery of function by rats with medial frontal damage was a result of the animals' experience on the maze, rather than time from surgery. The performance of rats with medial frontal damage that began retention testing three weeks after surgery was essentially the same as that of rats in group MF on all behavioral measures.

These data demonstrate that the frontal and limbic systems are differentially involved in short-term spatial memory. In addition, they demonstrate that recovery of function from frontal damage in the adult is dependant on experience.

204 RESPONSIVENESS OF S1 CORTICAL CELLS TO RECEPTIVE FIELD STIMULATION DURING DIFFERENT BEHAVIORS by John K. Chapin and Donald J. Woodward, U. Tx. Health Sci. Ctr. at Dallas, Dallas, Tx., 75235

Responses of single units in the S1 cortical area of awake freely moving rats were examined to investigate modulation of sensory input during different motor behaviors. Post-stimulus time histograms (PSTH's) were compiled following touch of the skin with a manually held probe, or after electrical stimulation through subcutaneously implanted electrodes in the forepaw. Unit activity was also correlated with a variety of spontaneous and evoked behaviors, including treadmill running. These were studied by computer analysis of films synchronized with EMG's. An aim of initial experiments was to determine behavioral conditions in which sensory transmission to the S1 cortex is enhanced or depressed. PSTH's produced either by probe activation of tactile receptive fields (TRF's) or by electrical stimulation were similar and included various combinations of: 1) two early peaks,(7-12 msec. and 14-40 msec. latency), 2) a following depression of firing (40-150msec.), and 3) a rebound facilitation following the depression. All phases of the response to just suprathreshold electrical stimuli, especially the longer latency components, were enhanced during a "freezing" behavior induced by holding the animal. Reduction or suppression of all components of the response was induced by active movements such as grooming, locomotion, and slow exploration.

An aim of later experiments was to test the modulation of natural sensory input during a variety of motor behaviors. About 60% of cells with TRF's covering the whole forepaw, especially those exhibiting prominent short latency PSTH's, fired in phase with the forelimb step cycle during locomotion. Yet many of these cells were found to be correlated with particular active movements of the forelimb in the absence of overt tactile stimuli, as observed in a variety of spontaneous and evoked behaviors. For example, cells phasic to step cycles often fired before footfall, ie. the expected sensation. Conversely, many cells not firing phasically during locomotion were found receptive to touch on the TRF with a manually held probe during the running sequence. These data suggest that certain inputs which are of special significance in the behavior may be selectively gated in. In addition it appears that cells with well defined TRF's may also fire in relation to central motor signals, suggesting a capacity for sensorimotor integration.

205 CENTRAL AUDITORY PROCESSING: PATTERNS OF RECOVERY, D.M. Daly, D.D. Daly, J. Pearson*. Dept. Neurology, UT Health Sci. Ctr., Dallas, TX. 75235.

Sparse acoustic stimuli (SAS) provide a measure of cortical auditory processing (Neurosci. Abstr. 2:5, 2:6, 1976). We report the results of serial testing in 2 patients with acute, resolving lesions of comparable extent in the left parieto-occipital region. Patients classified sets of SAS with systematic variations in the duration or extent of change in second formant frequency. Set 1: duration of rise yields |be⊢|wel; Set 2: duration of fall, |ge⊢|yel; Set 3: extent of change, |be⊢|de⊢|gel.

A 44 year-old male abruptly developed aphasia with severe comprehension defects and right homonymous hemianopsia. Computerized tomography confirmed an infarct in distribution of a posterior branch of middle cerebral artery. His native language was English; he also understood and spoke German and Spanish. Initially, with SAS presented to right ear he classified Set 1 without sharp boundaries; with SAS to left ear and binaurally he showed classes with vestigial sharp boundaries. With Sets 2 and 3 he reported great difficulty differentiating stimuli and had altered classes in all modes of presentation. Over 4 days visual defect resolved to superior quadrantanopsia; comprehension of speech improved and aphasia abated leaving primarily anomic deficits. He now showed sharp boundaries for classes in Set 1; these coincided with the earlier left and binaural vestiges. Classes for Sets 2 and 3 had not changed significantly.

A 45 year-old woman underwent craniotomy for a tentorial arteriovenous malformation. She was a fluent English speaker; she had never been able to understand or speak French or Spanish, but could read both languages. Postoperatively she had aphasia, difficulty in comprehending speech and right homonymous hemianopsia. As comprehension improved, hemianopsia contracted to upper quadrantanopsia. Five months later, aphasia testing revealed severe alexia and auditory comprehension defects although she spoke fluently with minimal anomia. Initially, for all sets classes were markedly altered; classes for Set 2 suggested inversion of perception. Two months later, classes for Set 1 showed sharp boundaries in the usual location. Set 2 classes were resolving; and with left ear-left hand testing a boundary had emerged. Ten months later, Set 1 classes remained intact. Classes for Set 2 continued to resolve with distinct boundaries for monaural SAS. For the first time she could differentiate among SAS of Set 3.

Despite differences in rate, the courses of recovery in these patients were similar. In both, perception of SAS in Set 1 was better preserved and resolved more rapidly than in Set 2. Initially, neither could differentiate among SAS in Set 3. At the last testings both classified Set 1 in the usual fashion. Both also classified Sets 2 and 3 consistently although each of them perceived SAS differently from the other. The alterations over time in their perceptions of SAS accompanied the resolution of their underlying pathologic processes. In contrast, in patients with static lesions such alterations have persisted unabated for more than 2 years. Some persons with difficulty in speaking and comprehending a second language have auditory perceptual domains different from those usually seen; the differences between these two patients may partly reflect disparate premorbid auditory perceptual domains.

These findings accord with experimental studies in animals and indicate that auditory cortex analyzes complex transformations on the basilar membranes. The apparently genetically-determined disparate perception of SAS may reflect alterations in cortical circuitry as well as significant variations among the cochleae of individuals or between cochleae in an individual.

206 EFFECTS OF RADIATION AT VARIOUS PRENATAL STAGES ON DEVELOPING RAT CORTEX AND CORTICOSPINAL SYSTEM. CONSTANCE J. D'AMATO AND SAMUEL P. HICKS, Department Pathology, University of Michigan Medical Center, Ann Arbor, MI 48109

Prenatal irradiation (Xrays) causes highly reproducible patterns of malformation and disturbed function of the nervous system. The degree of malformation is the result of a balance between damage done and the capacity for repair. Highlights of some experiments with 150R were: a deficient disordered cortex and clumsy locomotion on a narrow path but ability to jump from one platform to another in offspring irradiated on the 17th prenatal day (hereafter "17th day rats", etc.); a large subcortical ectopia, thin cortex, malformed spinal cord, synchronous hopping gait, and inability to run in 14th day rats; and only slightly abnormal brain, locomotion, and jumping ability, despite severe initial damage to cerebral vesicles, in 12th day (26 pairs of somites) rats.

To better study the development of the malformed cortices, corticospinal (CS) neurons were labeled with horseradish peroxidase from their cut axons in the cervical spinal cord in infant and mature rats. In normal mature rats, CS neurons formed a caudal band corresponding to areas, 3,4,6 separated by a gap from a rostral band in area 10. These were derived from a more extensive array of CS neurons in the infant including numerous CS neurons in the gap. Gap neurons normally lost their cord projections 2 weeks after birth. If the caudal band was ablated in infancy, gap neurons kept their cord projections into adult life, a kind of plasticity. Seventeenth day rats developed CS neurons in a recognizable layer V corresponding to the caudal band and gap, but not the rostral band. Some CS neurons had bifurcated apical dendrites, the polarity of others was askew. In 14th day rats, despite disorder of early cell migrations, CS neurons developed in a layer V of the cortex, irregularly distributed in the two bands and the gap. Some CS neurons were mislaid in the ectopia, but still sent axons to the cord. Possibly the persistence of gap neuron projections was caused by too few CS neurons being produced. In mature 12th day rats, CS neurons formed the two bands and gap nearly normally, but polarity of some CS neurons was abnormal. In 12th day rats 7 or 10 days old, the normal infant gap CS neurons were present.

Undoubtedly the abnormal CS system contributed to the movement abnormalities in the 14th and 17th day rats, but in addition to other cortical abnormalities these rats had striatal and commissural deficiencies, and 14th day rats had malformed spinal cord gray matter. (USPHS NS 10531)

207 MULTIPLE UNIT RECORDING IN AUDITORY CORTEX OF CATS DURING BEHAVIOR. Dept. of Physio., Univ. of Pa., Phila., PA 19104 Stephen Evanczuk * and George Gerstein.

Previous attempts to describe functional connectivity within the auditory cortex have met with only limited success due to technical and, possibly, physiological problems. In physiological preparations involving paralyzed animals where adequate control of stimulation and recording conditions is possible, the behavioral state of the animal is usually unsatisfactory. Since it is likely that the behavioral state of the animal is related to the degree of "activation" of the cortex, it would seem to be important(particularly in a study of intracortical functional connectivity) to record from an animal in a known behavioral state.

In this study, cats are trained in a two-response operant-conditioning paradigm (J.L. Orr et. al., J. Acoustical Soc. Amer., 62(5): 1269(1977) to respond to a pair of clicks for water reward. If the pair of clicks (separated by Δt=250 msec.) emanate from two different locations on the azimuthal plane (level with the cat's ears), the cat is required to lift one forepaw for a correct choice. If the pair of clicks appear to come from a single location, the correct response is lifting the other forepaw. Ablation studies (e.g., Neff, et. al., J Neurophys. 19: 500(1956) suggest that a functioning auditory cortex is necessary for solution of this task, particularly at small angular separations of the two sound sources. Throughout the behavioral session, a masking broadband noise is presented along with various tone bursts which are used as supplementary search stimuli for recording purposes.

Neuronal activity is recorded using an implant which allows independent microdrive control of several (independent) bundles of fine wires (10 μ, tungsten, factory-insulated with epoxy, ground to a 60° conical tip). The output of each wire is connected to a differential amplifier to attenuate correlated activity (noise). Computers are used to control the behavior, the data acquisition, and the analysis of spike trains. Preliminary data are discussed.

208 SYNAPTIC REORGANIZATION IN THE ADULT NEOCORTEX. Robert E. Foster and Ford F. Ebner. Neuroscience Section, Brown University, Providence, RI 02912.

Does neocortex in adults undergo substantial synaptic reorganization after deafferentation as has been demonstrated in areas such as the septal nuclei or dentate gyrus? We have chosen layer I of neocortex to study this problem because 1)layer I consists of acellular neuropil with identifiable boundaries, 2)layer I is narrow enough to allow sampling for quantitative electron microscopy and 3)afferent axons from the dorsal thalamus terminate mainly in the outer 100μm while commissural afferents occupy the complementary inner portion of layer I. We examined layer I at various times after cutting the commissural fibers. Commissurotomy was performed in adult opossums (D. virginiana)and the animals were allowed to survive 6, 30 or 60 days. In order to test for thalamic fibers as one possible source of new synapses in layer I, thalamectomy was performed on some of the animals on survival day 30 or 60. An additional 6-day survival was allowed to produce the electron dense phase of anterograde degeneration. The aldehyde fixed brain was chopped into 500μm slabs and every third slab was saved for frozen section histology (Nissl and Fink-Heimer stains). The remaining slabs were processed for electron microscopy. We chose layer I of the preorbital cortex as our sample area since it receives a uniformly dense commissural projection deep to the input from the dorsal thalamus. Quantitative EM on layer I followed the procedures of Ebner and Colonnier (JCN, 179:263). Two results of these procedures are striking. First, the number of vesicle-containing profiles per unit area does not vary significantly from normal at 30 or 60 days after removal of the commissural fiber terminals. At these times the neuropil in the commissural input zone of layer I looks remarkably normal. Second, the thalamic fibers form a dense terminal degeneration field in the inner portion of layer I (Fink-Heimer technique) in those animals that underwent thalamectomy at the end of 30 or 60 day survival periods. This degeneration field is unlike any seen in "normal" animals after thalamectomy alone with a 6 day survival. Our results suggest that at least layer I in adult mammalian neocortex can undergo synaptic reorganization and that thalamic fibers contribute to this process. (Supported by NIH grant NS-13031 and NS 05561.)

209 DIFFERENTIAL DEPRESSANT EFFECTS OF N. RAPHE DORSALIS STIMULATION ON ELECTROCORTICAL ACTIVITY IN CATS. J. García Ramos. Physiol. Lab., Escuela Médico Militar. México 10, D. F. MEXICO.

It has been shown that N. Raphe dorsalis stimulation depresses the basal electrocortical activity, evoked potentials and strychnine spikes. Under certain conditions, however, evoked potentials and/or strychnine spikes could be enhanced over a depressed basal activity. The study of these conditions has shown that this occurred when the afferent impulses inducing the evoked potentials are relatively strong, or the direct cortical stimuli eliciting the local strychnine spikes are applied at a relatively high-rate, and when the basal electrical activity is constituted by low-voltage, high-frequency waves. The observations were made on unanesthetized curarized animals. The required basal cortical activity was obtained by constant stimulation of an afferent somatic nerve at a rate of 50 to 100 per sec, or by sound stimulation with white noise, between 60 and 80.

The cortical areas explored were the somatosensory, auditory, and an associative one such as the suprasylvian area. The obtained results were similar in all of them, thus supporting the idea that the liberated serotonin acts in a diffuse manner as a neurohumoral substance. It is suggested that a similar mechanism might be involved in the process of attention in which low relevant information would be blocked, leaving dendritic membranes in a condition under which high-value information could find priority for its processing by the brain.

210 PREFERRED TANGENTIAL ORIENTATION AND SPATIAL ORDER IN DENDRITIC FIELDS OF CAT AUDITORY CORTEX: A COMPUTER-MICROSCOPE STUDY OF GOLGI STAINED MATERIAL. E.M. Glaser, H. Van der Loos*, and M. Gissler*. Institute of Anatomy, University of Lausanne, CH1011 Lausanne, Switzerland.

Basal dendrites of pyramidal neurons and all dendrites of stellate neurons in layers IV and V of the primary auditory cortex (A1) of cat exhibit preferred orientations in the tangential plane. This was shown by means of a computer-microscope analysis of Golgi-Cox stained neurons in 100μm and 300μm thick sections. The 44 neurons we analyzed were harvested from 2 cats. The neurons were randomly selected, with the assistance of the computer, from an initial survey of 1115 stained neurons residing in optimally sectioned regions of A1. Neurons in the 300μm thick sections were studied with high power optics by means of 'obverse-reverse' computer microscopy, a technique that views a neuron from both sides of a double coverslip-section 'sandwich' (Glaser and Van der Loos, sub. for publ.) and then reassembles the acquired dendritic data by computer analysis. In this way it was possible to minimize the effects of truncation upon the dendritic trees. Only the apical dendrites of the pyramidal cells suffered truncation. Two techniques were used to represent the 3-dimensional structure of the dendrites: the 'dendritic stick' and the 'dendritic trumpet'. The former dismembers a dendrite into individual approximating chord segments of about 25μm length. The latter technique also uses approximating chord segments. In it a principal dendrite is considered as an entity and represented by its centroid, its moments about the dendrite origin, and the dispersion of its dendrites tangentially (azimuth), vertically (elevation), and radially (i.e., with respect to the neuron's soma). Both dendrite representations were examined by spatial Fourier and statistical analyses. Their results show that within the tangential plane there is a significant ($p<.05$) and consistent preferred orientation of the dendritic sticks in an approximately dorso-ventral direction (nearly perpendicular to the suprasylvian sulcus). This orientation was observed in the two cats analyzed and seems to be close to the orientations of the isofrequency contours observed by others in electrophysiologically obtained maps of this region. The dendritic trumpet analyses of pyramidal cell basal dendrites also show that they have a distinctly non-random vertical (normal to the tangential plane) distribution. Dendrites of stellate cells, on the other hand, have apparently a random vertical distribution.

211 SOME PARALIMBIC CONNECTIONS OF THE MEDIAL PULVINAR NUCLEUS IN THE MACAQUE. E. C. Gower* and M.-M. Mesulam. Neurological Unit, Beth Israel Hospital, Boston, MA 02215.

The medial pulvinar nucleus of the rhesus monkey thalamus has reciprocal connections with association cortex of the temporal lobe, inferior parietal lobule, and prefrontal cortex. Our recent observations suggest that in addition to these well known relationships, the medial pulvinar has an orderly set of connections with some medial and basal areas of the cerebral cortex: namely with the cingulate gyrus (areas LA and LC), medial frontal cortex (FL), caudal orbitofrontal cortex (13 and 14), the temporal pole (TG), and the parahippocampal gyrus (TF). These projections were investigated with cortical injections of tritiated amino acids (TAA) and horseradish peroxidase (HRP). In the present communication we will describe some connections between the pulvinar nucleus and the cingulate gyrus in the rhesus monkey.

After HRP injections in the anterior cingulate gyrus (LA), labeled perikarya were found in the medial pole of the pulvinar nucleus, a region directly caudal to the densocellular division of medialis dorsalis (MD dc). Injections of HRP or TAA in more central portions of the cingulate gyrus (at the junction of LA with LC) resulted in anterograde (TAA) or retrograde (HRP) transport of tracer into the central zone of the medial pulvinar. Furthermore, injection of TAA in the caudal cingulate gyrus (LC and retrosplenial area) resulted in the deposition of silver grain in the superficial aspect of the medial pulvinar. In each of these cases, a substantial concentration of transported label was seen in the pulvinar, even though other thalamic nuclei were also labeled, in some cases more heavily.

It is not yet entirely clear whether these connections of the pulvinar are related to specific limbic or paralimbic sectors of the cytoarchitectonically heterogeneous cingulate gyrus. However, in view of our evidence for additional connections with caudal orbitofrontal, medial frontal, temporal polar and parahippocampal areas, it is not unlikely that the medial subdivision of the pulvinar nucleus may be characterized by significant connections on the one hand with lateral sensory association cortices, and on the other with the medial paralimbic belt. These data, along with the evidence for its direct efferent projection to the lateral amygdaloid nucleus (Jones & Burton, Brain Res. 104:142, 1976) suggest that the medial pulvinar may participate in a multifaceted interaction between cortical association systems and the limbic lobe.

212 DEGENERATION ARGYROPHILIA FOLLOWING LONG-STANDING DAMAGE TO THE HUMAN BRAIN. M.R. Grafe*, R.D. Schimpff* and C.H. Leonard. Depts. of Neuroscience and Pathology, Univ. of Florida, Gainesville, FL 32610.

In the course of a long term study on the cortical connections in the human brain, we have previously reported a case in which degenerating fibers and terminal arborizations were demonstrated with modified Nauta techniques after a two year survival (Anat. Rec., 190:405-406, 1978). The appearance of the two year old degeneration was strikingly similar to that of degenerating fibers originating from a 3 week old lesion found contralaterally in the same brain. Loss of myelin was not apparent in tracts coming from either area of damage. Since modern axonal transport techniques cannot be used in the human brain, we have further investigated the effectiveness of degeneration argyrophilia as a method for studying human neuroanatomy. We report here two further cases in which extensive staining of degenerating elements is seen following long-standing damage. In the first case, contusive injury was received on the left side of the head six years prior to death. The entire temporal lobe suffered extensive damage. Degenerating fibers are seen in corticothalamic fibers to the medial geniculate, corticostriate fibers, and the stria terminalis. The second case had cerebrovascular damage which occurred 12 years prior to death, primarily affecting the right inferior parietal cortex. In the pons, the first area to be investigated, typical, well impregnated degeneration is found only in the right lateral parietopontine tract.

Light and electron microscopic examination suggests that in the human CNS little change in the appearance of degeneration occurs after the initial response to cell death. This contrasts with the peripheral nervous system where degeneration is cleared within a few weeks, or the CNS of experimental animals where degeneration is markedly reduced within a year. The extended time course of degeneration in the human CNS may be due to the nature of the lesion, the phagocytic response, or factors associated with the long human lifespan. Whatever the mechanism, the phenomenon of long-lasting degeneration argyrophilia provides a useful tool for the experimental neuroanatomist interested in the human brain. We encourage the cooperation of neurologists and pathologists who may have access to significant cases for study.

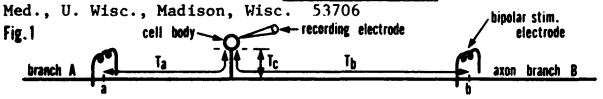
213 APPLICATION OF COLLISION TESTING TO INVESTIGATE PROPERTIES OF MULTIPLE ASSOCIATION AXONS ORIGINATING FROM SINGLE CELLS IN THE PIRIFORM CORTEX OF THE RAT. Lewis B. Haberly, Dept. Anat., Sch. Med., U. Wisc., Madison, Wisc. 53706

Fig.1



Collision between antidromic action potentials (APs) evoked at point a on axon A (fig.1) and antidromic APs evoked at point b on axon B will occur when the shock at point b follows that at point a at times $\leq$ an interval, $C_{a,b}$. The presence of collision can be detected by the failure of arrival of an AP at the soma following stimulation at point b. A collision interval $C_{b,a}$ can similarly be defined for stimulation at point b followed by point a.

If: T_a and T_b=latencies of antidromic activation of the cell body from points a and b respectively (fig.1).
T_c = conduction time in the axon proximal to the branch.
R_a and R_b = refractory periods for axon branches A and B.

Then: $C_{a,b} \simeq T_a + T_b - 2T_c + R_b$, and $C_{b,a} \simeq T_a + T_b - T_c + R_a$.

Combining equations for $C_{a,b}$ and $C_{b,a}$ reveals that:

$C_{a,b} - R_b \simeq C_{b,a} - R_a$, if separate axon collaterals of the same cell are antidromically activated as in fig. 1.

To establish that single unit recordings are obtained from cell bodies rather than axons, spontaneous or synaptically evoked APs can be collided with antidromic APs. Satisfaction of the well-known equations for such collision (within the limits of systematic error discussed by Fuller & Schlag, Br. Res., 112:283) provides strong evidence for a recording position near the soma.

Application of these methods to the piriform cortex has revealed that single cells give rise to association axons that are directed both rostrally and caudally. Three axonal branches were demonstrated for 2 units. Evaluation of T_c indicates that axonal branching occurred close to the soma in all cases (21 units).

Lesions were made at the recording sites for 13 units. The sites were located in layer IIa for 4 units, near the IIa-IIb border for 2, in layer IIb for 1, near the IIb-III border for 5, and in layer III for 1 unit. (Layers as defined by Haberly & Price, JCN 178:711). Conduction velocities (V_c) (calculated assuming straight axon trajectories) ranged from .45 to 1.25 m/sec for rostrally directed axons and .25 to .48 m/sec for caudally directed axons. For all units V_c in the rostral axon component exceeded that in the caudal. For most units T_a and T_b decreased slightly following spontaneous or evoked APs propagated in the opposite direction, indicating a possible increase in V_c.

Experiments were carried out in Dr. J.L. Price's lab, Dept. Anat. & Neurobiol., Wash U. Sch. Med., St. Louis. Supported by NIH grants #NS 09518 and NS 05612.

214 ABNORMAL SYNAPTIC CHEMISTRY IN ADULT RAT NEOCORTEX FOLLOWING PRENATAL TREATMENT WITH METHYLAZOXYMETHANOL. Michael V. Johnston* and Joseph T. Coyle. Dept. Pharmacology, Johns Hopkins Univ. School of Medicine, Baltimore, Maryland 21205.

The lateral neocortex of adult rats which had been treated prenatally on day 15 of gestation (DG) with 20 mg/kg of methylazoxymethanol (MAM), a potent nucleic acid alkylating agent, was examined with regard to the effects on presynaptic markers and postsynaptic receptors for component neurons. Treated rats gained weight normally but were microencephalic. The MAM treatment reduced the weight of the forebrain by 53% and of the lateral cortex by 67%, but the weight of the hindbrain was unaffected. Neocortical cytoarchitecture was strikingly altered; and cortical layers II and III were nearly absent.

The concentrations of the presynaptic markers for the GABAergic neurons - glutamate decarboxylase, endogenous GABA and [^{3}H]GABA uptake by P_2 fractions - were minimally altered in the MAM-treated cortex; however, the total amounts of the markers in the cortex were reduced by 60-70% ($p < .01$). The specific binding of [^{3}H]GABA to cortical membranes was similarly affected. In contrast, the concentrations of the presynaptic markers for the cholinergic neurons - choline acetyltransferase and endogenous acetylcholine - were increased 123% and 64% respectively ($p < 0.01$); however, the total amounts of these markers per cortex were depressed by 40% ($p < 0.01$). The specific binding of [^{3}H]quinuclidinyl benzilate to muscarinic receptors was reduced by 25% ($p < 0.01$) per mg cortex. The concentrations of the presynaptic markers for the noradrenergic terminals in MAM-lesioned cortex were markedly elevated with tyrosine hydroxylase activity increased by 336% ($p < 0.01$) and with [^{3}H]norepinephrine uptake by P_2 fractions and endogenous norepinephrine elevated by 130% ($p < 0.01$); however, the total amounts of the noradrenergic markers per cortex were only slightly reduced or unaffected. The specific binding of [^{3}H]dihydroalprenalol to beta-receptors was reduced by 29% per mg of cortex.

Since MAM primarily kills dividing cells, the resultant imbalance in the neurochemical markers in the adult neocortex reflects the selective vulnerability of distinct neuronal populations according to their time of mitotic activity in the fetal cortex. The cortical GABAergic neurons are severely affected whereas the cholinergic neurons are relatively spared after MAM treatment at 15 DG. The noradrenergic neurons, which cease dividing at 13 DG, appear to "hyper-innervate" the atrophic lesioned cortex although the total noradrenergic input remains comparable to control. MAM treatment is a promising tool for selectively lesioning the neocortex. (Supported by USPHS Grants MH 26654, RSDA KO2-MH 00125, and the National Foundation, McKnight Foundation).

215 DECORTICATION: WAS FLOURENS CORRECT? Bryan Kolb and Ian Q. Whishaw*. Dept. of Psychology, University of Lethbrdige, Lethbridge, Alberta, Canada, T1K 3M4.

Removal of the neocortex is known to produce a severe deterioration in the behavior of animals. The questions arise whether this can be alleviated by removing the tissue in infancy, thus allowing sparing of function or whether the effect is due to damaging some specific region.

The behavior of rats decorticated as adults was compared to that of rats decorticated at 7 days of age and to rats which received frontal lobe lesions. Following decortication the adult decorticates had severe difficulties in eating but would eat immediately after recovery from anesthesia if presented with a soft, easy to eat mash. The animals retained most of the normal movement patterns of locomotion, climbing, grooming, feeding and fighting. Nevertheless many behaviors were often not performed at the proper time and place. Thus hoarding, nest building, maternal behavior, social behavior and male sexual behavior were essentially abolished. The animals were never able to properly lick a metal water spout and were severely impaired at chaining together the components of grooming into a long behavior sequence and forepaw inhibition during swimming was abolished. The decorticate rats were also hyperactive in running wheels, but displayed good circadian rhythms and were able to develop a spatial reversal learning set in a Grice box, although considerably more slowly than controls.

Entirely removing the neocortex at 7 days of age had almost identical effects on behavior although grooming and swimming and sexual behavior were not as severely impaired. Removing the frontal lobe including the orbital frontal cortex, medial frontal cortex, and motor cortex produced the same behavioral effects as decortication whereas more posterior lesions did not. Lesions restricted to individual subfields of the frontal cortex (medial, orbital, motor) produced deficits on specific behaviors and the sum of the small lesions equalled the effect of the larger frontal lesion.

The results show that removing the neocortex in infancy does not allow sparing of function, although we have previously shown that removing the frontal cortex in infancy does. Further, the results imply that the motor deficits attributed to decortication in rats result from damage to the frontal cortex.

216 CORTICO-CORTICAL PROJECTIONS TO AREA 18 IN THE CAT: AN HRP STUDY. Lamont, P.* and M. Colonnier. Dept. Anat., Laval Univ., Quebec, P.Q., G1K 7P4.

Recent advances in HRP histochemistry (Rosene and Mesulam, J. Histochem. Cytochem., '78, 26:28) have significantly increased the sensitivity of the method and have permitted a better visualization of both retrograde and anterograde transport of the enzyme. This has led us to study the type and distribution of cortical cells projecting to small discrete patches of area 18.

0.1 to 0.25 ul of HRP was injected in area 18 of adult cats anaesthetized with fluothane. After a 24 to 40 hour survival period, the animals were perfused according to the protocol of Rosene and Mesulam. Frozen sections were cut at 50u and the HRP revealed with benzidine dihydrochloride.

Labelled axons can be followed from the injection site to ipsilateral areas 17 and 19, and to the contralateral area 18. HRP labelling is also seen in the Clare-Bishop area. In each of these zones, labelled cell bodies are seen, as well as a fine granular stippling of the background which is interpreted as being located in the terminal branching of axons after anterograde transport from cells in area 18, or along recurrent collaterals of the retrogradely labelled cells. Both labelled cells and terminal arborizations appear in clusters or columns which are quite strictly superimposed.

In area 17, both pyramidal and stellate cells are labelled. The pyramids are especially numerous in layers II and III but are also seen in IVA, V and VI. The many large stellates are concentrated in layer IVA. Fine anterograde labelling is practically absent from IVB, and densest in IVA and the lowest part of III. A prominent tangential plexus is seen in layer I. In area 19, labelled pyramidal cells are seen in layers II, III, V and VI but are much fewer in number. Fine anterograde labelling is virtually absent from layer VI, is most intense in IV, and only a few scattered grains are present in I. In the contralateral area 18, pyramidal cells are numerous but restricted to layers II and III. Discrete anterograde grains are nearly absent in V, and reach their maximum concentration in the upper part of IV and the lower part of III. Only isolated grains are seen in layers II and I.

The clusters or columns of cells are especially well-defined in area 17. The centers of the clusters are separated by intervals averaging about 0.5mm on transverse section, but which can average either 0.5 or 1.0mm in an antero-posterior direction, depending on the preparation. Even after small injections they extend over an area of at least 4 x 4mm (approximately 30 to 60 clusters). They contain numerous pyramids and stellates in the center of this area, but become smaller and consist only of a few pyramids more peripherally. The periodicity suggests that they relate to ocular dominance columns. Supported by MRC.

217 TEMPORAL PATTERN DETECTION IS NOT A FUNCTION OF ASSOCIATION CORTEX IN GENERAL. B.S. Layton,* A.W. Toga,* and S. Horenstein (SPON: R.G. Karis). Saint Louis University, Saint Louis, Missouri 63104.

The insular-temporal cortex (I-T) of the cat has been shown by anatomical or physiological methods to be multimodal, receiving auditory, visual and somatosensory projections as well as others from the posterior thalamic nuclear group, themselves multimodal. Colavita (Physiol & Behav, 18: 513-521, 1977) has shown that bilateral ablation of I-T results in inability to relearn a response to changes in temporal patterns of the form A-B-A to B-A-B independent of modality. This defect appears to be irreversible and does not occur after removal of large areas of primary sensory cortex (Colavita, 1977). The temporal pattern detection deficit cannot be explained simply as the result of indiscriminate loss of cortical tissue. It has not yet been established, however, whether loss of any heteromodal association cortex other than I-T might produce such a deficit. This investigation addresses the question of whether temporal pattern perception depends on the integrity of association cortex in general. The experimental design required the cat to detect changes in temporal patterns following bilateral symmetrical suprasylvian gyrus ablation. Adult cats were trained in a double-grill-box shock avoidance situation to detect a change in a continuous auditory temporal pattern from either soft-loud-soft to loud-soft-loud or the reverse. Each tone was 800 Hz and of about 900 msec duration. The tones were separated by about 100 msec of silence and the trials by 2000 msecs. The loud tone averaged 83 dB SPL and the soft 60 dB SPL. After achieving criterion performance of 18/20 correct detections on 2 successive days, large parts of the cortex of the suprasylvian gyrus were removed bilaterally in a single sitting. After a 2 week recovery period the animals were returned to the training situation and regained criterion level performance without delay. These results were compared to the performance of our own serially lesioned I-T cats and Colavita's simultaneously lesioned animals. The I-T cats showed no recovery of temporal pattern detection after weeks of postoperative training. Failure of suprasylvian gyrus ablation to interfere with this capacity demonstrates that temporal pattern perception is not a general function of association cortex. It appears somehow linked to the cells within the I-T region. The answer to the question of whether any other area of association cortex is similarly involved demands further research.

218 A NORADRENERGIC PROJECTION TO THE BARREL HOLLOWS OF MOUSE SOMATOSENSORY CORTEX.

Hart G.W. Lidov, Frank L. Rice, and Mark E. Molliver. Departments of Cell Biology/Anatomy and Neurology, The Johns Hopkins University School of Medicine, Baltimore, Md. 21205. U.S.A.

The noradrenergic (NA) innervation of mouse SI cortex was studied using the glyoxylic acid histofluorescence method, with particular attention to the distribution of NA fibers within the barrel field, a tangentially discontinuous specialization of layer IV. The demonstration of a NA projection to layer IV has been hampered by the difficulty in identifying cytoarchitectural features with fluorescence microscopy. This difficulty is obviated in rodent SI where the barrel field provides an unequivocal, in situ, marker for layer IV.

NA axons densely arborize in layers I,IV, deep V, and VI; the intervening layers have a markedly sparser innervation. The barrels are delineated by a striking autofluorescence restricted to the barrel hollows. Within the barrel hollows there are dense, ramifying nests of NA axons. The walls, in contrast, contain few fluorescent fibers. The barrel hollow is the principle site of interaction between thalamocortical (TC) afferents and the dendrites of stellate cells. The cohabitation of NA and TC afferents in the barrel hollows suggests that these two systems are intimately associated and may even share post-synaptic elements. The existence of functional noradrenergic innervation is supported by ultrastructural histochemical studies from our laboratory demonstrating numerous monoaminergic synapses in layer IV of young mouse cortex.

We find that in mouse SI cortex each of the zones that receives afferents from the thalamus - layers I,VI, the deep half of layer V, and the barrel hollows, subdivisions of layer IV - is also densely innervated by NA axons. We propose that the selective association between TC and NA afferents may be a general feature of cortical organization. Functionally, the postulated "regulatory" role of the NA system may occur at the level of the thalamic input to the cortex. (Support: USPHS NS-08153, NS-10920; H.G.W.L. supported by Training Grant GM-7309; F.L.R. supported by NIH Grant RR-5338 and fellowship NS-05790)

219 OXYGEN DISAPPEARANCE RATES IN THE GERBIL CORTEX UNDER HYPERBARIA.

Richard M. Martin*, James H. Halsey*, Daniel D. Reneau*. (SPON: P. E. Coyer). Dept. Neur., Univ. Ala. Med. Ctr., UAB, Birmingham, AL 35294, Dept. Biomed. Eng., Louisiana Tech Univ., Ruston, LA 71270.

Oxygen disappearance rates were measured in the cerebral cortex of barbiturate-anesthetized Mongolian gerbils subjected to bilateral carotid ligation while breathing 100% oxygen at various levels of hyperbaria. The rates of disappearance were seen to be a linear function of initial tissue pO_2 below that of hemoglobin saturation but at higher values (pO_2 > 130) became pO_2 independent. These results are in agreement with those predictions made by the mathematical modeling of tissue oxygen consumption presented by Reneau (JAICE 15: 916, 1969) i.e., at lower pO_2 the desaturation of hemoglobin produces a slower rate of disappearance, but as more oxygen can be drawn from dissolved oxygen in tissue fluid as would be the case under hyperbaria, the rates of disappearance should be constant depending solely on the metabolic rate.

From the slopes of the oxygen disappearance curves, the metabolic rates were calculated by means of the mathematical modeling of Reneau. Since the measurements were made via an oxygen microelectrode with tip diameter of 1 μm, these measurements represent very focal metabolic activity. These metabolic rates were found to be depressed after chronic exposure to hyperbaria as would be expected from a possible toxic effect induced by long-term exposure to a pure oxygen atmosphere.

220 Identification Of Cerebral Cortical Afferent Terminals In The Pontine Nuclei Of The Rat Using Golgi, Electron Microscopic And Combined Golgi-Electron Microscopic Procedures.

Gregory A. Mihailoff Dept. Cell Biology, Univ. Texas Hlth. Sci. Ctr., Dallas, Texas 75235.

The massive input to the basilar pontine nuclei (BPN) from nearly all regions of the cerebral cortex has been reported with only relatively minor phylogenetic differences in a wide variety of mammals ranging from opossum to macaque monkey. Two recent publications from our laboratory have extended these earlier observations and demonstrated with autoradiographic procedures the pattern of organization in the projections to the pontine nuclei from sensorimotor (Brain Res. 145: 347-354) and visual (Brain Res. 143: 139-146) cortices in the rat. This information is significant in its own right but also provides a foundation for electron microscopic studies designed to clarify from a structural frame of reference the role played by such afferents in the overall synaptic organization of the BPN.

Two general categories of neurons have been described in the rat BPN processed according to routine rapid Golgi or Golgi-Kopsch protocols. These categories include 1) a local circuit neuron and 2) projection type neurons with axons coursing into the cerebellum via the brachium pontis. The latter category may include at least two sub-types, those with relatively spine-free dendrites (aspiney) and those exhibiting numerous spines along with a variety of other somal or dendritic protrusions (spiney cells). It was the intent of this study to focus on the spiney projection neurons and describe the morphological features of their synaptic interaction with cerebral cortical afferents.

Subsequent to unilateral decortication, two types of degenerating axon terminals were observed. One group was small (up to 1.3 μm), consistently contacted small dendritic or spinous profiles and exhibited all the typical features of electron dense degeneration. The other group was larger on the average (up to 2.2 μm), contacted both small and intermediate-sized dendrites and exhibited an initial lucent or filamentous reaction prior to becoming electron dense. When lesions were confined to sensorimotor cortex, primarily small dark boutons were observed while lesions restricted to visual cortices produced mainly the filamentous type of degenerating terminals. These findings suggest that at least two populations of cortical axons project to the pontine nuclei. Furthermore, when animals were processed according to combined Golgi-EM procedures, isolated spiney relay cells were contacted by both filamentous and dark boutons suggesting a convergence of these two cortical afferent systems.

221 A LIGHT AND ELECTRON MICROSCOPIC STUDY OF LAYER I OF CAT PRIMARY VISUAL CORTEX AND ITS THALAMIC AFFERENTS.

John W. Miller, MB. Tank Buschmann and Louis A. Benevento. Department of Anatomy, College of Medicine, University of Illinois Medical Center, Chicago, Illinois 60612.

It is now known that primary visual cortex (area 17) receives input from more than one thalamic nucleus (Brain Res. 96:51,1975). We wished to expand on these findings in the cat by comparing cortical layers of termination and the ultrastructure of synaptic endings made by these thalamic regions. For light microscopy tritiated amino acids were iontophoretically or mechanically deposited in the dorsal lateral geniculate body (LGB) and the posterior thalamus. Layers I and VI of area 17 receive projections from the posterior nucleus (PN) and the pulvinar-lateral posterior nucleus (LP). However, layer IV and lower layer III receive input only from the LGB, corraborating numerous past studies. We further found that the extrageniculate projection to area 17 is visuotopically organized and reciprocal with the visuotopic organization of striatothalamic projections. The extrageniculate input to layer I is heavier than that to layer VI and was the focus of the electron microscopic studies. The ultrastructure of layer I shows a definite pattern in its composition. Adjacent to the pial surface is an organized astrocytic lamella of variable thickness made up of thick processes containing parallel glial filament bundles, microtubules, glycogen granules and mitochondria. Beneath the astrocytic lamella is an axonal plexus made up of both heavily and thinly myelinated axons. Proximal to the plexus is the general neuropil which forms the rest of layer I. The neuropil contains glial cell bodies but rarely a neuron. Its main composition includes numerous glial processes, a sparse number of scattered thinly myelinated axons, numerous dendrites and some unmyelinated axons. Occasionally the dendrites are seen with varicosities. Synaptic endings are seen throughout the layer extending from within the myelinated plexus to layer II. Apparently, they are exclusively of the asymmetrical type which contain round vesicles. The majority are small and end on dendritic elements which frequently contain a spine apparatus. However, there are also large boutons and it is not uncommon for boutons of any size to end on a dendritic trunk. We did not observe en passant contacts. Lesions were made of the thalamus with electrodes introduced through the opposite hemisphere. After lesions of the LGB some of the moderately to heavily myelinated axons found in the superficial plexus were degenerated. In contrast, after lesions of the posterior thalamus (which spared the LGB) the scattered, poorly myelinated axonal population was the one which degenerated. In these latter cases it was the small boutons in deeper layer I which showed evidence of degeneration.

222 IN VIVO STUDIES OF HYPOXIA ON CEREBRAL MITOCHONDRIAL NADH REDOX STATE AND EEG. Michael H. Mitnick, Dept. Physiology & Div. Neurosurgery, Sch. Med., Univ. of Pa. Phila., Pa. 19104

Using a television system microfluorometer suitable for in vivo studies, the effects of one to two minutes of hypoxia were noted for the intramitochondrial respiratory co-enzyme NADH and correlated with the EEG reaction to hypoxia. Optical monitoring of cortical areas was recorded on video tape for subsequent play back and data analysis, thus affording the opportunity to study the effect of the same hypoxic period on different geographic areas of cortex as well as the same spot over repeated hypoxic insults.

The results revealed three definite patterns of the brain's response to hypoxia. First, the NADH redox state response was heterogeneous both qualitatively and quantitatively over the surface of the cortex. Second, the NADH response was noted in almost all cases to differ, again both qualitatively and quantitatively, in the same field, with respect to the number of hypoxic exposures. Thus, as a consequence of the second or third hypoxic period, all showing similar blood gas changes, the NADH reduction was not constant. Lastly, the time from the introduction of hypoxia until the first discernable alteration of EEG Activity was noted decreased with subsequent hypoxic periods. For example, the second hypoxia, with identical blood gas changes to the first hypoxia, caused the EEG to begin to falter from 12% to 62% faster than the first hypoxic period.

The geographic heterogeneity might be reasonably expected as a result of various areas functional differences, cellular composition differences, regional variations of metabolic rate, etc. However the diversity of metabolic response with respect to the number of hypoxic periods and the apparent degenerate nature of the EEG response to hypoxia suggests the possibility of either a Delivery Lesion, where blood O_2 does not effectively reestablish transport to the mitochondria, or else a utilization lesion, where although intracellular Po_2 might be returned to control values, the bioenergetic machinery and/or ionic transport systems are unable to effectively function. These hypothesis are currently under study using the intracellular O_2 probe pyrenebutyric acid (PBA).

223 DEGENERATION OF THE COERULEO-CORTICAL PROJECTION: ORGANIZATION AND IMMUNOHISTOCHEMICAL CHARACTERISTICS. J. H. Morrison, M. E. Molliver & R. Grzanna* Dept. of Cell Biology & Anatomy, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Immunofluorescent (IFL) staining using a homologous antiserum directed against rat dopamine-ß-hydroxylase (DBH) demonstrated an abundant noradrenergic (NA) innervation in all areas of neocortex. The distribution of NA axons is characterized by a geometric orderliness that exhibits a predominantly tangential organization*. We have utilized a variety of lesions to analyze this projection and to demonstrate more definitively the specificity of the IFL staining. The most frequently employed controls for IFL specificity (e.g., omission, absorption or replacement of the primary antiserum) do not exclude the possibility that the antiserum may cross-react with tissue proteins other than the specific antigen. In order to show that the antiserum is a specific marker for NA neurons, it is necessary to demonstrate the absence of staining following selective and complete destruction of the ascending NA projection. Hence, we have made a series of bilateral electrolytic lesions of the dorsal NA bundle in the midbrain and a series of bilateral microinjections of 6-hydroxydopamine (6-OHDA) at the identical site; brains from both groups were analyzed by means of glyoxylic acid induced histofluorescence (GAIF) or with DBH IFL. Both types of lesion resulted in a complete or nearly complete loss of GAIF in NA axons throughout the cortex; notably, dopamine axons in anterior cingulate cortex remain brightly fluorescent, indicating the high sensitivity of this method. Five weeks after electrolytic lesions, the IFL method reveals a pattern of DBH-immunoreactive axons identical to that seen in unlesioned rats. In striking contrast, 6-OHDA lesions result in complete disappearance of DBH-positive axons throughout the cortex, a result which demonstrates conclusively the specificity of the antiserum for NA axons. Electrolytic lesions demonstrate the persistence of immunoreactive (but enzymatically inactive) DBH in axons which appear morphologically intact although mechanically severed from their cell body. The loss of immunoreactivity following the 6-OHDA lesion suggests that the axonal degeneration may depend on anterograde transport of this neurotoxin. These results indicate potential pitfalls in the interpretation of IFL stains following lesions. For example, it has been necessary to utilize GAIF to demonstrate the interruption of NA axons following coronal cuts of the dorsal neocortex. Initial results reveal a drastic reduction in NA fibers in all cortical layers caudal to the lesion and support our proposition that the NA projection takes a tangential course through the grey matter. Consequently focal cortical lesions may result in noradrenergic denervation of distant cortical areas. (Support: USPHS grants NS-08153 & NS-10920).

224 HEMISPHERIC SPECIALIZATION OF FACIAL RECOGNITION IN MAN BUT NOT IN MACAQUE. William H. Overman, Jr. and Robert W. Doty. Center for Brain Research, University of Rochester, Rochester, N.Y.14642

Among the various assymmetric functions of the human cerebral hemispheres one of the best documented is the superior ability of the right hemisphere for processing pictures of faces. One test requires the subjects to compare an unaltered photograph of a face with two composites of the same face which consist of the right half of the face plus its mirror image and the left half of the face and its mirror image. When asked to choose a composite which looks most like the unaltered face, normal right handed subjects on 70% of the trials choose the composite made from the right side of the face. This composite consists of features which fall primarily in the left visual field (LVF) when the normal face is viewed. Lesions of the right but not of the left hemisphere reduce the LVF bias to chance levels (Kolb, Milner and Taylor, in press, 1978). Twenty human subjects and six monkeys (Macaca nemestrina) were given this split-face test of facial recognition. The human subjects received 38 split-face comparisons (28 human faces and 10 monkey faces) in one test session while the monkey subjects received the identical split-face test trials at 3/day interspersed among 30 simultaneous matching to sample (SMS) trials which used human or monkey faces as stimuli. When viewing these photographs of monkey faces, both monkey and human subjects had a LVF bias no greater than chance (52% and 54%). However, when viewing human faces, the monkey subjects again showed no significant LVF bias (53%) while the human subjects had a LVF bias of 68%. This difference between man and monkey is statistically significant, $p < .01$. Two additional experiments indicated that monkeys perceive and react to projected colored photographs of faces as real faces. Monkeys displayed species-typical reactions to pictures of human and monkey faces but not to equally complex, non-facial stimuli. Inversion of the stimuli on a SMS task dramatically reduced recognizability of facial stimuli but not other classes of stimuli. Together these findings indicate that both monkey and human subjects perceive and react to photographs of faces in a similar manner but that man processes facial stimuli preferentially with one cerebral hemisphere while the macaque apparently uses either or both hemispheres.

225 THREE DIMENSIONAL ANALYSIS OF THE BRANCHING CHARACTERISTICS OF GOLGI IMPREGNATED PYRAMIDAL NEURONS IN THE HIPPOCAMPUS OF HUMAN IMMATURE BRAIN. Albert M. Paldino and Dominick P. Purpura. Dept. Neuroscience, Albert Einstein College of Medicine, Rose F. Kennedy Center for Research in Mental Retardation and Human Development, Bronx, New York 10461.

A unique version of the computer microscope has been utilized to obtain three dimensional coordinate information of fiber networks from Golgi impregnated neurons. A microscope-closed circuit TV system, and its associated electronics, was interfaced to an Interdata 7/32 minicomputer to provide an arbitrary code and the X-Y-Z coordinates of preselected topological sites on the fiber network. A dynamic representation of the evolving fiber network was presented to a Tektronix graphics terminal to assist the operator during the data input phase and also in the detection of any asymmetries inherent in the fiber network. To date, twenty five pyramidal neurons from the hippocampus of an 18 to 20-week-old human fetus (natural abortion) were measured and analysed according to their axonal and dendritic branching characteristics. Polar angle and H-distributions of axonal and dendritic terminals were obtained. These distributions suggest, in part, that 1) the large majority of axonal terminals end at a level below (within 100 µm) their respective soma locations; 2) no dominant polar angle exists for dendritic terminals; and 3) most dendritic terminals are confined to a level within 100 µm above their respective cell body locations. Also, radial and cylindrical radius distributions for these terminals indicate that most axonal and dendritic terminals are confined to lie within a sphere whose radius is approximately 120 µm and which is centered at the cell body. Branching angle distributions were obtained which suggest that the average branching angle for both axons (75^o) and dendrites (72^o) were approximately equal. Finally, fission angle distributions indicate that the average fission angle (that angle formed between two daughter segments at a bifurcation) for both axons (87^o) and dendrites (88^o) were also approximately equal. It has been shown that this system is capable of generating computer tracings from the three dimensional coordinate data which, compared to the corresponding camera lucida drawings, possess a high degree of accuracy. Furthermore, any orthogonal projection of the neuronal network can be obtained. Additional studies involving progressively more developed neurons from older fetuses and infants will be discussed. The data that will be obtained bear on the quantitative analysis of neuronal branching patterns in conditions associated with cases of (profound) mental retardation having a developmental and/or chromosomal substrate.

226 ASSOCIATIVE FUNCTION OF THE ARCUATE ZONE IN THE MONKEYS' PREFRONTAL CORTEX. Linda Z. Podbros* and John S. Stamm, Dept. Psychol., SUNY, Stony Brook, NY 11794.

Functional dissociations have been identified among distinct zones within the monkey's dorsolateral prefrontal cortex (e.g., Goldman et al., Exp. Neurology (1970), 27, 291-304; Stamm, J.S., Neuropsychologia (1973) 11, 181-190). Ablations of cortex in the arcuate sulcus (ARC) have resulted in severe deficits on an auditory conditional position response (CPR) task. The present experiment is concerned with ARC functions on a CPR with visual cues and with differing spatial cue-response contingencies. Seven Macaques were trained in a Wisconsin Test Apparatus that contained a dark vertical testing panel and two food boxes recessed within the left and right walls of the compartment. Two task variations were used: for vertical CPR, the cue (white light) was presented at the top or bottom of the panel, with reward in the left or right box, respectively; while for horizontal CPR, the cue at the left or right side of the panel indicated reward in the opposite direction. Bilateral ablations were made to either the arcuate sulcus (ARC), the principal sulcus (PRIN) or to cortex inferior to the principal sulcus (IDL). With a multiple-stage procedure a total of 15 ablations were applied. Post-operative training to the criterion of 85 correct responses in 100 trials showed substantial performance deficits only after ARC lesions. The means of total errors for both tasks were: 137 for the ARC, 22 for the PRIN, and 45 for the IDL group. The deficits were significantly greater for the ARC than either of the other groups. Also, greater ARC deficits were found for the vertical than for the horizontal CPR. These findings support the unique role of arcuate cortex in the mediation of spatial-response contingencies in tasks where the cue is located in a direction different from that of the instrumental response, regardless of the modality of the cue. It is suggested that the proprioceptive stimuli elicited by the monkey's orientation to the cue serve as guidance for the appropriate instrumental response; and this associative process is disrupted by ARC lesions.

227 MEMBRANE PROPERTIES OF IDENTIFIED HUMAN CORTICAL NEURONS. D.A. Prince, R.K.S. Wong and A.I. Basbaum, Dept. of Neurology, Stanford University School of Medicine and Dept. of Anatomy, UCSF School of Medicine.

The use of the in vitro brain slice technique, together with intracellular labelling with horseradish peroxidase has allowed us to begin to examine the membrane properties of identified human neocortical neurons. Eighteen high quality stable intracellular recordings were obtained from slices of neocortical biopsies in 3 patients. In all cases removal of normal cortex was required to approach a remote lesion. Three neurons showed short duration action potentials (< 1 msec) and a steep increase in firing rate with increasing depolarizing current. One of these cells was labelled with HRP and appeared to be a spiny stellate interneuron. Fifteen neurons showed long duration spikes (> 1 msec); 4 of these were labelled and appeared to be pyramidal in type. The passive properties of 4 labelled pyramidal type neurons were as follows; membrane potential (Vm) 67.5 mV (64-70 mV); input resistance (R_{in}) 39MΩ (30-50 MΩ); time constant 36.7 msec (25-55 msec). Fourteen of the 15 cells with >1 msec duration spikes showed subthreshold nonlinear membrane properties which were both voltage and time dependent. During hyperpolarizing pulses V_m reached a maximum in 20 msec and then "sagged" to a less polarized level. During depolarizing current pulses there was an apparent increase in R_{in} which began about 20 milliseconds after the onset of depolarization. Such anomalous rectification has not been previously described in neocortex. Nine of 15 neurons in this group generated depolarizing afterpotentials (DAPs) following single spikes. DAPs could be evoked by 2 millisecond current pulses in some cells and reached a maximum amplitude of 10 millivolts, with durations of up to 20 milliseconds. These potentials disappeared when V_m was shifted in a depolarizing direction. In 3 instances DAPs appeared to be responsible for generation of a second spike during threshold depolarizations or the rebound from hyperpolarizing current pulses. Trains of evoked spikes were frequently followed by afterhyperpolarizations and increased conductance lasting as long as 1 sec. One neuron from the cortex of a two year old generated high threshold tetrodotoxin resistant spikes during depolarizing pulses. These properties of human cortical neurons are entirely similar to those described in a variety of other species. The presence of anomalous rectification, depolarizing afterpotentials, and post activation hyperpolarizations suggests a possible role of calcium conductances in the control of activity in these cells. The neocortical slice preparation will prove useful for further studies of differences in properties of pyramidal type cells and interneurons. Supported by NIH Grants NSO6477, NS12151, NS11614, and DA01949.

228 THALAMIC PROJECTIONS TO AREAS 5 AND 7 OF PARIETAL CORTEX IN THE CAT. Richard T. Robertson, Department of Anatomy, College of Medicine, University of California, Irvine, CA. 92717

Projections from the thalamus to areas 5 and 7 of parietal cortex were studied in cats by the method of retrograde transport of horseradish peroxidase (HRP). Visually guided unilateral or bilateral injections of 50 - 100 nl of 40% HRP in water or saline were placed 0.5 - 1.0 mm below the pial surface. Following survival times of 1 - 3 days, animals were sacrificed by perfusion with 0.5% paraformaldehyde and 1% glutaraldehyde. Standard histochemical processing using benzidine dihydrochloride as the chromagen demonstrated both retrograde labelling of cell bodies and anterograde labelling of axon terminals. HRP reacted and adjacent unreacted sections were counterstained with neutral red to identify the precise injection site and the thalamic nuclei containing retrogradely labelled cells.

Cortical area 5a, situated in the banks of the ansate sulcus and extending onto the anterior suprasylvian gyrus, receives prominent projections from the medial division of the posterior group of nuclei (Pom). Less prominent projections originate in ventral parts of the lateral posterior nucleus (LP) and the central lateral nucleus (CL). A very few labelled cells were observed in the ventral lateral nucleus (VL) and paracentral nucleus (PC). Cortical area 5b, situated just caudally to area 5a, receives a major projection from the rostral and ventral parts of LP. Additional, but substantially less impressive, projections originate in CL, VL, and Pom. The ventral anterior nucleus (VA) sends a light projection to area 5b on the suprasylvian gyrus, but not the marginal gyrus.

Cortical area 7, lying just caudally to area 5b, receives prominent projections from LP and the rostral pulvinar (Pul). In addition, retrograde labelling indicates light projections from CL, PC, and the ventral lateral part of the lateral dorsal nucleus (LD). VA projects lightly to area 7 of the suprasylvian gyrus, but not the marginal gyrus.

Supported by NSF grants BNS 76-08523 and 77-23361, and NIH grant NS 14267.

229 DIFFERENTIAL BEHAVIORAL EFFECTS OF RIGHT VS LEFT CEREBRAL INFARCTION: EVIDENCE FOR CEREBRAL LATERALIZATION IN THE RAT. R. G. Robinson Johns Hopkins University School of Medicine, Baltimore, Md. 21205.

Right middle cerebral artery ligation in the rat leads to a transient period of spontaneous horizontal hyperactivity as measured in a photocell chamber (Nature 255:332, 1975). We have reported that this hyperactivity can be blocked by post-operative treatment with the norepinephrine (NE) uptake blocker desmethylimipramine or by preoperative destruction of catecholaminergic neurons with 6-hydroxydopamine (Biol.Psychiat. 12:669,1977) and that there is a transient decrease in the number of fluorescent varicosities in widespread areas of brain during this hyperactive period (Brain Res.132:259,1977). The current experiments were carried out using cages which allowed free access to food, water and a running wheel. Following right middle cerebral artery ligation (N=14) as compared with sham operated control animals, there was a transient increase in the number of revolutions per 24 hours of the running wheel. If the animals were postoperatively placed in these cages as a novel environment, the hyperactivity was evident by one day after cerebral infarction and lasted 10 days, while if the animals were allowed previous access to the cages before cerebral infarction, activity did not exceed preoperative control levels until 10 days after infarction. Animals undergoing left middle cerebral artery infarction (N=18) did not show any of these changes in spontaneous activity regardless of whether they were exposed to the running wheels as a novel or a familiar environment. Gross and histological observation of the infarcted brains revealed that left middle cerebral artery ligation generally resulted in a slightly larger infarct (but still limited to frontoparietal cortex) than did right middle cerebral artery ligation, but that when comparable sized lesions were obtained, animals with left hemispheric infarcts were not any more active than sham operated controls. There were no significant differences in food or water intake between animals with right or left hemispheric infarcts. We are currently investigating whether these behavioral differences are the result of differential effects of cerebral infarction on catecholaminergic neurons on the two sides of the brain.

230 UNIT ACTIVITY IN THE VENTRAL PREFRONTAL REGION OF MONKEYS PERFORMING IN VISUAL AND SPATIAL DELAYED REACTION TASKS. Carl E. Rosenkilde and Joaquin M. Fuster. Brain Research Inst. and Department of Psychiatry, UCLA, Los Angeles, CA 90024.

Extracellular unit activity was recorded with microelectrodes from the ventral prefrontal region in two rhesus monkeys performing in delayed matching to sample (DM) and spatial delayed response (DR). At the start of a trial a cue light was projected on a single translucent response key. In DM, the light was green or red, and centrally located; in DR, it was white and located on the right or left. A press on the key by the animal extinguished the light and initiated a delay lasting 6 to 10 sec. After the delay, two keys were illuminated for choice. Choice of the key whose color (DM) or position (DR) matched that of the cue resulted in delivery of juice into the animal's mouth. The intertrial intervals were 40 sec. Sixty-two of 101 units were held long enough to obtain data for both tasks and were analyzed off-line with a PDP-12 computer.

Changes of firing frequency in 85 cells were related to task events. The most common changes were observed in 82 cells at onset or offset of the cue. Half of these cells showed differences in discharge dependent on the color or position of the cue. Altered activity during the delay was observed in 51 units, 41 of which showed differential firing in relation to characteristics of the (no longer present) stimuli. Some units showed inhibition or no change in firing during the delay of trials with incorrect choice, whereas they had exhibited activation of firing during delays of correct trials. Forty-three cells changed discharge rate in the post-trial period; typically this change began 0 to 4 sec after the choice. Analysis of firing after errors and after gratuitous delivery of juice showed that post-trial activity was dependent on reward in some but not all cells. Most cells showed altered activity in several phases of the trials and differential responses in at least one phase. A typical cell would display inhibition at cue offset, excitation throughout the delay after a specific cue, and reactivation in all post-trial periods.

These results indicate the involvement of the prefrontal region in visual analysis and reaffirm the importance of this area in delayed reaction behavior. The post-trial activity may serve to represent information on the reinforcing effects of the instrumental choice, or to erase mnemonic consequences from discharge during the delays. (Supported by NSF grant BNS 76-16984 and the Danish Medical Research Council.)

231 CONVERGENCE OF VISUAL- AND SOMATIC SENSORY-RELATED CORTICAL PATHWAYS IN THE LOWER BANK OF THE INTRAPARIETAL SULCUS OF THE RHESUS MONKEY. Benjamin Seltzer* and Deepak N. Pandya, V. A. Hospital, Bedford, MA 01730 and Harvard Neurological Unit, Beth Israel Hospital, Boston, MA 02215

In the course of an architectonic study of the parietal lobe of the rhesus monkey, a distinct architectonic zone has been identified in the lower bank of the intraparietal sulcus. This region is situated caudal to area 2 but rostral to area 19. In terms of both cyto- and myeloarchitecture, it differs from neighboring zones, notably area 7 (PG) of the inferior parietal lobule. Characterized by a broad, but cell-sparse, third layer with prominent IIIc cells, this sulcal zone has relatively lightly populated fourth, fifth, and sixth layers. At more caudal levels, however, the lateral portion is more densely cellular. With regard to myelination, this zone has clearly defined inner and outer bands of Baillarger, as well as a dense plexus of vertically-oriented fibers deep to the inner band.

An analysis of cortico-cortical connections, studied by both autoradiographic and silver impregnation techniques, demonstrates a specific pattern of projections to this architectonic region. Thus, it is the recipient of a major projection from visual-related cortex of the peristriate belt, especially the lateral surface of the preoccipital gyrus. It also receives afferents from parietal cortex, but only from a small area in the rostral inferior parietal lobule (area PF of Bonin and Bailey), a region which itself receives input from the lower sector of somatic sensory cortex (head, neck and face representations) in the postcentral gyrus.

The lower bank of the intraparietal sulcus thus receives converging input from both visual- and somatic sensory-related cortical areas. Furthermore, since the rostral inferior parietal lobule also receives vestibular input (Frederickson et al., 1966), this suggests a possible functional role for the intraparietal sulcus in the integration of kinesthetic input from head, face and neck with vestibular and visual information.

232 GOLGI-COX IMPREGNATED BARREL NEURONS IN THE RAT SmI CORTEX. D.J. Simons* and T.A. Woolsey. (SPON: M.A. Fishman). Dept. of Anat. and Neurobiol., Washington U. Med. Sch., St. Louis, MO 63110.

Layer IV of SmI neocortex in rodents is characterized by discrete cellular aggregates called "barrels". Each barrel is related in a one-to-one fashion to a single vibrissa on the contralateral face. A previous Golgi study of mouse cortex demonstrated that two major classes of cells can be distinguished according to a number of morphological criteria. Since there are differences in the cytoarchitectonic appearance of the barrels in rat and mouse, we wanted to compare the two species with respect to neuronal morphology. In addition, we were interested in determining how these data compared with physiological studies. The brains of adult rats were prepared by the Golgi-Cox technique and counterstained with a Nissl stain so that the barrels could be visualized. Thick sections (125 μm) were cut in coronal or tangential planes. The principal results are: 1.) As in mouse, two classes of cells can be distinguished; class I cells have spinous dendrites where as the dendrites of class II cells are smooth with beads. The somata of class II neurons are quantitatively larger than those of class I. 2.) The majority (about 80%) of cells of both classes have their dendrites restricted to the barrel in which their somata are located. The remainder of cells distribute their dendrites to two or more barrels and most of these neurons have their somata located in the septa between barrels. In mouse 85% of cells have their dendrites restricted to a single barrel. 3.) In our present material it appears that there are fewer smooth cells than spiny ones. These cells are found in equal number in the mouse. The data indicate a marked similarity among neurons in homologous cortical regions in two different species, the mouse and the rat. Further, the results in the rat are consistent with our physiological studies which show that in layer IV two types of units can be distinguished on the basis of bioelectric properties and that in layer IV a majority of units of both types respond to deflection of single whiskers only.

233 CORTICAL PROJECTIONS OF THE LATERAL DORSAL NUCLEUS IN THE RAT. T. Spiro, L.C. Massopust, and P.A. Young. Dept. Anat., St. Louis Univ. Sch. Med., St. Louis, MO 63104.

Many studies have shown that the cingulate and subicular cortices project to the lateral dorsal nucleus (LD) of the thalamus. However, reciprocal connections have not been described. Therefore, the cortical connections of the LD were studied using autoradiography. Discrete amounts (0.4 μl) of 3H-leucine (50 μCi/μl New England Nuclear) were injected at separate anterior and posterior locations in the LD. From both locations labeled axons emerged laterally from the thalamus, passed through the superior thalamic radiation, and entered the caudate-putamen complex. Once within the caudate-putamen complex a number of labeled fibers coursed rostrally and terminated in layers I and III of areas 23 and 24 in the ipsilateral anterior cingulate cortex. The remainder passed dorsally where they entered the fasciculus cinguli and projected to the ipsilateral posterior cingulate and subicular cortices. Terminations were observed in areas 29b and 29c of the posterior cingulate cortex. Within area 29b, silver grains were arranged in layers I and III at its border with area 29c. In the anteriorly injected animals, area 29c exhibited an input to layers I, III, and IV at the lip of the hemisphere. After injections in the posterior part of the LD, a stronger distribution was observed within the same laminae at the border of 29b and c. Projections were also observed in the lamina dissecans and externa of the pre- and parasubiculum. These results show that the LD has strong reciprocal connections with the anterior and posterior parts of the cingulate gyrus and the subicular cortex.

234 EPd INFLUENCES VISUALLY DIRECTED BEHAVIOR. A.W. Toga,* B.S. Layton,* S. Horenstein, and D.G. Davenport.* Saint Louis University, Saint Louis, Missouri 63104.

Unilateral ablation of the entire ectosylvian region has been shown to result in specific changes in the pattern of visual choice on double simultaneous bilateral stimulation (DSS). This region has been shown to project to the homologous contralateral as well as the adjacent suprasylvian cortex. The goals of this study were to explore the relative influence of each component of the ectosylvian region on visually directed behavior and to consider the proposition that biased behavioral preference reflects hemisphere imbalance which can be altered toward normal by a contralateral lesion.

Eleven adult female cats responded to visual stimulation by entering either of two alleys of an automated equiangular Y-maze. Correct responses were rewarded by food. The subjects were trained to choose the illuminated alley when only one was lighted, but could select either compartment when both were lighted. The latter condition was DSS and presented randomly 20% of the time. Most animals demonstrated a hemiplane of response preference, the other side being referred to as subordinate. After preoperative learning and testing, one or more portions of either the ectosylvian region or the suprasylvian gyrus on the subordinate side was ablated. The postoperative performance on the same task was recorded after a suitable period of recovery. Then one or another portion of the contralateral ectosylvian or suprasylvian region was removed and the animal retested.

When a subject with unilateral cerebral damage responded at preoperative levels to single stimuli but changed its benavior upon DSS, it was regarded as having met the operational criterion for lateralized visual neglect.

In ten cases the lesions were confined to the intended regions and did not penetrate the optic radiations. In the eleventh, the second lesion extended into the deep white matter of the hemisphere resulting in an apparently hemianopic animal.

Within the temporal lobe, only lesions which included the posterior ectosylvian gyrus resulted in unilateral visual neglect. Further, if subsequent to its production the contralateral homologous cortex was ablated, the degree of neglect lessened and task behavior approached that of the original state. The functional mechanism thus appeared to seek equilibrium as the brain was restored to structural balance. This study then contributes to understanding of the role of the EPd cortex as an area involved in the regulation of visual behavior. Since it also receives projection from A_1A_{11} and the auditory thalamus, it may play a role in auditory-visual association.

235 EXCITABILITY CHANGES IN CORTICAL NEURONS FOLLOWING SLOW FREQUENCY ANTIDROMIC AND ORTHODROMIC ACTIVATION. E. Tzebelikos* and C.D. Woody. (SPON: E. Eldred) UCLA Med. Center, Los Angeles, CA. 90024

Effects of antidromic and orthodromic activation on the excitability of 63 neurons of the coronal pericruciate cortex were studied in awake cats. Both types of activation were accomplished by stimulating the pes pedunculi bilaterally with bipolar concentric electrodes (stereotaxic coord.: F 3.5, L 4.0, H 4.5) while recording intracellularly from the cortical unit. Single square pulses of 0.2 msec duration and 5 to 25V intensity were delivered at frequencies of 4-6/sec. The stimulation ordinarily produced facial movements such as eyeblink or nose twitch. Cortical cells were classified as antidromically responding if the spike latency measured at the peak amplitude of the induced discharge varied less than 0.05 msec. The cell was considered to be orthodromically responsive if otherwise activated. Other criteria for identifying antidromic discharge such as rates of following were not used because the procedures could have influenced unit excitability.

Unit excitability was measured separately as the threshold level of intracellularly injected current required for spike initiation (rectangular depolarizing pulses of 10 msec duration delivered at 100 msec intervals through the intracellular recording electrode). At least four such measurements were made during the period of stimulation of the pes pedunculi. When all measurements were consistently below or above the threshold initially measured for the cell, the excitability was considered increased or decreased, respectively. Neurons were studied for periods of 5 to 15 minutes. The resting potentials averaged 46+15mV. Mean threshold before stimulation was 0.64+0.20nA. The antidromic group included 28 neurons. In 9 of these cells excitability remained unchanged (0.69+0.27nA), in 11 it decreased (0.98+0.33nA), and in 8 it increased (0.32+0.20nA) during the stimulation period. In the orthodromic group (35 cells), 18 cells showed increased excitability (0.35+0.26nV) during the stimulation period, 5 decreased (0.92 +0.34), while 12 showed no appreciable change (0.70+0.30nA). 30 cells with resting potentials averaging 45+14mV, that were neither antidromically or orthodromically activated by the pes pedunculi stimulation formed a control group. Their mean threshold before stimulation was 0.65+0.34nA. During the period of the pes pedunculi stimulation this mean was 0.67+0.33nA. The effect on neural excitability of antidromic activation differed significantly from that of orthodromic activation (P = 0.02, Chi Square).

These direct observations of altered neuronal excitability compliment the assertion of Bindman et al. (J. Physiol. 1976) that high frequency antidromic activation of the pyramidal tract results primarily in decreased cortical excitability. Supp. by BNS 76-06886.

236 PROJECTIONS FROM THE ANTERIOR ECTOSYLVIAN GYRUS TO THE PERIRHINAL CORTEX. K. Yamaguchi and S. Horenstein. Saint Louis University, Saint Louis, Missouri 63104.

Projections from the anterior ectosylvian gyrus which have been commonly regarded as part of the secondary somatosensory system were studied by means of Fink Heimer, autoradiographic, and horse radish peroxidase methods. That the region was part of the somatosensory cortex was assured as previously described projections from it to the walls of the cruciate sulcus and sigmoid gyri (motor cortex), posterior sigmoid and coronal gyri (somatosensory I) and the suprasylvian sulcus were identified. Projections to the lateral wall of the posterior rhinal sulcus were found in each animal. We were unable to find an account of them in available literature. This projection appears to be direct and is represented within the perirhinal regions by a compact bundle of degenerating fibers stained by the Fink Heimer method which is found in the white matter deep to that part of the cortex which forms the lateral bank of the rhinal sulcus. It is distributed in columnar fashion, the fibers of termination appearing in the 2nd, 3rd, and molecular layers. Those in the third appear most dense. The course of this projection from the anterior ectosylvian lesion could not be traced. On autoradiography, grains were arranged in a columnar fashion in the superficial three layers of the cortex of the posterior rhinal sulcus, but were most dense in the third. Their cells of termination could not be identified. Injection of horse radish peroxidase into various perirhinal sites by stereotactic placement disclosed that only when the lateral bank of the posterior rhinal sulcus was injected at the plane of the posterior suprasylvian sulcus were cells of the anterior ectosylvian region filled with the reaction product. The cells of origin of the ectosylvian-rhinal projection appeared to be medium sized third layer and rare fifth layer pyramidal cells. We have found no studies describing the efferent projections of the lateral bank of the posterior rhinal sulcus of the cat. A similar region in the monkey is believed to have reciprocal connections with the entorhinal area (area 28). It would appear, therefore, that the secondary somatosensory cortex of the anterior ectosylvian gyrus has direct projections to the perirhinal cortex which may constitute a means of entry from it to the limbic system independent of other putative projections. Their functional significance is not currently known.

237 HISTOPATHOLOGY OF ELECTRICAL STIMULATION OF BRAIN: THE ROLE OF CHARGE DENSITY. Ted G.H.Yuen*, William F.Agnew, Leo A.Bullara* Deane B.Jacques, Robert H. Pudenz*. Neurological Research Laboratory, Huntington Inst.of Appl. Med. Res. Pasadena,CA 91105.

This report is a continuation of studies on the histopathological effects of chronic electrical stimulation of cat cerebral cortex surface using platinum and rhodium electrodes. The work comprises a part of a Neural Prosthesis Program whose ultimate aim is to develop techniques for supplementing or replacing lost function in persons with varied neurological deficits.

In previous brain stimulation experiments neural damage was assessed with respect to the relative significance of charge per phase (Q/ph), charge density per phase (QD/ph) and current density per phase (J/ph) when varied in 16 separate combinations. Although neural damage thresholds for 36 hour surface stimulations were roughly estimated, histological evaluation indicated a need for more definitive correlation between the extent of damage and responsible electrical parameters.

In the present study the relationship of QD/ph to neural damage has been investigated using surface stimulation of the parietal cortex of cats. Light and electron microscope studies were carried out on electrode sites of animals stimulated over a QD/ph range of 10 to 300 $\mu C/cm^2/ph$ for 36 hour (9 hr./day) stimulations. QD/ph variations were achieved by altering the electrode size (1.1 to 3.6 mm dia.) or Q(0.1 to 3.0 $\mu C/ph$). The neural damage threshold was observed at a QD/ph of approximately 20. Seizure activity appeared to be a function of numbers of neurons activated, i.e., when induced by using combinations of electrode size and QD/ph. For example, severe generalized seizures were observed with electrode sizes of 3.6 mm dia. (QD/ph 10) or 1.1 mm dia. (QD/ph 50-300) but were not observed with 1.1 mm dia. electrodes at QD/ph of 20 or 30. Work to date indicates that QD/ph-hours is the most closely correlatable parameter relative to neural damage.

Cerebrovascular permeability increases as indicated by Evans blue dye and horseradish peroxidase extravasation were generally limited to leptomeningeal vasculature even with the highest stimulation parameters. Histological changes were restricted to tissue 1-3 mm subjacent to stimulated electrodes and progressed in severity from mild to irreversible over a QD/ph range of 30 to 300. Ultrastructural alterations included increased sub-pial glycogen, astrocytic hypertrophy, and dendritic degeneration. With higher stimulations intracellular lipid and calcium hydroxyapatite crystals were present in degenerating neurons, astrocytes, axons and dendrites accompanied by marked phagocytic activity. Supported by Contract #NO1-NS-02275. Laboratory of Neural Control, NINCDS, NIH, Bethesda, MD.

238 FRONTAL LESIONS IN THE FERRET: CHANGES IN SPATIAL ALTERNATION AND ACTIVITY LEVEL. Yvette Zatz*, Ausma Rabe, R.K.Haddad, Ruth Dumas*, M.H.Lee* and H. Wisniewski*. New York State Institute for Basic Research in Mental Retardation, 1050 Forest Hill Road, Staten Island, N.Y. 10314.

Ferrets with bilateral frontal lesions were tested for spatial alternation in a T-maze and activity in an open field, both before and after surgery. Preoperatively, using a massed trials procedure, the ferrets were trained to alternate left and right turns in the maze to a criterion of 8 correct choices in 10 trials on two consecutive days. They were allowed a few laps of milk as a reward for correct choices. The open field measure of activity, the number of squares crossed, was taken for 5 minutes daily for 3 consecutive days. Dorsolateral frontal lesions were produced by aspiration (n=10). For the sham-operated control group (n=9) the skull was opened to expose the frontal cortex, but no tissue was removed. After recovery from surgery, all subjects were retrained following the same procedures.

The frontal ferrets were markedly impaired in their spatial alternation performance and were hyperactive in the open field. In the T-maze, the frontal ferrets made more errors postoperatively than preoperatively ($p < .001$) and also made more errors than the sham-operated controls ($p < .0001$). In the open field, the frontal ferrets were more active postoperatively than preoperatively ($p < .02$) and they were more active than the sham-operated controls ($p < .01$).

Enhanced activity level is a well established consequence of frontal lesions in cats and monkeys (e.g., Warren and Akert,eds: The frontal Granular Cortex and Behavior, 1964), as are deficits in spatial and alternation learning (e.g., see Markowitsch and Pritzel, Psychol. Bull., 1977, 34, 817-837, for data on rats, cats, and monkeys). The deficit in spatial alternation and the enhanced level in activity which we have demonstrated in the ferret with frontal lesions are thus consistent with the findings on frontal lobe function in other animals.

CHEMICAL SENSES

239 CHARACTERIZATION OF RECEPTOR SITES FOR INTRAVASCULAR TASTE IN FROGS. Peter A. Balnave* (SPON: J.H. Teeter). Monell Chemical Senses Center, U. of Pa., Philadelphia, PA 19104.

Intracellular recordings from taste receptor cells and nerve recordings from the lingual nerve indicate that those receptor sites which give rise to intravascular taste obey the same physicochemical laws as those at the apical surface of the taste cell. The response of the taste cell to intravascular stimulation is primarily dependent on the capillary permeability of the stimulus and the clearance of the stimulus from the extracellular space. The permeability of the capillary wall may be radically increased by using a non-oxygenated perfusate (Landis, Am J Physiol 83:528,1928). By restricting percutaneous O_2 absorption and by using non-oxygenated perfusates, intracellular recordings to NaCl, LiCl, NH_4Cl, $CaCl_2$, CH_3COOH, quinine-HCl, sucrose and saccharin were obtained. Tentative evidence suggests that the taste response profile of a receptor cell as determined by stimulus flow over the surface of the tongue is similar to that determined by intravascular stimulation. Recordings from the lingual nerve to successive pulses of intravascular stimuli quickly adapt out (Bradley, Am J Physiol 224:300,1973); however, electrical stimulation of the hypoglossal nerve which causes fasiculation of tongue muscles brings back approximately 30% of the maximum normalized response (n=4) while massage of the tongue brings back approximately 50% of the maximum normalized response (n=6). It is suggested that muscular movement may help clear the extracellular fluid space in the tongue in a manner analagous to the formation of lymph (McMaster, Ann N Y Acad Sci 46:743,1946). The complete adaptation of receptor sites to successive intravascular stimuli may be explained by the short time course of receptor adaptation (Sato,Brain Res 34:385,1971; Smith, Neurosci Abstracts 248,1977) compared to the much longer clearance time of extracellular space. Stimulus interaction with intravascular taste receptor sites is constrained by access to and clearance from the extracellular fluid space, when these parameters are manipulated the intravascular receptor sites seem to follow those equations developed by Beidler (J Gen Physiol 38:133,1954) to characterize the apical taste receptor sites.

240 GUSTATORY RESPONSES TO WATER. Linda M. Bartoshuk, Marion K. Frank* and Carl Pfaffmann. Pierce Foundation and Yale Univ., New Haven, CT 06519 and Rockefeller Univ., New York, NY 10021.

The effects of water on gustatory receptors were studied in 248 single fibers from the chorda tympani nerves of rat, cat, hamster, and squirrel monkey as well as the glossopharyngeal nerve of rat. Neural responses to water were contingent on the nature of the preceding or adapting solution. That is, a particular fiber did not respond to water per se but rather responded to water following NaCl or water following HCl, etc. Four adaptation solutions were tested on each fiber: NaCl, sucrose, HCl, and QHCl (quinine hydrochloride). Sixty fibers responded to water following only one of the adapting solutions, 19 fibers responded following two, 4 fibers responded following three, and 1 fiber responded to water following all four adapting solutions.

The NaCl adapting solution is of special interest because saliva contains NaCl. Twenty eight fibers responded to water following NaCl. The proportion of these fibers varied across species and nerves.

Responses to water following NaCl were very sensitive to the adapting concentration of NaCl. Although such fibers were maximally responsive to water, they were also responsive to NaCl concentrations lower than the adapting concentration. For example, if the tongue was adapted to .3 M NaCl, then .03 M NaCl produced a "water" response. This suggests that removal of NaCl is the event required for stimulation of this response.

Fibers responsive to water following NaCl also tended to be responsive to QHCl in species and/or nerves sensitive to QHCl. This suggests that water following NaCl tastes like QHCl in these cases. That is, water may take on particular taste qualities because the neural signal it generates mimics the input normally produced by conventional taste stimuli.

The most dramatic correlation of responses to QHCl and water following NaCl in the present data occurred in glossopharyngeal fibers innervating circumvallate papillae in the rat. This suggests that water should taste like QHCl to the rat adapted to the NaCl in its saliva. Behavioral data (Morrison, G.R., Canad. J. Psychol. 21: 141-152, 1967) support this conclusion.

241 CENTRAL DISTRIBUTION OF CRANIAL NERVES V, VII, IX, AND X IN THE MONKEY. R. M. Beckstead and R. Norgren. Rockefeller Univ., New York, NY 10021.

The central distribution of primary afferent fibers in the trigeminal (V), facial (VII), glossopharyngeal (IX), and vagal (X) cranial nerves have been re-examined with the autoradiographic fiber-tracing method. Fiber-labeling in the principal and spinal nuclei of the trigeminus after subtotal injections of ^{3}H-proline in various parts of the trigeminal ganglion confirms earlier classical descriptions and further suggests that the trigeminal fibers which enter the ventrolateral portion of the nucleus of the solitary tract (NST) originate from cells in the ophthalmic segment of the ganglion.

Injection of the geniculate ganglion labels fibers of the VIIth nerve which both ascend and descend upon reaching NST. The ascending fibers distribute in a compact and circumscribed zone immediately dorsal to the spinal V nucleus as far rostral as the caudal pole of the principal trigeminal nucleus. The descending fibers distribute to the lateral NST rostral to the level at which the roots of the vagus join the solitary tract. For a short distance caudal to this level, sparse labeling is present only in a small part of NST which lies ventrolateral to the solitary tract and appears to correspond to the zone of NST which receives direct trigeminal afferents. No labeled fibers could be traced to the contralateral NST. A few labeled fibers of VII descend in the dorsomedial sector of the spinal V tract to distribute sparsely in the dorsomedial part of the spinal V nucleus and in a restricted zone in the lateral margin of the cuneate nucleus.

Fiber-labeling after injections of the ganglia of nerves IX and X suggest the following. Although, upon reaching the solitary tract, a few fibers in either IX or X ascend as far rostrally as had those of nerve VII, both have a much larger descending component which distributes to more posterior levels of NST. Many of the IXth nerve fibers appear to terminate in the lateral part of NST and the dorsolateral margin of the medial part. Only a few travel as far caudal as the commissural part of NST. Fibers of vagal origin, on the other hand, are abundant in the medial and commissural parts of NST. Moreover, only X appears to have a crossed projection in the commissural nucleus and caudal portion of the contralateral NST. Some of the vagal fibers in the commissural part of NST continue into the nucleus of the posterior commissure in upper cervical segments of the spinal cord. A few fibers of the vagus also appear to enter the area postrema. A significant descending component of IX and X in the spinal V tract is present only when the superior ganglion of either nerve is involved by the ^{3}H-proline deposit.

Supported by NSF grant BNS 76-81408 and NIMH grant 15125.

242 ACUTE OLFACTORY SENSITIVITY OF SOCKEYE SALMON TO CALCIUM IONS AND ITS SIGNIFICANCE FOR MIGRATIONS. David Bodznick* (SPON: J. Palka). Dept. Zool., Univ. Washington, Seattle, WA 98195

The ability to discriminate between natural fresh waters based on their odorant characteristics is essential for the homing migrations of adult Pacific Salmon (Oncorhynchus) and the lakeward migrations of sockeye salmon fry (O. nerka). Both physiological and behavioral experiments with sockeye salmon indicate that the calcium ions found in natural waters may be useful odorants for these discriminations.

The absolute concentrations of the major cations and anions in natural waters vary greatly among water sources and depend on the characteristics of the particular watershed. Of these ions, olfactory stimulation with calcium and only calcium elicited gross potential (olfactory EEG) responses from the olfactory bulbs of sockeye at concentrations below the natural water range. Responses were reliably observed to 5×10^{-6}M $CaCl_2$ and most animals responded differentially to calcium concentrations throughout this natural water range. In addition, both mitral cells and granule layer cells of the olfactory bulbs responded to $CaCl_2$ at concentrations as low as 10^{-6}M. Responses in each case were ion-specific and not a result of changes in total ionic concentration or osmotic pressure.

Behavioral tests of preference in a 2-choice Y-maze showed that unconditioned fish would discriminate between 2 water sources that differed only in calcium concentration.

It is proposed that salmon recognize individual natural waters not by a unique odorant in each water but rather by the characteristic combination of odorant qualities present, and that the calcium concentration is one of these identifying odorant qualities.

243 ADAPTATION AND CROSS ADAPTATION OF THE PERIPHERAL OLFACTORY AND GUSTATORY SYSTEMS OF THE CATFISH TO AMINO ACIDS. John Caprio and Jesse J. Robinson*. Dept. of Zoology and Physiology, Louisiana State University, Baton Rouge, LA 70803.

Olfactory and gustatory systems of the channel catfish, Ictalurus punctatus, are highly sensitive to L-α-amino acids (Caprio, J. Nature 266:850, 1977). With continuous amino acid stimulation, the phasic gustatory neural response of the facial nerve is quickly adapting, whereas both olfactory neural and EOG responses exhibit a phasic response followed by a slowly declining tonic response level. Both systems also respond less to the second of two applications of an amino acid stimulus. The amount of reduction of the response to the test stimulus and the recovery of excitability depend on the relative efficacy, concentration and duration of the adapting stimulus, and the duration of the interstimulus interval (rinse time). However, the relationship between percent recovery of the response and rinse time is linear with a variable slope dependent upon the above factors.

In cross adaptation experiments, a continuously applied adapting solution of L-alanine (10^{-5}-10^{-4}M), the most effective taste stimulus, eliminates the taste responses to the other L-amino acids except L-arginine at tested concentrations up to and including 10^{-3}M. Conversely, L-arginine used as an adapting stimulus has minimal effect on the ordering of relative effectiveness of the other amino acids tested at 10^{-5} to 10^{-3}M. These and unit data (Caprio, J. and D. Tucker, Soc. Neurosci. 2:152, 1976) suggest that the peripheral facial taste system of the channel catfish is composed of taste cells containing primarily arginine specific binding sites which are innervated by arginine-best taste neurons. Other taste cells innervated by alanine-best taste fibers contain primarily alanine sites, but also have binding sites for other amino acids.

Olfactory cross adaptation experiments have shown that any of the more effective amino acids used as adapting stimuli will depress to varying degrees but not abolish the responses to the other amino acids. Presently, there is no evidence of specific olfactory receptors analogous to the arginine-best taste cells. (Supported in part by NIH Biomedical Research Support Grant S07 RR07039-06 awarded to LSU and a Summer Faculty Research Grant, both allocated by the Council on Research.)

244 AN EXTENDED OLFACTORY SENSITIVE PERIOD IN RATS. Catherine Cornwell-Jones. Dept. Psych., Princeton Univ., Princeton, N.J., 08540.

Three days of differential olfactory exposure before, but not after sexual maturation, influenced the odor preferences of Sprague-Dawley rats. Three days before testing, animals were placed in either cedar or pine shavings in isolated olfactory environments. On the fourth day, rats were given two odor preference tests in an apparatus which allowed animals to smell but not taste or touch stimulus shavings.

Pine-housed neonates 11 days old and juveniles 32 days old preferred the odor of fresh pine to fresh cedar shavings. Housing in cedar induced a preference for cedar odor in pups and tolerance in juveniles. Exposure did not influence scores of sexually mature males 66 days old on cedar vs. pine.

Cedar-exposed neonates showed a statistically greater preference than pine-housed pups for the odor of cedar nest shavings in which rats had been housed against fresh pine odor. Cedar-exposed juveniles and adults also preferred cedar nest to pine odor, but their averages did not differ significantly from pine-exposed averages. Thus, exposure induced differences in neonatal responses on both odor choices, and in juveniles responses on fresh cedar vs. pine, but failed to significantly influence adult responses to either set of odors.

A comparison of averages across age groups indicated that preference scores of cedar- but not pine-exposed rats changed significantly with age. The decline in the effects of olfactory experience therefore reflects a change with age in the behavior of cedar- but not pine-exposed rats.

Receptor adaptation cannot account for most of the differences observed. Exposure-induced receptor fatigue would have reduced, rather than increased preference for cedar nest odor in pups, and resulted in tolerance rather than preference for natural cedar odor. Habituation to familiar odors could explain the exposure-induced tolerance of juveniles for natural cedar odor, but not their preference for cedar nest odor. The data therefore implicate changes in central rather than peripheral neural substrates.

245 ROUTES AND TERMINATION PATTERNS OF THE CENTRIFUGAL AFFERENTS TO THE MAIN OLFACTORY BULB FROM THE RETROBULBAR AREA AND PIRIFORM CORTEX IN THE HAMSTER. Barry J. Davis, Foteos Macrides and William M. Youngs. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

The routes and termination patterns of projections to the main olfactory bulb (MOB) from the anterior olfactory nucleus (AON), hippocampal rudiment (HR) and piriform cortex (PC) were studied in the hamster with the autoradiographic technique. Injections of tritiated amino acids centered in pars externa of the AON revealed a heavy projection to the contralateral MOB via the bulbar limb of the anterior commissure (AC). These afferents were found to terminate most heavily in the superficial half of the granule cell layer (GRL), producing a ring of autoradiographic grains around the circumference of the GRL. Injections in the more caudal subdivisions of the AON revealed bilateral projections to the MOB via the AC. The AON fibers passed ventromedially from the AC to enter the caudal part of the MOB, and dorsally around the accessory olfactory bulb to enter the more anterior part of the MOB. Striking differences were seen in the termination patterns of the centrifugal projections from variods subdivisions of the AON. Injections in the lateral or caudal peduncle involving primarily pars lateralis, pars ventralis or pars posterior produced a heavy terminal pattern of grains bilaterally over the superficial half of the GRL, whereas the heaviest terminal labelling after injections centered in pars medialis was seen bilaterally over the deep half of the GRL. Injections in pars lateralis also revealed heavy terminations in the periglomerular region of the ipsilateral MOB. Such terminations were found bilaterally only after injections which involved pars posterior and pars ventralis. Injections in the HR and PC revealed projections to the ipsilateral MOB. The HR fibers traveled diffusely in the medial and dorsal sectors of the peduncle, entered directly into the GRL at caudal levels of the MOB, and coursed around the accessory olfactory bulb into the anterior part of the MOB. Like the projection from pars medialis of the AON, the centrifugal projection from the HR was found to terminate predominantly in the deep half of the GRL. The centrifugal projection arising in the PC was found to reach the MOB primarily via the AC and to a lesser extent via the deep portion of the lateral olfactory tract (LOT). The LOT component coursed ventrally and dorsolaterally into the MOB. The routes into the MOB taken by the AC component paralleled those taken by the projections from the AON. Anterior PC injections produced heavy terminal labelling over the superficial half of the GRL whereas the posterior PC appeared to terminate preferentially in the deep half of the GRL. These findings suggest that various subdivisions of the AON, the HR and the PC exert direct but heterogeneous influences on MOB function. (Supported by grants BNS75-07652 and NS12344)

246 DISTRIBUTION OF CANDIDATE TRANSMITTER AMINO ACIDS IN THE PIRIFORM CORTEX AS AFFECTED BY TRANSECTION OF THE LATERAL OLFACTORY TRACT. D.A. Godfrey, C.D. Ross, J.A. Carter*. Dept. Pharmacol. and Dept. Anat. and Neurobiol., Wash. U. Sch. Med., St. Louis, MO. 63110

Quantitative histochemical mapping procedures have been applied to study the distribution of GABA, glycine, glutamate and aspartate in the olfactory system of male Sprague-Dawley rats. In four rats, lesions (knife cuts made by Dr. Joseph L. Price, Dept. Anat. and Neurobiol., Wash. U. Sch. Med.) transected the lateral olfactory tract (LOT) just behind the olfactory bulb on the right side. The distributions in the piriform cortex of GABA, glutamate and aspartate were examined seven days later. (Glycine levels were too low to warrant detailed study.) The results are summarized in the table, with amino acid levels in mmoles/kg dry wt, mean ± SEM for the four rats:

Region	Control side	Lesion side
	GABA	
LOT	4.7±0.5	4.8±1.0
Layer IA	13.1±0.8	13.7±1.4
Layer IB	16.0±1.5	16.4±2.3
Layer II	17.6±0.6	16.2±1.8
Layer III	16.8±0.7	14.4±1.3
	Glutamate	
LOT	21±1	7±1
Layer IA	48±2	30±3
Layer IB	61±2	53±2
Layer II	66±2	62±2
Layer III	57±2	56±1
	Aspartate	
LOT	4.8±0.6	1.8±0.3
Layer IA	12.2±1.0	7.3±0.3
Layer IB	15.6±0.8	12.7±1.0
Layer II	16.1±0.7	14.2±0.8
Layer III	14.3±0.1	12.8±0.7

Both glutamate and aspartate levels were significantly reduced in the LOT, which contains the axons projecting to the cortex from the olfactory bulb (65% decrease), and in layer IA of the piriform cortex, which contains the terminals of these axons (40% decrease). These results support the possibility that glutamate and aspartate are preferentially associated with mitral and/or tufted cell projections to the piriform cortex.

247 AFFERENT SOMA POPULATIONS WITHIN THE GENICULATE GANGLION. Maximo M. Gomez. Dept. Anat., Bowman Gray Sch. Med., Winston-Salem, NC

This study was designed to distinguish specific subpopulations of geniculate ganglion (GG) soma that project via facial nerve branches on the basis of number, location and cytoarchitecture. One each of the greater superficial petrosal (GSP), chorda tympani (CT) and distal VIIth nerves was cut and desheathed in separate rats. The GSP was cut at its exit from the petrotympanic fissure, the CT was cut in the infratemporal fossa and all of the distal VIIth nerve was cut at the stylomastoid foramen. Dry flakes of horseradish peroxidase (HRP)were allowed to dissolve in tissue fluid surrounding the central stumps of cut nerves and reapplied every 6-8 hours over a total incubation period of 18-24 hours. After fixation, the GG were removed, reacted en bloc with diaminobenzidine (or Hanker-Yates reagent) and H_2O_2, and serially sectioned in Parlodion at 20um. All soma in each GG were counted and classified as either HRP positive or negative. Incubation of the GSP in three rats resulted in the labeling of a mean of 365±18 (S.E.) cell bodies which is 20% of the mean total of 1787±82 soma. Labeled cells are primarily located towards the apex of the GG, near the origin of the GSP, with a few cells scattered throughout the entire GG; nearly all are 15-25um in cross-sectional diameter with a few in the 30-40um range. CT incubation yields a mean of 506±35 HRP positive soma (N=3) or 28% of the 1799±80 GG cells. These cells are mostly located at the medial margin of the GG, along the base of the GG adjacent to the VIIth nerve, with some cells throughout the GG. The diameter of CT cells is similar to that of GSP soma with a few more large cells labeled. Distal VIIth nerve incubation labels an average of 838±56 (N=2) or 44% of the 1899±52 GG soma. They are located along the lateral side of the GG near the VIIth nerve. Labeled cells are scattered in the GG, including a small accumulation of cells well out along the GSP and some cells in the nervus intermedius. Combined percentages of HRP positive cells thus accounts for 92% of GG soma. Although from these data the tongue appears to receive a heavier gustatory innervation than the palate, the near total bilateral overlap of GSP fibers in the palate results in an equivalent density of innervation for the lingual and palatine fields. The GSP, however, contains 4.5 times more sensory fibers than labeled soma while the number of CT sensory fibers is about equal to the cells labeled from CT incubation. The excess of fibers over labeled soma in the GSP series may be due to axonal branching or to the presence of non-GG fibers elevating the GSP sensory fiber count. The above data also defines the number of potential information channels available for peripheral sensory coding and central input from the palatine and lingual gustatory fields.

248 Effect of Intranasal Irrigation of Mitotic Inhibitors on Olfactory Behavior and Biochemistry in Mice. J. W. Harding and J. W. Wright* Washington State University, Pullman, WA 99164.

Mice were intranasally irrigated daily with 100 microliters of normal saline, hydroxyurea (10 mM), and ethidium bromide (2 mm), or weekly with colchicine (1 mm). The mice which were pretrained to find buried food pellets (45 mg) or amyl acetate (5 λ of 1:40,000) scented sugar cubes, were tested daily in order to monitor olfactory mediated behavior. Both colchicine and ethidium bromide had dramatic effects on behavior - by day 6, none of the colchicine treated animals were capable of finding amyl acetate sugar cubes; by day 8, 20% or less of the ethidium bromide treated animals could find buried food pellets or sugar cubes. There was no change in the performance of the saline animals while the hydroxyurea animals exhibited only a modest and temporary decline in olfactory capabilities. Following 21 days of treatment the experiment was terminated. The behavioral results for the different experimental groups corresponded well with both bulb weights (saline - 94.2% of untreated control; colchicine - 59.5%; ethidium bromide - 63.2%; and the hydroxyurea - 95.9%) and the levels of the chemoreceptor neuronal marker, carnosine synthatase, (saline, bulb - 99.6% untreated control; epithelium - 97.6%; colchicine, bulb - 9.9%, epithelium - 3.4%; ethidium bromide, bulb - 7.6%, epithelium - 4.5%, hydroxyurea, bulb - 104.0%; epithelium - 108.0%). Additionally, the in vitro measurement of ^{3}H-thymidine incorporation showed a significant decrease in total incorporation by olfactory epithelium for all inhibitors tested. (colchicine - 69% of control; ethidium bromide 46%, and hydroxyurea 48%). Together the above results suggest that a functional mitotic process is necessary for continuous olfactory capabilities and the maintenance of stable population of chemoreceptor neurons.

249 UNIT ACTIVITY IN THE IPSILATERAL AND CONTRALATERAL OLFACTORY PATHWAY IN THE PIGEON. Larry V. Hutchison and Bernice M. Wenzel. Dept. Physiol., UCLA Sch. Med., Los Angeles, CA 90024.

Continuing neurophysiological study of central projections of the olfactory bulb (OB) in the pigeon has confirmed and extended identification of higher-order ipsilateral projection areas, viz., caudal neostriatum (NC), hippocampus (Hp), parahippocampal area (AHP), and the dorsomedial thalamus, both anterior (DMA) and posterior (DMP) subdivisions. Stimulation of one olfactory nerve (ON), after section of the contralateral ON, with 8-12 v pulses (single or train), 0.5-1.0 ms duration, at 0.1-1.0 Hz resulted in evoked responses with properties characteristic of polysynaptic connections and in significant modification of spontaneous unit activity (± 25% change in rate). The majority of affected units in NC, DMA, and DMP were enhanced by stimulation, while a smaller number of cells showed depression. All cells recorded to date in Hp and AHP showed enhancement.

A Fink-Heimer study of OB projections had shown degenerating fibers passing through the anterior commissure (ca) to the contralateral forebrain. Degeneration patterns showed that major direct OB efferents terminate in the contralateral parolfactory lobe (LPO), nucleus accumbens (Ac), and components of the paleostriatal complex, viz., paleostriatum primitivum (PP), paleostriatum augmentatum (PA), and the intrapeduncular nucleus (INP). Our pilot electrophysiological work had provided confirmatory evidence of paleostriatal connections. More extensive confirmatory data can now be reported from the study of unit activity in various contralateral sites. Response properties characteristic of monosynaptic stimulation were recorded in PP, PA, and LPO. Unit activity in PA was enhanced by contralateral ON stimulation, whereas units in LPO generally showed depression, results consistent with our previous findings in the same structures ipsilaterally. Cell populations in PP near the ca, which previous work had shown to be consistently inhibited by ipsilateral ON stimulation, showed only excitation during contralateral ON stimulation. Peak firing rates at a constant latency, consistent with the peak latency of the evoked potential recorded through the same electrode, have been observed in those areas where analysis has been completed. Tetanic stimulation of contralateral ON (20Hz-20sec) typically produced prolonged posttetanic changes in unit activity in projection sites.

Also confirmatory of anatomical findings, results to date show that contralateral ON stimulation enhances firing rates of cells in ventral hyperstriatum and AHP. (Supported by USPHS grant NS 10353 to B.M. Wenzel and NINCDS postdoctoral fellowship NS 05896 to L.V. Hutchison).

250 GUSTATORY DISTRIBUTION OF THE RAT GLOSSOPHARYNGEAL NERVE. Jerry W. Lawson. Dept. of Anatomy, Bowman Gray Sch. of Medicine of Wake Forest University, Winston-Salem, NC 27103.

It is known from degeneration experiments that the glossopharyngeal nerve innervates taste buds in the circumvallate and foliate papillae of the rat. Summated electrophysiological responses from the rat glossopharyngeal nerve indicate a greater sensitivity to quinine, a higher threshold for NaCl, as well as a longer latency to response onset and maximum. Zotterman has asserted that quinine sensitivity is a property of small diameter gustatory afferents, so a study of the rat glossopharyngeal was undertaken to determine the distribution of axon diameters. Male, Sprague-Dawley rats were perfused intravascularly with Karnovsky's glutaraldehyde-paraformaldehyde fixative and the glossopharyngeal nerves were dissected unilaterally on each animal and sectioned at the emergence from the posterior lacerated foramen. The nerves were post-fixed in osmium, dehydrated, embedded in epon and sectioned for electron microscopy. Montages of photomicrographs of nerve cross sections were reconstructed and axon counts, as well as diameters were determined. There were 1895 ± 41 (S.D.) (N=3) myelinated profiles and 1423 ± 125 unmyelinated profiles for a total of 3318 ± 92 axons or 57% myelinated and 43% unmyelinated profiles. The diameters of the 3 nerves were equivalent for the myelinated axons with averages from 2.7 ± .83 um to 2.8 ± 1.0 um with a range from 0.7 to 6.7 um. The unmyelinated profiles in these montages ranged from 0.4 to 2.3 um in diameter. The chorda tympani nerve in the rat contains a total of 1016 axons which include 60% myelinated and 40% unmyelinated profiles. Therefore, the proportion of myelinated and unmyelinated profiles in the glossopharyngeal nerves is nearly equivalent. Neuronal somata were counted from serial paraffin sections of 2 petrosal ganglia. These contained 6196 and 5616, respectively, which should correspond to the total number of sensory neurons of the glossopharyngeal nerve; however, there are, in addition to the oral distribution, the Herring nerve to the carotid body, the tympanic branch to the ear and a branch to the pharynx. Two morphological differences exist between the lingual glossopharyngeal and chorda tympani nerves: 1. The glossopharyngeal nerve contains about 3 times as many total axons as the normal chorda tympani; 2. The gustatory distribution of the glossopharyngeal nerve overlaps bilaterally to the midline circumvallate papilla and ipsilaterally to the foliate papilla, while the chorda tympani is ipsilateral to the fungiform papillae. The differences in the gustatory sensitivities between the rat glossopharyngeal and chorda tympani nerves cannot be ascribed to differences in axon diameter. Sympathectomy and intracranial deefferentation studies are in progress to specify the sensory axon population of the glossopharyngeal nerve. (Supported in part by NIH Grant NS 10389).

251 SEXUAL AND AGGRESSIVE BEHAVIOR IN MALE HAMSTERS AFTER LESIONS OF THE CORTICOMEDIAL AMYGDALA. Michael N. Lehman, Golda A. Kevetter, and J. Bradley Powers. Neurosci. Prog. and Neurosci. Lab. Bldg., Univ. Michigan, Ann Arbor, MI 48109.

Olfactory input to the main olfactory bulb and vomeronasal organ input to the accessory olfactory bulb are essential for normal mating and aggressive behavior in male hamsters (Winans & Powers, Brain Res., 126: 325; Murphy, Brain Res., 113: 95). Since neurons of the main and accessory olfactory bulbs project to adjacent but separate nuclei of the corticomedial amygdala, and since this is the major projection of the accessory system, we studied mating and aggression in male hamsters before and after bilateral electrolytic lesions of the corticomedial amygdala (n=14) or sham operations (n=4). Each male's mating behavior was observed in a neutral arena with an ovariectomized, estrogen and progesterone primed female hamster. Aggressive interactions were recorded after introducing an unfamiliar male hamster into the test male's home cage.

Sham animals showed no postoperative behavioral changes, but aggressive responses were severely diminished in 13 out of 14 lesioned males and were essentially eliminated in 11 of these animals. Mating behavior deficits in lesioned animals ranged from a total absence of copulation to no observed change, and the degree of deficit was positively correlated with the amount of damage to the rostral part of the corticomedial nuclear group. Males with lesions of the rostral corticomedial amygdala also spent significantly less time during postoperative mating tests investigating the anogenital region (but not the head or flank region) of the female. Males with damage confined to the caudal corticomedial amygdala, like sham operates, showed little impairment of either mating behavior or anogenital investigation of the female. In summary, the results suggest that the rostral nuclei of the corticomedial amygdala are relatively more important than the caudal nuclei in facilitating mating behavior. Aggressive behavior deficits showed no comparable localization; lesions in either the rostral or caudal part of the corticomedial amygdala led to similar deficits.

Since the major outflow of the corticomedial amygdala to the hypothalamus is by way of the stria terminalis, we also studied the mating behavior of male hamsters before and after bilateral electrolytic lesions of the stria terminalis (n=7) or sham operations (n=11). Although all stria terminalis lesioned males showed some increase in latency to ejaculation, 6 out of 7 lesioned males continued to mate postoperatively; stria terminalis lesions were thus not comparable to lesions of the rostral corticomedial amygdala. This suggests that non-strial efferents from the rostral corticomedial amygdala play a major role in the mating behavior of male hamsters.

252 SUBPOPULATIONS OF FUNGIFORM TASTE BUDS IN THE RAT. Edward H. Lubarsky* and Inglis J. Miller, Jr. Dept. of Anatomy, Bowman Gray Sch. of Med. of Wake Forest Univ., Winston-Salem, NC 27103

It has not been established whether taste buds function primarily as individuals or in groups, but lateral depression and disparity in response magnitudes from equal numbers of fungiform taste buds in different regions suggest interaction among neighboring taste buds. This report identifies groups of fungiform taste buds on the rat tongue which degenerate following the surgical section of each of the 5 major divisions of the chorda-lingual nerve in the tongue. Our designation of these divisions include 2 posterior branches, D and E; a midregion branch, C; and 2 anterior divisions, A and B, which distribute to the tip. Section of one or more of these divisions was accomplished in 15 Sprague-Dawley rats either unilaterally or bilaterally. The animals were allowed 10 days of post-surgical survival, sacrificed, perfused with Bouin's fixative and complete serial sections of the tongues were prepared in paraffin and stained with H & E or FitzGerald's silver technique. Microscopic examination was performed to determine the number and location of normal and degenerating taste buds on each tongue. The anterior branches, A and B, terminate in an overlapping distribution to fungiform taste buds on the rostral 15mm of tongue surface. An average ± S.D. of 35±15% (N=5) of total fungiform taste buds degenerate when A is severed, but 29% of these are located on the anterior 4 mm of the tongue tip. When B is sectioned, an average of 41 ± 13% (N=3) of fungiform taste buds degenerate, but only 13% are located on the anterior 4 mm. An average of 4 taste buds remain on the tongue tip with ipsilateral section of the entire chorda tympani nerve and these are innervated by axons which cross the midline. The midregion branch, C, distributes to 11±1% (N=3) of taste buds which lie anterior to the intermolar eminence 13-20 mm from the tongue tip. Posterior branches D and E innervate 8±3% (N=5) of fungiform taste buds located lateral to the intermolar eminence as well as 5-10 taste buds in the first 2 trenches of the foliate papillae. Degenerative changes ranged from a total absence of taste bud cells to a reduction in the size of buds and cell numbers. Silver-stained preparations reveal the presence of nerve fibers in partially degenerated taste buds due to the overlapping of axons from the unsevered nerve bundles. If the axons which are responsible for trophic maintenance of the receptors are the ones which mediate taste perception, then the major divisions of the chorda-lingual nerve correspond to regionally identifiable subpopulations of taste buds supplied by overlapping groups of facial gustatory neurons.

253 ODOR DISCRIMINATION AND MEMORY IN KORSAKOFF'S PSYCHOSIS. Robert G. Mair*, Cythnia Capra*, William J. McEntee, and Trygg Engen*. Neuro. Service, V.A. Hospital, Davis Park, Providence, RI 02908.

Korsakoff's psychosis is characterized by severe memory impairment, associated with consistent patterns of diencephalic and brain stem lesions including the mediodorsal thalamic nucleus in a high percentage of cases. We have recently reported evidence linking the memory impairment of Korsakoff's psychosis with decreased central noradrenergic activity. Patients with this disorder have been reported to be unable to discriminate between odors and to show a deficit in supra-threshold scaling suggesting impaired sensitivity to weak odors. We compared absolute olfactory sensitivity in 10 Korsakoff patients with matched normal controls using signal detection methods and found no impairment in their sensitivity to threshold level stimuli. We then proceeded to measure odor quality discrimination and memory by presenting separate blocks of similar and dissimilar odor pairs at time delays up to 30 seconds. The choice of similar and dissimilar odor pairs was based on extensive ratio scaling and recognition memory experiments with normal subjects. It was found that the patients had difficulty distinguishing between similar, but not between dissimilar odors, although matched normal controls performed at a higher level with both sets of stimuli. Furthermore, the Korsakoff patients showed no decline in odor memory performance over the time intervals tested. This latter finding is in marked contrast to the performance of the same Korsakoff patients on auditory and visual memory tasks. Treatment of Korsakoff patients with catecholamine agonist drugs which have improved performance on other memory tasks, had no effect on odor memory. These results suggest that Korsakoff patients are impaired in their ability to discriminate between two odors, but not in their ability to detect odorants. The failure of catecholamine agonists to improve performance and the equivalent results observed across time delays up to 30 seconds, suggest that the odor discrimination deficit does not directly result from the Korsakoff's memory impairment.

254 AN APPROACH TO CHEMICAL NERVE SECTION IN THE MOUSE OLFACTORY PATHWAY. F.L. Margolis and M. Grillo*. Department of Physiological Chemistry and Pharmacology, Roche Institute of Molecular Biology, Nutley, NJ 07110.

The use of a neurotoxic agent to selectively destroy or block the formation of certain cell types has been a powerful tool for the analysis of developmental and functional relationships in the nervous system. Intranasal irrigation with 0.17 M $ZnSO_4$ solution has previously been shown to have a long-term effect on the morphology and biochemistry of the olfactory bulb and mucosa, as well as on food-finding behavior (Brain Res. 140, 271 [1978]). We have now extended these studies to evaluate the effects of intranasal irrigation with a large number of compounds. Initially, we monitored the effect on food-finding behavior. Many compounds (3-acetylpyridine, kainic acid, xylocaine, pronase, tyrothricin, Ellman's reagent, etc.) had little or no effect on food-finding behavior. However, intranasal irrigation with vinblastine SO_4 (10 mM) had effects similar to 0.17 M $ZnSO_4$ on behavior, olfactory bulb weight, S-100 protein, olfactory marker protein (OMP), synthesis and transport of carnosine (STC) and carnosinase activity (C'ase). The use of lower concentrations of vinblastine SO_4 (VB-SO_4) caused a transient reduction in some of these parameters. Other agents such as Triton X-100, colchicine, N-ethyl maleimide and dimethyl-(2-hydroxy-5-nitrobenzyl)-sulfonium bromide at appropriate concentrations resulted in a rapid loss of those biochemical parameters associated with olfactory neurons (OMP, STC), but much smaller, rapidly reversed, changes in non-neuronal parameters (S-100, C'ase). The olfactory neuron specific markers return to control levels at 4-6 weeks after treatment. Essentially, identical biochemical patterns were seen in bulb and mucosa. Food-finding behavior followed a similar time course. Histological evaluation of these materials is not yet completed. However, the time course of the biochemical changes (for several of the treatments) is almost identical to that seen after surgical section of the olfactory nerve (Brain Res. 132, 11 [1977]). These data suggest that the olfactory neurons are especially susceptible to environmental insults and that these treatments may function as a chemical nerve section.

255 MODULATION OF OLFACTORY BULB EVOKED POTENTIALS BY STIMULATION OF CENTRIFUGAL INPUTS. Diane P. Martinez* (Spon: W.J. Freeman). Dept. of Physiol.-Anat., Univ. Calif., Berkeley, CA 94720.

Averaged evoked potentials (AEPs) from the main olfactory bulb of lightly anesthetized rats were recorded in response to electrical stimulation of the lateral olfactory tract (LOT), deep pyriform cortex (PC), the anterior limb of the anterior commissure (AAC), and the primary olfactory nerve (PON).

The LOT and AAC AEPs recorded at the surface and deep to the mitral cell layer were observed to be consistent with results reported by many authors. Stimulation of the region just deep to the PC activated centrifugal fibers from the cortex resulting in a long latency AEP (10-12 msec), initially surface positive but without a clear potential turnover. Part of this AEP could be due to input relayed through the anterior olfactory nucleus, although direct projections to the bulb from the cortex have been demonstrated anatomically. The PON AEP consisted of a damped sine wave superimposed on a nonoscillatory baseline shift. The initial peak of the oscillation and the baseline shift were negative at the surface and positive deep in the bulb. In some cases the PON compound action potential could be distinguished immediately following the shock artifact. With deep anesthesia the baseline shift of the AEP disappeared and the oscillatory component became more damped. The baseline shift was only recorded with PON stimulation and appeared to result from activation of periglomerular cells.

No potentials could be evoked in the bulb from stimulation of the nucleus of the horizontal limb of the diagonal band (HDB), a structure known to send centrifugal input to the granule cell and glomerular layers of the bulb. However, tetanization (200 per sec for 20 secs) of the HDB immediately prior to stimulation of the PON had a marked effect on the oscillatory PON AEP. The AEP became less damped, continuing to oscillate for longer periods, with an increase in the amplitude of the baseline shift. In contrast, tetanization of the AAC resulted in suppression of the PON AEP without a decline in the amplitude of the mitral cell compound action potential. While the AAC interconnects the two olfactory bulbs and is not a true centrifugal input, the HDB lies in the medial forebrain bundle where limbic, hypothalamic, and reticular systems project. This suggests that the modulating effect exerted by the HDB on the bulb controls arousal or background activity by acting at the level of the periglomerular cell population. Supported by MH 06686.

256 AMYGDALA RESPONSE TO ELECTRICAL STIMULATION OF VOMERONASAL NERVE. Michael Meredith. Worcester Foundation for Experimental Biology Shrewsbury Mass. 01545.

The vomeronasal organ and accessory olfactory bulb (AOB) in the golden hamster have been; 1) implicated in sensory control of mating behavior(Winans and Powers 1977); 2) shown to be sensitive to odor components of hamster vaginal discharge (Meredith 1977) and have been, 3) shown by experimental anatomical methods to project to the medial and posterio-medial cortical nuclei (PMCN) of the amygdala (Davies et al 1978). We have used electrical stimulation of the vomeronasal nerves (VN) to trace the functional connections through AOB to the amygdala, using bipolar and monopolar recording. The nerve was stimulated rostral to the main olfactory area to avoid activating inputs to the main olfactory bulb (MOB). When recording from the amygdala, VN stimulation was again used in preferrence to AOB stimulation to avoid activating MOB output fibers. Simultaneous recordings in AOB and PCMN give response latencies of 35-45 ms for the negative component of the AOB evoked potential, recorded at the level of the second order cells. The variation is due to differences in conduction distance. The surface N_1 component of the PMCN evoked potential has a latency of 8 ms from the AOB potential. A deep-negative, surface-positive component (P) follows N_1 in the PMCN with an additional latency of 5 ms. It reverses deep to N_1 and fails to follow 3/s stimulation. This suggests that the cells generating N_1 project to and activate cells in the deeper layers of the amygdala. Ongoing experiments are designed to identify these cells as belonging either to layer 3 of PMCN or to the deeper basomedial nucleus. Microelectrode recordings at the level of the maximum deep negative component corresponding to P show a relatively narrow layer of cells driven by VN stimulation.

257 THE LOCALIZATION AND FUNCTION OF SH GROUPS IN FROG OLFACTION. Muriel H. Nathan and Sarah S. Winans. Dept. of Anatomy, University of Michigan, Ann Arbor, Michigan 48109.

A replication of Getchell and Gesteland's (1972) electrophysiological study of the effect of N-ethyl maleimide (NEM), an SH group blocker, on the responses of the olfactory receptors to odor stimulation was undertaken. The results corroborated that the application of 4mM NEM for three minutes to the olfactory epithelium abolished the odor-evoked electro-olfactogram (EOG), whereas rinsing the epithelium with ethyl n-butyrate, an odorant, during the NEM application prevented the inactivation of the EOG. Getchell and Gesteland hypothesized that ethyl n-butyrate protected its receptor sites in the olfactory epithelium from NEM binding, and thus, preserved its receptor potential.

To determine the possible NEM binding sites within the olfactory epithelium, histological localization of SH and SS groups in 6 micron serial sections of the frog nasal cavity was accomplished using the APM (N-(4-aminophenyl)maleimide) dual staining technique (Sippel, 1978). Light microscopic examination of the sections revealed the nuclei, olfactory vesicles and cilia within the epithelium had a high content of SH groups. SS-rich granules, which may correspond to granules previously reported in supporting cells (Graziadei, 1971), were found in the apex of the epithelium. Larger granules in the Bowman's glands were also high in SS content. Treatment of the sections on slides or the epithelium in vivo with 4mM NEM required at least 4 hours to effectively block APM staining of SH groups.

Since a 3 minute application of NEM abolished the EOG but did not block APM staining of SH groups, tritiated NEM (2uCi/nostril) was applied to the olfactory epithelium for 3 minutes to determine the extent of NEM binding necessary to inhibit the EOG. The results of this experiment will be compared to odorant sites localized by washing the epithelium with unlabeled NEM mixed with an odorant followed by a rinse with H^3-NEM. This will indicate the feasibility of mapping specific receptor sites in the epithelium using maleimides.

258 INDICATIONS OF CHOLINERGIC INNERVATION OF TASTE BUDS. W.T. Norfleet*, F.M. Matschinsky* and D.A. Godfrey. Dept. Pharmacol., Washington U. Sch. Med., St. Louis, MO.

Circumvallate, foliate, and fungiform papillae in the tongues of male Sprague-Dawley rats were examined for choline acetyltransferase (ChAc) and acetylcholinesterase (AChE) activity through radiometric assay of samples dissected from freeze-dried microtome sections. The fungiform papilla was contrasted with epithelium surrounding this structure. Portions of circumvallate and foliate papillae close to the surface of the tongue where taste buds are absent were compared to deeper sections in which buds constitute a large portion of the papilla volume. Also, submucosal tissue directly adjacent to these two types of papillae containing buds and tissue more remote from the papillae were analyzed. The results are summarized in the following table with ChAc activity in μmoles/kg dry wt/min, AChE in mmoles/kg dry wt/min, mean ± SEM for "n" animals:

		ChAc	AChE
Circumvallate Papillae	Papillae w buds (n=7):	22.3±3.7	10.5±1.3
	Papillae wo buds (n=5):	1.0±0.4	2.1±0.3
	Nearby tissue (n=2):	14.3, 22.2	6.2, 11.2
	Distant tissue (n=1 or 2)	1.3, 8.8	1.0, ---
Foliate Papillae	Papillae w buds (n=6):	40.8±6.2	22.4±1.3
	Papillae wo buds (n=5):	-0.2±1.2	3.5±0.3
	Nearby tissue (n=1 or 2):	7.6, ---	14.6, 15.8
	Distant tissue (n=1 or 2):	1.1, ---	6.8, 1.3
Fungiform Papillae	Papillae w buds (n=2):	0.0, 3.9	1.9, 2.7
	Nearby epithelium (n=2):	0.6, 1.2	0.5, 0.3

Both ChAc and AChE were found in circumvallate and foliate papillae containing taste buds and in submucosal tissue adjacent to these structures. However, enzyme activity was low or absent in more distant submucosal tissue and in fungiform papillae. The results are consistent with cholinergic innervation of the taste buds of circumvallate and foliate papillae. This innervation may be part of an efferent neural system analagous to auditory and olfactory cholinergic pathways.

259 IXth NERVE TASTE RESPONSES DEPEND UPON AXOPLASMIC TRANSPORT
Bruce Oakley, Lee B. Jones*, Joyce S. Chu* and Mark A. Hosley*. Div. Biological Sciences, Univ. Mich., Ann Arbor, MI 48109.

We have examined impulse discharges and axoplasmic transport in intact and treated IXth nerves of the Mongolian gerbil (Meriones unguiculatus). Previously, we reported that following transection of the gerbil's IXth nerve, the summated impulse discharge to taste solutions declined in 1-4 hr to 0-25% of the initial response magnitude (Berland et al., In: Olfaction and Taste VI, J. LeMagnen and P. MacLeod, eds., Information Retrieval Ltd., Arlington, 1977). Control experiments indicated that impulse propagation mechanisms along the transected nerve were not disturbed. In addition, we found that the rate of taste response loss in transected IXth nerves was nerve length dependent, suggesting that a flow of axonally transported material normally sustains the taste response mechanism. To test this proposition, we injected into the petrosal ganglion of the IXth nerve 0.04 µl (1 µCi) of either ^{3}H-leucine or a complete mixture of ^{3}H-amino acids. Subsequent liquid scintillation counting of portions of the tongue and approximately 1.2mm serial segments of the IXth nerve indicated that labeled material was transported down the IXth nerve to the foliate and vallate taste papillae of the tongue. Following nerve transection, transport continued in the distal portion of the nerve, as predicted from the electrophysiological observations of the nerve length dependency of the taste response decline. The intact IXth nerve could be cooled for 15-60 min with a 3-10°C metal probe. This caused an accumulation of labeled material proximal to the cooled segment. Furthermore, taste responses also declined in intact nerves after such cooling. Thus, local cooling of the IXth nerve impaired both axoplasmic transport and taste response mechanisms.

We conclude that the integrity of the physiological taste response mechanism is maintained by materials supplied to the IXth nerve axon terminals by axoplasmic transport. The precise role of such transported material in taste function remains to be elucidated.

Supported in part by NIH grant NS-07072.

260 BEHAVIORAL EFFECTS OF CUTTING THE EFFERENT NERVES TO THE HAMSTER VOMERONASAL ORGANS.
Robert J. O'Connell* and Michael Meredith (SPON: F. Macrides). The Worcester Foundation for Experimental Biology. Shrewsbury, Ma. 01545.

The nasopalatine nerve (NP) has been shown to control stimulus access to the vomeronasal organ (VNO). Stimulation of this nerve activates a vascular pump in the organ which draws odor laden fluids from the nasal vestibule into the lumen of the VNO where the sensory epithelium is located. Removal of the afferent outflow from the VNO and the olfactory epithelium regularly eliminates male mating behavior. Presumably by interfering with the perception of odor cues from receptive females. Therefore we postulated that cutting the NP should also interfere with mating behavior by preventing stimulus ingress to the VNO.

In addition to the usual measures of mating behavior (ie. no. of mounts and their respective latencys) we were also interested in measuring male responses to the odor of estrous hamster vaginal discharge (HVD) using a standard two bottle preference test. This preference is regularly exhibited by normal males in the absence of other hamsters. The 12 males selected for study had a strong preference for HVD and were known to have mounted a receptive female during a single 5 minute mating test. Two groups, of six males each, were formed so that both had equal preoperative preferences for HVD. The NP of the experimental animals was cauterized through a small hole in the hard palate. Control males were treated similarly except that the NP was not cauterized. After a 4 day rest period all animals were examined for mating and HVD preferences. Four alternating mating and preference tests were spaced over a period of 14 days.

Three of the six experimental animals failed to show any postoperative preference for HVD. The remaining three animals had reduced preferences. In only 9 of the 24 individual trials was there any preference for HVD. In one of the experimental animals which continued to show a postoperative preference, histological examination revealed an incomplete nerve section on one side. Control animals prefered HVD in 21 of the 24 trials. There were no significant differences between the two groups on the mating tests. Further experiments are underway to determine if NP cuts coupled with deafferentation of the olfactory mucosa will eliminate both the preference for HVD and male mating behavior.
(Supported by NINCDS grant NS14453).

261 EFFECT OF PHOTOPHASE ON PRIMARY TASTE RECEPTORS.
Elizabeth Omand* and Jacob Zabara, Depts. Physiol., Temple Univ. Health Sciences Center, Philadelphia, PA 19140.

Richter thought receptor changes could account for altered taste preferences[1], but Pfaffmann did not show any electrophysiological differences between normal and adrenalectomized rats[2]. In insects, however, taste receptors do change. Butterfly larvae receptors have a lessened impulse frequency when their adequate stimuli had been present in ingested food prior to testing[3]. In satiated Blowfly adults, receptors show reduced impulse frequencies[4]. Fewer taste sensilla produce impulses during diapause in the Blowfly[5], and in the Locust following feeding, when sensillum tip resistance is high[6]. We now report similar multiple changes associated with photophase in Musca domestica.

A micropipette with stimulus and electrolyte (1/2 M sucrose and/or 1/3M LiCl) placed over a taste hair allowed the display of impulses and slow potentials passed through a Grass P16 preamplifier. Male flies, deprived 24-48 hr had been kept in briefly interrupted (1/2 hr/day) darkness or in the fall cycle of sunlight (through window glass) since the late pupal stage.

Under the regimen of darkness, receptor functions were reduced. Fewer sensilla and fewer cells in each produced impulses; impulse frequency was lower; impulse discharge was more brief.

These effects of light were offset by ingestion. By 72 hr of deprivation, responses were up, in spite of the darkness. With a 24-hr access to food (0.1M sucrose), lighted animals showed the reduced activity pattern: fewer sensilla responded, and with fewer impulse types, lower frequencies, and brief discharges.

In addition to spike potentials, slow oscillations recurred at about 1-2/sec and slightly increased the non-spiking excursions. Under each regimen, oscillations coincided with high receptor function but were absent from animals with low receptor function.

The observation that taste receptors change in relation to photophase as well as ingestion, is indicative of a broadly based regulatory system for taste receptor action.

262 NEURAL RESPONSES TO AMINO ACIDS IN THE RAT.
Thomas C. Pritchard* and Thomas R. Scott. Dep't Psychol., U. Delaware, Newark, DE 19711.

The role of gustation in selecting nutrients from the environment would seem to require sensitivity to complex nitrogenous molecules such as amino acids (a.a.'s). Although the environment more commonly provides nitrogenous compounds in peptide chains, individual a.a.'s have been shown to be effective taste stimuli in humans and lower animals. In this study we determined the neural effectiveness of 12 l-a.a.'s relative to .1 M NaCl and to each other across a range of concentrations. Responses were recorded from the whole chorda tympani nerve of adult male albino rats, stimulated by 40 ml of solution delivered to the anterior half of the tongue in 4 sec. The concentration of each a.a. ranged, usually in half log molar steps, from that which evoked no increase in whole nerve activity to the intensity at which the neural response reached asymtote or at which the solution in 25°C DH_2O was saturated. This included approximately ten concentrations of each stimulus, and 3-5 applications were made of each concentration. Trials of NaCl were interspersed throughout the stimulus series to verify stability of the neural response. The relative effectiveness of the a.a.'s, as defined by the response elicited by the highest concentration, correlated +0.89 with their solubility in water. Thus, such a definition of responsiveness is more a measure of how concentrated the solution could be made than a test of taste sensitivity to various molecular species. Perhaps a better measure is the concentration at which a threshold response was elicited, threshold being arbitrarily defined as a 10% increase from spontaneous activity level. By this definition, the order of a.a. effectiveness was histidine > cysteine HCl > lysine > arginine > methionine > alanine > leucine > isoleucine > glycine = threonine > proline > tryptophan. This sequence correlated +0.88 ($p<.001$) with that of human thresholds for the same stimuli. (supported by NIH grant NS 10405).

263 CENTRIFUGAL EFFERENTS TO THE OLFACTORY BULB IN THE RHESUS MONKEY. Douglas L. Rosene, Lennart Heimer, and Gary W. Van Hoesen. Harvard Neurological Unit, Beth Israel Hospital, Boston, MA 02215, Dept. of Anatomy, University of Virginia, Charlottesville, VA 22904, and Depts. of Anatomy and Neurology, University of Iowa, Iowa City, IA 52242.

In humans, olfaction is often ignored or viewed as a somewhat vestigial sensory modality and comparative neuroanatomical studies indicate that primate olfactory centers do not share in the phylogenetically progressive development of non-olfactory limbic structures. Nevertheless in the presumably microsmatic rhesus monkey, olfactory bulb efferents are widely distributed to the same telencephalic structures as in macrosomatic rodents. Utilizing injections of the retrograde tracer horseradish peroxidase (HRP) into the olfactory bulb of the rhesus monkey we now report that centrifugal efferents to the olfactory bulb originate from a surprisingly widespread group of central structures.

Ipsilateral to the HRP injection heavy labeling was observed in all subdivisions of the anterior olfactory nuclei (AON) except the pars externa. Contralaterally the pars externa was heavily labeled while lighter labeling was observed in the AON. The lateral transition cortex between the pars lateralis of the AON and the primary olfactory cortex (POC) was labeled bilaterally while the medial transition cortex (MTC) between the pars medialis of the AON and the induseum griseum was labeled only ipsilaterally. Previously the MTC has been identified by others as part of the anterior hippocampal rudiment.

In the POC labeled neurons were seen ipsilaterally in both layers II and III. In adjacent entorhinal cortex labeled neurons were found in the superficial layers of the most rostral, transitional subdivision of lateral entorhinal cortex. In the amygdala labeled neurons were found throughout the anterior amygdaloid area as well as superficially in the cortical amygdaloid nucleus. Labeled neurons were also found in both the vertical and horizontal limbs of the diagonal band, the nucleus basalis, the lateral and dorsal hypothalamus, the ventral tegmental area of the midbrain, the dorsal and medial raphe and the locus coeruleus.

Both the quantity and wide distribution of these centrifugal efferents suggest that pathways for centrifugal efferent modulation of the olfactory bulb in the primate may be comparable to macrosmatic mammals. Thus while the primate olfactory system does not show a progressive development, there is little anatomical basis for regarding olfaction as a vestigial system.

264 EVIDENCE FOR A CENTRAL ORIGIN OF CHOLINERGIC STRUCTURES IN THE OLFACTORY BULB. C.D. Ross, D.A. Godfrey, A.D. Williams* and F.M. Matschinsky*. Dept. Anat. and Neurobiol. and Dept. Pharmacol., Washington U. Sch. Med., St. Louis, MO. 63110.

The distributions of choline acetyltransferase (ChAc) and acetylcholinesterase (AChE) activities in the olfactory bulbs of 4 male Sprague-Dawley rats were studied one week after knife cuts were placed at locations caudal to the bulb on the right side (lesions made by Dr. Joseph L. Price, Dept. Anat. and Neurobiol., Washington U. Sch. Med.). In rats A and B, the lateral olfactory tract (LOT) was cut near the junction of the anterior olfactory nucleus and piriform cortex. In rat B, the lesion additionally extended through cortical layers II and III. In rats C and D, a cut through the olfactory peduncle separated the olfactory bulb from the rest of the brain, completely in rat D, but leaving a slight amount of dorsally located tissue intact in rat C. The table presents the ChAc activities in olfactory bulb layers on the lesion side as a percentage of those on the control side (+ difference significant at p=0.05; *difference significant at p=0.005). AChE results were similar, but less dramatic.

Layer	Rat A	B	C	D
glomerular	92	64*	12*	0.5*
ext. plexiform, superf.	93	59*	15*	0.4*
ext. plexiform, deep	88	103	12*	1.3*
mitral	93	80	16*	0.8*
int. plexiform	75+	45*	8*	2.1*
granular	79	54*	12*	2.2*

The percent loss of enzyme activity was related to the extent of the lesion. The virtually complete loss of enzyme activity following the lesion in rat D suggests that all cholinergic elements in the bulb derive from regions caudal to the bulb. The small decrease in enzyme activity following the LOT lesion (rat A) suggests that few, if any, of the cholinergic axons from these central locations are located in the LOT. In rat B, the decrease in enzyme activity was greater laterally than medially in the olfactory bulb, correlating with the lateral location of the lesion. In rat C, the residual ChAc activity in the ventral part of the bulb was similar to that in rat D, while the activity in the dorsal part was much higher. These results extend the concept of a cholinergic centrifugal pathway to the olfactory bulb by suggesting that the axons of this pathway are located somewhere deep to the LOT and may account for all cholinergic synapses in the olfactory bulb. (Supported by NIH grant NS-08000).

265 PATTERNS OF MITRAL AND TUFTED CELL PROJECTIONS TO LOCALIZED REGIONS OF THE RAT OLFACTORY CORTEX AND OLFACTORY TUBERCLE. John W. Scott and Russell L. McBride*. Dept. Anat., Sch. Med., Emory University, Atlanta, Ga. 30322.

Studies of the neuronal connections of the olfactory bulb (OB) have not found a topographic representation of the OB on the olfactory cortex (OCx) although some reports have described different origins for the projections to the medial and lateral olfactory tubercle (OTb). Recent retrograde transport studies of the OB projections with horseradish peroxidase (HRP) have disclosed a preferential tufted cell projection to the OTb and perhaps to anterior OCx (Brain Res. 1977, 129, 152; J. Comp. Neurol. 1977, 172, 1). Those reports emphasized labeling of small clusters of cells from all parts of the OB after localized injections into OCx or OTb.

This study tested whether larger groupings of labeled mitral/tufted cells would be seen if the OB was examined in regularly spaced frontal sections after small HRP injections into OCx or OTb. HRP was injected via an orbital approach. After a 24 hour survival, the brains were fixed and processed with the tetramethylbenzidene technique. The positions of labeled cells from every third 40μ thick section were plotted with a camera lucida. The distance of each cell from the top of the OB was measured along the mitral cell body layer. This distance was plotted along with the distance from the frontal pole of the OB onto two dimensional maps of the OB surface. The data were analyzed by dividing these maps into ten equal longitudinal strips (based on suggestions that the afferents to the OB are organized in longitudinal zones: Brain Res. 1973, 52, 115; 1974, 70, 506) and by testing with chi square against the hypothesis that mitral tufted cells from all parts of the OB project with equal probability to each localized part of the OCx and OTb. Of the 10 bulbs with enough labeled cells to apply this test, 7 show significance with $p<.001$. These distributions also differ significantly from each other, showing that they do not result solely from non-uniform distributions of mitral/tufted cells in the OB. Several bulbs show obvious clusters of labeled cells generally oriented in longitudinal zones. In some cases, there is a restriction to either anterior or posterior regions of the OB.

While we do not yet propose a topographic organization in this projection, we do have statistically reliable evidence that the OB does not project uniformly to each local part of the OCx and OTb.

266 EFFECTS OF pH ON OLFACTORY RESPONSES TO AMINO ACIDS IN THE FRESHWATER EEL. Wayne L. Silver and Don Tucker. Dept. of Biological Science, Florida State University, Tallahassee, Florida 32306.

Averaged neural activity recorded from small bundles of primary olfactory nerve and the underwater electro-olfactogram (EOG) were used to study the effects of pH on the olfactory responses to amino acids in the freshwater eel. Amino acids were dissolved in well water and introduced into the stimulator at 10^{-4}M. Solutions were diluted at least to 66% of the applied concentration as determined by photodensitometry of dye solutions. The pH of the stimulus solutions was adjusted with HCl and NaOH. Both the neural response and EOG appeared to be independent of pH over a relativity wide range between 3.0 and 9.5 regardless of the amino acid tested. At pHs above 9.5 the response magnitudes declined. In most cases the EOG became positive around pH 11.0 although the neural response, while diminished, was still present. Responses recorded at pHs below 3.0 differed for different amino acids. For L-gln, the neural response declined while the EOG increased; for L-cysh, low pHs had no effect on either response type; for L-ala and L-ala methyl ester both the neural response and EOG increased at pHs below 3.0. At low pH the initial neural response was often followed by an off response, but no off response was seen for the EOG. The pKs of the amino acids tested are around 2.0 for the carboxyl group and between 8.0 and 10.0 for the amino group. L-cysh has a third pK at 10.3.

The neural response to well water alone was independent of pH between 2.5 and 10.0. There was a decrease in response magnitude at pHs below 2.5 and above 10.0. At pHs around 2.0 only an off response was observed. The EOG response to well water increased at pHs below 4.5 and decreased around pH 10.0. At pHs above 10.5 only a positive EOG was seen. No EOG off response occurred at low pH.

pH effects on the olfactory bulb induced-wave response to amino acids in the rainbow trout appeared to be similar to those seen on the neural response in the eel. The response was independent of pH between 3.0 and 10.0. At high pHs there was a decrease in the bulbar response magnitude. (Supported by NIH grant NS-08814).

267 IS AN INTACT ACCESSORY OLFACTORY SYSTEM NECESSARY FOR DEVELOPMENT OF ADEQUATE MATERNAL BEHAVIOR IN THE RAT? Pauline J. Singh, Scott Manaker*, A. Marie Tucker* and Myron A. Hofer. Dept. of Psychiatry, Albert Einstein Col. of Med., Montefiore Hosp., Bronx, N.Y. 10467.

Schwartz & Rowe (1977) have reported serious deficiencies, such as cannabalism, in maternal behavior of primiparous rats after bilateral olfactory bulbectomy (BOB). However, this could be due to lack of function of 1) the main olfactory system, 2) the accessory olfactory system, or 3) both. Fleming and Rosenblatt (1973) found that irrigation of the nasal cavities with $ZnSO_4$ solution (which results in a nonfunctional main olfactory system only) did not interfere with the development of maternal behavior in virgin female rats. Thus it was hypothesized that denervation of the accessory system was primarily responsible for the deficiencies noted by Schwartz & Rowe.

In order to test this, 19 female rats and their litters were observed from the day the litter was born (Day 1) through Day 16. Nine females underwent vomeronasal nerve section (VN) which renders the accessory system nonfunctional; 6 were surgical controls (SC); and 4 were normal controls (N). Histology is being done to verify VN. Surgery was performed before mating occurred. No significant differences were found in litter size and pup mortality. Pup weights and temperatures were recorded daily, and no consistent differences were found among groups indicating that nursing behavior was not seriously impaired by the nerve section. Home cages were checked daily for changes in nest location and number of times pups were found out of the nest, and, again, no significant differences were found. Retrieving tests were conducted on Days 4, 7, 10, and 13. No consistent differences were found among groups in number of pup retrievals, number of times the mother nosed or licked the pups, and number of times all pups were returned to the nest by the end of the test. A number of other behavioral items (such as self-grooming, climbing or rising, and digging or burrowing in shavings) were recorded to get an indication of whether or not the mothers were disturbed. No significant differences were indicated.

These data indicate that an intact accessory system is not necessary for the development of adequate maternal behavior. The results of Schwartz & Rowe are due to 1) a nonfunctional main system, 2) nonfunctional main and accessory systems, either one alone being sufficient for adequate maternal behavior, or 3) secondary effects of BOB such as heightened emotionality and aggression. Further experiments are being done to clarify this issue.

268 BEHAVIORAL CORRELATES OF GUSTATORY INFORMATION PROCESSING IN THE HAMSTER CENTRAL NERVOUS SYSTEM. David V. Smith, Joseph B. Travers and Richard L. Van Buskirk. Dept. Psychol., Univ. Wyoming, Laramie, WY 82071.

Several approaches have been taken toward the behavioral classification of gustatory stimuli. Operant conditioning techniques were used by Erickson (Olfaction and Taste, 1963, 205) to examine taste similarities among stimuli in rats. Morrison (Canad. J. Psychol., 1967, 21, 141) also employed operant procedures to generate taste quality profiles based on the generalization of a learned task from a conditioning stimulus to several others. The taste aversion that occurs following association of a stimulus with gastrointestinal illness provides another tool for determining gustatory similarities (Nachman, J. comp. physiol. Psychol. 1963, 56, 343; Tapper & Halpern, Science, 1968, 161, 708). The reduced consumption of various stimuli following conditioned taste aversion was used by Nowlis & Frank (Olfaction and Taste VI, 1977, 241) to generate taste quality profiles for the hamster, which were then compared to single fiber sensitivities in the chorda tympani nerve. The present study provides a comparison between gustatory responses in the central nervous system to a variety of stimuli and taste quality profiles developed from the generalizations of hamsters following conditioned taste aversions to each of these compounds. These generalizations were measured by counting the number of licks to each stimulus following aversive conditioning. This approach allows the comparison among all the stimuli in a single test session. Hamsters were conditioned to avoid one of 10 stimuli, chosen to represent a range of taste experiences, at concentrations equal to those used in the neurophysiological analyses. The generalization of each compound to every other stimulus was measured as the percentage of reduction in the licking rate following aversion. These cross-generalization measures were used to generate a similarity score for each pair of compounds, based on the similarity in their generalizations to the other stimuli. These similarity profiles were then compared to the results of several types of analysis of neural responses from cells in the nucleus tractus solitarius (NTS) and parabrachial pons (PB pons) of the hamster. Cross-correlational profiles for each stimulus across all the others were directly comparable to the behavioral similarity profiles. There was very good agreement between these measures for both the NTS and PB pontine neurons, with the exception of the cross-correlations involving quinine from cells in the PB pons. Classification of these NTS and PB pontine cells into best-stimulus categories allowed an examination of the contribution of these neural channels to the neural representation of gustatory quality.

269 BIOCHEMICAL BASIS OF THE SYNERGISTIC TASTE EFFECT OF MSG AND 5'-RIBONUCLEOTIDES. Kunio Torii* and Robert H. Cagan. Monell Chemical Senses Center, Univ. of Pa. and Veterans Admin. Hosp., Philadelphia, PA. 19104

Monosodium glutamate (MSG) evokes a taste sensation that is characterized as "unique" or "distinctive"; it is called *umami* in Japanese, which translates as "savory." The remarkable synergistic effect of certain 5'-ribonucleotides in mixtures with MSG is well documented. The taste intensity of such a mixture is greater than the sum of the tastes of the two components. Neither the site of action nor the biochemical mechanism of glutamate taste has been known, although various possibilities were suggested [R.H. Cagan (1977) In *Chemical Senses and Nutrition*, ed. by Kare and Maller. Academic Press, N.Y., pp. 343-359]. In particular, attention was called to the synergistic action as an important criterion to guide biochemical studies.

We have measured directly the binding of L-[^{3}H]glutamate to preparations from bovine circumvallate (CV) (taste) papillae and from tongue epithelium (EP) devoid of taste buds as a control. Differential centrifugation of homogenates of EP and of the sidewall epithelium from CV resulted in a sedimentable fraction. Binding was assayed using L-[^{3}H]glutamate as a ligand with a rapid Millipore filtration method [J.M. Krueger & R.H. Cagan (1976) *J. Biol. Chem.* 251: 88-97].

Substantial binding occurs to CV, while the amount bound to EP is very low. The K_D for L-glutamate was estimated to be 17-20 mM. A remarkable enhancement of binding of L-[^{3}H]glutamate was caused by 5'-GMP. Scatchard analyses showed that the K_D for L-glutamate remained unchanged in the presence of GMP while the maximal binding capacity increased from 10 nmol/mg protein to 60 nmol/mg. The enhancement shows a degree of specificity for the nucleotide indicating that the effect is not merely a nonspecific perturbation. GMP, IMP, and UMP each caused enhancement. On the other hand, CMP and AMP were not effective, and none of these five nucleotides showed any stimulation of the low level of glutamate binding to EP. Guanine, GDP, GTP, adenine, ADP and ATP were ineffective in enhancing glutamate binding to CV.

We postulate (*i*) that the synergistic effect between MSG and 5'-ribonucleotides occurs peripherally at the taste receptor membrane, and (*ii*) that the mechanism of the effect is an increase in the number of available glutamate binding sites caused by the ribonucleotide. This may be related to the phenomenon of ligand enhancement of binding seen with the alanine taste receptors of the catfish [R.H. Cagan (1977) *Soc. Neurosci. Abstr.* 3: 77, Abstr. No. 222]. In the present case, it is possible that the ribonucleotide causes exposure of "hidden" glutamate binding sites.

[Supported in part by NIH research grant NS-08775 from NINCDS.]

270 RESPONSIVENESS OF DOG OLFACTORY RECEPTORS TO THE FATTY ACIDS BUTYRIC, MYRISTIC, OLEIC AND LINOLEIC ACID, AMYL ACETATE, DIMETHYLBENZYLCARBINYL ACETATE AND ANISOLE. Don Tucker and Sadao Kiyohara*. Biol. Sci., Florida State Univ., Tallahassee, Fla. 32306, U.S.A.

Olfactory nerve twig preparations were used for electrical recording of action potential responses from the axons of olfactory receptor cells. The overlapping impulse activity, due to the large numbers of about 0.2 μm diameter axons contained in the smallest possible nerve twigs, was quantified with the leaky-integrator technique to yield a moving average of the firing rate of a small population of the olfactory receptors. The stimuli were delivered to a nasal breathing chamber with a continuous flow of air by the naris at 100 cc/sec. Concentrations were varied over the range 10^{-3} to unity of vapor saturation at 20°C.

Amyl acetate elicited the largest response and was used as the standard for comparison; only two other odorants were available at any time in the olfactometer. Breathing patterns were so variable under Nembutal anesthesia that tracheostomies were performed and air was pulled through the ipsilateral nasal cavity (contralateral nostril plugged). The response dependence on nasal flow rate was least for amyl acetate, responses tending to reach concentration-dependent plateaus at the limit of 100 cc/sec.

Response-concentration curves, at 32 cc/sec, ranged highest to lowest in the order amyl acetate, anisole, butyric a., dimethylbenzylcarbinyl acetate (DMBCA), linoleic a., myristic a, and oleic acid. Nitrogen gas was used in the odor-saturated line to avoid air oxidation of the sensitive unsaturated acids. The magnitude of response to DMBCA was small, although in turtles the maximal values for amyl acetate and DMBCA are about equal. The butyric a. response relative to the amyl acetate response was noticeably greater than in turtle and rabbit. However, responses to the large fatty acid molecules were small. The butyric acid response dependence on flow rate was so strong that the response was approaching that to amyl acetate at 100 cc/sec.

A response to either a residual contaminant in the olfactometer or an odor derived from the front of the dog's nose appeared as an increasing function of nasal flow rate. The flow-rate response, appearing before application of a stimulus, made measurements of small response ambiguous. For example, linoleic a. response measured from the level of flow rate response was much smaller than if measured from the no-flow baseline level. The linoleic a. response may have been accelerating similar to the butyric a. response as a function of flow rate. Also, use of butyric a. caused responses to other stimuli, including that responsible for the flow-rate response, to increase. This effect was interpreted as an increase in accessibility to the olfactory receptors caused by reflex changes in nasal dimensions.

Supported in part by NIH Grant NS08814.

271 X-IRRADIATION INDUCED GRANULOPRIVAL OLFACTORY BULB: PRELIMINARY BEHAVIORAL AND ANATOMICAL FINDINGS. C. P. Walters* and R. G. Struble* (SPONSOR: J. Altman). Lab. Devel. Neurobiol., Dept. Biol. Sci., Purdue Univ., West Lafayette, IN 47907.

Low-level X-irradiation is known to kill mitotic and migrating precursors of neurons. By starting X-irradiation schedules of the olfactory bulbs of male rats soon after birth and continuing until 17 days postnatally, a dramatic loss of small neurons (granule cells) can be obtained with little if any effect on mitral or tufted cell numbers. Behavioral and anatomical data from the granuloprival main bulb preparation were obtained.

The main bulb of the X-irradiated animals is reduced in volume by about 80% relative to control bulbs. All of the subdivisions of the main bulb (e.g. external plexiform layer, internal granular layer) are affected, with the possible exception of the nerve layer. Granule cells are greatly reduced in number, while there is a normal but more tightly packed complement of mitral and tufted cells. Golgi-Cox analysis of the mitral cells suggests abnormalities of cell shape and dendritic field.

The behavior of the X-irradiated animals was indistinguishable from controls on tasks that presumably involve olfactory orientation and/or detection: initial homing to cage shavings; finding buried food; learning an olfactory mediated "Y" maze; reacting to the odor of a cat; mating; and acquisition of a conditioned food aversion.

In contrast, where the olfactory components are more subtle and may require greater integration with non-olfactory information, testing reveals group differences. X-irradiates, as compared with controls, show decreased preferences in food selection tests; take longer to eat a novel food in a novel environment; do not modify their behavior after a noxious tone in an open field; and decrease activity at a slower rate in a novel environment, while they are more activated by novel visual and visual-tactile objects in that environment.

In sum, there are gross anatomical differences between X-irradiated and control animals' main bulb. Surprisingly, there are minimal differences on tasks that may be directly olfactorily mediated. Conversely, the two groups differ when the tasks are not obviously olfactorily mediated. Further, the behavioral effects resulting from neonatal X-irradiation are not similar to reported effects of bulbectomy, arguing against a mass effect and for a selective cell loss hypothesis.

272 POSTNATAL NEUROGENESIS AND REGENERATION OF THE VOMERONASAL EPITHELIUM FOLLOWING AXOTOMY IN GARTER SNAKES. Ruu-Tong Wang, Louis Guida* and Mimi Halpern. Dept. of Anatomy & Cell Biology, SUNY Downstate Medical Center, Brooklyn, N.Y. 11203.

Previous morphological observations of the vomeronasal (VN) epithelium of adult garter snakes (Wang, Kubie & Halpern, Neuroscience Abstract, Vol. 3, p. 85) revealed heterogeneity in cell morphology particularly in both the undifferentiated (Ud) and bipolar (Bp) cell layers suggestive of a continuous process of cell proliferation, differentiation, maturation, aging and cell death. This report confirms the dynamic nature of the epithelium. The VN nerves of garter snakes (Thamnophis sirtalis & T. radix) were bilaterally transected. ^{3}H-thymidine was injected intracardially 24 h prior to sacrifice in animals surviving 1 to 28 days. ^{3}H-proline was injected into the VN organs 24 h prior to sacrifice in other animals surviving 4 to 16 weeks. One VN organ was removed and processed for electron microscopy. The head containing the remaining VN organ was processed for autoradiography.

Following axotomy ultrastructural changes are observed in Bp neurons on postoperative day 2. Degeneration marked by retrograde necrosis and cell loss in the Bp cell layer commences on postoperative day 4, reaches a climax two weeks following axotomy and declines drastically throughout an eight week period. On the other hand, one week following axotomy, the Ud cell layer expands to occupy a portion of the former Bp cell layer. Ud cells continue to increase in number and, by 4 postoperative weeks, occupy two-thirds of the original cell column.

Studies of ^{3}H-thymidine uptake reveal that following VN nerve lesions, the number of labeled Ud cells increases over control (unoperative) levels and this increase is proportional to the length of the postoperative interval.

Eight weeks following surgery and continuing into the 16th postoperative week signs of neuronal maturation are observed among the Bp cells at the apex of the cell column. These neurons sprout a distal process (dendrite) oriented toward the luminal surface of the organ, and a central process destined to terminate in the accessory olfactory bulb (AOB). Injection of ^{3}H-proline into regenerating VN organs reveals that these axons transport labeled macromolecules. Label is found in the AOB in animals surviving eight weeks following axotomy.

These studies suggest that Ud cells are a source for postnatal replacement of neurons in the VN organ. The mitotic activity of Ud cells presumably for the purposes of neuronal replacement under normal conditions is low, but can be enhanced by axotomy. Apparently, after axotomy the VN epithelium regenerates through postnatal neurogenesis.

273 INTRACELLULAR RESPONSES AND CHARACTERISTICS OF TASTE BUD AND LINGUAL CELLS OF THE MUDPUPPY. Charles H. K. West and Rudy A. Bernard. Dept. Neurophysiology, Univ. of Wisconsin, Madison, WI 53706 and Dept. Physiology, Michigan State Univ., East Lansing, MI 48824.

Due to their exceptionally large size, the cells of the mudpuppy tongue are advantageous for intracellular recordings. Therefore, this animal was selected to investigate certain aspects of taste reception such as taste bud cell specificity, electrotonic coupling, and correlation of physiological responses with the different anatomical types of cells. Intracellular recordings of membrane potentials of mudpuppy lingual cells were made with micropipette electrodes. Three types of cells were distinguished by their responses to chemical stimulation. Surface epithelial (SE) cells outside of taste buds responded with large membrane potential and resistance changes to a variety of stimuli representing the four taste qualities. Salts and acids evoked particularly large and rapid potential changes, and $MgCl_2$, acids and quinine greatly increased the membrane resistance. One type of taste bud cell (TB-1) was characterized by large depolarizations to K-salts, and the other type of taste bud cell (TB-2) characteristically hyperpolarized to $MgCl_2$, acid, and sugar solutions. Membrane resistance changes accompanying TB-1 and TB-2 cell responses were relatively small compared to those of SE cells. Electrotonic coupling was observed between pairs of SE and TB-2 cells but not for pairs of TB-1 cells nor cells of different types. After recording cell responses, dye marking with Procion navy blue dye allowed verification of results in situ and histologically. From the identification of cells in section, it is hypothesized the TB-1 and TB-2 cells identified physiologically here correspond to the morphologically defined light and dark cells respectively. Responses of TB-1 cells imply a taste receptive function; whereas, TB-2 cell responses suggest secretory, supportive, and/or receptive function.

274 TASTE NEURON RESPONSE PROFILES: NO EVIDENCE FOR TYPES. D.C. Woolston* and R.P. Erickson. Dept. Psychology, Duke University, Durham, NC 27706.

Frequently in taste neurophysiology the possibility of types of neurons corresponding in some sense with the "primary" taste qualities of Henning has been entertained; recently types of gustatory neurons have been proposed by Frank according to which of the classical "primary" stimuli single neurons give their best response (ISOT VI: 241, 1977); considerable variation occurs in response profiles of neurons of the same type. This variation and previous research by Erickson (Psych. Rev. 75: 447, 1968) and associates suggest that there may be instead a more or less continuous distribution of neuron profiles. To resolve this issue, the responses of 50 single neurons (recorded from the gustatory nucleus tractus solitarius in anesthetized female Sprague-Dawley rats) to as many as 32 chemical stimuli were analyzed by multidimensional scaling and hierarchical cluster analyses. No evidence for clusters of highly similar neuron response profiles was found by either method; similar analyses of the stimuli showed no clear evidence for stimulus types, but the possibility of complex stimuli clouds this issue. The results question the relevancy of the term "primary" for neural coding in taste, and suggest that not all neuron populations need be subdivided into types for an understanding of their organization and function. It is concluded that, just as in audition and color vision where stimulus dimensions are better understood, taste neurons can profitably be depicted in a coherent neuron-stimulus space. In this taste space, the neurons are evenly distributed along stimulus dimensions, as auditory neurons are spaced in an ungrouped fashion along the frequency dimension. (Supported by grants from the US Army and NSF).

275 RESPONSES OF OLFACTORY RECEPTORS IN FETAL AND NEONATAL RATS. R. A. Yancey* and R. C. Gesteland. Northwestern Univ. Dept. of Biological Sciences, Evanston, IL 60201.

The relations between sensitivity to olfactory stimulation and developmental age of olfactory receptor neurons were investigated in rat fetuses from day 11 to term and in neonates from birth to 20 days of age. The olfactory receptors are first seen in fetuses about 12 days old. Responses of the olfactory organ as measured by electro-olfactograms (EOGs) and of single receptor neurons measured by recording action potentials extracellularly are clearly evident between two and four days after the receptors first differentiate from neural anlagen tissue. Responding cells in day 14 to day 17 fetuses appeared non-selective, showing excitation to all stimuli presented (amyl acetate, n-butanol, eugenol, and valeric acid). After day 17 cells were selective in their responses. This is the time when synaptic connections between the receptors and the cells of the olfactory bulb are established. Typically cells were excited by one or more substances and inhibited or not affected by others. They generally were not excited by all four. Fetal EOGs were like those evoked by odors in neonates and adults except that the peak amplitudes were low between days 14 and 17. This may be due to low receptor cell density, shunting of the small tissue mass by bathing saline, or reduced response capacity. Recording from single receptors was remarkably easy in fetuses 16 or more days old. In most preparations only a brief search was required to isolate units with either a platinized metal microelectrode or a pipette with a tip diameter of 3 microns filled with 3M NaCl made up in a 1.5% by weight gelatin solution. The activity of single cells was usually followed for less than 30 minutes, although some units lasted for more than an hour. Responses to stimulation were repeatable during this period. EOG amplitudes were stable for periods exceeding 5 hrs in the best preparations. Commonly the log of the EOG amplitude varied linearly with the log of the stimulus concentration over a range of 0.004 to 0.4 times saturation. Slopes varied from 0.38 to 1.25 and were functions of the stimulus substance and the particular preparation. Fetal olfactory receptors from day 17 on are much like their post-partum counterparts both with respect to the patterns of stimulus-evoked activity and to the irregular, bursting spontaneous activity. For these experiments the olfactory epithelium was quickly exposed after ligation of the unbilical cord and removal of the fetus from the anesthetized (pentobarbital, 35 mg/kg) mother. The fetus was immediately transferred to an experimental chamber maintained at room temperature with an atmosphere of moisture-saturated 95% O_2-5% CO_2. Supported by NSF Grant No. BNS 75-02339.

276 A THEORETICAL MODEL OF THE FLY NERVOUS SYSTEM IN FEEDING. Jacob Zabara and Elizabeth Omand* (SPON: A.R.Freeman)Department of Physiology & Biophysics, School of Dentistry, Department of Physiology, School of Medicine, Temple Univ., Phila., PA 19140.

It has been postulated that, in addition to sensory input, neural autorhythmicity is an important element of the central excitatory state (CES) which culminates in feeding behavior†. We describe by this model some possible relationships between the sensory and autorhythmic activities of the fly's nervous system. In this limit cycle representation, every major element of the feeding system may oscillate at a different phase or lag time. The minimum of the cycle corresponds to the satiety state and the maximum to the fully developed feeding behavior leading to ingestion. Sustained ingestion completes the cycle as satiety supervenes.

The gain of the system relates to the development of the CES. The fully developed CES represents a state of autorhythmic activity upon which is superimposed sensory input activity. We assert in this model that a corresponding region of the brain neuropil is involved in the development of the CES. A single oscillation of the limit cycle begins with an increase in the autorhythmic activity of this neuropil, which then initiates food searching behavior. Ingestion is consequent to direct chemoreceptor stimulation (labellar nerves), producing an increment in the CES. The increment is a partial function of prior receptor potentiation. The CES and receptor activation show a parallel and either can indicate the gain of the system. Other cyclic phenomena (e.g. photophase) can interface with feeding through the action of the CES.

By this model, the overall excitational state of the neuropil can be summarized as follows:

$$S_i = \int_{i=o}^{i=n} \frac{de}{dz} \cdot Z_i \, dz,$$

where S_i = the central excitatory state (CES)
Z_i = the equivalent synapse
e = excitation
$\frac{de}{dz}$ = the excitability factor

This model, which represents an integration of receptor dynamics with centrally mediated processes, will be discussed in relation to pertinent mammalian studies. (NIH Grant RO1-NS-14209-A).

COMPARATIVE NEUROBIOLOGY

277 HETEROLATERAL INFLUENCE OF LIGHT UPON RETINAL SHIELDING PIGMENTS POSITION IN THE CRAYFISH. B. Barrera-Mera, G.Y. Berdeja-García* and J. Cibrian-Tovar*. Depto. de Fisiología, Fac. Med., U.N.A.M. & Rama de Entomología, Col. Postgraduados S.A.R.H., Chapingo, México, D.F.

The strong tendency to maintain the same frequency and phase angle of the electroretinogram (ERG) of both left and right eyes during circadian oscillations in Procambarus bouvieri (Barrera-Mera, 1978 in Press) as well as the bilateral diminution of the ERG voltage seen after sustained (60 min) photic stimulation of either eye (Barrera-Mera and Abasta, Brain Res. Bull. 3: 101-106, 1978) suggested that bilateral input of light activates the neuroendocrine system of the sinus gland in both eyestalks and thus modulates the crayfish retinal sensitivity. We have found that eye glow area (EGA) diminution, due to the light adaptation position of retinal shielding pigments (RSP), can also be heterolaterally induced (Fig. 1 Ac). This response, better observed during the rest phase of ERG circadian oscillations, has a relative long latency (15-20 min), is proportional to the intensity of the heterolateral photic stimulation and is suppressed by surgical bisection of the supraesophageal ganglion (Fig. 1 Bc).

The equal migration toward the light adaptation position of the distal (d) RSP on both sides in intact animals (Fig. 2 A) but not in splitbrain animals (Fig. 2 B) contrasts with the mobilization of proximal (p) RSP. Since the ERG, EGA size and dRSP follow a similar time course we believe RSP mobilization is an important modulating influence on the retinal sensitivity due to the action of light adapting hormone.

Fig. 1

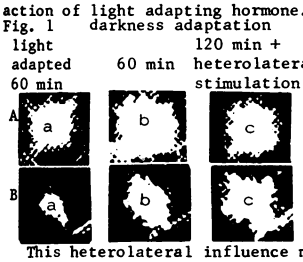

Fig. 2

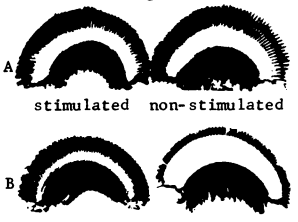

This heterolateral influence mediated by the position of the peripheral effectors dRSP, may be the synchronizing process for the entrainment of the left and right ERG during circadian changes. This interesting model seems to be the first for which the coupling mechanism of symmetrical circadian pacemakers of apparently similar hierarchical importance has been found.

278 OLFACTORY PATHWAYS IN THE CHANNEL CATFISH, ICTALURUS PUNCTATUS. Andrew H. Bass. Division of Biological Sciences, University of Michigan, Ann Arbor, MI 48109.

Secondary olfactory pathways in channel catfish were studied by autoradiographic and Fink-Heimer methods. Seven animals were injected with 100-200 nl of ^{3}H-proline in the olfactory bulb and allowed to survive 7-12 days. The olfactory peduncle was cut in 3 animals who survived 3-10 days.

The present analysis utilizes the nomenclature of Nieuwenhuys (J. Hirnforsch. 6:171, 1963). The olfactory bulb projects to the ipsilateral subpallium, pallium, preoptic area, hypothalamus, and contralateral olfactory bulb. As the medial olfactory tract (MOT) courses along the ventromedial surface of the subpallium, a sparse terminal field appears lateral to the ventral subpallial nucleus (Vv). Fibers course dorsomedially to terminate in a capsular fashion about the dorsal subpallial nucleus (Vd). An additional terminal field appears lateral to Vd. The lateral olfactory tract (LOT) courses along the ventrolateral aspect of the pallium to terminate in an expansive ventrolateral zone. The latter comprises rostral and caudal (Dp) divisions. Dp receives the largest, densest olfactory input in the pallium. The area dorsal and medial to Dp also receives olfactory input. This area (Dc) contains a dorsal region receiving a sparse olfactory input, and a central area receiving a denser input. Continuous with Dp, an additional terminal field, the intermedial nucleus of the subpallium (Vi), extends ventromedial.

Olfactory fibers proceed caudally to terminate in the nucleus preopticus periventricularis anterioris. Olfactory fibers also terminate in a caudal medial region of the hypothalamus. All terminal fields are bilateral. The MOT crosses in the anterior commissure (AC) and gives rise to an interbulbar commissure also. The LOT crosses in the AC and the habenular commissures.

These findings generally confirm those in the bullhead catfish (Finger, JCN 161: 125, 1975). Additional subpallial and preoptic inputs are described.

279 BASAL METABOLISM PREDICTS SIZE OF VERTEBRATE CNS. Robert J. Blumenschine*, Jonathan W. Mink*, and David B. Adams. Dept.Psych. Wesleyan Univ., Middletown, CT 06457.

We have found that in most vertebrates between two and ten percent of the total basal metabolism is used by the CNS. The relationship is practically linear for the following animals: perch, trout, sharks, frogs, python, turtles, chicken, pigeon, sparrow, swallow, emu, shrew, bats, rabbit, horse, zebra, elephant, various rodents, ungulates, carnivores, primates, and cetacea. Whole body metabolism was available for most animals, but CNS metabolism was available only for a few mammals and was calculated for the other animals from rates of CNS metabolism and brain and spinal cord weights. On a log-log scale, 105 individual determinations correlated .96 to a regression equation with a slope of .95.

Data for a few vertebrates do not lie close to the regression line. Humans use a remarkably high 20% of their resting metabolism for the CNS. The whale's low percent (0.15%) may be due to a recent phylogenetic increase in body size which has not been matched by brain size, since smaller cetacea (porpoise and dolphin) are similar to other vertebrates. The low values for domestic livestock (pig, cow, sheep, horse) may be due to domestic selection for increased body size without selection for increased brain size, since other domestic animals (cats, dogs) show predicted values.

If the above exceptions,humans,whale,and domestic livestock, are removed from the regression equation,then the remaining 88 determinations show a correlation coefficient of .98 and a slope of .99. The slope of unity means that the equation is a linear one,unlike the logarithmic equations which have been used traditionally to predict body metabolism or brain size from body size.

The direct linear relationship of CNS and body metabolism makes possible an improved method for predicting CNS size of any vertebrate. Previous methods using non-linear equations, have required separate factors for poikilotherms and homeotherms. The new equation is based on the linear relationship of CNS and body metabolism for all vertebrates. It is complicated only by the calculation of CNS metabolic rate which is known to vary as an orderly function of temperature, temperature acclimation,and neuronal packing density. The latter,in turn,is proportional to body size.

The data suggest a new interpretation for the dramatic increase in ratio of brain to body weight which occurred in the phylogenetic transition from poikilothermy to homeothermy. By increasing their resting metabolic rates by an order of magnitude, homeotherms were able to afford CNS metabolism which was also an order of magnitude greater. The increase came mostly in CNS size rather than in CNS metabolic rate which increased a smaller amount up to the level which would be expected for a poikilotherm at 37°.

280 ORGANIZATION OF THE THALAMUS IN THE LONGNOSE GAR, LEPISOSTEUS OSSEUS. Mark R. Braford, Jr. and R. Glenn Northcutt. Division of Biological Sciences, University of Michigan, Ann Arbor, MI 48109.

Following cytoarchitectonic analyses, graphical reconstructions, and the study of various afferent fiber systems with degeneration and/or autoradiographic methods, the thalamus of gars has been divided into three major zones. The pars dorsalis and the pars ventralis form longitudinal zones, whereas the pars tuberculi posterioris lies caudoventral to them (cf. Bergquist, Acta Zool., 13, 1932). The pars dorsalis consists of three major cell groups: a rostral complex comparable to DM-DL of Schnitzlein, which receives a retinal input, and two caudal groups --the dorsal posterior nucleus, which receives a tectal input, and the central posterior nucleus. Between the pars dorsalis and the pars ventralis lies a slightly migrated group, nucleus intermedius, a portion of which receives a retinal input. Whether this group is part of the dorsal thalamus or the ventral thalamus, or constitutes a separate zone (see Bergquist) is unclear without further data. The pars ventralis consists of a prominent, laminated, periventricular group, the ventromedial nucleus, which receives a cerebellar input, and a smaller migrated group, the ventrolateral nucleus, which receives a retinal input. The pars tuberculi posterioris lies dorsal to the hypothalamus and rostral to the tegmentum. In gars, as in the actinopterygian fishes generally, the pars tuberculi posterioris is relatively much larger and more complex than in any other group of vertebrates. Its major constituents include nucleus tuberis posterior (which receives an input from the olfactory bulb), the preglomerulosus complex (which receives an input from the telencephalon proper), nucleus thalami posterior, and nucleus supramammillaris. No true nucleus glomerulosus is present in gars. The so-called nucleus geniculatus lateralis receives a retinal input but appear to be a superficial pretectal nucleus rather than a part of the thalamus.

This work was supported by PHS Grant 1 R01 EY02485 to RGN.

281 THE CROCODILIAN MIDBRAIN TEGMENTUM: A KEY TO UNDERSTANDING THE AVIAN THALAMUS. Steven E. Brauth, Cheryl A. Kitt & John L. Ferguson, Dept. Psychology, Univ. of Md., College Park, Md. 20742

In birds, two paths descend from the thalamus: a thalamocerebellar path originating from the nucleus spiriformis medialis (SpM), and a thalamo tectal path originating from the nucleus spiriformis lateralis (SpL) (Karten & Finger, 1976; Brecha, Hunt & Karten, 1976). However in the mammal there are no direct paths from the thalamus to either the cerebellum or the superior colliculus. In an attempt to interpret these major differences in avian and mammalian thalamic organization, neuroanatomical tracing techniques were employed to determine the origin of midbrain or thalamic afferents to the cerebellum and tectum of a crocodilian, Caiman crocodilus. Fossil evidence suggests that Crocodilians may closely resemble the ancestors of birds.

Two nuclei: nucleus circularis (Cr) and the interstitial nucleus of the posterior commissure (nICP) were identified in the midbrain tegmentum of Caiman each of which projects upon lobus medialis of the cerebellum. Also a nucleus, the dorsal nucleus of the posterior commissure (nDCP) was identified in the midbrain tegmentum of Caiman which projects to the tectum. Like SpL of birds, nDCP receives projections from the paleostriatum as shown by autoradiographic tracing of anterograde projections of the paleostriatum (nucleus basalis of Kuhlenbeck) in Caiman. These pathways allow the basal ganglia to influence the tectum in both birds and crocodilians. Thus, cell groups exist in the midbrain tegmentum of Caiman, which, based on afferent and efferent connections are comparable to posterior diencephalic nuclei in avian forms.

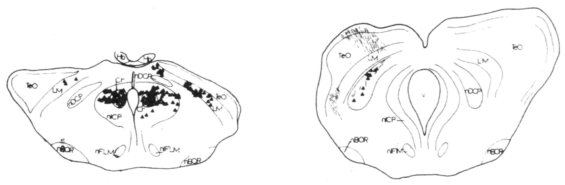

Figure on the left represents the pattern of label in Cr and nICP after an HRP injection in the lobus medialis of cerebellum in Caiman. On right, cells in nDCP are labeled after tectal HRP.

282 EFFECTS OF SERIAL LESIONS OF TELENCEPHALIC COMPONENTS OF THE VISUAL SYSTEM IN PIGEONS. Nellie M. Bugbee*, William Hodos, and Tatiana Pasternak. Dept. of Psych., Univ. of Maryland, College Park, MD 20742

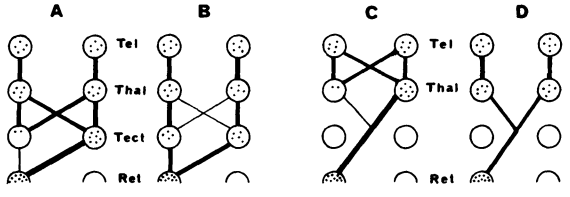
Pigeons were trained to discriminate three types of stimuli in a quasi-random sequence: color stimuli (yellow vs. green), intensity stimuli (0.8 log unit difference) and two sets of pattern stimuli (vertical vs. horizontal bars and triangles with apex up vs. apex down). Following this training, one group of birds received lesions in the visual Wulst, which is the telencephalic component of the thalamofugal visual pathway. In a second group, lesions were made in ectostriatum, the telencephalic component of the tectofugal pathway. Postoperatively, both groups were retrained to criterion. As previously reported, birds with visual Wulst lesions were only mildly impaired while birds with ectostriatum lesions showed moderate to severe impairment on intensity and pattern problems.

After postoperative reacquisition of the discriminations, the ectostriatum-lesion group received lesions of the visual Wulst and the visual Wulst-lesion group received lesions of ectostriatum. In general, the effects of ectostriatum lesions in pigeons with prior visual Wulst lesions resulted in a postoperative return to chance performance followed by a protracted period of retraining to criterion. Thus, ectostriatum lesions seem to produce the same effects in birds with prior visual Wulst lesions as in birds with visual Wulst intact. In contrast, the effects of visual Wulst lesions in pigeons with prior ectostriatum lesions resulted in a profound and seemingly permanent impairment of pattern discrimination performance. Color and intensity discrimination were initially impaired but improved after retraining. Thus, the visual Wulst lesions produced markedly different effects in birds with prior ectostriatum lesions as compared to birds with ectostriatum intact. In a third group, simultaneous lesions of visual Wulst and ectostriatum were made. The performance of these birds was equivalent to that of pigeons with visual Wulst lesions that had been made after ectostriatum lesions.

These data indicate an order effect of visual Wulst lesions; i.e., the relative sparing of pattern discrimination following visual Wulst lesions depends upon an intact ectostriatum. No order effect was seen after ectostriatum lesions. Since the destruction of ectostriatum after visual Wulst lesions produces no greater impairment than lesions of ectostriatum alone, ectostriatum does not appear to serve as a "surrogate visual Wulst" in birds with visual Wulst lesions.

283 A POSSIBLE MECHANISM FOR THE CHANGE OF CENTRAL NERVOUS SYSTEM PATHWAYS OVER EVOLUTION. Ann B. Butler. Dept. Anat., Georgetown Univ., Washington, D.C. 20007.

From recent studies on visual system pathways, some common patterns can now be recognized within various groups. Figures below show general patterns of retinotectofugal projections in non-mammals (A) and mammals (B). While most non-mammals have predominantly crossed retinotectal projections, the tectum sends substantial projections to both the ipsilateral and contralateral thalamus. In mammals, however, the retinotectal projection is substantial ipsilaterally (Hubel et al,'75; Graybiel,'76; Harting and Guillery,'76; Tigges et al, '77) as well as contralaterally, and the subsequent tectothalamic projection is almost completely ipsilateral. Thus, similar net input from each retina to thalamus and telencephalon is achieved in both groups but via quantitatively differential development of different parts of the pathways. Taking the condition of predominantly crossed retinal projections to be ancestral among vertebrates, it is hypothesized that the increase in ipsilateral retinotectal projections in mammals resulted in a quantitative change in the post-synaptic pathway in this system--a decrease in contralateral tectothalamic projections--and this is referred to as trans-synaptic evolution. The same phenomenon may account for the presence of bilateral thalamotelencephalic projections in sharks, birds, and lizards (C) but not in mammals (D). This phenomenon, combined with sprouting of new pathways seen in response to deafferentation of a structure (Steward, '76), as would be the effect of decreased contralateral tectothalamic projections in mammals, can be envisioned to have occurred over evolution, resulting in changes of neural interconnections throughout the brain. Supported by NSF Grant BNS77-26022.



284 REFLEX CONTROL OF POSTURAL MUSCLE STIFFNESS IN HERMIT CRAB. William D. Chapple., Physiology Section, Biological Sciences Group, University of Connecticut, Storrs, CT 06268.

Phasic mechanoreceptors in the ventral epidermis of the hermit crab abdomen reflexly excite motoneurons innervating the ventral superficial muscles (VSM), the major group of abdominal muscles supporting the shell during standing and walking. Mechanical stimulation activates three motoneurons on each side of each segment. Muscle tension is elevated by the initial high frequency burst of the motoneurons and slowly declines during the after-discharge. The VSM are composed of four parallel groups of muscle fibers, each with characteristic sarcomere lengths.

Isometric length-tension curves of the VSM are complex. As the muscle is extended there are several tension plateaus, which suggests that in different types of muscle fibers, maximum tension is developed at different extensions. Constant velocity lengthening of the VSM and epidermis shows that the passive tension is high compared with the increment of force produced by a train of stimuli. In addition, tension is a linear function of velocity throughout stretch. In a muscle composed of muscle fibers with different length-tension curve maxima, nonlinearities during lengthening due to the short range elasticity of one muscle type may not be present. Such muscles would maintain specific positions by the reflex increase in muscle stiffness.

285 SPERM RELEASE EVOKED BY ELECTRICAL STIMULATION OF THE BRAIN OF THE GOLDFISH, CARASSIUS AURATUS. Leo S. Demski. School of Biological Sciences, Univ. of Kentucky, Lexington, KY 40506.

Stimulation sites were tested on 60 dorsoventrally directed electrode tracks in 9 fish (14-20 cm standard length). Semen release was evoked at 41 sites and 28 of these were identified histologically with Prussian blue. In general techniques used previously on sunfish (Demski, Bauer and Gerald; J. Exp. Zool., 191: 215-232) were employed. The main difference was that except for the first fish (2 stimulation sites) the anesthetic level (0.15%) was half that used with sunfish. The "standard procedure" of testing at each .1mm was used for 16 points and the technique of "maximizing the response" by moving the electrode up and down was used for 12 sites. Since there appear to be no significant differences in the results obtained using the two methods, the data from each have been combined. Several low threshold sites (15-50 μA) were found in and just dorsal to the nucleus glomerulosus complex while moderate to high threshold points (51-300 μA) were scattered throughout this region as well as the preoptic area, dorsal hypothalamus, subhabenular region and basolateral medulla (see table below). Allowing for species differences in brain anatomy, the results in goldfish appear comparable to those obtained earlier in sunfish. Thus, it can be suggested that similar sperm release mechanisms may exist in many teleosts.

Regional distribution of stimulation sites from which sperm release was evoked

Region stimulated	Threshold (μA)				
	15-25	26-50	51-100	101-200	201-300
Preoptic and adjacent areas	0	0	5	4*	1
Hypothalamus-near postoptic commissures	0	1	1	1	0
Subhabenular region	0	0	1	0	0
Tegmentum-near the n. glomerulosus complex	4	3	0	1	1*
Basolateral medulla-cerebellar to midvagal lobe levels	0	2	1	0	2

*one site was tested using the higher anesthetic level

286 BIVALVE HEART MUSCLE CELLS: RESPONSE TO IONTOPHORETICALLY APPLIED ACETYLCHOLINE. Ellen J. Elliott* (SPON: R.M. Steinman). Dept. Zool., Univ. Md., College Park, MD 20742.

The response to iontophoretically applied acetylcholine (ACh) was observed by intracellular recording from heart muscle fibers of three species of bivalves: Mytilus edulis (mussel), Mercenaria mercenaria (clam), and Crassostrea virginica (oyster). These species were chosen as representatives of the different types of response to bath-applied ACh (excitation, inhibition, and mixed excitation-inhibition) which have been reported for bivalve hearts. Hearts were bathed in an artificial sea water (ASW) solution in which $MnCl_2$ was substituted for $CaCl_2$ in order to abolish spontaneous contractions. Heart fibers were impaled with 80-100 MΩ microelectrodes filled with 2M KCl-1M Kcitrate or with 3M Kcitrate. The mean resting potentials recorded were -47, -50 and -44 mV for Mytilus, Mercenaria and Crassostrea, respectively. 20-50 MΩ iontophoretic microelectrodes were filled with 1M AChCl. In Mytilus, iontophoretic pulses of ACh caused a rapid depolarization which in a few cases was followed by a slower and smaller hyperpolarization. In Mercenaria, ACh caused only a relatively slow hyperpolarization. In Crassostrea, ACh always produced a biphasic response, consisting of a depolarization followed by a hyperpolarization. The two types of response were distinguished by differential sensitivities to antagonists and by different ionic dependencies. The depolarizing response was blocked completely by 5×10^{-5} M d-tubocurarine or hexamethonium, while the hyperpolarizing response was much less sensitive to these two drugs. The hyperpolarizing response was blocked completely by 10^{-7} M methylxylocholine, to which the depolarizing response was much less sensitive. The depolarizing and hyperpolarizing responses were both accompanied by apparent increases in membrane conductance, as determined by passing short pulses of current through an extracellular suction electrode. In Na-free ASW (substituted with Tris or glucoseamine) the depolarizing response disappeared completely and reversibly. In K-free ASW the hyperpolarizing response increased and in elevated-K ASW (22, 45 and 67 mM) it decreased progressively. The highest K concentration often caused reversal of the hyperpolarizing response, even though the resting membrane potential was significantly depolarized. In Cl-free ASW (substituted with isethionate and sulfate), the hyperpolarizing response was unchanged. These results suggest that the depolarization results from an increase in Na conductance and the hyperpolarization from an increase in K conductance. These two types of ACh response are similar in terms of pharmacology and ionic mechanism to two ACh responses seen in ganglionic neurons of Aplysia and other gastropods. The presence of a biphasic ACh response is also similar to the situation found in some gastropod neurons.

287 PHYLOGENY OF ENTERIC SEROTONERGIC NEURONS. J.T. Goodrich and M.D. Gershon (SPON: C. Noback). Dept. Anat., Col. P&S, Columbia Univ. New York, N.Y. 10032.

Serotonergic neurons have been identified in the enteric nervous system of humans, sub-human primates, rodents and chicks. These neurons have a high-affinity uptake system for serotonin which is Na^+- and energy-dependent. The neurons can be grown for long times in organ culture and so are intrinsic to the gut. These enteric neurons can synthesize serotonin (5-HT) from L-tryptophan and contain immunocytochemically demonstrable tryptophan hydroxylase. The high-affinity uptake of 5-HT permits visualization of these neurons by radioautography. These neurons have been found to develop early in ontogeny. Nevertheless a phylogenetic study of their evolution has not yet been done. Such a study would provide insight into whether these neurons in mammals represent a well established neuronal system common to all vertebrates. Baumgarten et al., have reported serotonergic neurons in the lamprey gut. However, since modern cyclostomes have diverged considerably from the ancestral form that gave rise to higher vertebrates, it is necessary to demonstrate enteric serotonergic neurons in another cyclostome species before one can consider them to be characteristic of cyclostomes generally and not just a specific feature of the lamprey bowel. The present study was undertaken to investigate the other major class of cyclostome, Myxine glutinosa (Hagfish). Serotonergic neurons were identified by radioautography. Both strips of muscularis externa with attached myenteric plexus and diced whole tissue were incubated with ^{3}H-5-HT (0.9uM) with excess (9uM) norepinephrine added to prevent 5-HT uptake by catecholaminergic mechanisms. Additional controls were done by adding either a 100-fold excess of cold 5-HT to rule out non-specific binding or Lilly 110140 (fluoxetine), a potent 5-HT uptake inhibitor, fifteen minutes prior to the addition of ^{3}H-5-HT. Radioautography revealed uptake of ^{3}H-5-HT into axons in both the muscularis externa and in the submucosal region. This uptake was prevented by the addition of cold 5-HT or Lilly 110140 prior to the addition of ^{3}H-5-HT. Occasionally, labelled cell bodies could be seen in the muscularis externa and submucosal regions. We conclude that serotonergic neurons are present in the enteric nervous system of these primitive vertebrates and the cell bodies are intrinsic to the gut. Since enteric serotonergic neurons are found early in ontogeny and phylogeny and have been retained in evolution of both birds and mammals, it seems likely that they are a general feature of vertebrates and are probably critical to enteric function. Supported by NIH grants #NS 12969 and GM-02042.

288 TECTAL AFFERENTS IN GOLDFISH AS REVEALED BY RETROGRADE HRP LABEL. B. G. Grover* and S. C. Sharma.
Dept. Ophthalmology, New York Medical College, N.Y.C. 10029.

The optic tectum in fish has long been considered a primary site of sensory motor integration. However, recent studies in several teleosts failed to confirm the existence of tectocerebellar and tecto-oculomotor pathways. The only efferents to the optic tectum in fish that have been studied with modern techniques are those from the retina and telencephalon. Detailed information is necessary before the role of the fish tectum can be understood. We have used retrograde transport of HRP to determine the centers which project to the tectum in goldfish.

Following injections of HRP into the tectum, labelled cells are found in the telencephalon, several diencephalic-pretectal nuclei, the contralateral tectum and a number of tegmental centers. The diencephalic-pretectal areas include the area pretectalis, nucleus pretectalis, nucleus dorsomedialis and nucleus dorsolateralis.

HRP labelled cells were found in the rostral dorsolateral tegmentum, in the torus semicircularis and the nucleus isthmi. A large group of cells caudal and rostral to the nucleus glomerulosis also projects to the tectum. A number of HPR labelled cells were found in the group of efferents that exit the lateral tectum. Some of these cells appear to have one process that reaches the tectum and another that continues down the ipsilateral ventral rectus of the tectobulbar tract (TTB). Cell bodies were also found in the lateral reticular formation of the pons, in the vicinity of the TTB. A few small cells in the area of the dorsal oculomotor complex were found to contain HRP. The tectum also receives a heavy projection from the nucleus lateralis valvula; it is possible that the axons of these cells were mistakenly identified as the dorsal tecto-oculomotor and tecto-cerebellar tracts by early workers.

Fibers of passage through an injection site often pick up HRP. We have traced fibers through the intertectal commissure into the contralateral tectum and out into the contralateral torus semicircularis, where they form terminal fields. These fibers apparently originate from cells in the torus semicircularis on the injection side.

HRP-containing fibers are found in the TTB as far caudal as the gustatory lobe. These fibers probably represent tectal efferents because labelled cell bodies were not found at these levels.

289 GANGLIOSIDE PATTERNS IN VERTEBRATE RETINA AND BRAIN: REGIONAL AND PHYLOGENETIC VARIATION. Louis Irwin and Carol Irwin* (SPON: G. Adelman). Dept. Biochem., Shriver Center, Waltham, MA 02154.

Gangliosides are sialoglycosphingolipids which separate chromatographically according to molecular complexity into patterns that vary phylogenetically. Since regional differences in ganglioside patterns have been reported for the mammalian CNS, particularly differences between the retina and the brain, the observed phylogenetic variations could be due to the gross differences in brain morphology between evolutionarily diverse groups. To examine this possibility, we have analyzed ganglioside patterns from the retina and three morphologically distinct brain regions (medulla, midbrain, forebrain) in each of five species (goldfish, bullfrog, lizard, chick, rat) from different vertebrate classes. Gangliosides were extracted with chloroform:methanol (2:1, v/v), filtered through a Unisil column, eluted with chloroform:methanol: water (10:10:3), resolved by thin layer chromatography on Silica Gel G, and visualized with resorcinol reagent. The full range of ganglioside complexity typically seen in mammalian brains was present in all five species, indicating widespread distribution among the vertebrates of a full set of enzymes for ganglioside synthesis and breakdown. However, the ganglioside patterns varied in detail uniquely for each species, suggesting species-specific differences in the quantitative expression or activity of identical enzymes and/or gene duplication of functionally related enzymes. In contrast to the phylogenetic differences in ganglioside pattern, different neural samples from the same species always showed similar ganglioside patterns despite gross morphological differences. Even the retina differed in ganglioside pattern less from homospecific brain samples than from heterospecific retinal samples. Thus, differences in brain morphology alone cannot account for the phylogenetic variation in ganglioside patterns. (Supported by NSF Grant BNS 77-20575).

290 ARCHICORTICAL FORMATIONS IN DOLPHIN BRAIN. Myron S. Jacobs*, Peter J. Morgane and Willard L. McFarland. Dept. Path., NYU Coll. Dent., New York, NY 10010; Worcester Found. Exp. Biol., Shrewsbury, MA 01545; NIH, Bethesda, MD 20014.

Our studies of the archicortex (Acx) in the cetacean brain have distinguished a number of interesting and critically different features as compared to brains of other mammals. The archicortical formations merge with those of the paleocortex (Plcx) bilaterally in the unci and anteriorly in the septal area. In the temporal sector the archicortical formations are most definitive as in higher mammals with expanded, temporalized hemispheres. Anteriorly they merge with the periamygdalar area of the Plcx and laterally border on the entorhinal area (periarchicortex,Periacx). The dentate area (FD), characterized by small granule cells, is highly reduced, attenuates rapidly posteriorly and is confined to the temporal sector. The cornu ammonis about the shallow hippocampal sulcus (HS) is also distinctive. Areas h5 and h4 are less pronounced than in primates. Area h5 contains only scattered polymorphic cells in the hilus of FD. The medium sized pyramids of area h4 organize into superficial hyperchromatic and deep lighter staining zones. The more cellular areas h3 in the floor, and h2 and h1 along the medial wall of HS show increasing separation into two cell zones towards the subiculum (Sb), the superficial layer being broken up into nests of hyperchromatic larger pyramids. The Sb cell plate is broader and its smaller cells radially oriented. Although cytoarchitecture of the Sb and presubiculum of the Periacx is not as definable as in man, their architectonic transition is marked by a steplike notch in the cellular plate. In the retrosplenial sector, the Acx extends over the splenium as the fasciola cinerea (FasCin) and is less definitive. The hippocampal plate, reduced to 7-10 cell layers, shows only rudimentary characteristics of areas h5-h1. The Sb is less cellular, but its transition with the Periacx is clear. In the supracallosal sector the Acx is maximally reduced. The FasCin continues forward as the indusium griseum (IndGr) which consists only of scattered small hippocampal pyramids. Anteriorly, areas of the hippocampal rudiment (HR) become obliterated. Bilaterally, the fiber bundles of the taeniae tectae (TT) separate the IndGr from the slighly more cellular Sb. The transition of Sb with limbic cortex is still evident. In the subcallosal sector the HR expands into subcallosal, geniculate and medial olfactory gyri. The TT fuse to form a zonal layer over the subcallosal gyri. In summary, the cetacean Acx, especially its inferior part, is temporalized and better developed than in retrosplenial, supracallosal and subcallosal regions. It exhibits regressive features that render morphological criteria somewhat less definitive than in other mammalian brains. (Supported by NSF Grant # BNS 77-08660).

291 DEOXYGLUCOSE MAPPING OF THE VISUAL SYSTEM IN THE GARTER SNAKE. John L. Kubie and Theresa O. Allen*. Dept. of Physiol. and Dept. of Psych., Univ. of Penn., Phila., PA 19104

The (^{14}C)-2-deoxyglucose (2DG) method of neural mapping has revealed dramatic patterns of activation in the mammalian visual system (e.g., Hubel, Wiesel & Stryker, Nature 269:328, 1977). We have attempted to extend this method to a reptilian visual system.

Unanesthetized garter snakes (Thamnophis sirtalis parietalis) with one eye removed or patched were restrained and exposed to a pattern of moving vertical stripes for five minutes preceding delivery of a pulse of 2DG (14 μCi/100 g body weight, sc). Control animals were kept in darkness for the 60 to 84 minute 2DG incorporation period. Brains were processed according to the technique of Kennedy, Des Rosiers, Jehle, Reivich, Sharpe & Sokoloff, (Science 187:850, 1975).

X-ray autoradiographs revealed contralateral activation of all brain structures known to receive direct retinal input, with the possible exception of the nucleus of the ventral supraoptic decussation (Halpern & Frumin, J. Morphol. 141:359, 1973). These included the nuclei of the lateral geniculate and pretectum, the basal optic nucleus, and the superficial layers of the optic tectum. The optic nerve and tract were unilaterally activated, indicating that some fiber systems can be traced with the 2DG method. Some evidence was seen for activation by secondary visual projections: anterior dorsal ventricular ridge activity appeared to be greater contralateral to the stimulated eye.

A number of structures were bilaterally activated independent of visual stimulation. Most of these structures (including olfactory bulb, habenula, interpenduncular nucleus and posterior colliculus) correspond to structures exhibiting high activity in resting, awake rats (Schwartz & Sharp, J. Comp. Neur. 177: 335, 1978). Bilateral activity was also seen in the accessory olfactory tracts, the habenula-interpeduncular tract, the nucleus sphericus, and the anterior dorsal ventricular ridge.

292 THE SYMPATHETIC NERVOUS SYSTEM IN THE PRODUCTION OF GASTRIC EROSIONS IN RATS OF DIFFERING SUSCEPTIBILITY. Menachem Melinek*, Sigurd H. Ackerman*, Nansie S. Sharpless, Myron A. Hofer and Herbert Weiner. Dept. Psych. M.H.M.C. and Albert Einstein College Med., Bx., N.Y. 10467.

Increased gastric sympathetic activity during restraint stress in the rat has been postulated as an important factor in the pathogenesis of restraint-induced gastric erosions. This has been inferred, in part, from the fact that α-adrenergic receptor blockade protects against restraint-induced erosion formation (Djahnguiri, et al., J. Pharm. Exp. Ther., 184, 163 , 1973). We used surgical sympathetic denervation of the stomach prior to restraint, or α-adrenergic blockade with phenoxybenzamine (Pbz) during restraint, in order to disrupt gastric sympathetic innervation. The surgical and pharmacologic interventions were tested for their possible effect on restraint erosion production without predicting the direction of the effect (protection or exacerbation). To detect effects in either direction we used both rats at high risk (prematurely weaned) and low risk (normally weaned) for the development of restraint erosions. Without surgical or pharmacologic intervention, prematurely weaned rats had a 68% incidence of erosions and normally weaned rats had a 7% incidence of erosions when tested on postnatal day 30.

Surgical sympathetic denervation, by removal of the superior mesenteric and coeliac ganglia, had no effect on erosion incidence in either group. Completeness of the gastric sympathetic denervation was indicated by a fall in gastric mucosal norepinephrine content from 369.6$\pm$ 20.5 ng/gm to 11.9$\pm$ 2.9 ng/gm.

α -adrenergic blockade with a high dose of Pbz (30 mg/kg) decreased the incidence of erosions in the prematurely weaned group (from 68.4% to 38.9%). Lower doses (20 mg/kg and 10 mg/kg) had no protective effect. However, lower doses of Pbz completely blocked peripheral α -receptors as indicated by the absence of a norepinephrine pressor response. Pbz reduced O_2 consumption but this was unrelated to its protective effect since Pbz treated rats at all doses had comparable reductions in O_2 consumption. On the other hand, behavioral and electrophysiological studies showed marked increases in sedation with progressive increases in Pbz doses.

We conclude that peripheral surgical or pharmacological disruption of the sympathetic innervation of the stomach had no effect on erosion pathogenesis. Pbz appears to protect against restraint erosions formation though CNS effects which correlate with sedation.

293 CEREBRAL BLOOD SUPPLY IN THE DOLPHIN, TURSIOPS TRUNCATUS. Peter J. Morgane, Willard L. McFarland, and Myron S. Jacobs*. Worcester Foundation for Experimental Biology, Shrewsbury, Mass. 01545; NIH, Bethesda, Md. 20014; NYU, N.Y., N.Y. 10016

The tremendous development of retia mirabilia as the sole cerebral blood supply of Cetacea has attracted considerable interest. The hypertrophy of this system in whales has been thought to be related to diving in these totally aquatic mammals. In our studies on the cerebral blood supply of the dolphin, we have carried out anatomical dissections, vascular casting and angiographic investigations in the anesthetized animal, all of them mutually confirmatory as to the cerebrovascular pattern. The entire cerebral blood supply of the dolphin passes through the massive arterial thoracico-spinal rete mirabile. The internal carotid artery becomes non-patent in the adult extracranially and is reduced to a fibrotic strand in the tympanic cavity. This vessel is patent in early embryogenesis, however (Boenninghaus, '04). Neither vertebral nor basilar arteries are present. The intercostal arteries and posterior thoracic artery supply the huge thoracic rete mirabile which lies retropleurally on the posterior wall of the thorax and is innervated by sympathetic fibers. Extensions of this rete pass through the intervertebral foramina to form the extradural spinal rete mirabile filling the dorsolateral space of the spinal canal. Bilateral spinal meningeal arteries lie on the dorso-medial aspect of the spinal rete, becoming larger as they course rostrad. These extradural vessels enter the foramen magnum, become intradural, and sweep laterally over the cerebellum and temporal poles. They pass ventromedially and form an internal ophthalmic rete investing the pituitary region and optic nerves. Intracerebral arteries then emerge from this retial complex. Vessels possibly homologous in a positional sense to the anterior and middle cerebral arteries were seen. The circle of Willis as such does not exist. Histological examination of the retia revealed presence of collagenous fibers in the walls of the arteries of the spinal rete but relative lack of these in the arteries of the thoracic and ophthalmic rete. While retia mirabilia are not an exclusive feature of aquatic mammals, they have reached their greatest development in the Cetacea. As the retia are innervated, it may be that blood is shunted there to serve as a reservoir of oxygenated blood in pressure-impervious bony channels for the heart and brain during dives. We found that this structure has a marked pulse dampening effect. Presence of retia in other orders of mammals in different ecological niches, makes it important to continue comparative morphological and functional studies of the retia so we can understand how such specializations have evolved in response to environmental conditions and life habits. (Supported by NSF grant BNS 77-08660.)

294 ELECTROPHYSIOLOGICAL EVIDENCE FOR AUDITORY RESPONSIVE AREAS IN THE DIENCEPHALON AND TELENCEPHALON OF THE BULLFROG, RANA CATESBEIANA. Karen M. Mudry* and Robert R. Capranica, Section of Neurobiology and Behavior, Cornell University, Ithaca, NY 14853

In a recent anatomical study Neary (Anat. Rec. 178: 425, 1974) identified an ascending projection from the torus semicircularis to a region of the posterior dorsal thalamus in the bullfrog. Our electrophysiological recordings of evoked potentials verify that this diencephalic center responds to acoustic stimulation. In the bullfrog this center is selectively sensitive to bimodal stimuli containing low-and high-frequency energy which excites the two respective auditory organs (amphibian and basilar papillae) in the inner ear of this species. Such bimodal dependence for excitation of the diencephalon provides support for hierarchial processing of vocal signals and other complex sounds in the central auditory system of anurans.

Evoked potential mapping studies of the telencephalic lobes reveal at least two higher auditory responsive areas (ventral striatum and medial pallium) in the forebrain of the bullfrog. To elicit a response from these regions, like the auditory thalamic area, it is necessary to use stimuli whose spectral and temporal properties resemble biologically significant sounds (such as mating calls); for example, clicks fail to evoke a response from either of these telencephalic centers. Based on our electrophysiological recordings and the previous anatomical studies of afferent projections to the telencephalon by Kicliter and Northcutt (J. Comp. Neurol. 161: 239-254, 1975), it appears that the ventral striatum is the next direct ascending center above the thalamus in the anuran auditory pathway. (Supported by N.I.H. Grant NS-09244).

295 CEREBELLAR EVOLUTION IN CARTILAGINOUS FISHES. R. Glenn Northcutt. Division of Biological Sciences, University of Michigan, Ann Arbor, MI 48109.

Cerebellar variation was examined in 58 species representing 43 genera. The ancestral condition was likely a non-convoluted corpus, divided into anterior and posterior lobes of equal size. This condition is retained in chimaerids, in squalomorph and squatinomorph sharks, and in Heterodontus, Scyliorhinus, Gymnura, and most rajiform skates. The corpus has hypertrophied, resulting in a foliated condition, 2 or 3 times independently in other cartilaginous fishes. In each case, the anterior lobe has been selected for and in sphyrnids and most myliobatiforms, it accounts for 50-75% of the total cerebellar volume. In each case, the anterior lobe is divided into rostral and caudal lobules with the greatest increase occurring in the rostral lobule. This condition appears to have independently evolved in advanced myliobatiforms, lamniforms and carcharhiniforms. An allometric analysis of cerebellar foliation indicates that batoids exhibit a 13 fold increase in the volume of the anterior cerebellar lobe, whereas sharks exhibit only a 4 fold increase. The functional significance of cerebellar evolution in these fishes is presently unknown.

This work was supported by a Rackham Faculty Research Grant from the University of Michigan.

296 PROJECTIONS TO EFFERENT VOCAL CONTROL NUCELI OF THE CANARY TELENCEPHALON. F. Nottebohm (Rockefeller Univ., New York, NY 10021) and D.B. Kelley (Dept. Psychol., Princeton Univ., Princeton, NJ 08540).

Canary song is a learned behavior characteristic of adult males during the breeding season. Song is produced by the syrinx, an organ innervated by axons from the hypoglossal nucleus. These motoneurons receive projections from a specialized telencephalic nucleus, hyperstriatum ventrale, pars caudale (HVc) via a synapse in nucleus robustus archistriatalis (RA) (Nottebohm et al., J. Comp. Neurol. 165:457, 1976). Investigation of the efferent connections of the auditory telencephalic nucleus, field L, revealed projections to a thin "shelf" of neostriatum outlining the medial and ventral borders of HVc (Kelley and Nottebohm, Abs. Soc. Neurosci., 1976).

The present study investigated afferent connections of HVc and RA by means of the retrograde tracers, horseradish peroxidase (HRP) and tritiated adenosine. Nucleus HVc receives input from the magnocellular nucleus of the anterior neostriatum (MAN) and from nucleus interface (NIF). Nucleus RA receives projections from HVc and from MAN. A neostriatal area adjacent to the ventrocaudal edge of field L projects to a "cup" of tissue apposed to rostro -ventral RA. Nuclei HVc and RA also receive projections from thalamic nuclei.

Intensified diaminobenzidine staining of retrogradely HRP filled neurons in NIF shows that these cells are multipolar with axons directed dorsally towards the lamina hyperstriatica. Cells in NIF are larger than those in adjacent field L; diameters range from 13 to 20 u. Nucleus MAN has been shown to contain androgen-concentrating cells (Arnold et al., J. Comp. Neurol. 165: 487, 1976), as has nucleus HVc. Hormone concentration by cells in these nuclei may be involved in seasonal modulation of song. However, we still lack direct evidence that connections between NIF, MAN and telencephalic vocal control nuclei function in the control of vocal behavior.

297 TELENCEPHALIC AFFERENTS AND THE VISUAL SYSTEM IN GOLDFISH. S. C. Sharma and B. G. Grover*. Dept. Ophthalmology, N.Y. Medical College, New York, N.Y. 10029.

Knowledge of teleostean forebrain connections is based almost exclusively on data obtained with classical anatomical methods. A recent study of telencephalic efferents in two fish (Vanegas & Ebbesson, J. Comp. Neur., 1976) failed to find any projection to the lateral geniculate nucleus (LGN). These authors suggested that retino-thalamo-striatal system may be lacking in teleosts. However, from recent studies of retinal and tectal efferents, it appears that thalamic nuclei considered to be homologous across teleosts are not homologous with respect to their connections (afferents). Therefore, a retino-thalamo-telencephalic system in teleosts might not involve the nucleus heretofore identified as the LGN.

We have investigated telencephalic afferents and retinal efferents in goldfish using HRP label. Following injection of HRP into the forebrain, labelled cells were found in the contralateral telencephalic lobe, and ipsilaterally in the optic tectum, the nucleus preglomerulosus and in the region of the striolobar bundle in the hypothalamus. Intraocular injection of HRP confirmed the visual projections obtained with degeneration methods. In addition, a few fibers were found entering the telencephalon. Following tectal injection of HRP, labelled cells were found in the central core of the ipsilateral telencephalic lobe.

Since the telencephalon does not appear to receive input from any diencephalic areas which receive direct retinal input, we have no evidence for the existence of any retino-thalamic-telencephalic system in the goldfish.

Supported by N.I.H. EY 01426 and 05137.

298 INFRARED RESPONSES OF NEURONS IN THE LATERAL DESCENDING NUCLEUS OF THE TRIGEMINAL SYSTEM IN THE RATTLESNAKE, CROTALUS VIRIDIS. L. R. Stanford* and P. H. Hartline. Neural and Behavioral Biology Program, University of Illinois, Urbana, IL 61801.

Extracellular single unit responses were recorded in the lateral descending nucleus (DLV) in a snake which has infrared-sensing facial pits. This trigeminal nucleus receives input principally from the afferent fibers that innervate the sensory membrane of the pit organs. Data were collected on the receptive field properties and response characteristics of DLV neurons responsive to infrared stimulation.

Receptive fields of neurons in the DLV are smaller (average horizontal diameter; 25°, range; 9°-41°) than receptive fields reported in either the primary afferents or tectal neurons. Many DLV neurons have receptive fields with excitatory and inhibitory regions. Inhibitory regions do not completely surround the excitatory region but commonly flank it on one or two sides. The units show local adaptation; adaptation of the response to a repeated stimulus in one position in the receptive field does not adapt spatially separated regions of the same field. Small receptive field size, the presence of inhibitory regions and local adaptation indicate convergence of primary sensory afferents onto DLV neurons.

DLV neurons typically displayed a low level of background activity. The response to an infrared stimulus introduced into the excitatory region of the receptive field for three seconds was as follows: 1. a transient increase in discharge (1700 msec.); 2. complete depression of discharge (next 1050 msec.); 3. return of the background discharge. A variable period of post-stimulus depression followed the termination of the stimulus. Stimulation of the inhibitory region of the receptive field produced a depression of the background discharge, followed by a gradual return of activity. No post-inhibitory excitation was noted at the termination of the stimulus, the most common response was a second depression. Simultaneous presentation of stimuli in the excitatory and inhibitory regions of the receptive field resulted in a weaker response than occurred with presentation of the excitatory stimulus alone.

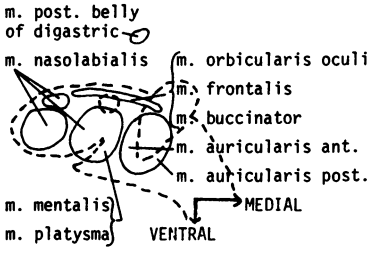
Comparison of these findings with those reported in the primary afferents and tectal neurons indicates that the responses of DLV neurons are more phasic than those of the first order cells but less phasic than the tectal responses. The receptive field data suggests that considerable sharpening of the infrared "image" could occur in the DLV.

299 THE TOPOGRAPHIC ORGANIZATION OF THE RAT FACIAL NUCLEUS. C.R.R. Watson* and S.T. Sakai* (SPON: P.D. MacLean) Depts. of Psychology, Biophysics and Neuroscience Program, Michigan State University, East Lansing, MI 48824.

The topographic organization of facial nucleus motoneurons in the rat was investigated. The horseradish peroxidase retrograde tracing technique with tetramethyl benzidine and hydrogen peroxide as the histochemical indicator was used.

Individual muscles and muscle groups were found to be represented in the nucleus in the same topographic order as is found in the face (see below). Notable findings of this study are: (i) the relatively unremarkable size of the vibrissal muscle representation; there is no increase in size of this part of the nucleus commensurate with the specialized sensory functions of the vibrissal facial area (ii) the posterior belly of the digastric muscle is represented about 1 mm dorsal to the main facial nucleus in a small cell group, the suprafacial nucleus. This cell group may be homologous with the separate dorsal facial nucleus found in non-mammalian vertebrates and monotremes. Since the posterior belly of digastric is involved in swallowing rather than facial expression, its motoneurons may be restrained from further ventral migration by the neurobiotactic influence of the nucleus of the solitary tract.

(Supported by NIMH fellowship MH 05390).



Legend: The subdivisions of the facial nucleus as seen in coronal section are enclosed by solid lines and the muscles represented by them are labelled. The facial nucleus comprises dorsolateral, ventrolateral, intermediate and medial cell columns and a dorsal sheet. The orientation of the rat face as represented in the nucleus is shown in dotted outline.

300 SOMATOTOPIC ORGANIZATION OF THE MOTOR NUCLEUS OF VII BASED ON RETROGRADE AXOPLASMIC TRANSPORT OF HORSERADISH PEROXIDASE FROM SEVERED RAMI TO NEURONAL PERIKARYA. Cyprian V. Weaver. Dept. of Anatomy, University of Minnesota Medical School, Minneapolis, MN. 55455, St. John's University, Collegeville, MN 56321

In an earlier report (Weaver, Anat. Rec., 190:578, 1978), it was suggested that the somatotopic organization of the motor nucleus of VII could be demonstrated on the basis of the uptake, retrograde axonal transport of exogenous protein, and subsequent labeling of cell bodies. The purpose of this suggestion was to introduce an alternate experimental method which could elucidate the discrepancies existing between earlier studies based on degenerative changes effected by retrograde chromatolysis of the perikarya following axotomy of various peripheral branches of the nerve (Papez, J. Comp. Neurology, 43:159, 1927; Courville, Brain Res., 1:338, 1966). In reference to some of the major branches of VII and their cellular groups of origin in the medulla of the cat, this preliminary report indicated both areas of agreement and deviation from the somatotopic organization derived from these chromatolytic studies. Subsequent to this preliminary report, additional rami have been analyzed with further modification of the previous somatotopic divisions and the protocol revised to enhance discrete labeling of cell bodies. In recent experiments, unilateral extirpation of peripheral rami was carried out on eighteen cats. 5 ul of a 25-50% (w/v) suspension of Horseradish peroxidase (Sigma type VI) in buffered saline was applied to the cut end of the nerve for 20 minutes. Survival periods ranged from 16-18 hours. Each cat was then perfused transcardially with isotonic saline and a fixative of 1% paraformaldehyde and 1.25% glutaraldehyde in 0.1M Sorensen's phosphate buffer (pH 7.2). This was followed by a perfusate of 0.1M Sorensen's phosphate buffer to which 20% sucrose had been added to remove unbound fixative. No post-fixation was employed in order to reduce the attenuating effects of aldehyde fixation on the enzymatic activity of HRP. Sections were cut 40 u in thickness on a freezing microtome and then processed for the chromagenic oxidation of benzidine dihydrochloride (BDHC) which polymerizes to form the blue reaction product (Mesulam, J. Histochem. Cytochem., 24:1273, 1976). The sections were then counterstained with neutral red to yield optimum contrast between the blue reaction product of the label and the stained cell body under light microscopy. The results have given positive labeling of perikarya localized by histochemical reaction at the sites of HRP activity and have permitted a more satisfactory differentiation between cellular groups within the motor nucleus.

301 TORUS SEMICIRCULARIS AFFERENTS IN THE BULLFROG, RANA CATESBEIANA. Walter Wilczynski. Neurosciences Program, University of Michigan, Ann Arbor, MI 48109.

Horseradish peroxidase (HRP) histochemistry was used to determine afferents to the torus semicircularis in bullfrogs (Rana catesbeiana). Animals survived 4-8 days at 22°C after receiving unilateral toral injections of 75-150 nl of Sigma VI HRP. The animals were then sacrificed and the brains processed for HRP histochemistry by standard techniques.

The ipsilateral superior olive and contralateral dorsal medullary complex of VIII were filled with HRP-positive cells and appeared to be the major sources of toral inputs. The labeled dorsal complex cells were mainly located in the dorsal (acoustic) division. Labeled cells were also seen in the ipsilateral dorsal medullary complex, bilaterally in the reticular formation above the olive, and occasionally in the contralateral superior olive. At obex levels, HRP-positive cells were present in portions of the contralateral perisolitary band adjacent to the spinal tract of V and the dorsal funiculus. Few spinal cord cells were labeled, although autoradiographic experiments have revealed a spinal projection to the torus (Neary and Wilczynski, personal observation). Other afferent populations include the superficial isthmal reticular nucleus and other tegmental fields bilaterally; the contralateral torus; the ventral half of the ipsilateral lateral pretectal nucleus; and possibly the ipsilateral posterior thalamic nucleus. Finally, a few HRP-positive cells were seen in the ipsilateral anterior entopeduncular nucleus and interposed between the lateral and medial amygdala. In addition, autoradiographic experiments have revealed a preoptic projection to the laminar nucleus of the torus overlying the hypothalamic input described by Neary and Wilczynski (Anat. Rec., 187:665, 1977). The cells responsible for the preoptic and hypothalamic inputs have been difficult to visualize with the HRP method. Additional autoradiographic experiments are underway to confirm the inputs seen with the HRP technique and to determine the arrangement of their terminal fields within the torus.

303 RETINOFUGAL PROJECTIONS IN THE RED-BACKED SALAMANDER: EVIDENCE FOR AN IPSILATERAL RETINOTECTAL PATHWAY. H. Zakon, Section of Neurobiology and Behavior, Cornell University, Ithaca, NY 14853

The projections of the optic nerve in Plethoden cinereus, the red-backed salamander were studied by the Fink-Heimer technique. Animals were unilaterally enucleated, allowed to survive for 5 to 12 days, perfused, and frozen sections cut at 30μ for staining.

Degeneration was observed bilaterally along the optic tracts, and in diencephalic and mesencephalic neuropil areas. In the contralateral thalamus, a broad continuous sheet of degeneration occurs in the ventrolateral neuropil (VLN) and more dorsally in the neuropil of Bellonci (NB). Ipsilaterally the VLN displays less dense degeneration and extends far less caudally while the NB appears as a distinct compact patch above it. A dense terminal field enters the pretectal neuropil bilaterally.

In the mesencephalon a well developed accessory optic tract and basal optic nucleus are found contralaterally. A broad band of degeneration, with no apparent lamination, appears in the dorsal half of the centralateral tectal neuropil running the entire rostro-caudal extent of the tectum. In addition, a sparse ipsilateral tectal projection terminates just below the level of the contralateral projection, and innervates the rostral third of the tectum.

Recently, direct ipsilateral retino-tectal projections have been described in a number of amphibia using autoradiographic methods. However, these methods may involve transsynaptic transport of label, and since tecto-tectal pathways terminate in the same layer as the presumed ipsilateral retino-tectal pathway, the direct retinal origin of this pathway is unclear. This study using a technique which has no transsynaptic effects at these survival times, verifies the existence of a direct ipsilateral retino-tectal pathway.

302 PATTERNS OF BEHAVIOR IN SOLITARY AND COMMUNAL SPIDERS. Peter N. Witt, N. C. Mental Health Research, Raleigh, N. C. 27611.

When speed and amount of food uptake, web-building activity throughout the day, movement characteristics, and production of offspring in the laboratory and outdoors are compared between the solitary orb web builders like Araneus diadematus Cl. (A. d.) and colonial spiders Mallos gregalis Simon (M. g.) from Mexico, different forms of behavior emerge. While young A. diadematus females (mean weight 55 mg) readily consumed radioactively labeled glucose (injected into a live fly), close to 100% in 120 min, a group of M. gregalis of the same average body weight took more than 1,000 min to ingest the same amount. The latter animals followed a pattern of approaching and leaving the prey repeatedly in 24 hrs. Increasing activity of hungry individuals together with movement to fly-catching surface of the three dimensional web apparently helps M. gregalis to distribute food evenly throughout a 20 member colony. Time-lapse movies and animal counts on different web parts provide data supporting such observations. The relatively greater fly-holding capacity of the Mallos web, measured by Jackson (Beh. Ecol. Sociobiol., 1978), makes it possible for the slower spiders to eventually eat as much of the trapped prey as A. diadematus without attack and wrapping. Slow movements across the web with frequent meetings in M. gregalis seem to have exploratory as well as communication function. In contrast, A. diadematus moves in the laboratory only for web renewal or when prey has hit. No evidence for recycling of silk could be found in M. gregalis using radioactive labeling techniques, while Peakall (J. exp. Zool., 1971) has shown that A. diadematus digests and incorporates 98% of old silk into daily renewed webs. Under controlled, steady laboratory conditions M. gregalis raise offspring all year round; in the changing climate of Mexico, Burgess (dissertation, 1978) found a seasonal rhythm in appearance of spiderlings. A. diadematus maintain circadian and annual rhythms even in a constant environment. — It is hypothesized that in spiders a relatively flexible, environment-dependent behavior is associated with communal living, while predominantly innate patterns of rigid behavior characterize the solitary life style. DEVELOPMENT AND AGING

304 THE EFFECT OF LEAD ON MYELINATION. S. Aitchison*, A. Goldberg and J. Frangia* (SPON: G. McKhann). Dept. Neurology, Sch. Med. and Sch. of Hygiene, Johns Hopkins U., Baltimore, MD 21205

The developing central nervous system is vulnerable to the toxic effects of lead. Some earlier studies directed at the understanding of the pathogenesis of chronic toxicity have been complicated by the bservation that lead administration also resulted in malnutrition. Under our conditions, malnutrition was not significant.

Mice are exposed to lead immediately after birth by substituting a solution of lead acetate (5 mg/ml) for plain water in the mothers diet, thus exposing the off-spring to lead via the mother's milk. All litters are normalized to 3 pups within 24 hours of parturition. Lead is removed from the drinking water at 18 days and the animals are weaned at 21 days. Body and brain weights obtained were identical in the lead-exposed and control groups of animals.

We have previously shown that the optic nerve is a useful system in which to study myelination. Biochemical and morphological characteristics of optic nerves in lead-exposed and control animals were studied. Light and electron microscopy showed that the axons of lead-exposed animals were smaller than those in control animals. The ratio of myelin to axonal size was found to be constant within each group and between the two groups. This suggests that the effect of lead toxicity is primarily on neurons, rather than oligodendrocytes.

Cerebroside sulfotransferase activity was decreased in the lead-exposed animals, but followed the same developmental profile as the control animals. When measuring 2',3'-cyclic nucleotide phosphohydrolase and myelin basic protein, the onset of myelination appeared to be the same in the two groups of animals. In the lead-exposed animals, however, the total enzyme activity was decreased by 40% and the amount of myelin basic protein decreased by 60%. Thus, the hypomyelination in lead-intoxicated mice may be the result of a primary pathological process involving neurons. The significance of this possibility will be presented.

305 SURPLUS ACCUMULATION OF NEUROTRANSMITTER SYNTHESIZING ENZYMES IN CELL BODIES OF DOPAMINERGIC AND SEROTONERGIC NEURONS DURING DEVELOPMENT. H. Baker, L. Iacovitti, D.H. Park, T.H. Joh, D.J. Reis, Laboratory of Neurobiology, Cornell University Medical College, 1300 York Ave, New York, NY 10021

During postnatal development of rat brain there is a substantial increase in the activities of the enzymes subserving the biosynthesis of neurotransmitters. We sought to determine by use of specific antibodies whether the postnatal increase of enzyme activity was the result of changes in the number or catalytic activity of enzyme molecules and to assess the relationship between the increase in enzyme activity in cell bodies and in terminal fields. Tyrosine hydroxylase (TH) was assayed in substantia nigra (SN) and caudate nucleus (CN), and in locus coeruleus (LC) and hippocampus, representing respectively cell bodies and terminals of dopamine (DA) and noradrenergic (NE) neurons. Tryptophan hydroxylase (TrH) was assayed in nuclei raphe dorsalis and centralis and in hypothalamus representing cell bodies and terminals of a serotonin (5HT) system. In cell bodies of DA and 5HT neurons enzyme activity was 10-20% of adult (60 day (d)) values at birth and increased slowly until d 5 in DA neurons, and d 12 in 5HT neurons, at which time enzyme activity began to rise rapidly. TH activity in DA neurons surged to 255% ($p < 0.001$) of adult values by d 18. In 5HT neurons TrH activity increased to 124% ($p < 0.001$) of adult values by d 24. Enzyme activity returned slowly to adult levels by d 30-60. By immunotitration with specific antibodies the overshoot of TH activity in SN and TrH activity in raphe was demonstrated to be attributable to increased accumulation of enzyme protein. The 2.5 fold increase of TH activity on d 18 in SN was not attributable to cell death as the number of SN neurons immunocytochemically stained for TH on days 18 and 60 did not differ (10129 ± 198 vs 9785 ± 830; n.s.). However, on day 18, but not 60, there was marked staining for TH in SN, pars reticulata, perhaps indicating enhanced filling of dendrites with enzyme. In terminal areas of DA and 5HT neurons enzyme activity was 10% of adult values at birth and increased in parallel with enzyme activity in cell bodies, but with a 3 d delay. In contrast, TH activity in LC neurons, which was 20% of adult values at birth, increased slowly from d 6-18 exhibiting no overshoot. TH activity in hippocampus was 70-80% of adult values at birth and increased gradually over time. We conclude that postnatal increases in the activities of brain TH and TrH are due to increased accumulation of enzyme protein, and that in cell bodies of DA and 5HT neurons, but not NE neurons, there is a transient surplus accumulation of enzymes during a period of major postnatal growth of target organs and enlargement of terminal fields. (Supported by NIH grants HL 18974 and NS 03346.)

306 CROSS SECTIONAL ANALYSIS OF HIPPOCAMPAL SYNAPTIC RESPONSE WAVEFORM IN RAT: EVIDENCE FOR CONSTANCY OF CABLE PROPERTIES IN GRANULE CELL DENDRITES. C. A. Barnes and B. L. McNaughton. Department of Psychology, Dalhousie University, Halifax, Nova Scotia, CANADA B3H 4J1.

We previously demonstrated that the waveforms of the extracellularly recorded granule cell response elicited by separate stimulation of the medial and lateral perforant pathways differ in rise time (McNaughton and Barnes, J.Comp.Neur. 1977, 175, 439-454). It was suggested that these differences in rise time may reflect the passive dendritic cable properties of these hippocampal neurons, since the more distally terminating fibers (lateral perforant path) resulted in more slowly rising potentials and the relationship between rise time and width at one half amplitude was similar to that predicted from cable theory for intracellular records.

Observations on both hemispheres of three adolescent (3 months), three middle aged (12 months), and three senescent (28 months) rats show no significant differences in the range or frequency distribution of EPSP rise time when the perforant pathway was systematically explored with multiple stimulating electrode penetrations.

If the assumption that the waveform of the extracellular EPSP reflects the passive dendritic cable properties is correct, then the data indicate that these factors remain constant throughout a large portion of the lifespan of the healthy rat.

307 DEVELOPMENT OF THE ENKEPHALIN AND ENDORPHIN-CONTAINING SYSTEMS IN THE RAT BRAIN. Alejandro Bayon*, Wm. J. Shoemaker, and Floyd E. Bloom. A.V. Davis Ctr., The Salk Institute, San Diego, CA 92112.

Radioimmunoassays (RIA) that use antisera directed either towards β-endorphin or to Leu-enkephalin (see footnote to Table I) were used to determine the regional concentration of brain endorphins and enkephalins during pre- and postnatal development in the rat. Although the absolute amounts of both endorphin and enkephalin, as well as tissue protein, increase with age in all the regions studied (see Table I), the concentrations, expressed on a protein basis, reveal interesting differences. Between embryonic day 20 (ED20) and postnatal day 6 (PN6), the concentration of endorphin decreases in all regions studies; the greatest decrease (about 50%) occurs in the corpus striatum (CS), and continues decreasing to very low levels at adulthood. The CS shows the highest endorphin concentration in the brain before birth, whereas the hypothalamus is the richest in the adult. The concentration of enkephalin does not significantly change from ED20 to PN6 in any of the regions studies; enkephalin concentration remains almost constant after birth except for a marked increase (about 3-fold) in the region containing the preoptic areas and the septum. The CS contains the highest concentration of enkephalin in both the embryonic and adult rat. In contrast to the brain, the pituitary concentrations of both endorphin and enkephalin remain constant from ED20 to PN6; both peptides subsequently increase severalfold by adulthood.

Table I. Total Brain Content of Enkephalin and Endorphin

Age	Enkephalin Units*	Endorphin Units†	Brain Protein (mg)
ED-20	1.3 ± 0.2	6.4 ± 0.8	8.1 ± 0.5
PN-6	7.4 ± 0.5	11.2 ± 1.3	48.5 ± 1.8
PN-25	40.7 ± 2.5	76.7 ± 2.4	263.1 ± 16.5

*Enkephalin immunoreactivity is expressed as the ng of Leu-enkephalin that would give an equivalent trace displacement in the enkephalin RIA.

†Endorphin immunoreactivity is expressed as the ng of β-endorphin that would give an equivalent trace displacement in the endorphin RIA.

The RIA for β-endorphin reads the Leu^{14}-His^{27} segment and cross reacts 100% on a molar basis with both β-LPH and the 31K protein. The Leu-enkephalin RIA shows 3% cross-reactivity for Met-enkephalin. Results are expressed as the mean of 3-4 determinations ± the standard error of the mean.

308 EFFECTS OF SENSORY DEPRIVATION ON THE DEVELOPMENT AND MAINTENANCE OF THE OLFACTORY SYSTEM IN MICE. T.E. Benson* and D.K. Ryugo. (SPON: J. Wells) Depts. Anat., University of Vermont, Burlington, VT 05401, and Harvard Med. School, Boston, MA 02115.

Littermate albino mice have been unilaterally deprived of olfactory sensation by right or left nares closure on postnatal day 1 (PN1) and histologically prepared on PN30. Experimental nasal fossae taken on PN3 and PN6 revealed that no direct damage had occurred to the olfactory receptor sheet (ORS); thus, this study addresses the effects of sensory deprivation without the added complication of transneuronal degeneration.

The olfactory bulbs (OB) of both sides exhibited normal gross morphology, except the deprived OB was reduced in total volume by 30% ± 6 (N = 6). Morphometric volume analyses comparing each of the OB layers between nares-closed OB and nares-open OB were performed by planimetry of traced semi-serial projections and are expressed as mean percent difference (MD% ± SEM). There was always a reduction on the closed side. In untreated littermate controls, the MD% between each component of the two OB's never exceeded 7%.

	Olfactory System Component	N	MD%	SEM
ORS:	a) Receptor packing density (Rpd)	1	20	
	b) Nerve Layer volume (NLv)	4	20	7
Glomerulus number (G#)		9	18	3
Mitral Cell Layer volume (MCLv)		4	19	4
Glomerular layer volume (GLv)		4	29	4
External Plexiform Layer volume (EPLv)		4	46	13
Granule Cell Zone volume (GCZv)		4	36	8

Although our sample is relatively small at this time, we feel that some preliminary conclusions may be drawn. The reduced Rpd and NLv suggest that central changes observed in the OB are related to changes occurring at the periphery. Grouping of these data according to the magnitude of the effect (MD%) further suggests that the deprivation acts differentially on OB components: (1) Commensurate with the ORS changes, there is a direct effect which reduces G# and affects primary postsynaptic cells (MCLv). (2) There is a much larger effect mediated through secondary synapses involving cells and neuropil of predominantly postnatal origin (EPLv and GCZv). Related to this finding are preliminary ^{3}H-thymidine autoradiographic data indicating that the number of postnatally-generated granule cells is reduced on the closed side. (3) Finally, in GLv where both primary and secondary synapses as well as postnatally-generated components are present, there appears to be an intermediate effect. (Supported in part by U.VT. GRS grant PHS 5429-40)

309 METABOLIC REQUIREMENTS FOR GROWTH AND DIFFERENTIATION OF EMBRYONIC SYMPATHETIC NEURONS IN CULTURE. Emanuel M. Bloom and Ira B. Black, Dept. of Neurology, Cornell University Medical College, N.Y., N.Y. 10021.

The embryonic mouse superior cervical ganglion (SCG), which does not require added nerve growth factor for survival in culture, was used to define the metabolic requirements for neurite elaboration and biochemical differentiation of sympathetic neurons in vitro. Ganglia from 14 gestational day mice were cultured in the absence of added nerve growth factor. In the presence of actinomycin-D, which inhibited RNA synthesis by more than 95%, ganglia elaborated neurites for at least 6 hrs. in culture. The activity of tyrosine hydroxylase (T-OH) increased 4-fold by 24 hrs. in control explants, but failed to rise in the presence of actinomycin-D. Ganglion explants also elaborated neurites for at least 6 hrs. in the presence of concentrations of cycloheximide or puromycin which inhibited protein synthesis by more than 95%. However, blockade of protein synthesis prevented the increase in T-OH activity. To define the role of DNA synthesis in differentiation, and to eliminate the influence of non-neuronal support cells, explants were cultured with cytosine-arabinoside (Ara-C), an inhibitor of DNA synthesis. Blockade of DNA synthesis resulted in the virtual absence of support cells. However, neurons elaborated abundant neurites which terminated in growth cones unassociated with support cells. Moreover, T-OH activity increased 3-fold in the presence of Ara-C.

These observations suggest that embryonic sympathetic neurons, cultured in the absence of added nerve growth factor, elaborate neurites in the absence of ongoing protein, RNA or DNA synthesis. Moreover, support cells are not necessary for neurite elaboration at this stage. In contrast, development of T-OH activity requires RNA and protein synthesis, although support cell presence is unnecessary.

310 PHOSPHORYLATION AND AGEING: cGMP DEPENDENT PROTEIN KINASES IN HUMAN STRIATUM. Diethelm H.Boehme* and Neville Marks. The V.A. Hospital East Orange N.J. 07019 and Institute for Neurochemistry and Drug Addiction. Wards Island. N.Y. 10035.

Alterations in synaptic density along with the effects of biogenic amines in vitro on levels of cyclic nucleotides in brain slices point to a decreased synaptic function in senescence. To study this in more detail the changes in protein kinases with age were examined in different brain regions of post mortem tissues from man and compared to those of rat. Synaptosomal membranes were purified from regions known to be subject to senile pathologies such as caudate nucleus and putamen, substantia nigra and compared to those of thalamus and frontal cortex. Membranes from man and rat were incubated according to the conditions of Ueda et al (JBC 248, 8295,1973) followed by analysis on SDS slab-gels and radioautography. Post-mortem tissues within 6 h of death gave a similar pattern of phosphorylated proteins as that observed for rat membranes with a mol.wt range of above 250K to 12K when compared to protein markers. Membranes prepared from human tissues were characterised by a high intensity band of above 250K present only in striatum and largely absent from other brain regions. The intensity of phosphorylation of synaptosomal proteins changed with age in membranes obtained from a 4 month infant to older (senile) patients aged 56-83 years. Human synaptosomal membranes did not respond to cAMP addition but phosphorylation was stimulated in presence of cGMP with the appearance of new band in all anatomical regions in the 80K region. Addition of cGMP gave marked inhibition of the striatal components in the high molecular range and an inhibition of the 12K region dependent on the region studied. These effects were absent in a single case of Alzheimers disease and a case of degeneration of basal ganglia. The availability of an assay system using human post-mortem material capable of responding to cyclic nucleotides such as cGMP provide an experimental system for investigating the diverse effects of agents known to alter cGMP levels or dependent protein kinases in vivo and may be linked to the ageing process.

311 POSTNATAL CEREBELLAR NEUROGENESIS IN RAT IS ALTERED BY HYDROCORTISONE: AN AUTORADIOGRAPHIC AND LIGHT MICROSCOPIC STUDY. Martha Churchill Bohn* and Jean M. Lauder, Dept. Biobehav. Sci., Univ. of Connecticut, Storrs, CT. 06268.

Rat pups injected with hydrocortisone acetate (HCA) on days 1-4 (200ug/day)were sacrificed by ether anesthesia and cardiac puncture on days 2,5,7,10,12,15,18,21 or 24 and brains embedded in paraffin after immersion in Bouin's fixative. Planimetric measurements of the area and width of the external granular layer (EGL) in matched sagittal sections of vermis showed that the growth of the EGL was reduced during the HCA treatment but partially recovered thereafter. Disappearance of the EGL was not significantly retarded. The mitotic index in the EGL (number of mitotic cells/total number of cells) was depressed during the treatment, but exceeded control values during the second week. Nevertheless, the total number of cells produced by the EGL in HCA rats was reduced, presumably due to a severe inhibition of EGL cell proliferation during the HCA treatment.

In treated rats sacrificed by formalin perfusion at 72 days, the foliation pattern in sagittal sections was reproducibly changed. In lobule VIII, the total area and areas of the molecular layer (ML) and internal granular layer were decreased by 14%,17% and12%, respectively. The numbers per unit area of granule cells and small neurons in the inner ML were unchanged whereas the number of stellate cells per unit area in the outer half of the ML was reduced by 23%. Due to areal decreases, however, there were deficits in the total numbers of granule cells and ML interneurons.

A long survival autoradiographic study was undertaken to determine the effects of HCA on the "birthdays" of granule, basket and stellate cells. HCA animals and vehicle injected controls were injected with ^{3}H-thymidine on days 1,2,5,7,10,15,21 or 24 and sacrificed at 72 days. Plots of heavily labeled cells/total cells (HLC/TC) vs age (lobule VIII) indicated that during the treatment greater proportions of both granule cells and ML interneurons completed early final cell divisions. At day 10, HLC/TC was depressed for granule cells, probably as a result of the increase in cell proliferation (mitotic index) following release from HCA treatment. The proportion of neurons formed at later ages (days 15-24) was not significantly changed.

In conclusion, neonatal HCA treatment results in final cell deficits in both granule cells and ML interneurons, apparently as a result of inhibition of EGL cell proliferation. Moreover, a small number of cells stop dividing prematurely and permanently. These cells may be those nearing their last division and thus more sensitive to the HCA treatment. (Supported by NIH Grants 09904, MH05572 and 13481).

312 MORPHOMETRIC STUDIES ON AGING CHANGES IN VISUAL CORTEX AND HIPPOCAMPUS IN THE RHESUS MONKEY. Kenneth R. Brizzee, Neurobiology Department, Delta Regional Primate Research Center, Tulane University, Covington, La. 70433

Brains of three young adult (ages 5-7 years) and three aged (estimated ages 20-24 years) rhesus monkeys were fixed by intracardiac perfusion with glutaraldehyde (1%) and paraformaldehyde (1%) in 0.12 M phosphate buffer, pH 7.3. Tissue blocks from visual cortex and hippocampus were postfixed in OsO_4, embedded in Epon sectioned at 4 μm and stained with toluidine blue.

The mediolateral width of the CA-1 zone of the hippocampus decreased from 1040 μm in young adults to 960 μm in aged animals, but the difference did not attain the level of statistical significance. However, the mean depth of the lamina pyramidale of the hippocampus decreased significantly from 150 um in young adults to about 100 μm in aged monkeys ($p<.05$). The mean number of neurons in a 55 μm segment of the lamina pyramidale in the CA-1 zone decreased from 106 per 55 μm segment to 52 ($p<.01$), while the mean number of glia cells increased from 8 to 32.

The mean depth of visual cortex decreased from 1380 μm in young adults to 1320 μm in aged monkeys but the difference was not statistically significant.

The mean number of neurons per "counting chamber" in the visual cortex (approximately 180,000 μm^3) decreased from 26 to 22, and the mean number of glia increased from 10 to 14 from young adults to aged animals, but the differences were not statistically significant.

These preliminary observations suggest that structural alterations in the hippocampus in nonhuman primates may occur at an earlier age and exhibit greater severity than in cerebral cortex.

313 DELAYED DEVELOPMENT OF THE INPUT-OUTPUT ORGANIZATION FOR KITTEN MOTOR CORTEX. I. C. Bruce* and W. G. Tatton. Fac. Med., Univ. of Calgary, Calgary, Alberta, Canada T2N 1N4 and Playfair Neuroscience Unit, Univ. of Toronto, Toronto, Ontario, Canada M5S 1A8.

The study was undertaken to determine whether 'higher level' reflex circuits, such as those involving motor cortical neurons (MCNs) are organized prenatally or develop postnatally like some neuronal circuits in perceptual systems such as the visual cortex.

This work was carried out in chronically-prepared kittens 9 to 67 days of age. Recordings were made from 411 cortical neurons while the contralateral forelimb was displaced at random intervals by a torque motor so as to rotate the elbow joint and stretch triceps brachii. EMG recordings were made from triceps in response to the displacements and to intracortical and immediately subcortical microstimulation. Average response histograms (ARHs) for the units activity and averaged rectified EMG responses were constructed by computer. 'Synaptic effectiveness' (SE: firing probability/msec/presentation above baseline firing probability) was calculated for the ARH response peaks.

The findings were: 1) SE values for responses of neurons in primary somatosensory cortex (areas 1 and 2) were in the range found for adult cats as early as 9 days postnatally. Response latencies were longer (25-28msec) than those in adults (10-12msec), in keeping with the lowerperipheral and central conduction velocities previously reported. 2) In marked contrast, MCNs (area 4) showed responses with low SE values and long latencies (30-280msec) up to 45-45 days of age. Immediately after this time, the responses attained adult values in both latency and SE values. 3) Microstimulation in the white matter immediately subjacent to area 4 evoked weak triceps EMG responses in kittens less than 20 days old at latencies 5-10 times those of the adult. Adult latencies were attained during the 40-60 day period. 4) Intracortical microstimulation did not evoke triceps activity until approximately 40 days of age. 5) Of the three peaks of the triceps EMG response to displacement seen in adult cats, only one occurs in kittens 9-16 days old. During the following 20-30 days, variable low amplitude EMG activity follows this peak, and at 40-50 days of age the EMG response shows the distinct peaks characteristic of adult cats.

Thus, though mechanoreceptor input to primary somatosensory cortex is effective from 9 days or younger, the immediately adjacent motor cortex does not show adult-like responses until about 45 days. The development of mature mechanoreceptor input to motor cortex immediately lags the development of effective output linkages to alpha motoneurons and occurs over the same interval as the appearance of adult-like EMG responses to forelimb displacements.

ICB is a Dystonia Foundation Fellow.

314 ONTOGENETIC APPEARANCE AND DISAPPEARANCE OF NORADRENERGIC ENZYMES AND CATECHOLAMINES IN RAT EMBRYONIC NEUROBLASTS. Philippe Cochard*, Menek Goldstein and Ira B. Black, Dept. of Neurology, Cornell Univ. Medical College, N.Y., N.Y. 10021 and Dept. of Psychiatry, N.Y.U. Medical Center, N.Y., N.Y. 10016.

The ontogenetic pattern of noradrenergic differentiation in rat embryonic autonomic neuroblasts was defined in vivo. Noradrenergic characters were examined by documenting the appearance of transmitter enzymes and catecholamines (CA) using immunohistochemical and histofluorescent methods. Tyrosine hydroxylase (T-OH), dopamine-β-hydroxylase (DBH) and CA were undetectable in the neural crest cells before or during their ventral migration. T-OH, DBH and CA first appeared at 12 to 12.5 days of gestation (30-35 somite stage) in neuroblasts aggregating at the level of the sympathetic anlage. There was a striking degree of synchrony in the appearance of T-OH, DBH and CA. Fluorescence intensity and the number of fluorescent cells increased dramatically thereafter. In addition, T-OH and CA transiently appeared in scattered presumptive neuroblasts in the gut mesenchyme. The enzyme and transmitter were first detectable at 11.5 days of gestation. During the following day, the number of T-OH and CA-containing neuroblasts in the gut increased rapidly, and thereafter decreased progressively so that by 14.5 days only rare cells were encountered. Once again there was remarkable synchrony in the appearance (and disappearance) of T-OH and CA. These observations suggest that a number of noradrenergic transmitter mechanisms develop in close temporal proximity in the differentiating neuroblast.

315 REQUIREMENT OF ADDITIONAL FACTOR(S) FOR NORMAL INTERACTION BETWEEN SCHWANN CELLS AND NERVE FIBERS. M. Cochran*, R. Bunge & M. Bunge. Dept. Anat. & Neurobiol., Wash. Univ., St. Louis, MO 63110.

Explants of fetal rat dorsal root ganglia can be cultured under conditions that allow growth and differentiation of neurons and Schwann cells (SCs) in the absence of fibroblasts (Wood, '76). In this type of culture, occasionally there are regions in the outgrowth where nerve fibers (NFs) are not attached to the collagen substrate, appearing as guy ropes. These suspended regions of fascicles are abnormal in that they lack SCs in most areas and those SCs present are in occasional small aggregates along the fascicle. Electron microscopic study has shown that, within these aggregates, SCs are perched on fascicle perimeters and ensheath only a few of the NFs in the fascicle periphery and do not form myelin sheaths. If a plastic strip coated with collagen is placed upon the suspended fascicles, within 1 day the SCs start to divide and migrate along the fascicle and within a few more days the fascicles appear normal and also contain forming myelin sheaths (Bunge and Bunge, '78).

To determine whether this abnormality is restricted to sensory ganglia and to explore the nature of the factors involved in correcting it, cultures of partially dissociated 21 day fetal rat superior cervical ganglia were prepared on collagen (Bornstein, '58) or poly-L-lysine substrates. When the cultures are placed on polylysine, SCs neither increase in number nor ensheath NFs although neuritic outgrowth is comparable to that on collagen. When a collagen clot, polymerized in balanced salt solution, is placed on this type of unensheathed neuritic outgrowth on polylysine, SCs proliferate and align along neurites within 24 hours beneath the clot but not elsewhere. When the culture medium lacks 9 day chick embryo extract (EE), however, SC proliferation and alignment do not occur under the clot. Other cultures grown on collagen in a medium lacking EE exhibit less SC proliferation and ensheathment after 5 days than do cultures on collagen in medium containing 10% EE. When the cultures lacking EE are then given medium with EE, many SCs become aligned along neurites within 24 hours. We conclude that for normal proliferation and differentiation of SCs in relation to NFs in the relative absence of fibroblasts 1) additional factors are needed and that 2) this requirement appears to be satisfied by a collagen substrate modified in some way by a component of EE. (Supp. by N.I.H. Grant NS09923.)

316 EXPOSURE TO ETHANOL IN UTERO MAY DELAY MATURATION OF HYPOTHALAMO-PITUITARY-ADRENAL FUNCTION IN THE RAT. Beatrice Cooley-Matthews* and Anna N. Taylor. Dept. of Anatomy and Brain Research Institute, UCLA, Los Angeles, CA 90024.

Our laboratory has shown that treatment of neonatal rats with corticosterone results in delayed onset of circadian hypothalamo-pituitary-adrenocortical rhythmicity. Treatment with corticosterone or ACTH during the neonatal period leads to persistent alteration of some characteristics of adrenal secretion, suggesting permanent modification of the central neural substrate involved with regulation of adrenal rhythmicity. Since ethanol has been shown to activate the adrenal cortex in man and animals, this investigation was designed to assess the effects of ethanol administration during gestation upon the development of the adrenocortical rhythm in the rat.

Pregnant female Sprague-Dawley rats (Simonsen) were delivered to the laboratory 6-9 days prior to parturition. They were pair-fed until delivery on a liquid diet with 25% of the calories as ethanol or an isocaloric liquid diet with sucrose substituted for the ethanol. A third group was fed Breeder Blox (Wayne) ad libitum. Rats were housed under 14 hours light and 10 hours dark (lights on 0400-1800 h). On day 1 following birth, pups were weighed and culled to 10 (5 males and 5 females where possible) and fostered to untreated lactating mothers which had cast litters in the previous 1 or 2 days and which were fed Breeder Blox throughout pregnancy and lactation. Plasma was collected following decapitation of one-half of each litter at the time of the nadir (0900 h) and one-half at the time of the peak (1700 h) of the adult adrenal rhythm and fluorometrically assayed for corticosterone. Litters were sacrificed on days 15, 18 or 21.

No offspring from any group exhibited the skeletal or central nervous system deformities characteristic of the Fetal Alcohol Syndrome in humans and other species. Neither were there any significant differences in body weights at any time. However, significant elevations of the 1700 h corticosterone value over the 0900 h value were found only in the chow group at day 21. There was no similar rhythm in either the EtOH-fed or sucrose-fed groups on any of the days sampled.

These data suggest a delay in maturation of the hypothalamo-pituitary-adrenocortical axis following this regimen of ethanol and/or liquid diet during gestation. Further investigation of the effect of the diet alone is under way.

317 DEVELOPMENT OF THE CONDITIONED ELEVATION OF STEROIDS TO THE FORCED EXTINCTION OF A TASTE AVERSION. S. Coyle*, J. D. Weisberger*, K. M. Salter* and S. Levine. Dept. of Psychiatry & Behavioral Sciences, Stanford Univ. School of Med., Stanford, CA 94305.

In a taste aversion paradigm, the behavioral and physiological responses of an adult animal can be manipulated by varying the amount of deprivation prior to testing. Under "free extinction" procedures of little or no deprivation, adult rats show a behavioral suppression of drinking, and no elevation of glucocorticoids. With acute deprivation (forced extinction), adult animals show a suppression of drinking, and also show an elevation of corticosterone similar to the elevation seen following the injection of LiCl during conditioning. The failure of saline-injected animals to show a steroid response shows that the steroid elevation is due to the reexposure to the conditioned substance, and not to the stress of deprivation.

In our experiments, we examined the development of these behavioral and physiological responses under the conditions of free and forced extinction. Animals aged 22, 26, 32 and 40 days were conditioned to avoid a sucrose solution by pairing the novel taste with LiCl. When tested for the retention of the aversion 4 days later, LiCl injected animals of all ages and under all deprivation schedules suppressed drinking in comparison with their saline controls. The two oldest ages showed the adult pattern of no steroid elevation during free extinction, and a rise in corticosterone levels following forced extinction procedures. The two youngest ages, however, did not show an elevation in glucocorticoids in response to the forced extinction paradigm. This absence of the physiological response is not due to the young animals' inability to show a steroid response, since the injection of LiCl during conditioning caused a long-lasting steroid elevation in all ages.

These data imply that the behavioral responses of an animal may develop independently of the physiological response to the test situation. The dissociation of physiology and behavior suggests that the neural mechanisms which are responsible for the control and coordination of these functions develop at different times.

318 EFFECTS OF ALPHA AND BETA BUNGAROTOXIN ON THE DEVELOPMENT OF TROCHLEAR NUCLEUS AND SUPERIOR OBLIQUE MUSCLE. Tony L. Creazzo* and G. S. Sohal, Dept. Anat., Medical College of Georgia, Augusta, GA 30902

A loss of approximately 50% of the neurons occurs during normal ontogeny of the trochlear nucleus of the white Peking duck embryos. Prior to death all trochlear neurons send their axons to the superior oblique muscle (periphery). The sequence of degenerative changes in the normally occurring and the experimentally induced (by removal of periphery) cell death is identical. These observations suggest that the periphery may be involved in determining whether a neuron survives or dies.

The use of α and β- Bungarotoxin in blocking neuromuscular transmission is well documented. The α- Bungarotoxin binds primarily with nicotinic acetylcholine receptors at the motor endplate whereas the β- Bungarotoxin binds with the presynaptic nerve terminal. The effects of pre and post synaptic blockades on the developing trochlear nucleus and the superior oblique muscles were investigated. α- toxin (50 µg) was directly applied daily to the vascularized chorioallantoic membrane of the white Peking duck embryos from day 8 through 25 of incubation. Embryonic motility was greatly reduced in most embryos and virtually non-existent in others. Brains were fixed in 10% formalin on day 26 and processed routinely for paraffin sectioning. Cell counts were made by counting cells with nucleoli in alternate sections stained with thionin. The extraocular muscles were frozen and processed for esterase and silver stain. Preliminary results indicate an increase in the number of surviving neurons by as much as 50%. The muscle remains largely undifferentiated and the motor endplates are virtually absent despite the presence of numerous nerve terminals.

β- Bungarotoxin with and without phospholipase A_2 activity was directly applied to the chorioallantoic membrane from day 8 through 25 of incubation. Embryonic motility was virtually absent. The gross examination of the brains showed marked reduction in the overall size and particularly that of the tectum and cerebellum. Cell counts and muscle morphology are currently being investigated. (Supported by NIH grant GM 23484)

319 SLOWER RATES OF PROTEIN DEGRADATION IN DEVELOPING RAT BRAIN. June L. Dahl and Victor J. Weibel*, Dept. Pharmacology, Univ. of Wisconsin Medical School, Madison, WI 53706.

The contribution of changes in rates of protein degradation to the increase in protein content of developing rat brain was assessed. Five-day old rats were each given a single intraperitoneal injection of $[^{14}C]NaHCO_3$, and the average rate of protein degradation was estimated from the rate of disappearance of radioactivity in brain over a 12-day time course. In all subcellular fractions examined, decay of protein-bound radioactivity was slower than in the adult animal. Proteins in the soluble and crude mitochondrial (P_2) fractions turned over at 70% of the adult rates, whereas proteins in the microsomal fraction turned over at only 25% of the rate observed in the adult. These results contrast with previous reports that degradation rates in the brains of neonatal animals are faster than in the brains of adult animals. They are similar, however, to observations in bacteria, skeletal muscle, kidney, and cultured mammalian cells which have shown that the rate of disappearance of radioactivity from labeled protein (the degradation rate) is slower under conditions of rapid growth. (This research was supported by NIH Grant DA 00697).

320 ALTERATIONS IN PITUITARY-ADRENAL ACTIVITY OF RATS TREATED WITH $ACTH_{1-24}$ NEONATALLY. Susan M. Dray-Klauss, Berrilyn J. Branch*, and Anna N. Taylor. Depts. of Psychol. and Anat., Brain Research Institute, UCLA, Los Angeles, Ca. 90024.

Early life experiences are known to exert profound effects on adrenocortical reactivity. We were therefore interested in studying whether neonatal hormone levels influence this phenomenon. In a previous study (Lorenz,et al.,Fed.Proc.32:296,1973), we observed that Long-Evans rats treated with $ACTH_{1-39}$ (Armour, 4 IU/10g b wt) on days 7-9 exhibited significantly lower responses to restraint stress than corresponding gel controls. In the present study, Sprague-Dawley rats were injected sc with $ACTH_{1-24}$ in $ZnPO_4$ (Organon, 4 IU/10g b wt) or with an equal volume of vehicle on days 7-9. Animals were housed in 14 hrs light and 10 hrs dark. Eye opening was significantly advanced by ACTH treatment (14.58±.09 [SEM] days vs. 15.82±.15, $p<.0001$).

As adults, animals were subjected to ether stress and jugular tap and stress blood samples were drawn 15 min later for determination of plasma corticosterone (B), just before lights off (peak values) or immediately after lights on (trough values). There was a significant Drug X Sex interaction in both basal and stress levels. ACTH-treated females had significantly elevated basal levels at both peak and trough periods, but did not differ in stress responses. Conversely, there were no differences in basal levels of males, but drug treatment did significantly depress stress levels, especially in the peak period. The percentage change further supported this. Males treated with ACTH showed significantly less elevation of plasma B in response to stress in the peak period than did vehicle males (62%±18% [SEM] vs. 124%±17%). These same animals had smaller adrenals at sacrifice. To rule out a simple adrenal effect, a group of animals, both males and females treated with ACTH on days 3-5 neonatally, was injected with 2 IU of $ACTH_{1-24}$ in $ZnPO_4$, sc, as adults, and bled 2 hrs later, at which time controls have essentially basal levels of B. Neonatal ACTH-treated animals did not differ from vehicle animals in their response to exogenous ACTH. This suggests that the effects on stress responsiveness do not represent hyporesponsiveness of the adrenal to ACTH. Since we have previously shown that exposure of rats at this age to B does not affect adult stress responsiveness (Turner & Taylor,Endocrinol.98:1, 1976), the present data suggest that ACTH produces persistent central effects on pituitary-adrenal reactivity.

321 NEURONAL RESPONSE TO PYRAMIDOTOMY IN THE ADULT AND 15-DAY-OLD HAMSTER. T.E. Durica* and S.K. Jacob* (SPON: M.L. Klawans). Dept. Anatomy, Rush College Health Sciences, and the U. of Illinois at the Medical Center, Chicago, Il. 60612.

In hamster facial motor neurons the chromatolytic response to axotomy has been shown to vary with the developmental state of the neuron. Pyramidal tract lesions were used to study the chromatolytic response of developing neurons contained entirely within the central nervous system. This study was performed to determine if there is a comparable age dependent response in the developing pyramidal cell after axotomy. Unilateral pyramidal tract lesions were made in the medulla, rostral to the pyramidal decussation, in adult and 15-day-old hamsters. Animals were cardiac perfused with a formol saline-gum acacia solution four days following pyramidotomy. Brain stems and cerebral cortices were then double embedded in Parlodion and paraffin. The brain stems were serially sectioned for examination of the lesion site. The cortices were serially sectioned and every tenth section of the adult and every fourth section of the 15-day-old cortices were collected. Both brain stems and cortices were stained with buffered thionin. The pyramidal cells on the experimental side were pale and rounded in shape due to somal and nuclear swelling. The Nissl substance was dispersed and finely granular. The nucleolus had a predominant dark staining area and small pale staining area unlike that seen in the nucleolus of the normal pyramidal cell which has a small peripheral dark area (the DNA portion) and a larger, central pale area (the RNA portion). Pyramidotomy in the 15-day-old hamster results in a different neuronal response than that seen in the adult pyramidal cells. In the response of the immature neuron there was a more localized chromatolysis, however there was no swelling nor was there any apparent change in the nucleoli. Our findings indicate that for central (pyramidal) neurons there is a differential response to axotomy which is similar to that seen in peripheral (facial motor) neurons in the adult and immature hamster. It has been suggested that these differences in the chromatolytic response may be due to the metabolic state of the developing neurons at the time of the injury.

322 EFFECT OF DORSAL-VENTRAL LIMB ROTATIONS ON THE DEVELOPMENT OF MOTOR CONNECTIONS. Betty Ferguson* (SPON: R. J. Wyman) Dept. Biol., Yale Univ., New Haven, Ct 06520.

Specific motoneuron nuclei innervate particular muscles selectively in the developing chick hindlimb. Each muscle is innervated by a coherent group of neurons in a characteristic position in both the rostro-caudal and medio-lateral planes (Landmesser, L. T. (1978) J. Physiol., in press). However, mechanisms for the establishment of the peripheral connections of motoneurons and of appropriate central connections onto motoneurons are unknown.

To test the possibility that motoneurons are grouped in the spinal cord according to similar function (and therefore connectivity), motor pools for three shank muscles of the chick were localized with the technique of retrograde transport of horseradish peroxidase (HRP): the peroneus, the tibialis, and the medial gastrocnemius. The peroneus overlies the tibialis in the adult limb and both are derived from the dorsal muscle mass (DMM) but are antagonists. The peroneus and medial gastrocnemius are derived from different muscle masses, dorsal and ventral muscle mass (VMM), respectively, yet are synergists (Bekoff, A., Stein, P. and V. Hamburger (1975) Proc. Nat. Acad. Sci., 72:1245-1248).

The position of the shank motoneurons in the spinal cord was found to be related to the embryonic origin of the muscle but not to its function. Thus motoneurons innervating muscles derived from the DMM were situated laterally and those innervating the VMM situated medially regardless of muscle function. From these and similar studies on the thigh (Landmesser, L. T. (1978)) it is evident that central connections onto motoneurons cannot form in a simple topographical fashion according to position.

Supernumerary limb studies in this and other laboratories have shown that motoneurons are capable of innervating muscles that they normally would not have synapsed with. However, in view of the strict correlation found between medio-lateral positions of motoneurons and whether they would innervate the VMM or DMM, dorsal-ventral limb bud rotations (leaving the anterior-posterior axis normal) were done at stage 17 (Hamburger and Hamilton), prior to motoneuron outgrowth.

HRP backfills at stages 35-36 showed that medial motoneurons still innervate the VMM, even though this is now in a different position. Similarly, lateral motoneurons still innervate the DMM.

These results suggest that the limb bud is capable of affecting motoneuron projection patterns to result in selective innervation of DMM and VMM by lateral and medial motoneuron populations by stages 35-36.

Characterization of the actual routes taken by motoneuron axons at earlier stages should clarify the mechanisms involved in the establishment of these specific projection patterns. Supported by NIH Grant NS 10666.

323 ONTOGENY OF VISUOMOTOR BEHAVIOR IN NORMAL AND NEONATALLY COLLICULECTOMIZED HAMSTERS. Barbara L. Finlay, David Cordon (*) and Karen Marder (*). Dept. of Psychology, Cornell University, Ithaca NY., 14853

Neonatal hamsters, after lesions of the superior colliculus, show upon maturity sparing of visuomotor behavior that would be lost after a similar lesion made in an adult. We have analyzed the ontogeny of visuomotor behavior in normal and neonatally colliculectomized hamsters with regard to the mechanism of this sparing of function. Various indices of non-visual sensory and motor development, including general viability, were similar for the two groups, with the exception of general activity, which was depressed in the colliculectomized animals prior to eye opening (75% of normal) and dramatically increased after eye opening (200-400% of normal). Upon eye opening, photophobia, visually-elicited exploration, avoidance of a visual cliff and avoidance of stationary barriers were the same in both groups. Orientation to, and pursuit of small food objects was retarded in initial appearance in the colliculectomized group, but the pattern of deficits observed on first appearance was retained into adulthood. Thus we find little evidence for any role of experience in the sparing of function observed after collicular damage in the hamster. In the neonatal operate, as in the adult operate, deficits in visually-guided behavior after collicular lesions are limited to a restricted class of visuomotor behavior, that of orientation to and pursuit of small moving objects.

324 RETINAL SYNAPTIC ARRAYS OF LARGE AND SMALL GOLDFISH. Leslie J. Fisher and Stephen S. Easter jr. Dept. Anatomy and Div. Biological Sci. U. Of Mich. Ann Arbor, Mich. 48109.

The retina of goldfish grows, as the goldfish itself grows, continually throughout its life. During growth, the inner nuclear layer (INL), the inner plexiform layer (IPL), the retinal diameter, the number of neurons, and the retinal magnification factor all change. Do these grossly observable changes have concomitant synaptic changes? We have quantitatively compared the IPL synaptic arrays of retinas of small goldfish--less than 1 year old--with those of large goldfish--3 to 4 years old.

Two distinct synaptic types were identified and counted: conventional synapses (made by amacrine cells) and ribbon synapses (made by bipolar cells). The results are expressed as numerical density of synapses (number per unit volume of neuropil). When expressed in synapses per 1000 cubic micra, conventional density was 125±9.1 for small fish and 144±8.6 for large fish while ribbon density went from 29±2.2 for small to 17 ±9.1 for large fish.

A more complete picture of the synaptic organization may be had by accounting for parameters of retinal growth other than numerical density. The synaptic data are analyzed in terms of the INL nuclei (synapses per amacrine or bipolar cell), planimetric density (synapses per unit surface area of the retina), and visual field (synapses per square degree of visual field).

The data so analyzed indicate that bipolar and amacrine synapses differ in their strategies of continuing synapse formation. Conventional synapses are maintained at a constant numerical density regardless of the size of the eye, while bipolar synapses decrease in numerical density as the eye grows. The planimetric density of ribbons remains constant. Since the magnification factor is greater in the larger fish, the number of ribbon and conventional synapses subserving a given area of visual field is increased. The average number of synapses per neuron increases significantly as the retina grows.

Supported in part by NIH grant EY01281 and EY00168

325 AGING IN MOUSE BRAIN: CHANGE IN ASTROCYTE POPULATION. Lynda H. Fleming* and Brian R. Unsworth* (SPON: E. Stein). Dept. of Biology, Marquette Univ., Milwaukee, WI 53233.

Most information on changes in glial cells with age has been provided by electron microscopic and autoradiographic analysis of brain sections. These studies have demonstrated gliogenesis in old brain, but have not enabled biochemical analysis of the glial cell populations. We have applied bulk isolation techniques to the preparation of glial cells from gross dissected regions of mouse brain. Glial cells prepared from young (6 month) and old (24 month) animals were found to band at different sucrose concentrations, when centrifuged on identical discontinuous sucrose gradients. This age-related difference in glial cell population was restricted to the brainstem and telencephalon, and was not observed in cerebellar preparations. Repeated experiments confirmed that the alteration in bouyant density was associated with astrocyte-like cells. The population of astrocytes from young and old animals were readily characterized by their different bouyant densities when separated on continuous diatrizoate gradients. Glial cells have been functionally implicated in the maintenance of the brain permeability barrier, and in the control of the ionic content of the perineuronal intercellular environment. We are presently investigating the possibility that an alteration in the glial cell population, of sufficient magnitude to be reflected in a change in bouyant density, may indicate major age-associated changes at the biochemical level. Supported by NIH Grant NS 12334.

326 ONTOGENY OF [C^{14}]2-DEOXYGLUCOSE UPTAKE IN THE RAT BRAIN WITH SPECIAL REFERENCE TO DAY-NIGHT DIFFERENCES IN THE SUPRACHIASMATIC NUCLEUS. Jannon L. Fuchs* and Robert Y. Moore. Dept. of Neurosciences, Univ. of California at San Diego, La Jolla, CA 92093.

The regional pattern of [C^{14}]2-deoxyglucose uptake (2DG) in the adult rat brain has been shown by Schwartz and Sharp (J. comp. Neurol. 177: 335-360, 1978). In addition, Schwartz and Gainer (Science 197: 1089-1091, 1977) have shown a clear day-night difference in 2DG uptake in the suprachiasmatic hypothalamic nucleus (SCN), in accord with the view (Moore, 1978) that the SCN is a circadian oscillator in the mammalian brain.

In the present study albino rats maintained in a 12:12 light-dark cycle were injected with [C^{14}]2DG at 1, 3, 5, 7, 10, 14 and 21 days postnatally. At each age, one group was injected during the light period and another during the dark. Additional groups of animals were maintained in darkness during the expected light period and in light during the expected dark period.

The 21-day brain exhibits distinct regional differences similar to those observed in the adult. At day 1 there is much less regional differentiation in 2DG distribution. Between days 1 and 21 there is a differential maturation of cerebral metabolism from one brain area to another as demonstrated by the 2DG method. The day-night differences in 2DG uptake in the SCN appear to be present by day 1 and are marked by day 10. This observation suggests that a circadian rhythm in metabolism in the SCN is present early in development, perhaps as early as day 1. No such difference is evident in any other brain area at any age. Consequently, the data obtained here provide further support for the view that the SCN is a circadian oscillator in the mammalian brain. Supported by USPHS Grant NS-12267.

327 EFFECTS OF ENRICHED AND RESTRICTED POST-WEANING REARING ENVIRONMENT ON ACTIVITY, AVOIDANCE, OVERRESPONSIVENESS, EXPLORATION, AND LEARNING. R. E. Gallagher* and Rhawn Joseph* (SPON: Nancy J. Leith). Depts. Psych. & Anat. Vanderbilt U. Nashville TN. 37232

One hundred eighty-five Zivic-Miller rats, reared in either a restricted or enriched environment were removed from their respective rearing conditions at 72 days of age, housed singly in standard laboratory suspended cages, and randomly assigned to one or several experiments. Several aspects of overresponsiveness were studied, including baseline activity, response suppression, locomotor hyperactivity in a complex closed field, the acquisition of repetitive "response habits", and simple passive and escape avoidance. In addition, the influence of exploration in the acquisition of learning errors was assessed in a food seeking task. All subjects were tested between 80 and 105 days of age.

Running wheel and open field testing (Experiments 1 & 2) indicated a sex difference but no environmental influences on activity level. However, when tested in a closed field (Exp. 3) restricted Ss became hyperreactive, and over subsequent testing increasingly responsive, suggesting a failure to habituate. In Exp. 4, hungry Ss were trained to shuttle between 2 goal boxes for a food reward. When complex novel stimuli were added to the testing environment, enriched Ss engaged in more exploration than restricted animals. This observation is similar to an earlier report (Joseph, J. Psychol. In press 1978) and thus disproves the supposition that restricted Ss do poorly on maze learning tasks due to excessive exploration. Restricted Ss may have failed to explore as much as enriched due to their tendency to develop response habits, i.e. a propensity towards repetitive responding in a limited circumscribed manner, in this case shuttling between goal boxes. This interpretation was extended in Exp. 5, in which it was found that restricted animals and females in general have difficulty suppressing a learned repetitious pattern of rewarded response when it is subsequently punished.

In tests of step-down and escape avoidance (Exp. 6), restricted animals were shown to be comparatively deficient in the ability to passively avoid noxious stimulation, or to control and direct their behavior so as to escape electric shock. Moreover, repeated exposure to the testing apparatus several days prior to testing (Exp. 7) improved the passive and escape avoidance performance of enriched animals only.

In all experiments involving learning, enriched animals were superior to restricted, suggesting that the inability of restricted Ss to suppress and inhibit spontaneous behavioral expression, as well as their tendency to overrespond, not only reduces their ability to make behavioral adjustments, but significantly interferes with learning.

328 VASOPRESSIN SYNTHESIS DURING DEVELOPMENT OF HYPOTHALAMIC MAGNOCELLULAR NEURONS IN THE RAT. D.M. Gash, C.D. Sladek, and D.E. Scott. Dept. of Anatomy, Sch. Med., Univ. Rochester, Rochester, N.Y. 14642

Although vasopressin (AVP) from the fetus has been postulated to play an important role in parturition in mammals, little is known about the functional development of the hypothalamo-neurohypophyseal system. We have endeavored to determine the course of appearance of immunoreactive vasopressin in the developing rat fetus and do correlative ultrastructural studies on the magnocellular neurons of the supraoptic (SON) and suprachiasmatic (SCN) nuclei.

The ventral hypothalamus and hypophysis were excised from 16-21 day rat fetuses, homogenized in 0.25% acetic acid, and radioimmunoassayed for vasopressin. Minimum sensitivity of the assay was approximately 10pg AVP/homogenate. Vasopressin was undetectable in 16-day rat fetal homogenates. By 18 days the ventral hypothalamo-hypophysis contained 130 ± 20pg AVP/animal. There was approximately a 3- to 4-fold increase in immunoreactive vasopressin on each subsequent day until shortly after parturition, when neonates contained 6342 ± 545pg AVP/animal.

Preliminary electron microscopic observations are consistent with RIA data. The SON of 21-day neonatal rats (regardless of sex) demonstrated the ultrastructural correlates of heightened synthetic activity. SON neurons exhibited marked nuclear clefting and distinct nucleoli. Their cytoplasmic matrices harbored numerous neurosecretory vesicles in close association and often within extensive Golgi cisterns. Substantial aggregations of rough endoplasmic reticulum, coated vesicles, and free polyribosomes were characteristic at 21 days of intrauterine development. Axosomatic synapses were not frequently observed at this stage of neonatal development.

Supported by USPHS Grants RR-05403, AM-19761, NS-00259.

329 LOSS OF AXO-SOMATIC SYNAPSES WITH ADVANCED AGE. Y. Geinisman, W. Bondareff and J.T. Dodge*. Dept. Anat., Sch. Med., Northwestern Univ., Chicago, IL 60611.

A loss of axo-dendritic synapses was previously shown to occur in the dentate gyrus of 25-month old rats relative to 3-month old rats (Neurosci. Abstr., 1976, 2:194; 1977, 3:106). In this study an attempt has been made to elucidate the question whether axo-somatic synapses are also lost in the rat dentate gyrus with advanced age.

Five young adult (3-month old) and five aged (25-month old) rats were perfused with Karnovsky's fixative. A 1 mm-thick slice, which included the rostral portion of the right dentate gyrus was dissected, postfixed in 1% OsO_4 and embedded in Araldiate-502. The region of the dorsal blade of the dentate gyrus, located opposite to the lateral end of its ventral blade, was trimmed down and cut into 75 nm-thick coronal sections. Three sections, one each from the rostral face, middle, and caudal face of a tissue block, were mounted on formvar coated, slot grids and stained with uranyl acetate and lead citrate. Each section was scanned along the most dorsal row of the granule cell layer to obtain electron micrographs of the first 10 profiles of granule cell somata sectioned through the nucleus. Mean values for each rat were derived from analyses of 30 soma profiles. Mean values for groups of young adult and aged rats were calculated from individual means and treated statistically with the "t" test.

Comparison of data obtained from the two age groups showed no difference in the size of neuronal soma profiles. The length of plasma membrane of neuronal soma profiles was virtually the same in young adult and aged rats. The mean number of synapses per unit length of neuronal soma membrane was significantly lower (by 15%) in the group of aged rats relative to the young adult group. The length of synaptic apposition, as well as the synaptic covering percentage were found to decrease significantly (by 10% and 22%, respectively) in aged rats as compared to young adult rats.

Because the age-related decrease in synaptic numbers per unit length of neuronal soma membrane is not associated with an age-related change in the size of neuronal somata or in the length of their plasma membranes, it suggests an absolute loss of axo-somatic synapses with advanced age. This synaptic loss is also suggested by the substantial age-related decrease in the synaptic covering percentage which cannot be solely explained by the diminution in the length of synaptic apposition. The findings of this study indicate that the loss of axo-somatic synapses contributes to the process of age-related partial deafferentation of neurons in the rat dentate gyrus.

330 MORPHOLOGICAL DEVELOPMENT OF IDENTIFIED NEURONS FROM AN IDENTIFIED NEUROBLAST DURING GRASSHOPPER EMBRYOGENESIS. C.S. Goodman* and N.C. Spitzer. Dept. of Biology, UCSD, La Jolla, CA. 92093.

We are investigating the differentiation of a class of identified neurons from a single identified neuroblast in embryos of the grasshopper Schistocerca nitens, by direct observations with interference contrast optics, intracellular recordings, and intracellular dye injections. We have found that the dorsal unpaired median (DUM) neurons in each segmental ganglion are direct desendents of the dorsal unpaired median neuroblast. Two plates of about 30 ventral neuroblasts, one on either side of the midline, reside at the center of each body segment in a 7-8 day embryo (development takes 21 days at 34°C). Each segmental array of neuroblasts contains a single unpaired neuroblast dorsal to the paired plates of ventral neuroblasts and at the posterior end of the segment. Each neuroblast is a stem cell giving rise to daughter cells by asymmetric mitoses.

In the thoracic ganglia, two chains of pairs of cells are first seen extending anteriorly from the DUM neuroblast, with a single rather than pair of cells at the end of the right hand chain (more chains appear later in development). Specific identified DUM neurons develop from specific DUM daughters along the left and right chains. By injecting Lucifer Yellow into growing neurons, we have been able to identify individually a number of embryonic cells and observe some of the processes of axonal outgrowth, extension of growth cones, and formation of arborizations in vivo. The asymmetric left and right chains contain different types of DUM neurons; the cells on the left extend laterally out peripheral nerves and the cells on the right extend longitudinally in the ventral nerve cords. Intraganglionic DUM neurons are born later than these first DUM neurons. On the left hand chain, the three outside cells, from most anterior, bifurcate and extend bilaterally out peripheral nerves 3, 4, and 5; out nerves 3 and 5; and out only nerve 5 (this third cell is DUMETi). The single cell at the anterior end of the right hand chain is termed the "H" cell since it bifurcates and each lateral branch bifurcates again, running up and down the ventral nerve cords. The next two cells are mirror image cells which extend anteriorly in only a single ventral nerve cord.

The single cell at the end of the right hand chain is the "H" cell in the meso- as well as in the metathoracic ganglia, suggesting that the left and right chains are producing homologous neurons in homologous positions in different thoracic ganglia. Thus, a constant subset of adult neurons are the descendents by a fixed lineage from a single identified neuroblast in each segmental ganglion.

331 PROPERTIES OF MONOCLONAL ANTIBODIES DIRECTED AGAINST DEVELOPING BRAIN AND MUSCLE CELL SURFACES. Jeffrey Greve and David Gottlieb. Dept. Anat. and Neurobiology, Sch. Med., Wash. Univ., St. Louis, MO 63110.

An investigation of the cell surface biochemistry of developing brain and muscle cells from the embryonic chick has been undertaken using monoclonal antibodies as molecular probes. Spleen cells obtained from mice immunized with viable suspensions of embryonic chick brain or muscle cells were fused with a drug-marked myeloma cell line. Lymphocyte-myeloma hybrids were selected using the methodology of Galfre et al. (1). Anti-brain or anti-muscle cell surface andibody secreted by hybrid cells (hybridomas) was detected by an indirect radio-immune binding assay. A typical fusion yields a minimum of 24 independently arising clones with activity directed against the muscle or brain cell surface. Antibody secreting cells were cloned in soft agar and clonal lines established. The antibodies from these clones show saturable binding to muscle and brain cell surfaces. Binding activity co-migrates with authentic IgG on Bio-gel A-0.5 chromatography and is abolished by antimouse IgG antibody. Antibodies from different clones differ in banding patterns upon isoelectric focusing, indicating that products from different clones are distinct antibody molecules. Hybridomas produce tumors in syngeneic carrier mice. The serum from tumor-bearing mice is a rich source of monoclonal antibody which can saturate the target cell surface at dilutions of up to 10^5. Antibody from the serum of tumor-bearing animals has been labeled with ^{125}I and direct binding to the cell surface of embryonic brain and muscle cells demonstrated. Competition studies with a battery of unlabeled monoclonal antibodies indicate that different clones recognize distinct antigenic determinants on the cell surface. Therefore, the developing muscle and brain cell surface is not dominated by a single antigenic determinant. At least four such determinants have been demonstrated. The tissue distribution of one antigenic determinant, 59-B5, was studied. This determinant is 10-fold more abundant on brain than muscle, gut, liver or heart cells, and is highly trypsin sensitive. We conclude that monoclonal antibodies are valuable molecular probes for the surface of developing excitable cells.

332 DEVELOPMENT AND SEXUAL DIFFERENTIATION OF THE SONG SYSTEM IN THE ZEBRA FINCH. M. Gurney* and M. Konishi* (SPON: A. Van Harreveld). 216-76 Div. of Biol., Calif. Inst. of Tech.,Pasadena CA 91125.

Unique to the songbird brain is a robust neural system which controls the frequency patterning of song. In the adult zebra finch, the individual song system nuclei are conspicuously sexually dimorphic in volume [Nottebohm, F. and Arnold, A. (1976) Science 194: 211]. We have examined the ontogeny and sexual differentiation of this system.

The birthdates of nuclei within the song system have been determined using ^{3}H-thymidine autoradiography. The internal and external striata comprise separate proliferative zones. Proliferation in the dorsal ventricular ridge produces a spatiotemporal gradient of time of origin with first born neurons lying deep in the matrix of the external striatum. At hatching, little cytoarchitectonic differentiation has occurred within the telencephalon. In the peri-hatching period rearrangement of neurons through migration, and glial proliferation characterize telencephalic maturation. As the telencephalon matures, the individual song nuclei coalesce and increase in volume, yet as late as 20-25 days post-hatching the sexes are equivalent. During days 25-35, the song system nuclei, RA and HVc, rapidly expand in volume in the male.

The programmed sexual development of the song system occurs independently of either song vocalizations or song crystallization. Injections of estradiol benzoate (1 µg/g body weight) in oil on day 2 post-hatching suppresses song vocalizations and courtship behavior in the male, while the nuclei of the song system achieve normal volumes. Deafening on day 30 post-hatching prevents song crystallization through interruption of auditory feedback yet allows song vocalizations. Again, no effect on song system development is observed.

333 PSYCHOPHARMACOLOGICAL EVIDENCE FOR A SUBNORMAL SENSITIVITY OF SEROTONIN RECEPTORS IN PROTEIN MALNOURISHED RATS. Robert D. Hall and Wendy M. Robertson*. Worcester Foundation for Experimental Biology, Shrewsbury, Mass. 01545.

Stern and coworkers (Exp. Neurol., 1975, 49, 314 - 326) found that rats subjected to chronic protein malnutrition had higher levels of brain serotonin than well-nourished rats at most of the ages at which measurements were made. The model of malnutrition was one in which female rats were placed on an 8% casein diet 5 weeks before mating, and they were maintained on that diet until their pups were weaned at 21 days of age. The pups were then fed the same low protein diet. The present study, using the same model of malnutrition, asked if there might be some adaptation to the chronically high levels of brain serotonin, specifically, whether there might be a reduced sensitivity of serotonin receptors in the malnourished animals.

Thirty malnourished rats of both sexes and 31 well-nourished rats raised on a 25% casein diet were trained to run in a treadmill to avoid electric shock. Following 3 sessions in which only the 1% ascorbic acid vehicle was injected, a 2-mg/kg dose of N,N-Dimethyltryptamine (DMT), a serotonin agonist, was administered i.p. to half of the rats in each diet group 15 min before the treadmill test. The other half of each group received 4 mg/kg DMT. There followed two additional vehicle-only sessions and a second drug test in which each rat was given the 2- or 4-mg/kg dose of DMT it had not received in the first test.

The DMT impaired performance in a dose related way, as measured by the time to the first fall from the treadmill. The malnourished rats were affected significantly less than the well-nourished ones.

Ten of the rats were tested a third time, and methysergide, 10 mg/kg, was administered 30 min before they were given DMT, 4 mg/kg. The methysergide completely blocked the effects of the DMT, suggesting that the effects of the DMT in the first two tests resulted from the stimulation of serotonin receptors. It appears that there is an adaptation to the high brain serotonin levels in the form of a reduced receptor sensitivity in rats subjected to chronic protein malnutrition.

334 AN INVESTIGATION OF THE OCCURRENCE INTRAMEDULLARY SCHWANN CELLS FOLLOWING X-IRRADIATION OF THE MID-THORACIC AND LUMBOSACRAL LEVELS OF NEONATAL RAT SPINAL CORD. Jeanne K. Heard* and Shirley A. Gilmore. Dept. Anat., Univ. Arkansas Med. Sci., Little Rock, AR 72201.

The presence of intramedullary Schwann cells has been observed following x-irradiation of lumbosacral spinal cords of three-day-old rats (S. A. Gilmore and D. Duncan, Anat. Rec. 160: 675, 1968). In the present investigation intramedullary Schwann cell development was studied in three groups of rats irradiated at three days of age. In one group the irradiated zone was limited to a 5 mm length of mid-thoracic spinal cord (T only), in another group the irradiation was limited to a 5 mm length of lumbosacral spinal cord (L only), and in the third group 5 mm lengths of both mid-thoracic and lumbosacral spinal cord (T/L) were irradiated. All these animals received a single exposure to 4000R of soft x-rays having a half-value layer of 0.16 mm Al. Sham-irradiated littermates served as control animals.

Groups of rats were killed at intervals from 9 through 60 days following irradiation by perfusion of 10% phosphate-buffered formalin through the abdominal aorta. Spinal cords were embedded in paraffin and sectioned transversely at 8 micrometers. Sections were mounted in an interrupted serial fashion and stained by the following methods: hematoxylin and eosin, gallocyanin, Holmes' method, Wilder's reticulum stain, and luxol fast blue-periodic acid Schiff for myelin. Light microscopic observations were made to determine the presence of and area occupied by intramedullary Schwann cells. Schwann cells appeared in the lateral portion of the lumbosacral dorsal funiculus of L only and T/L irradiated spinal cords as early as 9 days post-irradiation. By 17 days post-irradiation Schwann cell development was extensive with the cells occupying the lateral and deep medial portions of the dorsal funiculus. Schwann cells were not observed in the mid-thoracic regions of T only and T/L irradiated rats until 13 days post-irradiation. The accumulation of these cells in the mid-thoracic region was not extensive, and, in general, the cells were confined to the lateral portion of the dorsal funiculus. In animals examined thus far the development of Schwann cells in the thoracic region was never as extensive as in the lumbosacral region. An additional difference between T only and L only irradiated rats is that irradiation of the lumbosacral area results in a decreased number of neuroglia with accompanying alterations in myelin, whereas similar changes were not observed after irradiation of the thoracic region. In general, the T/L irradiated spinal cords showed more necrosis and more Schwann cells when compared to either the T only or L only irradiated spinal cords. (Supported in part by USPHS Grant NS 04761.)

335 DEVELOPMENT OF THE LOCUST FLIGHT SYSTEM: PRECOCIOUS APPEARANCE OF AN IDENTIFIED SYNAPSE. David Heathcote* and David Falk* (SPON: David Bentley). Zoology Department, University of California, Berkeley, CA. 94720.

Insects perform many specific behavior patterns only as adults, for example flight, courtship and copulation. Examination of the neural events underlying the appearance of these behaviors may reveal how patterned neural outputs develop and how the expression of behavior is controlled. Locust flight is a behavior appearing only in the adult. Nymphs lack wings and the coordination necessary for effective flight, even though the flight muscles and their motor neurons are present. The onset of coordination is rapid and it develops during late postembryonic development, in the time immediately around the final molt. Three types of changes could underlie the appearance of coordination in this system. First, previously existing synapses could be strengthened around the critical time; second, new synapses could be formed, and third, previously existing strong synapses could become effective by the removal of an inhibitory block somewhere in the circuit. These hypotheses were tested by examining a critical monosynaptic connection between two identified neurons in the flight system of adults and nymphs.

The Wing Stretch Receptor sensory neuron (SR) has been shown to make a monosynaptic connection with the ipsilateral First Basalar motor neuron (1-BA) and with other wing depressor motor neurons. The SR synapses are essential for flight since their inactivation decreases flight frequency to a nonfunctional level. The forewing SR/1-BA synapse was monitored by intracellular recording from the soma of 1-BA in mature adults and in 6th (last), 5th, and 4th instars. At each stage, the synapse was characterized by measuring (i) voltage amplitude (ii) latency (iii)time course and (iv) decrement with repeated activation. Recordings from 1-BA in the last or 6th instar, show that the synapse is present before the animal can fly. The synapse is also present in 5th and 4th instar animals and it exhibits the physiological properties of the adult synapse.

Therefore, this synapse is present and is effective long before a coordinated flight pattern. It may be that basic connections underlying adult behavior patterns are laid down very early in the development of the nervous system.

336 DEVELOPMENT OF TRIGEMINAL MOTOR NUCLEUS IN CHICK EMBRYO: LIGHT MICROSCOPIC OBSERVATIONS. Marieta B. Heaton and Sally A. Moody. Dept. Neurosci., Univ. Fl. Coll. Med., Gainesville, Fl., 32610.

The development of the trigeminal motor nucleus in the chick embryo was studied, using autoradiographic, cell staining, fiber staining and axonal transport techniques. It was found that this nucleus arises very early in neurogenesis, with the first cells produced at 48 hours of incubation (stage 12), peak cell production at 50-55 hours (stage 16), and neuroblast proliferation completed by 72 hours (stage 18). As has been described in mammalian embryos, the primordial trigeminal cells move from the ventricular layer to accumulate as part of the common medial column, and later migrate in a ventrolateral direction to form the definitive lateral motor nucleus. The first identifiable component of the trigeminal system is the semilunar ganglion, which flanks the neural tube at stage 12, and sends afferents into the metencephalon by stage 13. By stage 14, the medial column is apparent and a few cells have moved to begin formation of a lateral nucleus. At this time, a thin motor root can be seen exiting the brainstem. The temporal sequence of ganglionic afferent ingrowth followed by initiation of medial column migration may be significant, in light of our previous findings demonstrating a profound influence of the ganglionic presence on the development of the lateral nucleus (Moody and Heaton, Neurosci. Abst., 3:114, 1977). During subsequent stages, migratory traffic from medial to lateral column increases, with cells frequently moving in association with fiber processes in the marginal zone. These fibers are presumed to emanate from secondary sensory, reticular, and medial column neuroblasts. By day 5, the medial column is greatly depleted and by day 6-7, the definitive lateral motor nucleus is formed. Beginning at 5 days, the dorsal motor nucleus can be detected, with cells from the lateral nucleus appearing to stream in a dorsomedial direction for its formation. Injections of horseradish peroxidase (HRP) into the mandibular process of the first visceral arch resulted in retrograde labeling of lateral nucleus cells as early as 3 1/2 days of incubation. In addition, migrating cells, intermediate between medial column and lateral nucleus, were similarly labeled. These observations indicate that processes of the lateral nucleus cells and those of migrating cells are well into their peripheral field at this age, but we cannot conclude that neuromuscular affiliations have been established, due to the possibility of HRP diffusion and growth cone uptake. HRP uptake by the migrating medial column cells is the first clear demonstration of the extent of axonal differentiation possible in migrating cells, although such a condition has long been suspected. (Supported in part by NIMH grant MH-27677).

337 TARGET SELECTIVITY OF MOTOR POOLS IN CHICK EMBRYOS. Margaret Hollyday, Dept. Pharmacol. Physiol. Sciences, Univ. of Chicago, Chicago, IL 60637.

A detailed map of the organization of the motor pools supplying muscles of the leg and wing in the hatched chick and in stage 38 embryos has been made using intramuscular injections of horseradish peroxidase (HRP). The adult organization of the motor pools is present before stage 38. The motor pools are grouped according to the embryonic origin of the muscles of the limb which they supply, and not according to the joints on which they act nor to their physiological action during locomotion. Motor pools for muscles derived from the ventral muscle mass are in the medial portion of the lateral motor column; muscles derived from the dorsal muscle mass are supplied by lateral motor pools. The birthdates of motor pools for muscles of ventral mass origin are from stages 17-19 in segments 23-28 and from stages 19-20 in segments 28-30. Motor pools supplying muscles derived from the dorsal mass are born from stages 19-22. In both thigh and calf, the nerves innervating dorsal mass muscles are separate from those innervating ventral mass muscle; in the thigh they are supplied by distinct nerve pathways and in the calf by different fascicles of the sciatic nerve.

Supernumerary legs and wings have been grafted in young embryos so as to be innervated by rostral lumbar segments 23 to 25 or 26. Motor neurons supplying individual muscles of both grafted and host limbs have been labeled using HRP injections in stage 38 embryos. Limb muscles derived from the ventral muscle mass (lat. gastrocnemius and biceps brachii) are supplied by medial motor neurons in clusters whose normal target is muscle of ventral mass origin. Limb muscles derived from the dorsal muscle mass (femorotibialis, post. iliotibialis, peroneus and triceps brachii) are innervated by more lateral motor neuron clusters which normally innervate muscles derived from the dorsal mass. The points of entrance and distribution of the nerves supplying the supernumerary limb are normal even with the reduced number of innervating segments.

These observations suggest that the formation of specific neuro-muscular connections during development may be based on a selectivity for either dorsal or ventral muscle mass tissue. This target selectivity may be further related to motor neuron birthdate and a subsequent expression of pathway selectivity.

338 ABSENCE OF AUDITORY AFFERENTS ALTERS THE GROWTH PATTERN OF AN IDENTIFIED AUDITORY INTERNEURON. Ronald Hoy*, George Casaday*, Sharon Rollins*: (SPON: H. Howland) Cornell Univ., NB&B, Langmuir Lab, Ithaca, NY.

We have studied the effect of the absence of auditory afferent axons during postembryonic development on the adult morphology of a uniquely identified auditory interneuron in the prothoracic ganglion of the cricket Teleogryllus oceanicus. The ear, on the tibia of the foreleg, differentiates wholly during postembryonic development. Thus, unilateral amputation of the tibia immediately after hatching and subsequent amputation of the regenerating tibia prevented the development of any auditory afferent fibers on the operated side. We examined the morphology of the identified interneuron (Interneuron-1)[1] in unilaterally operated and sham-operated animals by retrograde transport of cobalt chloride from the cut end of its axon in the cervical connecture.

In sham-operated animals and on the normal side of unilaterally operated animals, Interneuron-1 has (1) a large lateral dendrite lying in a bundle of incoming auditory afferents and (2) several smaller medial dendrites ramifying throughout the ipsilateral ventral acoustic neuropil (VAN), the region of termination of one class of auditory afferents. In unilaterally operated animals (1) the lateral dendrite on the operated side is usually reduced in diameter and/or length, and (2) some of the radial dendrites originating from Interneuron-1 of the operated side are greater in diameter than normal and, rather than remaining ipsilateral, cross the midline to terminate in the contralateral VAN.

Their results suggest that (1) contact with auditory afferent axons facilitates normal growth of the lateral dendrite, and (2) contact with a normal VAN facilitates termination of the medial dendrites.

339 POSTNATAL DEVELOPMENT OF HAMSTER PREOPTIC AREA: A GOLGI STUDY. Chia-Hung Hsü*, C. Sue Carter, and William T. Greenough. Depts. Psychology and Ecology, Ethology & Evolution, and Program in Neural and Behavioral Biology. Univ. of Illinois, Champaign-Urbana 61820.

We have followed the development of dendritic morphology in Golgi-Cox stained neurons from the medial preoptic area at 0, 5, 10 and 20 days of age in golden hamsters (Mesocricetus auratus). The distance between the anterior commissure and the base of the brain was stable by 10 days of age. Dendritic field area and total dendritic length increased with age through day 20. Soma size increased with age until day 10 and was stable between days 10 and 20. Dendritic spines were infrequent on day 0, more numerous by day 5, and became abundant by days 10 and 20. Only about half of the neurons with first order branches had bifurcations on the day of birth. The probability of bifurcations increased until day 10 and then stabilized, or perhaps actually declined slightly, at 20 days. "Multifurcations" (more than 2 secondary branches), often originating from a varicosity, were most frequently observed on day 5, declined on day 10 and were rare on both days 0 and 20. Prospective branches, from multifurcations and possibly from bifurcations, appear to be lost during development, suggesting that the loss of processes, as well as continuing growth, may be involved in dendritic pattern generation in this region. These findings also indicate that although neuronal growth is probably still continuing to a small extent at 20 days of age, most aspects of development including soma size, and dendritic branching are beginning to stabilize or decline. Supported by PHS RR 07030 and the University Research Board.

340 DEVELOPMENTAL CHANGES IN GANGLIOSIDE COMPOSITION OF HIPPOCAMPUS, RETINA, AND OPTIC TECTUM. Carol Irwin* and Louis Irwin. Dept. Biochem., E. K. Shriver Center, Waltham, MA 02154.

The progressive emergence during development of precise cellular lamination and a topologically organized circuitry in regions such as the hippocampus, retina, and optic tectum of many vertebrates ideally suits these regions for a study of chemical correlates of differentiation and positional coding in the nervous system. We have miniaturized methods for the extraction and analysis of gangliosides in order to correlate changes in the quantity and molecular heterogeneity of these sialoglycosphingolipids with morphological changes during early stages of differentiation in the rat hippocampus and chick retina and optic tectum. Gangliosides from as little as 1 mg of tissue were extracted with chloroform:methanol (2:1, v/v), filtered through Unisil, eluted with chloroform:methanol:water (10:10:3), quantified by sialic acid assay, and resolved into separate molecular species by thin layer chromatography. Ganglioside content varied allometrically (as a log linear function of tissue mass) over a 50 fold increase in tissue dry weight, from very early stages of differentiation to neural maturity. The chromatographic pattern of different ganglioside species developed into the typical adult pattern during the period of maximum differentiation and synaptogenesis, with a disialoganglioside (G_{D1a}) in particular emerging rapidly during this phase. However, even at the earliest stages, prior to a significant degree of differentiation (6 days gestation for chick and tectum, 2 days prenatal for rat area dentata), all the major ganglioside components were present in small amounts. Slight variation in ganglioside content and pattern within subregions of the hippocampus and retinotectal system were detected at early stages, suggesting transient variation in ganglioside distribution within the tissue. These overall results indicate that retinal and brain cells can synthesize all the major gangliosides very early in development, but that shifts in the relative proportion of specific gangliosides occur as the tissue differentiates and becomes topologically specified.
(Supported by NSF Grant BNS 77-20575)

341 DEVELOPMENT OF CEREBRAL CORTEX TRANSPLANTED TO CEREBRAL CORTEX OR TECTUM OF NEWBORN RAT HOSTS. Christine B. Jaeger and Raymond D. Lund. Depts. Biol. Struct. and Neurol. Surgery, Univ. Wash. Sch. Med., Seattle, WA 98195.

We studied the effect of transplantation on the development of the cortex by grafting portions of the dorsal telencephalic vesicle of rat embryos of gestational ages E15-E22 (birth at E22) to the cortex of newborn rats. Embryonic graft tissue was labeled with tritiated thymidine (^{3}HT) prior to transplantation and grown for 1-8 weeks in the host.

Dilution of the ^{3}HT label in neurons of the graft indicates continuation of cell division after transplantation. Furthermore, evidence of ^{3}HT uptake after transplantation by unlabeled graft tissue supports this finding.

Staining of neurofibrils reveals the presence of fiber bundles which course immediately below the surface and within the substance of the transplant. While in cortical implants, fiber fascicles characteristically run between neuron clusters, a markedly different fiber pattern occurs in implants derived from embryonic tectal tissue transplanted to similar host regions. The tectal implants have interwoven fibers not clearly separable into individual fascicles. In cortical implants growing adjacent to the host's midbrain, a prominent fiber bundle can usually be followed running between the implant and the host tectum (or pretectum). This fiber bundle contains, at least in part, efferent axons from the implant.

Golgi impregnation of transplants showed that variations of the two main classes of known cortical neurons, namely pyramidal and nonpyramidal (e.g., stellate) forms, can be recognized in the implant. Pyramidal cells have a single large dendrite which seems to correspond to the apical dendrite except that it has no preferred radial orientation. The basal dendritic field is enlarged. The orientation of neuron dendritic processes relates most obviously to oriented fiber bundles within the implant. In developmentally young implants (up to 4 weeks survival) impregnated neurons have certain characteristics of immaturity, such as spiny somata and hair-like dendritic appendages. These are not seen in older implants. Electron microscopy of cortical implants reveals synaptic patterns characteristic of normal cortex.

These results indicate that embryonic cortical tissue continues differentiation after transplantation and develops connections with the host nervous system. Such connections can persist for at least 8 weeks even though the transplant may be situated in an abnormal site. (Supported by USPHS Grant EY-01950 from the National Institutes of Health.)

342 ULTRASTRUCTURAL STUDY OF MORPHOGENESIS IN THE AUDITORY SYSTEM OF CHICK EMBRYOS: NUCLEUS MAGNOCELLULARIS. Jhaveri*, Sonal, and D. K. Morest, (SPON. J. A. Andrezik). Department of Anatomy, Harvard Medical School, Boston, MA 02115; and University of Connecticut Health Center, Farmington, CT 06032.

The development of the cochlear nerve endings and their target cells was studied with electron microscopy of perfusion-fixed brains from embryonic day 12 (E12) to hatching. E12-13: Somatic processes extend from the perikaryon. The cytoplasm of the soma and processes contains free ribosomes, mitochondria, lysosomes, rough endoplasmic reticulum, golgi apparatus, and an eccentric, heterochromatic nucleus. Small vesiculated profiles of cochlear nerve fibers make specialized contacts, including some synapses on the distal somatic processes but rarely on the proximal processes or soma. The postsynaptic zones contain a flocculent matrix. E15-17: Somatic processes disappear and occasional attachment plaques are seen between cells. The nucleus appears euchromatic. The cytoplasmic organelles form a dense matrix indicative of intense metabolic activity. Somatic spines are evident. The afferent axons form large vesiculated profiles located increasingly on the cell body and somatic spines, with many points of synaptic contact. At each ending a band of amorphous flocculent material fills the postsynaptic cytoplasm. E18-hatching: The somatic cytoplasm becomes less dense; stacks of rough endoplasmic reticulum start to condense. Afferent axon terminals mature, especially the synaptic membrane complex and associated densities. The postsynaptic flocculent material diminishes in extent until it is found associated only with somatic spines.

Conclusions: Primary cochlear fibers initially contact distal parts of the somatic processes of the developing cells. As the somatic processes disappear or withdraw, the axonal endings move to the soma, resulting in large axosomatic end-bulbs. The findings suggest a role of the transiently appearing, flocculent material of the postsynaptic regions in the formation of synapses.

343 ADULT RAT DISSOCIATED SYMPATHETIC NEURONS IN CULTURE: MORPHOLOGICAL AND CYTOCHEMICAL STUDIES. M. Johnson. Dept. of Anat. & Neurobiol., Wash. Univ. Med. Sch., St. Louis, MO 63110.

Although perinatal rat superior cervical ganglion (SCG) neurons (cultured either as explants or as dissociated cells) maintain a number of adrenergic characteristics, they acquire certain cholinergic properties. The neurons accumulate choline acetyltransferase (ChAT) and the vesicles which have dense cores early in vitro become predominantly clear. Synaptic interactions between dissociated neurons are blocked by hexamethonium. Explants taken from adult rats, however, have much reduced levels of ChAT and the vesicles remain dense-cored. Thus, the ability to acquire cholinergic function seemed to be present only during early developmental stages. To further explore this question it was necessary to obtain preparations of dissociated adult neurons. Dissociation was most successful using a 3 hour incubation of small SCG chunks in 0.25% collagenase (Worthington CLS 4194), followed by 1 hour in 0.25% pronase (Calbiochem 53702). After rinsing and gentle trituration the neurons are plated out on air dried collagen in medium containing 10% chick embryo extract, 25% human placental serum and 25 ng/ml NGF. Following dissociation many of the neurons retain multiple branched processes but 24-48 hours later the neurons are rounded and have eccentric nuclei. The growth of new processes is delayed compared to the early neuritic outgrowth from perinatal neurons. Subsequent development is rapid with the neurons increasing in size and the nuclei becoming central. Studies of varicosities or synaptic endings of neurons known to have cholinergic interaction after 28 days in vitro (Wakshull et al., this volume) have shown 64% of the profiles to have a high percent of clear vesicles with a small number of dense core vesicles. The vesicle population is similar to that of the dual function neurons studied by Landis (PNAS 73: 4420-4424, 1976). Because a small number of cholinergic neurons may exist in the SCG and neuronal yield in this culture system is small, studies are in progress to rule out the preferential survival of the cholinergic population. The development of this technique for culture of dissociated adult neurons will allow study of their plasticity, adrenergic properties (such as NGF dependence), and regenerative capacity. (Supported by NIH Grants NS14416 and NS09923).

344 CONCOMITANT AGE RELATED BEHAVIORAL AND NEURONAL CHANGES IN THE NIGROSTRIATUM OF THE RAT. J. A. Joseph, C. Filburn*, S. P. Tzankoff* and B. T. Engel* (SPON: J. B. Appel). NIA, Gerontology Research Center, Baltimore, MD 21224.

Age differences in rotational behavior were examined in two experiments in young (6 mo.) and old (25-29 mo.) Wistar rats. In the first experiment 40 rats were grouped according to age and sex (10/group) and radio frequency lesions were produced in the left substantia nigra. The ratio of left to right turns for each 30 minute session was computed (L/R) following i.p. amphetamine injections so as to eliminate differences in overall turns between young and old unlesioned rats. After lesioning both old and young rats showed dose-related increases in L/R following amphetamine administration; however, age-dependent deficits were observed: young rats showed greater increases in L/R than the old (e.g., 5 mg/kg young rats 80 ± 25; old rats 20 ± 8). No sex differences were observed either prior to or following the lesion. Age related changes were not seen in these animals either when dopaminergic receptors were stimulated directly with apomorphine (.25-5 mg/kg) or when they were blocked with graded doses of haloperidol (.25-2 mg/kg) given prior to a 5 mg/kg dose of apomorphine.

In a second experiment 8 young and 6 old 6-OHDA lesioned males were used in an attempt to potentiate amphetamine-induced turning by pretreatment with 5 mg/kg of l-dopa 1 hour prior to a 1 mg/kg injection of amphetamine. Decided differences in the degree of potentiation were observed between young and senescent animals. Young rats increased their L/R's by 50% while old rats showed a 23% decline in L/R's. These age-related deficits in rotational behavior may be the result of presynaptic changes within the striatum, and subsequent neurochemical analyses have supported this hypothesis, i.e., (a) a 50% reduction in dopamine (DA) (ug/g) in the unlesioned striatum of the old rat making differences in DA levels between lesioned and unlesioned striata less in the old rat (young unlesioned striatum 10.9 ± .9 lesioned 1.8 ± .7; old unlesioned striatum 5.12 ± .7, lesioned 2.03 ± .7); (b) a 12-17% depression in both stimulated and unstimulated tyrosine hydroxylase activity in old unlesioned rats, indicating that basal activity (p mol/min/mg, 15 um tyrosine) measured at saturating (1 mM) and subsaturating (.1 mM) levels of $DMPH_4$ was depressed in the old striata. Addition of heparin (50 ug/ml) to activate the enzyme produced comparable stimulation of activity from both groups at both concentrations of cofactor, indicating a decrease in total enzyme with no significant change in kinetic state. Thus, it would appear that there are deficits in neuronal functioning which can alter rotational behavior in the senescent rat.

345 ASTROCYTIC CELL LINEAGE. AN IN VITRO STUDY. B.H.J. Juurlink*, S. Fedoroff and L. Hertz*. Department of Anatomy, University of Saskatchewan, Saskatoon, Saskatchewan, S7N OWO, Canada.

In order to study a particular cell lineage, one must be able to identify its stem cells and the various progenitor cells as well as the end products of the lineage. Recently developed dissociated brain cell colony cultures (1) facilitate the study of cell lineages in the developing CNS. Dissociated cells of the isocortex of mice of various fetal and postnatal ages, if planted in low numbers, form discrete colonies in culture. The most immature cells in such preparations are believed to be those forming the type A colonies. These cells, in culture, undergo a sequence of morphological changes. In vitro experiments have indicated that the A type colonies develop into the morphologically different C type colonies, which in turn transform into the type B colonies (1). The latter react to addition of the dibutyryl cyclic AMP by intense formation of processes leading to cells which morphologically(1) and biochemically (2) resemble mature astrocytes found in vivo.

In order to determine the precise orgin of the cells which form type A colonies, the subventricular and cortical regions of new born (PO) mouse isocortex were isolated, dissociated and cultured. The number and frequence of various types of colonies that formed were determined. About 80% of all colony-forming cells from the isocortex came from the subventricular zone, and from all astrocytic precursor cells which form type A colonies, about 80% arose from the subventricular zone and 20% from the cortical area of the brain. The colony cultures from P7 mouse subventricular and cortical areas had less than half the number of type A colonies than cultures of PO mice and twice as many type C colonies. These experiments indicate that the cells which form type A colonies in culture come from the subventricular cell population and that some of the cells in newborn mouse brain apparently migrate from the subventricular zone into the cortical area. It also appears that the astrocytic cell lineage progresses from type A colony-forming cells to type C colony-forming cells in vivo as well as in vitro.

346 THE APPEARANCE OF SYNAPTIC JUNCTIONAL MACROMOLECULES DURING BRAIN MATURATION. Paul T. Kelly and Carl W. Cotman. Dept. Psychobiology, Univ. Calif., Irvine, CA 92717.

Direct biochemical analyses were used to examine the appearance of synaptic junctional (SJ) macromolecules during the formation of asymmetric synaptic contacts in the developing rat CNS. Relatively pure synaptic plasma membrane (SPM) and SJ fractions were isolated from immature rat brain at various stages of postnatal development by subcellular fractionation methods previously developed for mature tissues. Electron microscopy on OsO_4 and E-PTA stained synaptic fractions has revealed that immature SJs are morphologically similar to those isolated from adult brain. In particular, SJs isolated from immature rat brains displayed easily recognizable postsynaptic densities (PSDs). SJs isolated from immature brains (5-10 days of age) were smaller and their PSDs appeared incompletely formed. SJ fractions from immature animals contained a higher proportion of postsynaptic membrane specializations (postsynaptic membrane plus PSD) relative to intact SJs than did adult SJ fractions. The protein yield in SJ fractions increased 4-fold during development, a cnange that paralleled the temporal appearance of asymmetric synaptic complexes in situ.

The protein and [^{125}I] Concanavalin A (Con A)-binding glycoprotein compositions of SPM and SJ fractions were examined at different postnatal ages. A striking degree of similarity was observed in the composition of major proteins in SJ fractions obtained from rats at various postnatal ages (4-60 days of age). The relative levels of tubulin and actin in SJ fractions were constant throughout development. The Con A-binding glycoproteins, which in the adult are localized to the external surface of the postsynaptic membrane overlying the PSD, are present in similar quantities in immature (4-14 days) and adult SJ fractions. However, large differences in the composition of Con A binding-glycoproteins were observed in SPM fractions during postnatal development. An exception to these developmental similarities was the major PSD protein which, when compared to adult, was present in SJ and SPM fractions at greatly reduced quantities during the period of active synaptogenesis (8-18 days postnatal).

These results show that postsynaptic membrane glycoproteins which bind Con A are present in SJ fractions of immature rat brain before and during the stages of active synaptogenesis. The same is true for tubulin and actin. These macromolecules may therefore be involved in the early phase(s) of synaptic adhesion. In contrast, the major PSD protein may be associated with the final stages of structural and functional synaptic maturation. (Supported by NIH grant NS 08597 and post-doctoral fellowship 1F32 NS 05746).

347 FURTHER EXAMINATION OF LEUCINE INCORPORATION BY IMMATURE AND MATURE AXOTOMIZED FACIAL NEURONS. L.A. Kirschen and A. LaVelle. Dept. Anat., Univ. Ill.- Med. Center, Chicago, IL. 60612.

Previous work has shown that immature and mature hamster facial neurons differentially incorporate (^{3}H) leucine at 4 days after axotomy, the height of chromatolysis. This work was extended to correlate changes in isotope uptake with morphological changes known to occur with recovery of facial neurons from injury.

The right facial nerves in hamsters at 15 and 20 days postnatal age and in adults were severed. The opposite sides served as control. On postoperative days 4, 15 and 30 all hamsters were injected subcutaneously with 4 μCi/g body weight and sacrificed one hour postinjection (peak of uptake). Each whole nuclear group was removed by dissection, freeze-dried, weighed, and processed for liquid scintillation counting. Specific activities of the TCA soluble fractions for each nuclear group were taken to represent the free amino acid pool (Br. Res.,111:31,'76). These activities were not significantly different for any age and postoperative time. In addition, there was no increase in capillary endothelial cell (^{3}H) thymidine uptake on the experimental side in adult 4 day postoperatives. This is in contrast to Watson (J. Physiol., 180:'65), who claimed that such an increase in his material indicated local hyperemia. There was, however, a 20-fold increase in the number of labelled glial cells on the experimental side as compared to the normal.

In the 15 day operated series, axotomy results in minimal morphological changes compared to normal neurons. Isotope uptake showed no differences between control and injured neurons at any of the postoperative times. In 20 day operatives, axotomy results for the first time in distinct chromatolysis with somal swelling, features of the adult reaction, although these neurons are still immature morphologically. On postoperative days 4 and 15 the experimental sides showed an increase in isotope uptake over the control sides. By 30 days postoperative the difference in uptake was smaller. In the adult at 4 days postoperatively, the isotope uptake was extremely elevated on the injured side. This difference was diminished by 15 days, and by 30 days uptake was equal on both sides.

The differential degrees of both chromatolysis and isotope incorporation at the various ages and postoperative times are suggestive of stage specific levels of metabolism. The difference in rapidity of recovery between the 20 day and adult operatives reflects the fact that at 20 days, injury occurred at a time when the protein synthetic machinery had not yet fully matured. This correlates with cytological observations that the hamster facial neurons mature only after 20 days of age.

348 EFFECT OF LOW-LEVEL LEAD BURDENS ON CAUDATE NUCLEUS ONTOGENESIS AND SENESCENCE: A MORPHOMETRIC ANALYSIS. Martin R. Krigman, Edward Bertram*, Robert Bagnell*, and Elizabeth G. Bendeich, University of North Carolina, Chapel Hill, N.C. 27514.

Suckling Long-Evans rats were fed a single daily dose of either 0, 25, or 200 mg of lead/kg body weight by gastric gavage from the 3rd through the 30th day of life. Rats were then sacrificed at either 60 or 750 days of age and a predetermined region of the caudate nucleus was prepared for light and electron microscopy. Gross brain development as well as somatic growth and development were unaffected by the lead burdens, and qualitative differences were not discernible in the caudate nucleus of treatment groups evaluated at the two age periods by light or electron microscopy. Morphometric analysis, however, revealed in the 60-day-old group a reduction in the numerical density of neurons, synapses, and synapses per neuron. The degree of these changes at 60 days of age was dose related. However, by 750 days of age, the differences between the treated and control rats were not significant.

Low levels of a lead burden perturb ontogenesis of the caudate nucleus. If the lead exposure is restricted to the period of brain development, this early, but limited, lead exposure does not affect aging of the caudate nucleus. (Supported by USPHS NIH Grant ES 01104)

349 EFFECT OF SPINAL CORD DELETIONS AND REVERSALS ON MOTONEURON PROJECTION PATTERNS IN THE EMBRYONIC CHICK HINDLIMB. Cynthia Lance Jones* and Lynn T. Landmesser. Dept. Biol., Yale Univ., New Haven, CT 06520.

In the chick embryo, the combined use of electrophysiological and retrograde labelling techniques have shown that appropriate neuronal projection patterns, involving a tight correlation between axon termination site and motoneuron soma position, are established prior to muscle cleavage and the peak period of motoneuron cell death (Landmesser, J. Physiol., in press). In order to determine what factors might be involved in setting up these specific peripheral innervation patterns, several experimental manipulations were performed. The first, involving partial spinal cord deletions, was designed to see whether the projection patterns of the remaining spinal cord segments would be altered.

Part or all of chick lumbosacral spinal segments LS1-3 were removed prior to the onset of motoneuron production at Stage 15 or 16 of Hamburger and Hamilton. At Stages ranging from 31 to 37 the innervation pattern of the limb was examined by sequentially stimulating the lumbosacral nerves which were present and recording EMG's from various muscles. The limbs were subsequently fixed for microscopic characterization.

No regeneration of the deleted segments was observed and the distribution pattern of the remaining spinal nerves was electrophysiologically and anatomically normal. Muscles which would normally have been totally innervated by the deleted segments could not be activated by spinal nerve stimulation and showed signs of extensive atrophy. Muscles left partially innervated by the deletion were also atrophic, though qualitatively less, indicating that the remaining motoneurons which projected to these muscles did not entirely compensate for the missing motoneurons. The fact that the projection patterns of remaining segments are unaltered even when examined at stages before most of the motoneuron cell death has occurred, implies that the final innervation pattern observed does not require competitive interactions between different cord segments.

A second series of experiments consisted of the reversal of segments LS1-3 at the same stages. Preliminary results from spinal nerve stimulation at Stage 35 revealed that the displaced motoneurons had established connections with their normal muscles. These observations suggest that, in the case of small positional shifts, motoneurons are capable of forming appropriate connections even though their cranio-caudal position with respect to the limb has been altered. (Supported by NIH Grant NS 10666.)

350 APPARENT ACCELERATION OF BRAIN AGING PATHOLOGY BY PROLONGED ADMINISTRATION OF GLUCOCORTICOIDS. P.M. Landfield, J.D. Lindsey*, G. Lynch, Dept. Psychobiol., Univ. Calif., Irvine, CA 92717.

We previously found a significant correlation in aging Fischer rats between plasma levels of corticosterone (but not aldosterone) and quantitative measures of a sensitive index of age-dependent brain pathology (astrocyte reactivity in hippocampus) (Landfield and Lynch; Neurosci. Abstracts, 1977; Landfield, Waymire, Lynch, submitted). Moreover, it has been hypothesized that endocrine factors, in particular glucocorticoids, may play a major role in the development of age-related brain pathology (Landfield, 2nd Tarbox Parkinson's Dis. Symp.; Plenum; in press). In order to test this hypothesis and to examine the possibility that the above-noted brain-endocrine correlations may in part reflect cause-effect relationships, we have administered various hormonal treatments to groups of Fischer rats for a period of 7 mo., beginning at 16 mo.-of-age. (Groups: deoxycorticosterone acetate (DOCA) 5-8 mg/rat; corticosterone acetate (CTCA) 5-8 mg/rat; ACTH gel: 4-8 I.U. (Organon); and a potent synthetic glucocortcoid: 6-dehydro-16-methylene-hydrocortisone (6 DHMH) 0.4 mg/rat: (E. Merck). 6 DHMH is reported to be relatively more effective in its brain effects (suppressing ACTH secretion) than in peripheral effects. Control groups received vehicle. Injections were s.c., 3 x weekly. Animals were maintained in pathogen-free conditions behind an air-barrier filter system. No symptoms of infection were observed.

Glucocorticoid and ACTH treatments, when combined, significantly increased the degree of astrocyte reactivity in comparison to combined control and DOCA groups. However, some control animals exhibited extensive gliosis, and some glucocorticoid animals exhibited relatively mild pathology. Interestingly, control animals with elevated reactivity possessed the highest adrenal weights and in general, a significant correlation was found across groups between levels of glucocorticoid activity as assessed by adrenal weights and degree of hippocampal astrocyte reactivity. Plasma hormone analyses are in progress.

These data, then, are highly consistent with the hypothesis that glucocorticoids contribute, in part, to the rate of hippocampal age change. Moreover, they agree with our prior report of correlations between corticosterone (and adrenal weights) and astrocyte reactivity in aging animals. However, the possibility of hormone effects on astrocyte staining rather than on reactivity must be considered. Further analyses of our other material will allow for more certain conclusions. Moreover, studies in progress will allow us to determine whether or not we can also retard this syndrome. (NIH grants Ag 00341 (PL) and Ag 00538 (GL). We thank J. Waymire, C. Wurtz and L. Braun for important analyses.)

351 ALTERNATING RETINAL GANGLION CELL TERMINATION BANDS IN DOUBLY INNERVATED FROG OPTIC TECTA. Margaret I. Law* and Martha Constantine-Paton. Dept. Biol., Princeton University, Princeton, NJ 08540.

Two optic tracts were induced to innervate a naive tectal lobe through the implantation of a third eye primordium into the forebrain region of Shumay stage 17 Rana pipiens embryos. Autoradiographic analysis following intraocular injections of ^{3}H proline into either the supernumerary or the double innervating normal eye of animals ranging in age from Taylor and Kollros stage V to 3 mos. postmetamorphic revealed distinct eye-specific bands of labelled superficial neuropil. These bands extended rostral-caudally over the entire dually innervated tectal lobe. Grain counts in the unlabelled eye's bands were at the level of tissue background indicating relatively little overlap between the projections of each eye. These results imply that axons from each of the dually innervating eyes are competetively excluding axons from the alternate eye.

Electrophysiological recordings reveal that both the normal and the supernumery eye maps retinotopically. In many tectal locations the activity from one eye was more pronounced than from the other eye.

A similar banding pattern has also been observed when dually innervated tecta were generated through the removal of one tectal lobe in older animals.

We conclude that ganglion to ganglion cell interactions in addition to pre to postsynaptic neuron interactions are active in establishing the normal retinotectal projection. Moreover, the similarity between this experimentally induced banding and the ocular dominance columns of cat and monkey* suggest that the latter termination pattern may be established through cellular interactions basic to a wide variety of neuronal projections. (Supported by NIH grant EYO 1872 and by NIH service award T32GM 07312.)

352 DEVELOPMENT OF REACTIVITY TO AUDITORY STIMULI IN NORMAL AND NEONATALLY BRAIN-DAMAGED CATS. M.S. Levine, C.D. Hull, N.A. Buchwald and S.L. Hutchison*. Mental Retardation Res. Ctr.,Sch. Med. UCLA, Los Angeles, CA. 90024.

This is part of a series of experiments designed to assess the effects of early intervention upon behavioral maturation in the kitten. The purpose of this experiment was to determine (1) the development of behavioral reactivity to stimuli in kittens and (2) the effects of neonatal "medial forebrain bundle" ("MFB") lesions on subsequent development of reactivity. Tests were made on 29 normal kittens (varying from 10-150 days of age), 9 adult normal cats and 5 adult cats which had received bilateral lesions interrupting the nigrostriatal pathway ("MFB" lesions) at 10-15 days of age. The "MFB" lesions significantly reduced the concentrations of dopamine and its associated enzymes in the caudate nuclei bilaterally (80% depletion). The test procedure consisted of presenting each animal with a series of taped cat vocalizations and assessing its behavioral responses on a 6 point scale. Each animal received 2 sessions (24 hours apart) of 28 cat vocalizations (each lasting 12-15 sec) presented 1 min apart. During the first few stimulus presentations the amount of behavioral reactivity to the stimuli was directly related to the age of the animals. The youngest kittens reacted least, the adult cats the most. All animals showed a decreasing pattern of reactivity to the repeated vocalizations during session 1. This habituation was most marked and rapid in adult cats, occurring within 7 trials. Ten and 30 day old kittens habituated very slowly; their responses did not stabilize until the last 7 stimuli of the session. Cats with "MFB" lesions were more reactive during the first few presentations and habituated slower than intact adults during session 1. During session 2 the initial reactivity was no longer directly related to age. Adults, and older kittens had similar reactivity scores. These scores were then compared with the scores for the previous session. Only adults showed any savings. Their initial reactivity scores were 60% of session 1 scores. Ten day and 30 day kittens were as reactive on the second day as on the first. Thus, patterns of reactivity to stimuli are markedly different in young kittens than in adults. Kittens habituate more slowly and do not sustain habituation over a 24 hour period. Cats with "MFB" lesions were as reactive during session 2 as during session 1, showing no savings from the previous days experience. Although these animals were adults they displayed an immature pattern of reactivity.

353 SEGMENTALLY SELECTIVE INNERVATION OF MAMMALIAN SYMPATHETIC GANGLIA: RELATIVE ROLES OF INTRAGANGLIONIC POSITION AND POST-GANGLIONIC TARGETS. Jeff W. Lichtman, Joseph W. Yip and Dale Purves, Department of Physiology and Biophysics, Washington University School of Medicine, St. Louis, MO 63110.

The basis of preferential segmental connections in the peripheral sympathetic system was examined in the superior cervical ganglion of the guinea-pig by asking whether the innervation each neuron receives is correlated with its intraganglionic position or some aspect of its postganglionic target.

By analogy with other systems, selectivity might reflect a topographic matching of preganglionic axons from different spinal segments to particular regions of sympathetic ganglia. The influence of intraganglionic cell position in the superior cervical ganglion, however, cannot be very great since neurons located at different positions along the major ganglionic axes receive, on average, the same segmental innervation. Moreover, horseradish peroxidase-labelled ganglion cells innervating a particular target such as the eye are widely distributed. Thus intraganglionic position is probably not the basis for the selective segmental innervation of ganglion cells.

Preferential segmental innervation of ganglion cells might, on the other hand, be determined by postganglionic targets: for example, such innervation could insure appropriate activation of end-organs with similar functions, or proper activation of sympathetic targets within a particular region of the body. To determine whether the pattern of segmental innervation is more closely related to end-organ position or function, we examined the territory and modalities supplied by different spinal segments. Two different end-organs (blood vessels and the dilator pupillae muscle) at the same location (the iris) responded to stimulation of the same ventral roots. Conversely, the territory of a single modality (piloerector muscles) supplied by the neurons of the superior cervical ganglion showed a segmental pattern of innervation: hairs on the anterior face tended to be erected by stimulation of spinal nerves more rostral than those which activate hairs around the ear and back of the head. Thus sympathetic end-organs are activated by similar spinal segments if they are located in the same region, but tend to be innervated by different spinal segments if they occupy different positions.

These results suggest that segmentally selective synaptogenesis is related to the position of a ganglion cell's target rather than the position of its soma within the ganglion.

[Supported by NIH grant NS-11699.]

354 A QUANTITATIVE STUDY OF HIPPOCAMPAL PYRAMIDAL CELL POPULATION IN NORMAL AND SENILE DEMENTED HUMAN BRAINS. M. Linauts* and P.L. McGeer (SPON: W. Gibson). Dept. of Psych., University of B.C., Vancouver, B.C., Canada, V6T 1W5.

The area of the brain most clearly associated with memory is the hippocampus. There is a general clinical impression in humans that memory capabilities decline with age and are grossly deficient in senile dementia. In the latter condition, senile plaques and neurofibrillary tangles are characteristically noted in the hippocampus, particularly in the pyramidal cells of CA1 to CA3. In order to obtain quantitative information regarding the actual number of pyramidal cells in the hippocampus in various normal age groups, and in senile dementia, we counted cells in a series of human cases ranging in age up to 82 years. The hippocampus was dissected out, fixed in 10% buffered formalin, and sectioned at 50 μ on a freezing microtome. Every tenth section was mounted and stained with cresyl violet. There was a consistent decrease in pyramidal cell counts with increasing age in normal individuals, with substantially fewer cells in cases of senile dementia. An average number of cells per defined field is 1778 at age 37, decreasing to 1415 by age 76. In senile dementia cases, the average number was decreased to 1189 for the upper age category.

355 DEVELOPMENT OF MUSCARINIC AND β-ADRENERGIC RECEPTORS IN RAT PAROTID GLAND; EFFECT OF NEONATAL SYMPATHECTOMY. Jennifer M. Ludford* and Barbara R. Talamo (with the assistance of I. Elashvili). Depts. Neurol. and Physiol. Chem., Sch. Med., Johns Hopkins U., Baltimore, MD 21205.

Rat parotid gland is a favorable tissue for analysis of the development of the secretory process and the influence of autonomic innervation on this development. Maturation of acinar cells is largely a post-natal phenomenon (Redman and Sreebny, Dev. Biol. 25:248, 1971), and sympathetic fibers are actively growing into the gland at birth (Owman et al., Z. Zellforsch. 16:319, 1971). Each cell receives sympathetic and parasympathetic innervation. We have characterized β-adrenergic and muscarinic ligand receptors on membranes of mature and immature glands and determined the density of binding sites in developing glands. [^{3}H]-Quinuclidinyl benzilate (QNB) and [^{125}I]-hydroxybenzylpindolol (HYP) were used as muscarinic and β-adrenergic ligands to measure specific binding. Scatchard analysis of saturation curves gave dissociation constants (K_d) and receptor densities (B_{max}) of 0.10 ± 0.01 nM and 4.8 ± 0.4 pmoles/g tissue respectively for QNB (n=6) and 0.14 ± 0.02 nM and 3.3 ± 0.5 pmoles/g tissue for HYP (n=9) in mature membranes. In young animals (<10 days (d) of age), the K_d for each ligand is essentially the same as for adults. Binding is detectable at birth at 10% and 14% of adult levels (based on tissue weight) for QNB and HYP, respectively. Mature densities of both receptors are achieved by 25 d postnatal. Studies of the development of hormone-sensitive secretion indicated that isoproterenol-sensitive adenylate cyclase activity and amylase secretion are not detectable in 8 d animals, but are present at 15 d (Grand and Schay, Pediat. Res. 12:100, 1978). We find that β-adrenergic receptor levels have reached 22% of adult levels by 7 d and 51% by 14 d, indicating that a complete absence of β-receptors is not the explanation for the lack of sensitivity. Further increases occur in hormone-sensitive adenylate cyclase activity after 25 d, indicating that factors other than receptor number or basal cyclase activity are involved.

Chemical sympathectomy of newborn animals (6-hydroxydopamine, 100 mg/kg, daily, for the first 4 d of life) completely blocks sympathetic innervation of parotid glands in 7-41 d animals (norepinephrine is undetectable, i.e. <0.5% of littermate controls) but does not alter either the K_d or B_{max} for HYP up to 21 d. However, 41 d animals have twice the receptor density of untreated adults, with no change in K_d. Isoproterenol-induced glandular hypertrophy is greater in sympathectomized rats (Gresik and Barka, J.P.E.T. 200:101, 1977); increased β-adrenergic receptor numbers may partially account for the apparent postjunctional supersensitivity of such animals. (Supported by NIH Grant NS12839)

356 THE DEVELOPMENTAL PROFILE OF NEURONAL AND GLIAL ENOLASE IN RAT BRAIN. P.J. Marangos, A.M. Parma, D.E. Schmechel and F.K. Goodwin. (SPON: Henry deF. Webster). Clinical Psychobiology Branch, NIMH, Bethesda, Maryland 20014.

The isoenzymes of the glycolytic enzyme, enolase (E.C.4.2.1.11) from rat brain have been extensively studied in our laboratory. It has been shown that a neuron specific enolase (NSE) and a non-neuronal enolase (NNE) localized in glial cells, accounts for a major proportion of brain enolase activity (Science 199:313, 1978). A specific radioimmunoassay (RIA) has been developed for NSE and NNE which demonstrates that each protein represents about 1.5% of the total soluble protein in brain, making them major constituents of brain tissue.

The developmental profile of each isoenzyme was studied in six brain areas of newborn rat brain up to 25 days of age. In all six regions, brainstem, cerebellum, quadrageminal plate, hypothalamus, forebrain and olfactory bulb, NSE levels are low at birth, (1 ug/NSE/mg soluble protein). The pattern of NSE increase varies between brain regions in a manner that may be correlated with development or acquisition of functional activity. Brainstem levels of NSE increase earliest with the point of inflection occuring at 5-7 days. Other regions are more delayed with cerebellum being the slowest. The late appearance of NSE in development indicates that levels of this neuronal antigen are highly correlated with neuronal differentiation.

In contrast, NNE levels are much higher in the newborn brain (5-8 ug NNE/mg soluble protein) and increase much less dramatically to adult levels (10 ug/mg) at 25 days of age. The NNE/NSE ratio ranges from 5-10 in the various brain areas at birth and decreases to approximately 1 in mature brain. Since NSE is specifically localized in neurons, the low values of NSE in regions where neurons are already generated suggests that NNE is present in immature neurons and that differentiation or acquisition of functional activity correlates with a switch to NSE.

The results are consistent with the hypothesis that NNE is present in immature neurons and is replaced by NSE in a manner coincident with the neuronal differentiation process. Since NSE and NNE have been shown to be products of separate genes, (Brain Research, in press), it appears that the gene responsible for NNE synthesis is repressed, and the gene for NSE derepressed during the course of neuronal differentiation. The appearance of NSE at a late point in development where structural and functional maturation is in its final stages suggests that the neuronal enolase has properties specifically suited to the physiology of the functional neuron.

357 DEVELOPMENT OF GRANULE CELLS IN TWO INBRED STRAINS OF MICE DISPLAYING GENETICALLY-ASSOCIATED VARIATIONS IN THE HIPPOCAMPAL MOSSY FIBER SYSTEM. Dee Ann Matthews and James E. Vaughn. Division of Neurosciences, City of Hope National Medical Center, Duarte, CA 91010.

Certain genetically-associated variations, such as those found in the distribution of mossy fiber synapses upon hippocampal pyramids (JCN 156: 417, 1974), provide an opportunity to study developmental mechanisms involved in establishing specific synaptic connectivities. Previously, we have reported a reversal in the generation pattern of the mossy fiber target pyramidal cells in BALB/cJ mice, but not in SM/J mice. This reversal was limited to the portion of regio inferior that displays genetically-associated variations in the connectivity pattern of the mature mossy fiber system (JCN 173: 41, 1977).

As part of a continuing investigation of the developing mossy fiber system in BALB/cJ and SM/J mice, we have recently examined the genesis of the granule cells and their mossy fiber axons. No differences have been found between these strains either in the development of the granule cells, as examined by ^{3}H-thymidine radioautography, or in the temporal appearance of the mossy fiber system, as revealed by the Timm sulphide silver method. In both strains, the formation of the majority of the granule cells occurred between embryonic day 12 and postnatal day 21 in an "outside-in" generation pattern, and the formation of granule cells in the suprapyramidal limb preceded that of those in the infrapyramidal limb. The peak period of granule cell formation was between embryonic day 19 and postnatal day 7 in both strains. In addition, the percentage of the total labeled granule cell population that was labeled on each injection day was nearly identical for BALB/cJ and SM/J specimens. This finding indicated that granule cells were generated at a similar rate in both strains. In Timm-stained preparations, the mossy fibers were first demonstrated unequivocally on postnatal day 6 and the densely-stained mossy fibers were already visible throughout regio inferior. The prominent appearance of mossy fibers at this time suggests that the mossy fiber system was established prior to its earliest detection by the Timm method. Therefore, the reversed generation pattern observed for regio inferior pyramids of BALB/cJ mice is the only major change thus far identified in a developmental event that might produce the connectivity differences seen in the adult, BALB/cJ mossy fiber system. (Supported by U.S.P.H.S. grants NS10284 and 1 F32 NS05310).

358 NEUROCHEMICAL AND ANATOMICAL STUDIES OF NORMAL AND DEAFFERENTED OPTIC LOBES OF THE MOTH *MANDUCA SEXTA*. Gerald D. Maxwell and John G. Hildebrand, Dept. Neurobiol., Harvard Med. Sch., Boston, MA 02115.

The production of acetylcholine (ACh), γ-aminobutyric acid (GABA), and 5-hydroxytryptamine (5HT) by the optic lobes of the moth *Manduca sexta* is large compared with that in other regions of the CNS (Maxwell and Tait, Soc. Neurosci. Abstr. 3:409, 1977). Using our radiochemical screening procedure (J. Neurobiol. 2:231, 1971), we have compared the production of ACh, GABA, and 5HT in a distal portion of the optic lobe, containing photoreceptor terminals and the lamina (first synaptic neuropil), with that in a more proximal portion containing the medulla and lobula complex (second- and third-order neuropils). Under the conditions of our experiments, the labeling of the pools of neurotransmitter candidates was linear with time. At the conclusion of an incubation, the ratio of radiolabeled product in the distal portion of the optic lobe to that in the proximal portion is about 1.5:1 for ACh, about 1:3 for GABA, and about 3:1 for 5HT.

We have also examined the neurochemical and anatomical consequences of deafferentation of the optic lobe by removing the retinal primordia early in the pupal stage. This surgical intervention results in the development of an animal lacking an eye on the operated side. By light microscopy the lamina is not detectable in the operated lobe, and the medulla and lobula complex are present but slightly smaller than those in the control lobe. The pattern of staining with Luxol-fast blue in the medulla is similar on the operated and control sides. In order to determine the distribution of a likely postsynaptic marker (putative ACh receptors that bind α-bungarotoxin) in normal and operated optic lobes, we examined the binding of [^{125}I]α-bungarotoxin to frozen sections by autoradiography (in collaboration with Dr. L. Hall, MIT). The distribution and density of silver grains over the medulla were similar in operated and control lobes. When the production of ACh, GABA, and 5HT is examined in the deafferented optic lobes, it is found that ACh labeling is reduced about 80% relative to the control lobe; GABA, about 20%; and 5HT, about 50%. Labeling of all three products on the control side is comparable to that observed in an optic lobe from an unoperated animal.

These findings will be discussed with reference to the neurotransmitter chemistry and development of the cellular components of the optic lobe of *Manduca*.

359 GOLGI OBSERVATIONS ON MEDIAL FOREBRAIN BUNDLE (MFB) NEURONS IN NEWBORN RATS. Nathaniel T. McMullen and C. Robert Almli. Dept. Psychol., Ohio Univ., Athens, Ohio 45701.

The MFB is located in the ventrolateral diencephalon and basal forebrain and through its massive reciprocal connections with the limbic forebrain and midbrain forms the major longitudinal conduction tract of the hypothalamus. Interstitial neurons of the MFB (lateral preoptic and hypothalamic neurons) are of the reticular-type and are interspersed within a complex and heterogeneous fiber system. Path neurons of the MFB have fusiform or triangular somas with dimensions of approximately 30 x 18 u and 3-5, long, poorly-ramified dendrites which occasionally bear spines. The stout rectilinear dendrites may exceed 500 u in length and are preferentially splayed across the numerous chemically-coded ascending and descending fiber systems making up the MFB. In the present study, path neurons of the MFB from the LPO posterior to the LH at the level of the VMH were examined in newborn rats less than 12 hr old using a variant of the Golgi method. Serial coronal sections through the MFB, 100 u thick, were cut from the brains of 15 male and female rats, dehydrated, and mounted under a cover slip. Well impregnated neurons were drawn at a magnification of 625 using a Wild drawing tube. In these neonatal rats basal forebrain and hypothalamic neurons were undergoing dramatic development. The somas of these cells had average dimensions of 19 x 11 u and therefore have achieved approximately 62% of their adult dimensions. In contrast to the relatively smooth somas present in adult rats, path neurons in the neonates were frequently covered with thick budding processes and hair-like filopodia. The developing dendrites, similar to that seen in adults, were already aligned in a dorsal-ventral direction across the MFB. A wide spectrum of dendritic development was present within the neonatal MFB with some neurons having short stout processes approximately 20 u in length to long straight dendrites exceeding 250 u in length. The most striking feature of these sparsely-branched dendritic processes was their pronounced beaded appearance. Lumpy enlargements of cytoplasm at the tip and shaft of the growing dendrites-terminal and preterminal growth cones-were present in the majority of neurons. Thin hair-like processes were frequently present on the soma and dendrites of these cells. The developing dendrites appear to lose their varicosities and other contour irregularities as they grow in length. There was no evidence of any gradient in dendritic development within the MFB.

360 MEMORY PERFORMANCE ON A STERNBERG SEARCH PARADIGM IN SENESCENT ORGANIC AND FUNCTIONAL DISORDERS. Nancy E. Miller. National Institute of Mental Health, Bethesda, MD 20857

Anecdotal accounts suggest that primary memory remains intact both in advancing age and in conditions of altered brain function. To examine this hypothesis, a choice-R.T. memory scanning task was administered to 108 persons 50 years of age and up referred for psychiatric evaluation. In this procedure, digit strings ranging in length from 1 to 6 digits were displayed in a horizontal linear array for 3 seconds, followed by a 2-second delay. A single digit was then presented and the S was to decide whether the digit had appeared in the preceding sequence. Each S was evaluated for presence of brain dysfunction and for depression. Regardless of diagnostic classification, all Ss manifested a monotonic decline in accuracy as task difficulty increased. While those with brain dysfunction showed the steepest deterioration in performance with increasing digit set size, depressives also manifested significant impairment in accuracy of information retrieval. Correlations between accuracy of response and number of years of education were substantial and highly significant. These findings suggest that traditional assumptions regarding the imperviousness of primary memory to pathology-linked decline in the aged are not substantiated, and that accuracy of response in memory scanning is strongly related to behavioral measures of cortical intactness and amount of formal education.

361 CHANGES IN NEUROPHYSIOLOGICAL TASTE RESPONSES THROUGHOUT DEVELOPMENT IN FETAL, NEWBORN AND ADULT SHEEP. Charlotte M. Mistretta and Robert M. Bradley. Dept. Oral Biol., Sch. Dent., U. Mich., Ann Arbor, MI 48109.

To study changes in neurophysiological taste response characteristics during development, we recorded from 54 chemosensitive units in the solitary complex (nucleus and tractus solitarius) of fetuses, lambs, and adult sheep while stimulating the tongue with chemicals. Using tungsten microelectrodes, 24 single or few-unit records were made in 18 fetuses aged 84-126 days of gestation (term=147 days); 18 records were made in nine lambs aged 20-82 days after birth; and 12 records were made in six adult sheep aged 2-9 years. Twenty ml each of 0.5 NH_4Cl, 0.5M KCl, 0.5M NaCl, 0.5M LiCl, 0.1M citric acid, and 0.01N HCl were used to stimulate the anterior third of the tongue. The tongue was rinsed with 20 ml of distilled water after each stimulation.

With increasing age, taste units responded to more chemicals: in fetuses $\leq$ 108 days, 67% of units responded to only three (NH_4Cl, KCl, citric acid) of the six stimuli, and 0% responded to all six; in fetuses $\geq$ 114 days of gestation, 11% responded to three stimuli, 33% to six; in lambs and adults, 7% responded to three, 60% to six. Only after 114 days of gestation were responses to NaCl and LiCl recorded.

The adapted response frequency reached higher values in lambs and adults (range: 1-115 impulses/sec) than in fetuses (range: 1-47 impulses/sec). As gestational age increased, the pattern of taste responses during stimulation of the fetal tongue with NH_4Cl and KCl also changed, progressing from a rapidly adapting discharge to the more slowly adapting discharge characteristic of lambs and adults. The response discharge during stimulation of the tongue with citric acid was slowly adapting throughout development. Response latency decreased throughout gestation at a rate of about minus 30 msec/day, but adult values were not reached until after birth.

Developmental changes in response frequency, adaptation pattern, and latency most probably relate to maturation of taste synapses and fibers, whereas the increasing range of chemical responsiveness may reflect taste receptor maturation. Responses to stimulation of the tongue with NaCl and LiCl were only recorded in fetuses $\geq$ 114 days of gestation; receptors for these chemicals may be gradually added, or receptors already present may become more sensitive, as the taste cell matures. These results demonstrate that taste function changes throughout development, concomitant with changes in taste bud structure and with altered feeding experience. 362 DEVELOPMENT OF TRIGEMINAL MOTOR NUCLEUS IN CHICK EMBRYO: ELECTRON MICROSCOPIC OBSERVATIONS. Sally A. Moody and Marieta B. Heaton. Dept. Neurosci., Univ. Fla. Coll. Med.,Gainesville, FL. 32610.

Light microscopic analysis of the migration pattern of V motor neuroblasts has raised questions as to whether the different phases of migration can be identified by distinct ultrastructural characteristics. Initial studies have chosen the day 5 embryo because all three stages are distinct (Phase I=medial column, Phase II= intermediate, Phase III= lateral column; Heaton and Moody, Neurosci.Abst. IV,1978).

Migratory cells of the intermediate phase are elongated and often appear bipolar, aligned parallel to dense bundles of processes. The nuclei are elongated and have dispersed, granular chromatin and one to two nucleoli. The cytoplasm is characterized by abundant ribosomal rosettes, a few endoplasmic reticulum profiles and mitochondria. The processes upon which these cells lie have abundant mitochondria, cisternae and microtubules. Ribosomes are present but sparse. Close membrane appositions are found intermittently not only among fibers in a bundle but also between these fibers and the somas and processes of migratory cells. Such intimate contact mat be indicative of contact guidance and/or some ionic interaction via these junctions. Desmosomes and other adhesive junctions were not observed.

Cells with similar contacts to fiber bundles were also observed in the lateral columns. These cells are often seen aligned in chains to the incoming fascicles. They differ from those of the intermediate phase in that they are often rounded or ellipsoid and also contain Golgi apparati. These neuroblasts are tightly apposed to one another and are connected via direct intercellular bridges identical to those described in the developing cerebellum by Das (Cell,Tiss. Res.176: 475,1977). Up to four cells in thin section have been observed linearly linked via these bridges, which are typically seen as strings of round to ellipsoid vesicles separating two cells. No other membrane structures and no organelles, other than a few small particles are seen between the vesicles. The coupled cells are not undergoing mitosis since they left the mitotic cycle several days earlier (3-3 I/2). Still, it is possible that the joined cells are daughter cells which never totally cleaved during their final telophase and have migrated while remaining in an extended mitotic phase. However, no such bridges have been observed among Phase II cells as yet.

Although the temporal occurence of these junctions during the entire migratory process has not yet been determined, these observations suggest a communicative role important to some phase of migration much like that proposed by Loewenstein (Devel. Biol. Supple. 2: 151,1968).

363 AGE-RELATED CHANGES IN AXONAL AND TERMINAL DEGENERATION AFTER FRONTAL CORTEX (FC) LESIONS IN RATS. Elliott Mufson and Donald Stein. Department of Psychology, Clark University, Worcester, MA 01610

Investigations of FC have shown age-related changes in gross morphology as well as neuronal cell loss. Removal of FC in aged rats produces no significant deficits on spatial learning tasks as compared to younger animals (Stein and Firl, 1976). Differences in neuron density of the aged nervous system has been suggested as an explanation for these behavioral findings. Alternatively, age may also produce changes in the pattern of axonal connections associated with FC. There are, however, no investigations of age-related alterations in axonal pathways associated with brain lesions.

Male Fisher (344) strain rats, 3-4 per group, aged 90, 365 and 720 days sustained unilateral FC lesions intended to remove all cortex 2mm anterior to bregma and 3 mm ventral to the cortical surface, whereas 4 animals served as unoperated controls. Following lesion all rats survived from 1-7 days and were processed for histological analysis using the Fink-Heimer I procedure.

Light microscopic analysis of Fink-Heimer processed tissue revealed no observable age-dependent differences in either the quality or quantity of axonal degeneration. All FC lesions produced a pattern of degeneration similar to that described in young adult rats (Leonard, 1969). In contrast to the findings of Leonard (1969), heavy terminal degeneration was observed in the claustrum independent of age. In addition, only the 720 day old control rats showed consistent fiber debris in the stria medullaris, stria terminalis, anterior commissure, corpus callosum and fornix (see Naranjo and Green, 1977). Axonal debris was also seen in the cochlear, vestibular, medial cerebellar, mesencephalic trigeminal and motor trigeminal nuclei. Degeneration was more extensive in fiber tracts.

The age-related loss of axonal connections seen in control tissue suggests that the central nervous system undergoes atrophy which, over time, may be related to deterioration of sensory, motor or cognitive abilities. Finally, the fact that no age-related differences in axonal degeneration were seen using reduced silver staining does not eliminate the possibility that other more subtle techniques, such as radioautography, may reveal differences in axonal connections across ages.

364 PLACODAL AND NEURAL CREST CONTRIBUTIONS TO THE GLOSSOPHARYNGEO-VAGAL COMPLEX STUDIED BY THE METHOD OF INTERSPECIFIC TRANSPLANTATIONS BETWEEN QUAIL AND CHICK EMBRYOS. C.H. Narayanan and Y. Narayanan*, Dept. of Anat., Sch. Med., New Orleans, LA 70119.

Although cranial neural crest has been implicated in the origin of various cranial ganglia, the function of these crest neurons in the seventh and ninth cranial nerves has not been determined. In this preliminary report we present the results of two experimental procedures aimed at elucidating the relative contributions of placodal and neural crest elements of the glossopharyngeo-vagal complex. In the first series, neural crest and adjacent neural folds of caudal hindbrain levels from quail embryo donors was transplanted orthotopically to replace corresponding hindbrain levels of chick embryo hosts. In the second series, unilateral orthotopic transplantation of placodal material from quail embryo donors was made on to chick embryo hosts. Experimental embryos were recovered at representative stages of development. The heads were embedded in paraffin, sectioned and stained by the Feulgen and Rossenbeck's technique for detailed histologic analysis.

Quail cells were found consistently in the root ganglia of the IXth and Xth cranial nerves, indicating their origin from the neural crest and neural fold graft of quail embryo donors. Chick cells were absent in the root ganglia of IX and X. Placodal material from quail embryo donors transplanted to chick embryo hosts end up in the petrosal and nodose ganglia respectively. Quail cells were not observed in the root ganglion of IX and X in any of the experimental embryos of this series. Confirmatory evidence is provided by these experiments for a purely neural crest origin for the root ganglia, and a purely placodal origin for the trunk ganglia of cranial nerves IX and X.

365 EFFECT OF ALPHA AND BETA BUNGAROTOXIN ON NATURALLY OCCURRING MOTOR NEURON LOSS IN XENOPUS LARVAE. Anthony J. Olek* and Charles Edwards. Neurobiology Research Ctr., Biol. Dept., State University of New York at Albany, Albany, New York 12222

During normal development there is a decrease in the number of motor neurons in the lumbar spinal cord of Xenopus (Hughes A.J. Embryol. Exp. Morph. 9:269 1961). Recently, in embryonic chick spinal cord, the naturally occurring cell loss has been shown to be reduced by the use of neuromuscular blocking agents (Pittman, R.H., Oppenheim, R.W. Nature 271:364 1978). Similar effects have now been found in Xenopus.

Multiple injections of alpha bungarotoxin (α-BTX), which binds to acetylcholine receptors, into the hind limb bud during the period of normal cell loss, produced a significant increase (up to 50%) in the number of motor neurons compared to neuron counts in saline injected control animals. Although one limb was injected with the toxin, the numbers of motor neurons on both sides of the spinal cord were found to be elevated over the numbers found in untreated animals. These injections slow the rate of development of the animal and produce signs of atrophy in the injected limb. After stage 56, a period when normal rapid cell loss is essentially complete, injections of α-BTX were without effect on motor neuron numbers. Further, single injections of α-BTX at various times during the period of cell death also had no effect on cell numbers. The rapid rate of synthesis of acetylcholine receptors in the developing limb may require multiple injections of α-BTX to block receptors continually.

Beta bungarotoxin (β-BTX) is known to block neuromuscular transmission by actions on the presynaptic nerve terminal. Injections of β-BTX into one hind limb bud produced significantly increased motor neuron loss as shown by a comparison of the motor neuron counts in the injected and contralateral side. However the motor neuron counts on both sides of the injected animal were lower than cell counts in untreated control animals. The effect of β-BTX is maximal in animals injected early during the period of cell death. Injections after stage 56, when normal cell death is largely complete, did not produce a change in motor neuron numbers.

The period of cell death in Xenopus may reflect a time in the developmental history of the animal when motor neurons are particularly sensitive to changes in the peripheral environment.

366 EFFECTS OF ANTIBODIES AGAINST NERVE GROWTH FACTOR ON DEVELOPING AND DIFFERENTIATED ADRENERGIC NEURONS. Uwe Otten*, Martin E.Schwab*, Michel Goedert* and Hans Thoenen,(SPON: A.A.Borbély), Dept. of Pharmacology, Biocenter of the University, Basel, Switzerland

There is good evidence that nerve growth factor (NGF) is an absolute prerequisite for the normal development of the peripheral sympathetic nervous system. Administration of a single dose of purified anti-NGF antibodies to newborn rats leads to an extensive destruction of the superior cervical and stellate ganglion, as manifested by a drastic reduction of all norepinephrine-synthesizing enzymes. These biochemical effects seem to appear first in the neuronal cell body and then to extend to the nerve terminals in the heart, the submaxillary and the pineal glands. In contrast the anti-NGF effects in adults were smaller and reversible. Long-term exposure to antibodies against NGF was achieved by repetitive immunization of adult rats with 2.5 S NGF. Morphological analysis revealed a general reduction in the size of the adrenergic neurons which was also reflected at the biochemical level by a 40% decrease in total protein content and a corresponding reduction in all norepinephrine-synthesizing enzymes. Enzyme levels in target organs however,remained unaffected. All these effects were fully reversible. The recovery of normal enzyme activities followed closely the decrease of the antibody titre after cessation of boosting. The shift from the irreversible to the reversible effect is a gradual one and occured between day 12 and 16 after birth. The time-course of the morphological changes after anti-NGF treatment and the fact that NGF-antibodies are also effective in newborn mice genetically deficient in the C5 complement component suggest that immunosympathectomy does not result from a complement-mediated cytotoxic effect. Thus, adrenergic neurons from newborn animals depend on NGF or a cross-reacting NGF-like material for survival, whereas differentiated adrenergic neurons need this factor for the maintenance of their normal function but not for survival.

367 NEONATAL 6-HYDROXYDOPAMINE: EFFECTS ON THE DEVELOPMENT OF THE ACOUSTIC STARTLE RESPONSE AND MATURATION OF SENSORY SYSTEMS. Thomas Parisi*, James R. Ison, and Carol Kellogg (SPON: V. Laties). Dept. Psychology, Univ. of Rochester, Rochester, NY 14627.

In these experiments we investigated the effects of 6-hydroxydopamine (6-OHDA) administered neonatally on the development of acoustic startle behavior in the rat. In normal rats, the acoustic startle response (to a 10K, 110 db tone) can first be elicited at 12 days of age, and its susceptibility to modification by preliminary stimuli grows over the next seven days, attaining adult levels of facilitation and inhibition by 19 days. At short intervals (10 msec), preliminary stimuli facilitate the response. At longer intervals (50-100 msec), the response is inhibited. In the present experiments, rats were injected with 100 mg/kg 6-OHDA s.c. on days 3, 4, and 5 of life, with litter mates receiving vehicle injections. Behavioral testing began at 13 days. Treated animals lagged behind control animals by one or two days in the first appearance of the response. At day 13, all of the control animals (10) responded to the startle tone, whereas only 2 of 10 of the 6-OHDA treated animals did so. However, once the response was elicited, ontogenetic changes in modification by preliminary stimuli were the same for experimental and control groups.

Over days 14 to 18, the latency of the startle response, measured electromyographically, decreased from 15.0 to 11.8 msec in control animals. Preliminary data suggest that 6-OHDA treated animals respond slightly (1 msec) less rapidly at both ages. The retardation in acoustic/motor development seen in these animals was accompanied by a similar lag in eye opening. In normal animals, this was accomplished by 14 or 15 days, with treated animals again lagging about one day behind. Additionally, there was a difference in body weight, the treated animals running about 10% lower than controls. These data are consistent with hypotheses suggesting a role for norepinephrine in the support of developmental processes. Experiments are now in progress examining the relationship between changes in neuronal uptake of ^{3}H-NE produced by 6-OHDA and the behavioral observations.

368 DEVELOPMENTAL APPEARANCE OF ACETYLCHOLINESTERASE MOLECULAR FORMS IN CHICK MUSCLE CULTURE. Michael R. Patterson*, Hugo L. Fernandez and Barry W. Festoff (SPON: D.K. Ziegler). Dept. Neurology, Univ. of Kansas Med. Ctr. and Neurobiology Research Lab, VA Hospital, Kansas City, MO 64128.

Interest has developed recently regarding the presence and functional roles of several molecular forms of acetylcholinesterase (AChE; Hall, J. Neurobiol. 4:343, 1973) in nervous and skeletal muscle tissue. A large molecular weight form was thought to be a "marker" for nerve-muscle contact (Vigny et al, J. Neurochem. 27: 1347, 1976) and is approximately 18S in eel electroplax, 16S in rat and 19.5S in chicken and endplate-enriched regions of skeletal muscle. A recent report suggested that in rat primary muscle culture, 16S AChE only appears after "induction" by neuronal elements (Koenig and Vigny, Nature 271:75, 1978), while 19.5S was not detected in primary cultures of chick muscle (Rotundo and Fambrough, Neurosci. Abst. 3:527, 1977). Prior to assessing whether "induction" might be an in vitro expression of "trophic" dependence on some neural factor(s), we followed the temporal course of total and separate molecular forms of AChE in chick primaries.

11 day old embryos of specific pathogen free white Leghorn eggs were the source of dissociated muscle cultures (Hartzell and Fambrough, Dev. Biol. 30:153, 1973). Total and individual forms of AChE activity were assayed in the horse serum (HS,10%) and chick embryo extract (CEE) used to feed the cultures, and at 2,4,7,9,11, 14 and 16 days in Lubrol-WX extracts. Forms were separated by sedmentation on linear (5-20%) sucrose gradients in an SW41 rotor and activity estimated by a sensitive radiometric assay using BW284C51 as specific inhibitor. 5 molecular forms of AChE were seen as early as 2 days in culture, with gradual increase in activity until day 14 followed by a sharp decline. 6.5S and 11S forms predominated, but 19.5S, 15.5S and 4S were found. Because all forms of AChE gradually increased over the time course and then sharply decreased with no obvious change in morphological appearance of the cultures, we presently feel that exogenous AChE in HS or CEE may not account for their presence. Alternatively, a form of AChE has been shown associated with membrane surfaces in cultured muscle (Wilson et al Dev. Biol. 33:285, 1973) so we cannot exclude that the increase in minor forms with time represents binding of exogenous AChE to increasing numbers of "receptors" in growing myotubes. "Induction" could not account for their presence since cultures were grown aneurally. Experiments are in progress to determine whether these forms are produced by cells in culture or represents binding of AChE to myotube surface receptors.

369 COMPARISON OF TRANSNEURONAL CHANGES IN THE AVIAN ECTOMAMILLARY AND VENTRAL LATERAL GENICULATE NUCLEI. J. D. Peduzzi*, E. S. Baron* and W. J. Crossland. Department of Anatomy, Wayne State University, School of Medicine, Detroit, MI 48201

The avian ectomamillary nucleus (EMN) has been reported to undergo extensive transneuronal degeneration following embryonic eye removal while the ventral lateral geniculate nucleus (GLv) has shown only minor transneuronal changes. Following unilateral enucleation on a day of hatching, we studied the volumetric changes in the EMN and GLv at post-operative survival periods of 2 to 80 days. Since the visual pathway is completely decussated in the chick, the nuclei contralateral to the unoperated eye served as controls. In addition some unoperated animals were also examined.

Initially the relative volume ($\frac{\text{experimental volume}}{\text{control volume}}$) of the experimental EMN decreased rapidly then leveled off at 45% of control volume by the 60th day following enucleation. The experimental GLv also decreased rapidly in volume at first but leveled off at approximately 70% of control volume. However, the experimental EMN changed very little in absolute volume during the post-operative period while the experimental GLv increased in absolute volume paralleling a similar increase in the control side.

Cell measurements based on camera lucida drawings of control and experimental EMN cells on the 48th post-operative day reveal both a lower cell number (20%) and a smaller cross-sectional cell area (25%) on the experimental side. Hence the relative reduction of EMN volume results from both cell size differences and a reduction of cell number.

Our findings confirm and extend earlier observations of the sensitivity of the EMN to deafferentation. Furthermore, our results suggest that the mechanism of change may involve an arrest of development rather than, or in addition to, cell atrophy and death.

370 DEVELOPMENT OF DENDRITIC AND SYNAPTIC STRUCTURE FOLLOWING EARLY LEAD EXPOSURE. Ted L. Petit and Janelle C. LeBoutillier*. Dept. Psychology, Univ. Toronto, West Hill, Ont., Canada, M1C 1A4.

Early lead (Pb) exposure in children and experimental animals leads to a neurological sequel frequently culminating in severe intellectual impairment. To determine what neurobiological factors may underlie this behavioral deficiency, the effect of Pb on dendritic and synaptic development was examined in rats.

All litters were reduced to 6 males on the day following birth and the mothers maintained on an ad-lib diet of either ground chow (control group) or ground chow containing 4% lead carbonate (Pb group) from postnatal day 1 (PN1) to PN25. Brain weights were reduced by 12% and neocortical depth by 14% in Pb treated animals.

For analysis of dendritic development, animals were sacrificed on PN25, their brains processed with the Golgi-Cox method, and Layer V sensorimotor neocortical neurons dorsal to the first hippocampal section were drawn and analyzed according to the Scholl method. Fifty neurons were analyzed from each of 8 Pb and 5 control animals (each from different litters). While there was no difference between the groups in the number of dendritic processes leaving the cell body, the Pb neurons had fewer dendritic branches 80 μm and 100 μm from the cell body. The length of the primary apical dendrite was reduced by 5.6%.

Electron microscopic analysis of EPTA stained synaptic structure was carried out in the molecular layer of the visual cortex of 28 day old animals. For analysis of synaptic density, the number of synapses per 15,000 X field were counted. We did not find any significant differences in the synaptic density between the two groups. However, when one considers the 14% reduction in neocortical depth, there would be fewer total synapses in the neocortex of Pb treated animals.

The following synaptic parameters were measured in 50 synapses per animal, 3 animals per group, at 275,000 X: presynaptic length, postsynaptic length, cleft width, presynaptic thickness, and postsynaptic thickness. Although we did not find any group differences on any of the synaptic parameters, there may be a thinning of the presynaptic terminal in some Pb animals. The brains of more animals are being analyzed to confirm this finding.

Therefore, these findings suggest that early Pb exposure reduces dendritic development and the number of synapses, and may reduce the presynaptic terminal in some Pb animals. These deficiencies in brain development may, in part, account for the behavioral deficiencies observed in Pb exposed animals.

371 DEVELOPMENT OF FLAPPING IN WINGLESS CHICKS. Robert R. Provine. Dept. Psych., Univ. Maryland Baltimore County, Baltimore, MD 21228.

The development of "flapping" was studied in chicks that had their wings amputated at the shoulder on the day after hatching. This is a stage before which the wings are feathered and play a role in flight. The experiment was conducted to evaluate the role played by the periphery in the development of the neuronal circuitry responsible for the generation of the stereotyped, bilaterally synchronized motor pattern of wing-flapping. Flapping of wingless chicks was made visible by mounting sections of soda straws on the stumps of the amputated wings. Flapping was evoked by dropping chicks a distance of 5½ ft. using a tethering device and recorded using stroboscopic photography. The flapping frequencies of wingless and intact control chicks were similar at two weeks of age, a stage at which a mature pattern of wing-flapping is present. These data indicate that after the time of hatching peripheral wing structures and wing-flapping experience are not necessary for the development of the basic motor pattern that is involved in flapping.

372 **SEGMENTALLY SELECTIVE INNERVATION OF MAMMALIAN SYMPATHETIC GANGLIA: FURTHER EVIDENCE FOR THE IMPORTANCE OF POSTGANGLIONIC TARGET POSITION.** Dale Purves, Jeff W. Lichtman, and Joseph W. Yip. Department of Physiology and Biophysics, Washington University School of Medicine, St. Louis, MO 63110.

The influence of postganglionic target position on the innervation of ganglion cells was explored directly in the guinea-pig superior cervical ganglion by determining the segmental innervation of neurons whose axons run in postganglionic nerves to different regions.

Surprisingly, there is little difference in the average segmental innervation of ganglion cells emerging in the two major postganglionic nerves, the inferior and superior branches. Since the branches of the superior nerve join more rostral craniospinal nerves than those of the inferior postganglionic nerve, the segmental innervation of particular superior cervical ganglion cells is not primarily determined by the position of targets along the rostrocaudal axis. There was, however, a marked difference in the segmental innervation of neurons running in the divisions of the inferior nerve to the second and third cervical nerves: on average, ganglion cells whose axons run to C2 receive stronger innervation from caudal spinal segments than ganglion cells whose axons run to C3. This difference is unlikely to reflect selective innervation based on modality since the postganglionic contributions to adjacent cervical nerves would be expected to supply the same spectrum of sympathetic targets. The only obvious difference between these two cervical nerves is their anatomical distribution. C2 supplies targets occupying medial and dorsal positions, but makes only a small contribution to the cervical plexus which innervates the ventrolateral neck. C3, on the other hand, is distributed about equally to ventrolateral, medial, and dorsal regions. The apparent influence of dorsoventral position on segmental innervation was supported by recording sympathetic compound action potentials from the branches of single spinal nerves in response to stimulation of the thoracic ventral roots. Those branches running to dorsal regions showed a stronger response to stimulation of relatively caudal thoracic ventral roots than branches running ventrolaterally to the cervical plexus.

On the basis of the experiments reported in these abstracts, we conclude that the preferential connections between ganglion cells and preganglionic axons arising from different levels of the spinal cord are formed according to some property of individual ganglion cells correlated with the position of their postganglionic targets. Thus segmentally selective innervation of sympathetic ganglia appears to match positional values of pre- and postsynaptic neurons. [Supported by NIH grant NS-11699.]

373 TEMPORARY SYNAPTIC CONTACTS ON TRANSIENT NEURONS IN THE ALAR PLATE OF THE SPINAL CORD IN RHESUS MONKEY EMBRYOS. P.Rakic, E. Knyihar* and B. Csillik,* Dept. of Neuroscience, Children's Hosptial Med. Center, Boston, MA 02115 and Sect. of Neuroanatomy, Yale Univ., Sch. of Med., New Haven, CT 06510

The development of cellular and synaptic relationships in the posterior quadrant of the cervical spinal cord of rhesus monkey embryos was analyzed by electron microscopic and H^3-thymidine autoradiographic methods. The earliest synapses are found in the alar (sensory) plate on the 31st embryonic day (E31) of the 165 day gestation period in rhesus monkey. These synapses are located in the marginal zone in the region of the prospective posterior columns. The apposed pre-and postsynaptic thickenings are asymmetrical and separated by a 300 A gap. Small, round, clear vessels cluster at presynaptic sites. Electron microscopic montages and reconstructions from serial sections demonstrate that these earliest contacts occur between longitudinally oriented sensory afferent axons and either the borderline cells situated at the interface between the marginal and mantle layers or the leading processes of cells lying deeper within the mantle. H^3-thymidine autoradiographic analysis shows that the permanent neurons, have not yet been generated at this stage and thus are not involved in the initial period of spinal cord synaptogenesis.

The borderline cells undergo changes in position and morphology over the next three weeks of embryonic spinal cord development. By E40, the cells lie fully within the dorsal columns and become surrounded by fascicles of newly arrived afferent axons. Around E50, many borderline cells show cytological evidence of degeneration; some disintegrate and begin to disappear. Some dying cells retain synaptic contacts with apparently healthy axons. No borderline cells can be detected in the posterior columns at later developmental stages or in the adult. Thus, borderline cells seem to represent a transient cell population that forms temporary synaptic contacts during early embryonic stages. The fate of the axons that terminated on these cells is uncertain. At least some appear to enter the posterior horn following death of their primary target cells and terminate on the permanent substantia gelatinosa neurons that begin to be generated around E38, a few days before borderline cells start to degenerate. Thus, the complex synaptic architecture of the substantia gelatinosa in primates may be developed through a considerable rearrangement of cellular and synaptic relationships involving the death of an entire population of neurons and the translocation of its synaptic connections.

374 BLOOD-BRAIN BARRIER IN AGED RATS. Stanley I. Rapoport, Kikuo Ohno* and Karen D. Pettigrew. Lab. Neurosciences, Natl. Inst. of Aging, Balt., Md. 21224 and Theoret. Stat. Branch, Natl. Inst. o Mental Hlth. Bethesda, Md. 20014.

Cerebrovascular permeability to ^{14}C-sucrose and other water-soluble nonelectrolytes normally is extremely low and equal to nonelectrolyte permeability in aporous, bimolecular lipid membranes (Ohno et al., Am. J. Physiol., in press). It has been suggested that cerebrovascular permeability increases with age, so that brain-reactive protein antibodies can enter the brain through the vasculature and damage brain cells. In order to test this hypothesis, we used the method of Ohno et al. (op. cit.) to measure cerebrovascular permeability to ^{14}C-sucrose in 3-month and 28-month old restrained, conscious Fisher 344 male rats. 5 μC of tracer was injected intravenously. Tracer concentration in arterial plasma was followed until the rat was decapitated 50, 100 or 240 min after injection. Parenchymal tracer concentration, C_{brain}, was obtained by subtracting intravascular tracer (product of blood concentration and brain blood volume) from net regional brain radioactivity. It was assumed that tracer entered brain as follows (1): $dC_{brain}/dt = PA\ (C_{plasma} - C_{brain}/V_e)$, where PA = capillary permeability-area product (sec^{-1}), V_e = cerebral distribution space of ^{14}C-sucrose, t=time, C_{brain} = brain concentration (dpm/g) and C_{plasma} = plasma concentration(dpm/ml). Plasma concentration was represented by the following equation (2),

$$C_{plasma} = A_1 e^{-k_1 t} + A_2 e^{-k_2 t} \ldots\ldots,$$

which when inserted in Eq. gives C_{brain} (for i = 1,2,...)

$$C_{brain} = PA\left[\frac{A_i}{PA/V_e - k_i}\left(e^{-k_i t} - e^{-PAt/V_e}\right) + \ldots\ldots\right]$$

Eq. 3 was fit by computer to concentration data to obtain PA and V_e. PA in 3 month-old rats averaged 7.53 x 10^{-6} sec^{-1} in 14 brain regions and was not elevated in brains of 28-month old rats, except possibly at white matter and then by not more than 50%. Furthermore, Ve fell from an average of 0.126 in young animals to 0.070 in 28-month old rats. This 44% reduction probably reflected a reduced brain extracellular space in the older animals, although other interpretations are possible. The findings indicate that cerebrovascular permeability is normal in old rats, but that the brain extracellular space may be reduced.

375 FUNCTIONAL UNCOUPLING OF AN IDENTIFIED ELECTRICAL SYNAPSE: DEVELOPMENTAL MODULATION OF SYNAPTIC TRANSMISSION IN *APLYSIA*. Stephen Rayport* and Eric R. Kandel (SPON: V. Castellucci). Div. of Neurobiology & Behavior, Depts. Physiology & Psychiatry, Columbia University, P & S, New York, N.Y. 10032.

Recent studies of neuronal plasticity and of the cellular concomitants of simple forms of learning have indicated that chemical synapses differ from electrical synapses in being able to undergo profound and prolonged changes in effectiveness. For example certain types of chemical synapses become functionally inactivated for a week or more following long term habituation training (Castellucci *et al.*, in press). In contrast, electrical synapses between neurons are thought to be relatively non-plastic in post-embryonic life and to undergo only brief modulation consequent to conductance changes in the adjacent electrically excitable membrane (Spira & Bennett, Brain Res. 37:294, 1972).

We here describe a profound change in the functional effectiveness of an identified electrical synapse in *Aplysia* between the two giant cells, R2 in the abdominal ganglion and P1 in the left pleural ganglion, during a specific stage of development. We find that these two cells are tightly coupled electrically until a late stage (stage 11) in post-embryonic life and then become functionally uncoupled during a period of about one week.

Until stage 11, action potentials in either cell lead to one-for-one firing of the other cell. Depending on slight variations in thresholds, either cell may lead in response to common input. DC current flow is symmetrical from one cell to the other with a coupling factor of about 0.3. Loss of one-for-one firing occurs at the transition between stages 11 and 12. In parallel, the coupling factor decreases to about 0.1 and the input impedance of the cells drops by an order of magnitude. In the young adult, stage 13, the coupling factor becomes unmeasurable, and all that remains is a less than one mv biphasic PSP in P1 following an R2 spike, characteristic of the adult (Meunier & Tauc, Arch. Ital. Biol., 111:305, 1973).

This phenomenon is unlike the generalized coupling and uncoupling that occurs between all cells during embryonic development (Potter, Furshpan & Lennox, PNAS 55:328, 1966). Since R2 and P1 develop in separate ganglia, the two axons are presumably not initially coupled but rather seek each other out to form this very effective connection. The R2-P1 junction persists throughout the animal's life but becomes functionally uncoupled in adulthood. This finding provides a functional parallel in an electrical synapse to the synaptic uncoupling of a chemical synapse considered in the companion abstract, and suggests that certain types of synaptic contacts may have ontogenic or behavioral roles restricted to specific periods of development.

376 INFLUENCE OF UNDERNUTRITION ON THE DEVELOPMENT OF THE SLEEP - WAKE CYCLE OF RATS. José A. Rojas-Ramírez* and Ana Ma. Martínez-Rivas* (SPON: R. R. Drucker-Colín). Depto. Farmacología, Fac. Medicina, UNAM, México 20, D.F. México.

Since relationships between protein synthesis and sleep mechanisms seems to exist, it was decided to explore the effects of undernutrition on the sleep-wake cycle of rats. Fourteen pregnant rats at term were separated in two groups. The method of different numbers of litters was followed to induce undernutrition in the pups. One group of seven mothers (normally nourished, N) were allowed to rear 6-8 pups. The other group of seven mothers (undernourished, U) were allowed to rear 16-18 pups. These conditions were kept up until weaning (21-22 days after birth). From each litter a pup was retired at 6-9 (1st week), 14-16 (2nd week), and 21-23 (3rd week) days after birth for recording. After weaning, all pups were individually caged and those from the U group were provided with half amount of nutriments than those of the N group. On days 28-32 (4th week) and 60-64 (8th week) after birth another rat from each group was recorded. Needle electrodes on fronto-parietal areas and wire electrodes into the neck muscles were permanently implanted to record EEG and EMG respectively. Records were made in a 7B Grass polygraph keeping the animals within individual cages. Seven rats were studied for each group and age. In all cases visual observations were made along recordings during eight diurnal hours. Wake (W), slow wave sleep (SWS), and REM sleep (REM) states were measured and compared among groups. Results showed that sleep and wake times practically remained unaffected on the 1st and 2nd weeks. W time was significantly higher and SWS time lower in U group compared with N group on the 3rd week; REM time did not change. Similar changes for W and SWS times appeared at the 4th week, but in addition, U animals lasted less time in REM than N rats. At the 8th week the only parameter affected was REM time which was lower in U group. This study shows that undernutrition from birth is able to alter normal development of sleep-wake cycle, being REM the state that apparently endures permanent changes, and support the hypothesis that relates sleep with nutritional factors.

377 MATURATION OF COCHLEAR POTENTIALS IN THE RAT, AND THE EFFECT OF KANAMYCIN OF THE ONSET OF THE AUDITORY FUNCTION.

Raymond Romand, Alain Uziel*. Lab. Neurophysiol. Montpellier II, 34060 Montpellier Cédex France and Lab. d'exploration neuro-sensorielles. Hôpital St Charles - 34059 Montpellier Cédex France.

Maturation of cochlear potentials has been studied in 40 rat pups. Two potentials have been recorded on the round window, such as the cochlear microphonic (CM) and the compound action potential (AP). The CM has been obtained with tone bursts stimulation at various frequencies and the AP after clics and filtered clics stimulation of 0.5, 1, 2, 4 and 8 kHz. For each frequency, the input-output curves for amplitudes and latencies have been analysed. The CM has been recorded on the 8th postnatal day and the AP 5 days later. Adults values have been obtained at the end of the second week for the CM, and during the fourth postnatal week for the AP. Compared with others mammals such as the cat, rats show a faster cochlear potentials maturation.

On this model of maturation, the effect of kanamycin has been tested in relation with the period of administration after birth. Results show a clear ototoxic effect on the cochlear potentials when the treatment is performed during the second postnatal week. In contrast, if the treatment is achieved during the first postnatal week, none effect can be demonstrated. This result suggests a relationship of the ototoxic effect of the drug with the onset of the auditory function.

378 LIFESPAN CHANGES IN THE DIURNAL SLEEP PATTERN OF RATS. Richard S. Rosenberg and Allan Rechtschaffen* Sleep Laboratory, University of Chicago, Chicago Ill. 60637.

Awakenings during the night and naps during the day increase dramatically with advanced age in humans. These changes describe a decrease of the diurnal sleep rhythm amplitude. In a previous study (Sleep Res. 5:88, 1976) decreases in sleep rhythm amplitude with age were found in rats, but each was recorded for only a single day. The present study reexamines age-related changes in rat sleep in more detail with much longer recordings.

Eight male Sprague Dawley rats were recorded in a 12:12 L:D schedule for 10 days each. Three groups were distinguished: 4-8 months (Young), 15-17 months (Middle), and 25-28 months (Old). Measures of rhythm amplitude similar to the "A" statistic of Borbely (Brain Res. 95:89-101, 1975) were obtained using a moving 12 hour window which detected the maximal 24 hour rhythm amplitude in individual animals. In general, these rhythms corresponded to the L:D cycle. Rhythms of waking (W), NREM sleep (S), absolute amount of paradoxical sleep (P), and delta activity (Δ) were measured. Length of sleep bouts and latencies from S onset to P were scored for the last five recording days.

TABLE: Changes in rhythm amplitude measures with age.

	Young	Middle	Old
W	35.54	31.80	25.22
S	22.18	24.01	11.51
P	25.72	21.72	24.80
Δ	59.24	57.36	48.27

Diurnal rhythm amplitudes W, S, and remained fairly stable up to about 18 months of age and then dropped sharply (see Table). Paradoxical sleep rhythms, however, were stable in amplitude across the lifespan. The day-to-day variability of all rhythm amplitudes increased with age. Bout lengths and P latencies tended to decrease with age, but individual differences were large.

Six animals were recorded for 20 additional days in constant dark, and the S rhythms were analyzed with a modification of the Enright periodogram. Young rats showed expected free-running rhythms with period length near 24 hours. Rhythm amplitudes of the old rats were so low that reliable estimates of circadian period length could not be obtained. An ultradian rhythm with period length of three to six hours was prominent in both the cycling and constant environments in old rats.

Decreases in diurnal sleep and waking rhythm amplitudes and increases in day-to-day variability suggest that the rat may provide a model of some of the changes in human sleep patterns with age. Preliminary results in three animals indicate that reentrainment following 180° phase shifts of the light:dark cycle was more rapid in old rats, suggesting that the rhythms seen in the cycling environment are more driven than entrained.

379 EFFECTS OF AGING AND HYPOXIA ON LEVELS OF CATECHOLAMINES IN RAT BRAIN REGIONS. Isaac F. Roubein and Larry J. Embree, Veterans Administration Hospital and Department of Neurology, Louisiana State University Medical Center, Shreveport, Louisiana 71130.

Central catecholamine (CA) neurons through modulation of synaptic transmission and the brain's vasculature may play a key role in the regulation of cerebral metabolism, activity and reactivity. Age-related changes in catecholamines have been reported in the brains of different species. The brain however does not respond uniformly to aging, hypoxia or other insults, hence this study was undertaken to investigate the effects of aging and of aging and hypoxia on the level of catecholamines in seven discrete brain regions which are known to have varying vulnerability and functions.

Male Sprague-Dawley rats (15 months and 20 months old) were sacrificed by decapitation, the brains were removed and immediately dissected into the following regions: cerebral cortex, striatum, midbrain, cerebellum, pons and medulla, hypothalamus and hippocampus.

Spectrofluorometric determinations of norepinephrine (NE) in cerebral cortex, midbrain, cerebellum, pons and medulla, hypothalamus and hippocampus and of dopamine (DA) in striatum indicated that the level of NE was reduced in the cerebellum, midbrain, pons and medulla, and hypothalamus of aged animals when compared with young adult rats (3 months old). Further, our findings suggest that the changes in catecholamine levels in rat brain may begin at mid-age. If similar changes in catecholamine levels are confirmed in man the possibility exists for a pharmacological approach to the amelioration of some of the signs and symptoms of senile brain disease.

The effect of hypoxia on the level of CA in the seven brain regions from aged rat is currently under investigation and will be reported.

380 LOCATION OF MOTOR AND SENSORY NEURONS SUPPLYING IDENTIFIED MUSCLES IN NORMAL AND SUPERNUMERARY HINDLIMBS IN THE FROG (XENOPUS LAEVIS). David I. Rubin and Lorne Mendell. Depts. Anatomy and Physiology, Duke Univ. Med. Ctr., Durham, NC 27710.

Transplanted supernumerary hindlimbs in the frog (Xenopus) show movement coordinated with normal limbs, but are innervated by a separate set of motoneurons. The purpose of this study was to investigate the location of motoneurons innervating muscles in the normal and extra limbs. The location of motoneurons supplying identified muscles was determined by retrograde transport of horseradish peroxidase (HRP) after injection into the appropriate muscle.

Peroxidase activity was demonstrated by an enzyme method described by Hanker et al. (Histochem J. 9, 1977) in which p-phenylenediamine (PPD), a benzene derivative, and pyrocatechol (PC), a phenol, are used as substrates. This mixture yielded brown reaction granules which were more abundant and more readily visible in brightfield than when diaminobenzidene was used as substrate.

The location of motoneurons innervating extensor and flexor muscles in the leg and thigh was investigated in normal and extra leg animals. The position of each labeled motoneuron within the lateral motor column was plotted along the mediolateral and rostrocaudal axes. In normal hindlimbs, motoneurons supplying gastrocnemius, an ankle extensor, are located at the medial end of the motor column; those innervating tibialis anterior, an ankle flexor, lie at the lateral end. In each extra leg animal, HRP was injected into an identified muscle in the extra leg, and the corresponding muscle in the contralateral normal leg. Motoneurons supplying gastrocnemius in extra limbs lie in the same mediolateral position as those for normal gastrocnemius. Extra leg tibialis anterior motoneurons also lie in the same region as for the normal muscle.

Along the rostrocaudal axis, groups of motoneurons supplying different muscles are normally overlapping, so detection of changes in extra leg animals is difficult. Motoneurons supplying extra leg muscles, however, did appear to be slightly shifted toward the segment of innervation.

Counts of dorsal root ganglion cells and motoneurons revealed increases on the experimental side in most cases. For motoneurons, the increases were distributed differently in different animals (cf. Hollyday and Hamburger, J. Comp. Neurol. 170, 1976). For dorsal root ganglion cells, those ganglia supplying the normal limb on the experimental side always showed an increase in cell number; cell numbers in ganglia supplying the extra limb were more variable, and frequently showed a decrease. (Supported by NIH.)

381 UNCOUPLING OF AN IDENTIFIED CHEMICAL SYNAPSE: TRANSIENT APPEARANCE OF MORPHOLOGICALLY IDENTIFIABLE CONTACTS ON THE SOMA OF DEVELOPING NEURONS IN *APLYSIA*. Samuel Schacher* and Eric R. Kandel (SPON: K. Pfenninger). Div. of Neurobiology & Behavior, Depts. of Physiology & Anatomy, Columbia Univ., P & S, New York N.Y. 10032.

We previously described axo-somatic synaptic contacts which are unique to the early developing nervous system in *Aplysia* (Schacher & Kandel, Neuroscience Abstracts, 1977). Since these synapses are absent in adult animals, they may represent initial contacts that later "move" to more appropriate sites on the postsynaptic cell, or they may represent contacts that are later retracted. We here report that 1) these contacts retract, and 2) perhaps trigger profound morphological changes in the postsynaptic neuronal cell bodies.

Prior to contact, the postsynaptic cells contain few of the characteristic morphological features of mature neurons. The cells often have irregularly shaped nuclei containing large amounts of heterochromatin, numerous glycogen particles, few mitochondria, free ribosomes, and a poorly developed or no Golgi apparatus. In addition, the cells do not as yet have axons. Following the appearance of the contact, the neuronal nuclei round up, rough ER and Golgi sacs become evident, and axon formation begins.

In order to link the transient appearance of a soma contact with the changes in the postsynaptic cell, we have followed the time course of formation and retraction of a specific axo-somatic contact on an abdominal ganglion cell that can be reliably identified from animal to animal in the same and succeeding developmental stages. We found that 1) the axo-somatic contact invariably occurs on the same topographic region of the cell body; 2) the contact is always present at a particular time in development; 3) the contact is not present on any portion of the cell after the initiation of axon process formation.

These findings suggest that transient chemical synaptic contacts can be formed in development to mediate specific inductive signals critical for aspects of neuronal differentiation. As will be considered in the accompanying abstract, electrical synapses can also be formed and functionally uncoupled during development.

382 DECREASE IN ADRENERGIC AXON SPROUTING IN THE SENESCENT RAT. Stephen W. Scheff, Larry S. Benardo* and Carl W. Cotman (SPON: James L. McGaugh). Dept. Psychobiology, Univ. Calif., Irvine, CA 92717.

In the present study we investigated the capacity of adrenergic neurons to sprout in the septum and hippocampus of aged (26-31 month old) and young (3-6 month old)Sprague-Dawley rats. Axon sprouting of adrenergic neurons innervating the rat septal and hippocampal area was studied following a unilateral transection of the fimbria using a modified glyoxylic acid histofluorescence method for the cellular localization of monoamines. Both young adult and aged animals were subjected to a unilateral lesion of the fimbria-fornix which denervates portions of the septal area and hippocampus. In the septal area of both age groups we observed morphological changes in the catecholaminergic innervation in response to denervation. Thirty to sixty days after fimbria transection the most marked increase in noradrenergic innervation was found in those areas of the septum which receive the heaviest projections from the hippocampus. However, while aged animals with equivalent lesions showed a reinnervation pattern qualitatively similar to that of the younger animals, it was much less extensive.

The response of sympathetic catecholaminergic fibers in the hippocampus following transection of the fimbria was also examined. Previously it has been reported that fimbrial transections induce the growth of sympathetic catecholamine neurons to innervate the dentate gyrus. In four aged animals we found no indication of the anomalous innervation by the superior cervical ganglion. In one aged animal we observed a very minor reaction. These results indicate that axon sprouting of central catecholaminergic systems does occur in aged animals but to a much lesser extent than that in young adult animals. This may indicate that as neurons die with age reactive synaptic growth may provide an ongoing mechanism to replace those connections lost and thereby maintain synaptic populations in the wake of neuronal loss. If the new connections will functionally substitute for the original ones axon sprouting would serve as a homeostatic mechanism against neuronal loss. On the other hand, if the connections are inappropriate such processes could slowly and progressively disorder circuitry further hindering the processing of information in the aged brain. This might contribute to the deterioration of function with age. (Supported by grant AG00538)

383 GRANULE CELL NEURONS IN DEVELOPING RAT AND MONKEY CEREBELLUM CHANGE FROM GLIAL TO NEURONAL ENOLASE. D.E. Schmechel*, M.W. Brightman*, P.J. Marangos*, and I.J. Kopin. NIMH and NINCDS, Bethesda, Maryland 20014.

Two distinct isoenzymes of the glycolytic enzyme enolase (E.C. 4.2.1.11) exist in mammalian brain: neuron-specific enolase (NSE) found only in neurons and non-neuronal enolase (NNE) present in glial cells (Schmechel et al., Science 199: 313, 1978). During early development of rat brain, NNE levels are higher than NSE whereas in the adult the two isoenzymes are present in roughly equivalent amounts. In rat cerebellum, NSE only attains near-adult levels at one month of age.

In the present study, immunocytochemical localization of NSE and NNE in developing cerebellum was studied in a series of early postnatal rat brains and a rhesus monkey fetus (Macacca mulatta) at 100 days of gestation (E100) using the unlabeled antibody enzyme method of Sternberger. Antisera directed against purified rat NSE and NNE were used for rat and antisera against purified human NSE and NNE for monkey. In both rat and monkey cerebellum, cells of the external granule cell layer, a subventricular zone derivative which generates granule cell neurons, contain NNE but not NSE. Migrating granule cells located in the molecular layer also did not contain NSE despite the presence of immunoreactive NSE in the adjacent parallel fiber axons of the molecular layer and granule cells already present in the internal granule layer. In postnatal rat brain as well as the E100 monkey fetus, Purkinje cells and deep cerebellar neurons are uniformly NSE-positive. Likewise, NNE stains Bergmann glial cells and other glial elements as well as the external granule layer.

These results indicate that granule cell neurons of both rat and monkey are derived from cells which contain NNE--the glial isoenzyme. Significant amounts of NSE are still absent in the granule cells during elaboration of their parallel fiber axons and migration inward and only appear when the granule cell reaches its final destination in the underlying internal granule layer. The switch in production of glial enolase (NNE) to the separate gene product neuron-specific enolase (NSE) apparently occurs during migration or soon after arrival in the molecular layer.

The appearance of neuron-specific enolase (NSE), is therefore, a relatively late event in the differentiation of granule cells of the mammalian cerebellum.

384 DEVELOPMENT OF NEOSTRIATAL ACETYLCHOLINESTERASE (AChE) AND DOPAMINE (DA) CORRELATED WITH THE ONTOGENY OF MOTOR BEHAVIORS IN THE RAT. Cheryll A. Smith (1) and Larry L. Butcher (1,2). Dept. of Psychology (1) and Brain Res. Inst. (2), U.C.L.A., Los Angeles, California 90024.

Developmental studies are particularly useful in elucidating the neurochemical bases of motor behaviors since the ontogeny of such behaviors can be readily correlated with the maturation of neurobiological systems. We have focused our attention in this regard on the neostriatum (caudate-putamen complex) because that structure is known to play an important role in modulating movement and is rich in neurochemicals (e.g., AChE and DA) for which sensitive histochemical techniques are available.

The development of various motor behaviors (e.g., locomotion, exploration, and grooming) in albino rats aged 1-24 days were observed and compared to the ontogeny of these same behaviors in rats of the same ages given 20mg/kg of the muscarinic blocker atropine every 8 hours for 24 days. The forebrains of animals of different ages from both normal and atropinized groups were then processed histochemically for AChE and DA.

Many of the motor behaviors exhibited by the normal animals progressively increased in frequency until approximately 15 days postnatally, after which there was a decline to the lower, adult frequencies. In the animals treated with atropine, however, many of the same behaviors reached a higher incidence of occurrence than in normal rats and displayed no decline in frequency throughout the 24 day testing period. Our histochemical data suggest that in the neostriatum the DA system attains an adult distribution pattern earlier than does the AChE system: the former appears to reach the adult pattern between 12 and 15 days of age, whereas the latter achieves such a pattern between 15 and 17 days of age. The final maturation of the AChE system is concurrent with both a prominent upsurge in rat striatal acetylcholine (S.H. Butcher et al., submitted) and the decline in motor behavior frequencies noted in normal animals. These findings support the idea that central DA sytems facilitate, while central cholinergic systems inhibit, motor behaviors and suggest an interaction between these systems in behavioral development.

385 POSTNATAL DEVELOPMENT OF RETINOGENICULATE PROJECTIONS IN SYRIAN HAMSTERS: AN ANTEROGRADE HRP STUDY. Kwok-fai So* and Gerald E. Schneider. Department of Psychology, M.I.T., Cambridge, MA 02139.

In a study of the early development of the retinal projections (Brain Res.'78,142:343), our ability to detect the early appearance of terminating axons was limited by the relatively higher background radioactivity in younger compared to older animals. In order to overcome this problem, we have used horseradish peroxidase (HRP) histochemistry as an anterograde tracing technique. One eye in each of 29 animals was injected with 0.4 mg of HRP dissolved in 0.5 µl of Tris buffer (pH 8.6) at various postnatal ages. After 20 hr survival, each brain was processed using a sensitive HRP method with tetramethyl benzidene as chromogen (Mesulam and Rosene, Neurosci. Lett.,'77,5:7). In every case but 2, the optic tract and its terminals were clearly labeled with HRP reaction products, with an almost total absence of background labeling.

On day 0, axons have already begun to penetrate the nucleus from the superficial optic tract on both sides of the brain, but they have penetrated much more extensively in the mid-portion of the nucleus than at the dorsal and ventral edges. Thus, if one assumes that at this early age the mid-portion of LGBd is innervated by the central retina as in the adult, then the leading fibers appear to originate in the central retina. This finding is similar to that reported for the contralateral projection to the optic tectum of the chick by Crossland, Cowan and Rogers (Brain Res.,'75,91:1). The ipsilateral fibers, which had not been detected at this age with the autoradiographic technique, appear to lag slightly behind the most advanced contralateral ones, since they have reached only halfway into the nucleus, while the contralateral axons are seen at the medial margins.

Retinogeniculate axons distribute throughout the entire contralateral nucleus by day 1, but they remain sparser at the medial edge until day 4. The dorsal part of the ipsilateral nucleus has become completely penetrated by labeled fibers on day 3; beginning at this age, the labeling is denser at the medial edge, indicating the onset of an adult-like pattern of terminal arborization.

By day 7-8, the density and distribution of ipsilateral fibers in LGBd are similar to that seen in the adult animal. Confirming the autoradiographic study,the contra- and ipsilateral fibers overlap in LGBd until day 7. On day 7, partial segregation of the fibers from the two eyes is observed. By day 8, the nearly complete segregation of the contra- and ipsilateral fibers in LGBd closely resembles that of the adult.

386 ULTRASTRUCTURE OF THE NIGROSTRIATAL SYSTEM IN EARLY PRENATAL RAT BRAIN BY IMMUNOCYTOCHEMICAL LOCALIZATION OF TYROSINE HYDROXYLASE. L.A.Specht, V.M.Pickel, T.H.Joh, and D.J.Reis Lab. of Neurobiol., Cornell Univ. Med. Coll., New York, NY 10021.

By the immunocytochemical localization of the catecholamine synthesizing enzyme tyrosine hydroxylase (TH) for light microscopy, we have described the anlage of the nigrostriatal system at the end of the second week of gestation in the fetal rat (Neurosci. Abs. 3:369, 1977). In the present study, we sought to determine (a) the ultrastructure of the earliest appearing catecholaminergic perikarya of the substantia nigra (SN) and their processes which project to the caudate nucleus (CN), and (b) the relationship of the primitive TH containing distal proceses to cells of the CN. Sections of fixed brain from rat fetuses of embryonic day 13, 14, and 15 were incubated with specific antiserum to TH and immunocytochemically labeled for electron microscopy. Labeled perikarya of the SN had a lobulated nucleus surrounded by a scant rim of cytoplasm containing numerous free ribosomes, an immature Golgi apparatus, scattered mitochondria, a few saccules of granular endoplasmic reticulum, and occasional centrioles and multivesicular bodies. Labeled proximal processes of the nigrostriatal bundle contained ribosomes, saccules of smooth membrane, occasional mitochondria and microtubules, and small (300-500Å) round particles. Two populations of distal processes containing TH were examined in the rudimentary CN. One group was located in the ventral lateral CN and could be traced to the neurons of the SN. These processes were adjacent to unlabeled neuronal perikarya and processes, and did not form any specialized contacts. The second group of labeled distal processes was located along the ventricular lumen of the CN and could not be followed for more than 4µ; thus, their origin was uncertain. These processes were adjacent to mitotic ventricular cells and apical processes of the non-mitotic ventricular cells. Gap junctions of 70Å or less were often observed with the apical processes, and less frequently with the mitotic cells. Both groups of labeled distal processes contained organelles similar to those observed in the proximal processes. The application of the immunocytochemical technique for the localization of the catecholamine synthesizing enzyme TH to electron microscopic analysis in the fetal brain, has permitted the fine structural characterization of the chemically homogeneous group of neuroblasts of the SN, including the relationship of their earliest appearing distal processes to neuronal elements of the CN. The presence of TH within perikarya of the SN and their processes in the CN prior to the functional maturation of this system, and the association of TH containing processes with mitotic ventricular cells, are consistent with a possible regulatory role of catecholamines in early central nervous system development. (Supp: MH05651, NS06911, HL18974, RCDA MH00078).

387 PHYSIOLOGICAL DEVELOPMENT OF IDENTIFIED NEURONS FROM AN IDENTIFIED NEUROBLAST DURING GRASSHOPPER EMBRYOGENESIS. N.C. Spitzer and C.S. Goodman* (SPON: S. Barondes). Dept. of Biology, UCSD, La Jolla Ca. 92093.

We are investigating the cessation of electrical coupling and the onset of electrical excitability during the differentiation of a class of identified neurons in embryos of the grasshopper Schistocerca nitens, by intracellular recordings and dye injections of cells visualized with interference contrast optics.

In the thoracic ganglia, the dorsal unpaired median (DUM) neuroblast initially gives rise to two chains of DUM mitotic daughter cells. These chains extend anteriorly, and the DUM daughters divide again to produce specific identified DUM neurons. The process of temporal differentiation for a single DUM descendent cell is represented spatially in the chain of cells extending anteriorly from the DUM neuroblast at any one time. Neuronal differentiation of cells increases anteriorly with distance from the DUM neuroblast. In a 12 day embryo, the DUM neuroblast is still dividing and is surrounded by a string of daughter cells. These cells are electrically coupled, dye coupled (Lucifer Yellow, 450 MW), and electrically inexcitable; they have resting potentials of -70 to -80 mV and are not depolarized by 10^{-5} gm/ml veratridine, which specifically depolarizes cells possessing voltage dependent Na^+ channels. The cells more anterior along the chains become electrically uncoupled, dye uncoupled, and the input resistance increases. The next anterior cells begin to grow axons, and soon thereafter the axons become capable of carrying action potentials in which the inward current is carried predominantly by Na^+, since they are rapidly abolished by replacement of this ion or addition of 10^{-9} gm/ml TTX. Furthermore, these cells, like those still further anterior along the chains, are rapidly depolarized by more than 25 mV by exposure to veratridine; prior removal of Na^+ or addition of TTX prevents this depolarization.

Cells at the ends of the chains have -40 to -55 mV resting potentials and produce overshooting action potentials, 2-4 msec in duration. The inward current of the soma spike is carried by both Na^+ and Ca^{2+}; it persists in either the absence of Na^+ or the presence of Co^{2+}, but is blocked by both treatments applied simultaneously. Action potentials in a mature DUM neuron require the presence of both Na^+ and Ca^{2+} (Goodman & Heitler, Soc. Neurosci. 3, 426, 1977).

The onset of axonal outgrowth and electrical excitability occur after the disappearance of electrical coupling, but it is not known whether or not uncoupling is causally related to the other aspects of differentiation.

388 TIME OF ORIGIN OF NEURONS IN NUCLEUS CUNEATUS LATERALIS IN THE MOUSE. Elizabeth Taber Pierce, Seri Slastad* and Inger J. Onshus*. Dept. Anat., Harvard Med. Sch., Boston, MA 02115

Female mice Balb c/Gn were mated to SJL males. The pregnant mice were injected with tritiated thymidine, 5 uC/gm body weight. A series of off-spring was obtained pulse labeled with triated thymidine at a known hour during gestation. The brain of each off-spring was taken at two months after birth and processed by the autoradiograph technique to obtain data on the time of origin of neurons in the brain stem. The position of labeled neurons within specific nuclei was plotted by camera lucida from Nissl stained sections cut at 10 u in the transverse plane. For each day of gestation studied, every 5th section was plotted at a magnification of 200x. It has been determined that neurons within the nucleus cuneatus lateralis are born within the hours 255-294. Both large and small neurons arise at the same time. The peak time of neuron formation was observed at 281 hours. No definitive gradient, rostral to caudal, or medial to lateral, was observed.

389 EXPRESSION OF CATECHOLAMINE BIOSYNTHETIC ENZYMES DURING DEVELOPMENT OF THE AUTONOMIC NERVOUS SYSTEM

G. Teitelman*, H. Baker, T.H. Joh, D.J. Reis, Laboratory of Neurobiology, Cornell University Medical College, 1300 York Avenue, New York, NY 10021

After its detachment from the neural axis, the prospective sympathetic neurons migrate ventrally and eventually give rise to the sympathetic chain, paraganglia and adrenal medulla. We sought to determine, applying immunohistochemical techniques for visualization of the catecholamine (CA) biosynthetic enzymes tyrosine hydroxylase (TH), dopamine-β-hydroxylase (DBH) and phenylethanolamine-N-methyltransferase (PNMT): (a) at what point in their ventral migration these different enzymes appear, (b) if they do so in a sequential or in a simultaneous fashion, and (c) whether PNMT, which is principally, but not exclusively, found in the adrenal medulla, is detected only in those sympathoblasts that reach the adrenal anlage or if it has a more general distribution. Rat embryos at different stages of development were fixed in formalin, sectioned on a cryostat and processed for staining, by the PAP technique, either with rat anti-rabbit TH, DBH, or PNMT or with bovine anti-rabbit PNMT. The CA synthesizing enzymes were not detected prior to the 11th day (d) of development; by d 11 TH and DBH appeared simultaneously and were detected in cells localized in a) the future site of the primary sympathetic chain and b) the mesoderm of the gut wall. Since these latter noradrenergic cells were not observed after d 14 or in adult animals, they may eventually die or be transformed into enteric ganglioblasts expressing other neurotransmitter functions. By d 15 cells containing TH and DBH started to migrate from the sympathetic (suprarenal) ganglia towards the adrenal anlage. However, PNMT was detected 3 days later only in those sympathoblasts that reached the adrenal cortical tissue. We conclude that sympathetic neuroblasts express TH and DBH simultaneously during development, that contact of these cells with the adrenal cortex is required for the expression of PNMT and that a transient population of noradrenergic cells is present in the developing gut. We propose that migrating sympathoblasts express a labile noradrenergic phenotype. The microenvironment of their final destination will determine if they will synthesize only norepinephrine, or, provided they populate the adrenal gland, also epinephrine. If, on the other hand, the sympathoblasts colonize the gut wall, they may switch to the synthesis of other neurotransmitters. Supported by grants HL 18974, MH 24285 & NSG-2259.

390 PRENATAL DIAZEPAM EXPOSURE IN RATS: EFFECTS ON GROWTH AND BEHAVIORAL DEVELOPMENT OF THE OFFSPRING. Donna Tervo*, Carol Kellogg, Richard Miller*, and James Ison. Depts. Psych. and Obs-Gyn, Univ. of Rochester, Rochester, NY 14627.

Pregnant female rats of the Long-Evans Hooded strain were injected on days 13-20 of gestation (sperm positive vaginal smear= day 0) with diazepam (2.5, 5, or 10 mg/kg) or the vehicle. Marked sedation of the dam was noticeable only at the highest dose of diazepam (dz). Other rats were left undisturbed. All pups were fostered to uninjected dams within 24 hours after birth. All uninjected and vehicle-injected rats (total of 18) delivered on day 22 of gestation whereas all dz-injected rats (7) delivered on day 21. Hence, prenatal dz exposure shortened the gestation period by 5%. Birth weights did not differ among the groups, nor was there any apparent difference between the rate of growth over the first three weeks of life while all pups were nursed by uninjected dams. However following weaning on conceptual days 43-44 (postnatal day 21) differences in weight between the control and dz-exposed pups became increasingly apparent as the dz-exposed pups did not sustain the same growth rate as the control groups. By 104 days conceptual age the weights of the prenatally exposed rats were 84, 87% (male, female) of the uninjected controls.

The development of spontaneous locomotor activity was evaluated in isolated animals. The usual developmental pattern was observed in both control groups with activity increasing markedly to reach a peak at 38 days conceptual (16 postnatal) age and declining sharply thereafter. Animals exposed to the lowest dose of dz exhibited a similar developmental pattern, however peak activity was reached at 36 days conceptual (15 days postnatal) age. Animals exposed to the two highest doses of dz, however, showed only a gradual increase and decrease in activity over this time period, with no precise delineation of a peak. The development of the acoustic startle response was also evaluated from postnatal days 12-22. Animals from both control groups showed an increase over this period in the startle amplitude to a 110 db, 10 K tone against a background of 28-30 db whereas there was no apparent increase in any of the dz-exposed animals. Evaluation of the startle response against increasing background intensities demonstrated further effects of prenatal dz exposure. All control groups showed potentiation at a background intensity of 75 db whereas no potentiation was observed in any of the dz-exposed pups.

These studies have demonstrated that exposure of the fetus to dz during the period of marked neuronal differentiation can have pronounced and long lasting consequences.

391 EFFECTS OF POSTGANGLIONIC AXOTOMY ON THE REGENERATION OF SELECTIVE SYNAPTIC CONNECTIONS IN THE GUINEA-PIG SUPERIOR CERVICAL GANGLION. Wesley Thompson, Arild Njå, and Dale Purves. Department of Physiology and Biophysics, Washington University School of Medicine, St. Louis, MO 63110.

Neurons of the guinea-pig superior cervical ganglion are selectively innervated. Thus each neuron receives innervation from a contiguous subset of the thoracic spinal segments, one of which is dominant; these rules of segmental contiguity and dominance are presumably the neuronal basis for the characteristic pattern of end-organ responses elicited by stimulation of each thoracic ventral root in vivo (Njå and Purves, J. Physiol. 264: 565, 1977). The experiments we report were designed to test whether altering a ganglion cell's peripheral connections changes the specificity of the synapses it receives.

The major postganglionic nerves of the cervical ganglion were crushed in adult animals; at the same time, the preganglionic nerve was cut. We then examined the segmental innervation 1, 3 and 12 months postoperatively by recording intracellularly from ganglion cells while stimulating the thoracic spinal nerves in vitro. At all intervals axotomized neurons, as neurons after denervation alone, showed a strong tendency to be reinnervated by a contiguous subset of spinal segments, and to be dominated by one of them. Moreover, the final proportion of reinnervated neurons dominated by different spinal segments was about the same whether or not the postganglionic axons had been interrupted.

In contrast, the responses of end-organs to ventral root stimulation in vivo were decidedly abnormal following reinnervation of ganglion cells which had themselves reinnervated peripheral targets. Normal animals, or animals with reinnervated superior cervical ganglia, show marked pupillary dilation and widening of the palpebral fissure in response to stimulation of the first and second thoracic ventral roots, a weaker response upon stimulating T3, and little or no response to T4 activation. Three months after postganglionic axotomy, however, reinnervated ganglia no longer showed this rostrocaudal gradient. Stimulation of thoracic ventral roots now caused end-organ responses proportional to the number of ganglion cells innervated by each segment so that stimulation of T1 and T4 affected the eye nearly equally.

These results are consistent with the view that postganglionic axons reinnervate peripheral targets in an indiscriminate way, and that connections with peripheral targets different from (or in addition to) normal fail to elicit compensatory changes in ganglionic innervation. [Supported by NIH grant NS-11699.]

392 AUTORADIOGRAPHIC LOCALIZATION OF ^{3}H-ESTRADIOL IN RELATION TO STEROID RESPONSIVENESS IN CULTURES OF THE HYPOTHALAMUS/PREOPTIC AREA. C. Dominique Toran-Allerand, John L. Gerlach*, and Bruce S. McEwen. Columbia Univ., Coll. P&S, New York, N.Y. 10032, and Rockefeller Univ., New York, N.Y., 10021.

Earlier studies (Toran-Allerand, Brain Research, 106, 407, 1976) have shown that estradiol (E_2) and testosterone elicit a selective acceleration and enhancement of neuritic proliferation in specific regions of the newborn mouse hypothalamus/preoptic area (POA) in vitro. In order to relate this response to the presence of the specific steroid receptor, the distribution of E_2-concentrating cells in 7-day-old organotypic cultures was determined autoradiographically. Coronal explants of the newborn female mouse were maintained in Maximow assemblies. After 72 hrs exposure to E_2-deficient medium, cultures received $2x10^{-9}$ M ^{3}H-E_2 for 1 hr. 2 µm frozen sections were processed for thaw-mount autoradiography and, after 150 or 622 days exposure, were developed and analyzed. Radioactive label was observed in specific explant regions. Despite some in vitro architectonic rearrangements, the topographic distribution of the labelled cells was similar to that of the neonatal rat (Sheridan et al., Endocrinology, 94, 1386, 1974) and of the adult mouse (Warembourg, C.R. Acad. Sci., 250, 152, 1970; Stumpf and Sar, Anatomical Neuroendocrinology (Karger) 82, 1975). The largest number of labelled cells were found in the following general regions: medial POA; suprachiasmatic; interstitial nucleus of the stria terminalis; arcuate and ventral premamillary nuclei. A few cells were also seen in the anterior hypothalamus, ventromedial and periventricular nuclei and lateral septal region. Small clusters of cells, labelled solely cytoplasmically, were also observed. There is a strong correlation between the presence and topography of the E_2-concentrating neurons and the pattern and regional localization of the steroid response. In the dorsal (strial) POA and premamillary regions, for example, silver impregnation shows that the localized areas of steroid responsive neuritic proliferation appear to emanate from regions containing the labelled cells. The purely cytoplasmic labelling may be related to the immunocytochemical demonstration of intraneuronal α-fetoprotein (Benno and Williams, Brain Research, 142, 182, 1978), an E_2-binding protein. (Supported in part by NIH grant HD-08364; NSF grant BNS77-09859; National Foundation-March of Dimes grant 1-564, NIMH Research Scientist Development Award MH-00192 to DT-A and an Institutional grant from The Mellon Foundation; and by NIH grant NS-07080 to BMc and an Institutional grant RF-70095 from the Rockefeller Foundation).

393 CYCLIC AMP-DEPENDENT PROTEIN KINASE (PK) AND PROTEIN PHOSPHORYLATION IN HUMAN BRAIN DURING AGING. L. Truex*, R. Conway*, A. Routtenberg, and M. Schmidt. (SPON: J. Clemens). The Lilly Res. Labs., Indianapolis, IN and Northwestern Univ., Evanston, IL.

The activity of soluble cAMP-dependent PK and the phosphorylation of synaptosomal proteins were studied in autopsy samples of the cerebral cortex of humans. Subjects were 2 days - 82 yrs of age. PK activity ± cAMP was measured in the 27,000 g supernatant. Phosphorylation of synaptosomal membrane fragments was measured in vitro ± cAMP (5 µM). To assess the effects of postmortem autolysis on PK and phosphorylation, similar determinations were carried out on rat cortex 10 min - 16 hr after death.

No change occurred in the cAMP-dependent PK activity in rat cortex postmortem. Basal PK activity was higher 10 min after death than 6 or 16 hr postmortem. These changes parallel the postmortem rise and fall in endogenous levels of cAMP in the brain. Postmortem autolysis also did not alter cAMP-dependent or -independent phosphorylation of synaptosomal membrane fragments. These studies using the rat cortex established the validity of conducting similar experiments on human brain tissue postmortem.

We were unable to demonstrate age-related differences in phosphorylation of synaptosomal proteins from human cortex. The number and staining densities of the protein bands were also similar across age. PK activity was also not significantly different between ages. Maximal stimulation of PK occurred at 10^{-6} M cAMP (426 pmoles Pi incorporated/mg prot./min) with a basal activity of 54 pmoles Pi incorporated/mg prot./min. Subjects over 60 yrs of age tended to have lower PK activity but based on the limited sample size, these differences were not significant.

A comparison of 3 and 24 mo. old Wistar rats also failed to reveal significant differences in PK activity, cAMP stimulation of PK activity, or phosphorylation of synaptosomal proteins in the cerebral cortex.

These studies show the phosphorylation system in the cerebral cortex to be stable in the rat and human for periods as long as 16 hr postmortem. cAMP-dependent PK activity and the number, type, and phosphorylation of endogenous synaptosomal proteins in the human appear similar to analogous systems in the rat cortex. No changes in the system with advanced age were detected in either rats or humans. Additional tissue is being collected for study and findings with other components of the phosphorylation system (e.g., phosphoprotein phosphatase) will be discussed.

394 EFFECTS OF NEURONAL ACTIVITY AND CYCLIC NUCLEOTIDE DERIVATIVES ON THE DEVELOPMENT OF TRANSMITTER FUNCTION IN CULTURED SYMPATHETIC NEURONS. Patricia A. Walicke* and Paul H. Patterson. Department of Neurobiology, Harvard Medical School, Boston, MA 02115.

Recent evidence strongly suggests that individual sympathetic neurons taken from superior cervical ganglia of neonatal rats can either secrete catecholamines (CA) and form adrenergic synapses or, if grown in medium previously conditioned by incubation on appropriate non-neuronal cells (CM), secrete acetylcholine (ACh) and form cholinergic synapses. The effects of neuronal activity and exogeneous cyclic nucleotide derivatives on this choice of transmitter were studied. Adrenergic and cholinergic development were evaluated by determination of the rate of synthesis and accumulation of ACh and CA from radioactive precursors. Neurons treated with depolarizing agents, elevated KCl or veratridine, or stimulated directly with electrical current, either before or during exposure to CM, displayed up to 300-fold lower ACh/CA ratios than without depolarization, and thus remained primarily adrenergic. Since depolarization increases Ca^{++} entry into the neurons, the effects of several Ca^{++} agonists and antagonists were studied. The former (Ba^{++}) augmented the K^+ effect, while the latter (Mg^{++}, EGTA, or D600) largely blocked the effect of K^+ on cholinergic development.

Because cyclic nucleotides are known to be involved in the control of a number of cellular processes, often in conjunction with Ca^{++}, the ability of exogeneously added nucleotides to mimic the effects of depolarization were studied. Neurons exposed to 1 mM mono-or dibutyrl cAMP or cGMP (+phosphodiesterase inhibitors) for periods of 10 days or more, either before or during exposure to CM, displayed up to 10-fold lower ACh/CA ratios than controls. 1 mM butyrate did not mimic these effects. Agents which elevate cAMP levels (adenosine and PGE_1, +phosphodiesterase inhibitors) also lowered the ACh/CA ratio up to 10-fold. Since addition or withdrawal of the nucleotides for 2 days prior to assay did not significantly alter the ACh/CA ratio, these effects are interpreted as changes in developmental fate rather than acute alterations of transmitter metabolism. Thus the neurons can be influenced to remain adrenergic either by agents which increase cAMP and/or cGMP levels or by depolarizing agents whose effects may be mediated by Ca^{++} entry. Assay of the effects of depolarization and CM on neuronal cyclic nucleotide levels are in progress in an attempt to further elucidate the intracellular mechanisms controlling this developmental transmitter choice. (Supported by the American and Massachusetts Heart Association and NINCDS.)

395 ATTENTION AS AN ALTERNATIVE TO SELF-INDUCED MOTION FOR THE PERCEPTUAL BEHAVIOR OF KITTENS. Richard D. Walk, Jane D. Shepherd*, and David R. Miller*. Dept. Psychology, Geo. Wash. Univ., Washington, D.C. 20052.

In a classical study Held and Hein (J. Comp. Physiol. Psychol. 1963) reared kittens in the dark for 8 wks and then allowed them 3 hr/day light exposure under two conditions. One group actively locomoted in the light while the second group was passively exposed to the light in holders that prevented sight of the limbs. Only the first group developed depth discrimination. The authors concluded: "self-produced movement with its concurrent visual feedback is necessary for the development of visually-guided behavior."

In a prior study (Miller and Walk, Eastern Psychol. Assoc., 1975) we showed some depth discrimination in kittens reared in the dark for 4 wks. We have also replicated the Held and Hein study with 8 wk old kittens and found much the same results as theirs. While depth discrimination of 4 wk old passive kittens was essentially normal the depth discrimination of passive kittens reared in the dark for 8 wks prior to the period of light exposure was delayed until after active locomotion in the light; it did not appear with passive exposure to the light.

Depth discrimination may be innate but what maintains it? Is it self-produced movement or attention?

We raised kittens in the dark for 40 days and then divided them into 5 groups: (1) active locomotion, (2) passive exposure, (3) passive exposure to an attention provoking display, (4) passive exposure in a "go-cart" on wheels which the kitten could move forward by closing a microswitch above its head, (5) raised in the dark until tested. Groups 1-4 had 3 hr/day exposure to the light in a patterned environment for 10 days starting on day 40. All kittens were tested on the 49th day and thereafter until depth discrimination appeared. All passive kittens had the same type of holder; none could see the limbs or locomote.

Preliminary results indicate that passive exposure to an attention provoking display is sufficient for depth discrimination on the visual cliff. (Supported by NIH Grant MH-25864).

396 AGE-RELATED CHANGES IN SPINE NUMBERS ON CEREBELLAR BASKET CELLS IN POST-WEANLING RATS. Christopher D. West* (SPON: Michael J. Malone). Harvard Neurol. Unit, Beth Israel Hosp., and GRECC Unit, Bedford V. A. Hosp., Bedford, MA 01730.

Age-related changes in the numbers of dendritic spines were studied in two types of neurons of the cerebellar cortex which receive synaptic input from granule cells. Basket cells and Purkinje cells were examined in Rapid Golgi preparations of the rat cerebellar vermis. Albino rats, 1 to 6 months of age, were perfused through the aorta with either Karnovsky's fixative or 10% buffered formalin. Cerebella were fixed in classical Rapid Golgi solution, silvered, embedded in low-viscosity-nitrocellulous and sectioned in the sagittal plane at 150 micra. Only well impregnated neurons were studied. Basket cells with cell bodies located in the lower portions of the molecular layer and with at least one prominent pial-directed dendrite were photographed and drawn with a camera lucida. Purkinje cell terminal branch dendrites located in lower levels of the molecular layer near the cell body were photographed and drawn. Dendritic spine profiles were counted on terminal portions of the dendrite located in a single focal plane. Drawings and photographs of basket cells revealed marked decreases in dendritic spine numbers over the age range examined. Photographs, drawings, and counts of Purkinje cell dendritic spines revealed no corresponding decrease. (Supported by USPHS Grant No. 1 R23 AG00607-01 from the NIA and by the Veterans Administration).

397 MORPHOGENESIS OF SYNAPTIC ENDINGS OF COCHLEAR FIBERS IN THE CHICK BASILAR PAPILLA. M. C. Whitehead and D. K. Morest. Department of Anatomy, University of Connecticut Health Center, Farmington, Connecticut 06032.

Developing acoustic ganglion cells provide an opportunity to study the morphology of identified populations of fibers and their target cells. These cells have peripheral processes contacting hair cells and centrally directed axons ending on neurons in N. magnocellularis and N. angularis. This study, using rapid Golgi and Golgi- aldehyde methods, details the growth of the peripheral processes of acoustic ganglion cells and the formation of their endings in the basilar papilla (organ of Corti).

At 4½- 5 days of incubation (equivalent Hamburger- Hamilton stage), acoustic ganglion cells lie just beneath the receptor epithelium: their peripheral fibers, sprouting from the soma, bear growth cones with filopodia. A few longer, tapered fibers, have already entered the epithelium where they emit 1- 2 short, fine branches. At 6- 6½ days,most fibers run lengthwise below the basal lamina where they branch and end as thin, tapered terminals or growth cones. Some end- branches take an abrupt radial course into the epithelium. By 7½- 9 days,the acoustic fibers have many end-branches in a restricted zone of the receptor epithelium and small varicosities, growth cones, filopodia, and tapered endings extending between the young hair cells often as far as the luminal surface. Between days 10- 13,the fibers develop large, bulbous, terminal swellings from which irregularly shaped processes extend into the hair cell region. Thin, beaded, efferent fibers are first seen in the epithelium during this stage. By late embryogenesis (days 14- 17), the swellings of the acoustic endings are smaller and have thickened, foot- shapes with a few claw- like appendages (end- bulbs) around the bases and sides of hair cells.

The sequence of structural events defined here compares to that of the acoustic axons in N. magnocellularis (Jhaveri and Morest, Neurosci. Abstr., 1977). Between days 11- 13, while peripheral endings have terminal swellings, the central axons expand and ramify. After day 15, while the peripheral endings become smaller, there is a corresponding condensation of the central terminals to form, ultimately, the end- bulbs of Held.

398 SEGMENTALLY SELECTIVE INNERVATION OF MAMMALIAN SYMPATHETIC GANGLIA: COMPARATIVE INNERVATION OF CERVICAL AND THORACIC GANGLIA. Joseph W. Yip, Dale Purves, and Jeff W. Lichtman. Department of Physiology and Biophysics, Washington University School of Medicine, St. Louis, MO 63110.

The guinea-pig superior cervical ganglion can be dissected in continuity with the cervical trunk and the thoracic portion of the peripheral sympathetic system. The ventral roots of the spinal segments which contribute innervation to the ganglion can then be stimulated in vitro while recording synaptic responses in individual ganglion cells. Such recordings show a segmentally selective pattern of innervation. Although each neuron in the mature ganglion typically receives synaptic contacts from about a dozen different preganglionic axons arising from an average of 4 of the 8 ventral roots which contribute innervation to the ganglion, the segments of origin of the preganglionic axons to individual neurons are nearly always contiguous. Typically, one of the ventral roots supplying preganglionic axons to a neuron provides the dominant innervation to that cell (as measured by either the amplitude of the postsynaptic potential or the number of innervating axons), while adjacent ventral roots contribute a synaptic influence which diminishes as a function of distance from the dominant segement.

These rules of contiguity and segmental dominance are also evident when similar recordings are made from the stellate and the fifth thoracic ganglia. These three ganglia differ from one another, however, in the spinal levels from which their innervation arises. Most of the axons innervating the superior cervical ganglion arise from thoracic spinal segments T2 and T3, while the stellate receives most of its innervation from T3-T5, and the fifth thoracic ganglion from T5. Thus, although the innervation to these ganglia arises from the same set of thoracic segments, there is a net caudal shift in the origin of the majority of axons innervating progressively more caudal ganglia. In addition, these several ganglia differ in the relative homogeneity of their spinal inputs: while individual cervical or stellate ganglion cells may be dominated by any one of several innervating segments, most neurons in the fifth thoracic ganglion are dominated by T5. A possible explanation for this difference in segmental innervation is that the fifth thoracic ganglion innervates a more restricted region than the superior cervical or the stellate ganglion.

These findings show that the segmentally selective innervation of superior cervical ganglion cells is characteristic of other sympathetic ganglia, and suggest that differences in the segmental innervation of ganglia may be a function of the territory they innervate. [Supported by NIH grant NS-11699.]

DRUGS OF ABUSE

399 INFLUENCE OF BRAIN CATECHOLAMINES ON BARBITURATE WITHDRAWAL CONVULSIONS. William M. Bourn. School of Pharmacy, Northeast Louisiana University, Monroe, LA 71209.

Rats were addicted to sodium barbital by daily administration of the drug with weekly incremental increases in the daily dosage for a four week period. Interference with brain catecholamine function by intracerebroventricular administration of 250 ug of 6-hydroxydopamine one week prior to withdrawal resulted in no increase in audiogenic seizure susceptibility, but a marked increase in severity of the sound-induced convulsions at 48 hours post-withdrawal. Ro 4-1284, an agent which depletes brain amines (catecholamines and 5-hydroxytryptamine), produced an increase in severity of- and susceptibility to sound-induced seizures at 48 hours post-withdrawal from barbital. Desipramine, an agent which enhances noradrenergic function by blocking uptake at the noradrenergic nerve terminal, provided significant protection from audiogenic seizures during withdrawal. These data support the hypothesis that brain norepinephrine acts as a modulator of sound-induced convulsive seizures during barbiturate withdrawal.

400 COMPARISON OF NARCOTIC AGONISTS AND ANTAGONISTS IN THE TAIL-SHOCK VOCALIZATION TEST IN RATS. P. J. K. Dobry. The Upjohn Company, CNS Research, Kalamazoo, MI 49001.

Narcotic agonist ("analgesic") and antagonist properties were compared in an up-down shock titration procedure, which measured the threshold for vocalization during an electric shock. All compounds were administered subcutaneously in 0.9% saline.

Methadone hydrochloride, morphine sulfate, profadol hydrochloride, meperidine hydrochloride, and codeine phosphate were good-to-excellent agonists (elevated vocalization threshold above 750 uA). None antagonized morphine (16 mg/kg) analgesia. All except 64 mg/kg profadol were completely antagonized by naloxone hydrochloride (5 mg/kg).

At the other extreme, naloxone hydrochloride, nalorphine hydrochloride and cyclazocine completely antagonized morphine, and levallorphan tartrate almost completely antagonized morphine. None of these elevated vocalization threshold above 750 uA, and none was antagonized by naloxone. Only naloxone was completely devoid of agonist activity at all doses tested (up to 64 mg/kg).

Dezocine, pentazocine lactate (Talwin^{R}, injectable), buprenorphine hydrochloride, and butorphanol tartrate antagonized morphine to the level of analgesia shown by the antagonist alone. These four intermediate compounds varied in their amount of agonism and in their response to naloxone. Dezocine and pentazocine caused the most analgesia of these four compounds, but naloxone almost completely antagonized 64 mg/kg dezocine and did not antagonize 32 or 64 mg/kg pentazocine. Buprenorphine and butorphanol caused weak analgesia which was completely antagonized by naloxone. Buprenorphine is the only compound tested whose dose-response curve showed a ceiling effect.

In conclusion, the vocalization threshold test for analgesia is a stringent assay which demonstrates the greatest efficacy for strong narcotic agonists and weak analgesic efficacy for strong antagonists. In general, test results are consistent with the results of other laboratories demonstrating that naloxone is a better antagonist against relatively pure agonists than against mixed agonist/antagonists with strong antagonist properties.

401 CYTOLOGICAL EVIDENCE OF A CHANGE IN RNA/PROTEIN SYNTHESIS IN HAMSTER NEURONS FOLLOWING INGESTION OF ETHANOL. C.R. Dunmire-Graff* and F.W. LaVelle* (SPON: C.H. Anderson). Dept. Anat., Loyola Univ. Stritch Sch. Med., Maywood, IL 60153.

The neuronal intranucleolar body (INB) of the hamster, first reported by LaVelle and LaVelle (Exp. Neur., 49:569, 1975), is regarded by us as a reserve of nucleolar RNA-rich material destined to take part in the synthesis of cytoplasmic protein in neurons. In this study chronic ingestion of ethanol was found to alter the size and frequency of INBs in the hamster brain. Adult golden hamsters were fed either (1) water and food pellets or (2) a 10-15% ethanol solution and food pellets for periods of 23 or 46 days, after which they were perfusion fixed. Brains were double-embedded and prepared for light microscopy. Transverse sections (4 μm) were cut at all brain levels and stained with buffered thionin. The diameter and frequency of INBs were then determined in: (1) facial motor neurons, (2) cells of the medullary and pontine reticular formation, and (3) cerebellar Purkinje cells. Each neuron containing a nucleolus was judged to possess either no INB, a punctate-sized INB, or a prominent INB. In all three brain areas the cells of the alcohol treated animals exhibited a higher percentage of prominent INBs than the controls ($p < 0.005$). The greatest change occurred in Purkinje cells: ±40% of control cells contained a prominent INB vs ± 70% of cells exposed to alcohol. Measurements of the prominent INBs in both control and alcohol treated animals showed for all brain areas studied a statistically significant ($p < 0.05$ - $p < 0.005$) increase in diameter following chronic ingestion of alcohol. Furthermore, the longer the exposure to alcohol, the greater the INB size. For example, in facial neurons, which contained the largest INBs, the mean diameter increased from 1.67 μm (controls) to 1.88 μm after 23 days and 2.07 μm after 46 days of alcohol ingestion. Within the cerebellum an additional study was made of a specific regional difference found in the nodule; here the Purkinje cells were normally less advanced than their counterparts elsewhere, as evidenced by a high percentage of nuclei with multiple nucleoli and nucleoli still attached to the nuclear membrane. After injection of ethanol, there was a significant shift ($p < 0.005$) to single nucleoli in this region, with many of them containing a prominent INB. Since our evidence consistently indicates a build-up of nucleolar RNA reserves (larger INBs) after alcohol ingestion, we suggest a decreased utilization of this material, which agrees with biochemical evidence of a decreased synthesis of cytoplasmic brain proteins following chronic exposure to dietary alcohol. We suggest that the nucleolar portion of this chain of synthetic events remains intact.

402 ALTERATIONS IN BEHAVIORAL RESPONSIVENESS AMONG OFFSPRING OF MALE MICE INJECTED WITH MORPHINE PRIOR TO MATING. G. Friedler* (SPON: C. Kornetsky). Boston University Medical School, Boston, MA. 02118.

We have previously reported a decrease in response to morphine sulfate (morphine) challenge among offspring of rodent parent(s) which were injected prior to mating (Pr) with morphine (In Perinatal Pharmacol. (Raven), 207-216, 1974; Pharmacol., 16: 203, 1974). Two studies were designed to explore whether alterations in responsiveness among offspring of opioid parentage were restricted to response to morphine challenge or would be extended to other behaviors. In the first study, female Swiss albino mouse offspring-- derived from male parents injected Pr with morphine or saline-- were tested at 12 weeks of age on a step-through avoidance procedure (.16mA scrambled footshock, 2 sec duration). At 18 weeks, offspring were retested in a straight alley swimming maze (water temp 18°C) for 20 trials with 30 sec cutoff and 20 sec intertrial interval. Swimming time (as a measure of performance) and errorless trials (as a measure of maze learning) were recorded. Offspring of Pr morphine-injected fathers showed an increase in swim time and decrease in errorless trials (<.001) when compared with saline-derived controls. In the second study, both male and female offspring -- derived from male parents injected Pr with morphine, methadone or saline -- were tested on the avoidance procedure at 6 weeks and on the swimming maze at 8 weeks. Significant deficits in both swim time and error-free trials (<.01) were again observed among morphine offspring. Methadone offspring did not differ from saline-derived controls. In both studies, the morphine and saline groups did not differ on the swimming maze alone, i.e., if not preceded by the avoidance task. The findings suggest that an altered responsiveness to stress may be responsible for the behavioral changes observed in offspring derived from rodent parents injected Pr with morphine.

403 ENHANCED PLACENTAL TRANSFER OF MORPHINE WITH INCREASING GESTATIONAL AGE. Margaret L. Kirby. Department of Anatomy, School of Medicine, Medical College of Georgia, Augusta, GA 30902

Placental transfer stdies of dihydromorphine and etorphine on the 21st day of gestation have shown that both drugs reach higher concentrations and are present longer in the fetuses than in maternal brain (Sanner and Woods, JPET 148:176, 1965; Blane and Dobbs, Br., J. Pharmacol. 30:166, 1967). The present study was undertaken to compare the amount of placental transfer of morphine on different days throughout gestation. On days 11, 13, 15, 17 and 19 of gestation pregnant Wistar rats were injected with 180 μCi of ^{3}H-morphine containing 4mg/kg cold morphine. At 1/2, 1, 2, 6 and 12 hours after injection, the fetuses were delivered by Caesarian section and all but 11 day fetuses cut into head and body pieces, which were analyzed individually. Placentas, maternal liver, brainstem and diencephalon-caudate were also analyzed. One group of animals was injected chronically with 10mg/kg of morphine twice daily between days 7 and 15 of gestation. On day 15, these animals were injected with ^{3}H-morphine and treated as described above. The tissues were homogenized in 0.5 to 4 ml ethanol and centrifuged. Free ^{3}H-morphine in the supernatant was isolated by thin-layer chromatography. Less than 100 ng/g of free morphine was found in individual whole fetuses on day 11. The amount of morphine found in fetuses grows progressively higher between days 11 and 17 of gestation. The highest concentrations of morphine occur at broad peaks between 1 and 2 hours on days 11, 13 and 15. On days 17 and 19 there is a sharp peak at 1 hour. The peak concentration on day 19 is less than on day 17. This decrease may represent metabolism by the placenta and fetal liver. On days 15, 17 and 19 measurable amounts of morphine are still present in the fetuses 12 hours after injection but not in the maternal brains. On day 11 the fetuses have less free morphine than the maternal brains. However on all the other days measured fetal tissues have higher concentrations than maternal brains on a per gram basis. On day 15 of gestation fetuses chronically exposed to morphine show a peak concentration at 1/2 hour after injection. This concentration is higher than the 1 hour peak in naive fetuses. In conclusion, these results imply that morphine passes through the placental barrier more easily as gestation progresses and that the concentration of morphine in the fetus can be altered by prior morphine exposure.

404 MORPHINE AND NALOXONE EFFECTS ON SPONTANEOUS AND EVOKED EEG AND UNIT IMPULSE ACTIVITY - TESTS FOR TOPOGRAPHIC AND DIURNAL DIFFERENCES. W. R. Klemm and C. G. Mallari Dept. Biology, Texas A&M Univ., College Sta., TX 77843.

Studies were conducted on 27 adult rats, locally anesthetized, paralyzed with Flaxedil, and artificially respired. Recording semi-microelectrodes were implanted in the caudate, amygdala, and at two levels of the central grey (CG); stimulating electrodes were put in the olfactory bulb and substantia nigra (SN). Stimuli of 4 intensities were delivered as 5-sec trains of 10/sec pulses. Unit activity was filtered, stimulus-artifact suppressed, differentiated, discriminated, and tallied every 5 secs. After baseline activity was determined, the 1st drug (morphine, 15 mg/kg, or saline) was injected, and activity re-determined 30-min later; then a 2nd drug (naloxone, 1 mg/kg) was given and activity re-determined. Diurnal effects of morphine were not evident in either spontaneous or evoked field potential (EEG) or unit activity. Morphine's main effect on spontaneous EEG was a naloxone-reversible slowing of frequency in all areas. With olfactory stimuli, morphine caused a naloxone-reversible increase in response in the amygdala of many rats and a decrease in others. Responses to SN stimuli in all areas were usually decreased by morphine (naloxone reversible). Morphine's main effect on spontaneous unit activity was a naloxone-reversible depression, especially evident in the caudate and CG. Both CG loci had depressed activity, but neurons of a few rats discharged faster; naloxone usually reversed the morphine depression, but not the excitation. In saline controls, naloxone had no clear effects in any brain area. Olfactory stimuli caused mostly excitatory responses, most evident in the amygdala; morphine not only failed to depress responses well, but often enhanced or reversed them; naloxone usually reduced the effect. Morphine usually caused a naloxone-reversible depression of evoked activity in the other areas, when they were responsive. SN stimuli generally caused excitatory responses, but were least effective in the amygdala. Morphine caused a naloxone-reversible depression of responses, especially in the CG. In saline-injected controls, naloxone commonly depressed or even reversed responses to both kinds of stimuli, suggesting involvement of enkephalinergic pathways. (Supported by NIDA grant, DA 00784).

405 OPIATE RECEPTORS IN AGGREGATING CELL CULTURES OF EMBRYONIC RAT BRAIN. E.L. Knodel* and E. Richelson. Depts. of Psychiatry and Pharmacology, Mayo Fdn., Rochester, MN 55901.

Mechanically dissociated fetal rat brains in rotation-mediated aggregating cell culture have been extensively characterized in our laboratory for their neurochemical properties(1). To study opiate drug interactions with these cells, we cultured fetal rat brains of 15-16d gestation, and characterized opiate receptor binding in homogenates of these cultures using [^{3}H]dihydromorphine ([^{3}H]DHM). [^{3}H]DHM bound to homogenates of aggregates in the absence of sodium ions in a saturable and stereospecific manner. Scatchard plots of binding data from studies of aggregates cultured for 10, 20 and 28d *in vitro* showed a single binding site for [^{3}H]DHM, with an average K_D = 1.2nM (range 0.9-1.3 nM) and B_{max} = 8-16 fmol/mg protein. After 4 weeks of treatment with 50 nM dextrorphan or 50 nM levorphanol, opiate receptor binding was unchanged compared to controls with respect to K_D and B_{max}.

In preliminary experiments, morphine sulfate (1-10μM) decreased endogenous levels of adenosine 3',5'-monophosphate in cultures incubated with this drug for up to 30 min. However, the effects of morphine were not reversed by equimolar amounts of naloxone. These data suggest that aggregating cell cultures of fetal rat brain may be a useful system for studying biochemical correlates of opiate binding and their possible effects on brain developmental processes.

406 HIPPOCAMPAL UNIT RESPONSES TO LOW DOSES OF MORPHINE AND NALOXONE IN DRUG-NAIVE AND MORPHINE-DEPENDENT RATS. M.A. Linseman. Addiction Research Foundation, Toronto, Canada, M5S 2S1.

The effects of opiates on single unit responses of the hippocampus were studied and compared to those previously obtained and reported for units in medial thalamus. The hippocampus, in comparison to medial thalamus, is characterized by a low density of opiate receptors, and there is no or negative evidence of its involvement in opiate tolerance and dependence. The comparison was of interest to determine whether the two areas might be distinguishable also on the basis of neurophysiological responses to opiates.

The spontaneous activity of hippocampal units was recorded prior to and following an i.v. injection of 0.625 mg/kg morphine (M) in drug-naive, chronically-prepared, paralyzed rats. Previous experiments established this dose to be generally just above threshold for producing a change in the simultaneously recorded fronto-cortical EEG. Responses of hippocampal units did not differ in terms of absolute latency, or latencies relative to cortical EEG changes from those previously recorded in medial thalamus. However, there was a marked difference in the pattern of responses in the two areas. Whereas medial thalamic units had shown consistent sustained decreases in rate in response to the drug, the hippocampal responses were more heterogeneous and variable. The majority of hippocampal responses were increases in rate, but there were also several decreases, as well as changes in the direction of increased or decreased variability of rate compared to baseline. Even when the overall rate had increased or decreased, it was often accompanied by greater variability than had been evident prior to M.

In contrast to the effects of M, the majority of responses of hippocampal units following an injection of 0.0125 mg/kg naloxone in morphine-dependent animals (1-75 mg pellet implanted s.c. for 3 days) were sustained decreases in rate. Hippocampal units were no less responsive to this low dose of naloxone (also just above threshold for producing a change in the cortical EEG) than were medial thalamic units, and like medial thalamic units, the latency of hippocampal responses tended to coincide with or follow the change in cortical EEG.

These results constitute evidence that medial thalamus rather than hippocampus might be a primary site of action of morphine only if one assumes that an internally consistent pattern of response to morphine might be characteristic of such an area. Neither area may be a primary site of action of naloxone as both hippocampal and medial thalamic changes following naloxone in dependent animals may have been secondary to previously occurring changes in the cortex.

407 OPIATE RECEPTORS MEDIATE THE EXCITATORY (EUPHORIGENIC?) EFFECT OF ETHANOL, CHLORDIAZEPOXIDE AND MORPHINE ON BRAIN STIMULATION REWARD. S. A. Lorens and S. M. Sainati*. Dept. Pharmacology, Stritch School of Medicine, Loyola University, Maywood, Illinois 60153.

Rats were trained to press a lever to deliver a 0.2 sec train of bidirectional 0.1 msec pulses (100 pairs/sec) through bipolar electrodes implanted in the lateral hypothalamus (LH) and medial frontal cortex (MF). The animals were run in 10 min sessions at least once daily. A 5 min period separated testing at each electrode site. Drug tests were initiated after responding for a threshold current intensity had stabilized (see Psychopharmacol. 48(1976)217). Different drugs and doses (expressed as the base) were administered i.p. following a 10 min control session once every 4-7 days according to a randomized design. Naloxone (NOX) was injected 5 min before or 1 hr after saline (1.0 - 2.2 ml/kg) or the other compounds. The animals then were tested hourly for 5 hr post-injection.

Ethanol (ETOH, 0.2 - 0.8 g/kg, 30% v/v) and chlordiazepoxide (CDP, 2.0 - 8.0 mg/kg) enhanced the response output for LH but not MF self-stimulation (SS). In contrast, morphine (MOR, 1.0 mg/kg) elevated responding for both LH and MF SS. NOX (0.5 - 16.0 mg/kg) did not affect SS rates at either site. However, NOX (5 mg/kg) both prevented and reversed the increase in LH SS response output produced by ETOH (0.4 g/kg) and CDP (4.0 mg/kg). Likewise, NOX (1.0 mg/kg) blocked the facilitatory effect of MOR (1.0 mg/kg) on both LH and MF SS. Dose-response relationships indicate a competitive antagonism.

That the excitatory effect of ETOH, CDP and MOR on LH SS is mediated by opiate receptors is strongly supported by preliminary findings indicating that the (-) isomer (M2266), but not the (+)isomer (M2267), of the narcotic antagonist, 5,9α-diethyl-2-(3-furylmethyl)-2'-hydroxy-6,7-benzomorphan (5.0 mg/kg), blocks the facilitatory effect of ETOH (0.4 g/kg) and CDP (4.0 mg/kg) on LH SS. M2266 (1.0 - 5.0 mg/kg) alone does not affect SS responding, but prevents the excitatory effect of MOR (1.0 mg/kg). CDP and ETOH thus appear to release an endogenous opioid which acts on opiate receptors associated with LH SS, but not MF SS, resulting in enhanced rates of response. This mechanism of action, furthermore, may mediate the positively reinforcing or euphorigenic property of ETOH and CDP.

408 THE TRIPHASIC RESPONSE OF THE RABBIT PUPIL TO MORPHINE. R. B. Murray* and R. J. Tallarida* (SPON: E. B. Geller) Dept. Pharmacol., Temple U. Sch. Med., Philadelphia, Pa. 19140.

Change in pupil size upon narcotic administration is commonly determined by direct observation or still photography. A study using serial photographs taken at 30-sec intervals reported the surprising finding that morphine (M) administered i.v. to albino rabbits produces only a transient miosis which is followed by large amplitude fluctuations in pupil size (Tallarida et al., JPET 201:587,1977). The present study was undertaken to describe in detail the action of M on the rabbit pupil using continuous pupillography.

The pupillary responses of 36 albino rabbits to i.v. doses of M (1 to 12 mg/kg) were recorded with a specially designed infrared video pupillometer which measures pupil area in real time (Murray and Loughnane, Fed.Proc.37:275,1978). All experiments were carried out under constant low ambient light (luminous flux at eye = 0.87 $mW \cdot cm^{-2}$). The typical response (see figure) consists of 3 phases: 1) an immediate mydriasis lasting up to 20 sec; 2) a brief miosis which peaks within 4 min; and 3) large amplitude fluctuations in pupil area lasting approx. 2 hrs. This triphasic response is blocked by prior i.v. administration of 0.2 mg/kg of naloxone. The magnitude of phase 2 miosis is dose related. The amplitude of phase 3 fluctuation may reach 100% of the control pupil area. Time series analysis reveals that the power of pupil area fluctuations increases by 2 to 6 times and that the peak frequencies have periods in the range of 1.5 to 3 min after M administration.

Local blockade of the iris sphincter with scopolamine abolishes all phases of the M-induced pupil effects. Based on evidence from other investigators that M's pupillary action is of central origin, this finding indicates that M-induced transient miosis and pupil fluctuation are produced by perturbation of the pupil servo-control (parasympathetic) system.

409 **INTERACTION BETWEEN MORPHINE AND REWARDING OR AVERSIVE BRAIN STIMULATION IN THE SHUTTLEBOX.** **Alex E. Popov*, Carol Palmer* and Robert A. Levitt. Dept. Psych., So. Ill. Univ., Carbondale, Ill. 62901 and Dept. Psych., Univ. Ala. Birmingham, Birmingham, Ala. 35294**

Systemic injections of morphine increase the total time rats leave on hypothalamic electrical stimulation in the shuttlebox paradigm, as well as increasing the average ON time per crossing. Further, in the lever-press paradigm, rats given naloxone, a narcotic antagonist, during intracranial self-stimulation (ICSS) of the central grey, show rate decreases. In the current study, using the shuttlebox, the effect of morphine on hypothalamic (LHA) ICSS was replicated and compared with the ICSS effects with and without morphine in the septal area (LSA)., periaquaductal gray (PAG) and the mesencephalic reticular formation (MRF). The results indicate marked stimulation site dependent differential morphine effects, as well as inter-subject consistency. All experimental groups differed markedly from non-stimulated controls. The LSA subjects, compared to the LHA subjects, showed moderate rates of shuttling and a similar increase in total ON time, decrease in shuttling and increase in average ON time when given morphine. The PAG subjects showed extremely high baseline rates of shuttling and reliable increases in ON time, decreased shuttling and greatly increased average ON time under morphine. The MRF subjects, who showed marked aversion to the ICSS, had baselines characterized by low rates of shuttling and very low ON time. These MRF subjects under morphine generally further decreased ON time and rates of shuttling. Thus the general findings indicate morphine increases the amount and duration of reinforcing ICSS tolerated and does not facilitate tolerance of aversive ICSS. These results demonstrate a possible interaction between morphine and putative transmitters and add evidence to an aversion suppression hypothesis of morphine action.

410 ENHANCED SECRETORY PROTEIN SYNTHESIS RATES IN DISCRETE BRAIN REGIONS ASSOCIATED WITH DEPENDENCE DEVELOPMENT ON MORPHINE. K.C. Retz* and W.J. Steele. Dept. of Pharmacology, College of Med., Univ. of Iowa, Iowa City, IA 52242.

Ramsey and Steele (in Opiates and Endogenous Opioid Peptides, H.W. Kosterlitz, ed., Elsevier, 1976) have shown that the degree of dependence on morphine (1 pellet over 3 days), as assessed by wet dog shakes, correlates well with increases in secretory protein synthesis rates in the pons-medulla. However, because it has been reported (Psychopharmacology 52:55, 1977) that such treatment produces a low degree of dependence we decided to re-examine this question.

Rats were rendered dependent on morphine as follows: 1 pellet over 2 days (S1), 3 over 4 days, i.e., 1 on day 0, 2 on day 2 (S2) and 6 over 7 days, i.e., 1 on day 0, 2 on day 2, 3 on day 4 (S3); controls received placebo pellets. Protein synthesis rates were measured in vivo by pulse-labeling for 7 min with ^3H leucine, 2.5 mCi/0.5 mmol/kg. Brains were dissected into regions and free (non-secretory) and membrane-bound (secretory and membrane) polysome compartments were isolated therefrom (J. Neurochem. 28: 517, 1977). Separate groups were used for assaying dependence following pellet removal and naloxone, 10 mg/kg, s.c. Total drug dose was estimated as the product of daily dose times days, assuming delivery of a constant proportion of the pellet's morphine content over 3 days (Psychopharmacologia 28:35, 1973).

A linear relationship between increases in protein synthesis rates and log dose was exhibited in the secretory protein compartment of the pons-medulla (PM) and striatum-septum (SS). No changes were observed in either compartment of the cerebrum, cerebellum, mesencephalon, hippocampus-amygdala, or thalamus-hypothalamus. There was a linear relationship between maximal body weight loss during withdrawal and log dose, indicating that the former correlates well with the degree of dependence. In contrast, hypothermia was observed only with S2 and S3, suggesting that it is a less sensitive measure of dependence than weight loss. Finally, the magnitude of the increases in secretory protein synthesis rates in the PM and SS (up to 20-30% with S3) correlated closely with that of dependence assessed by maximal weight loss (17-20% with S3). Our findings not only confirm that morphine enhances secretory protein synthesis in the PM, but also extend earlier work by demonstrating that morphine induces similar changes in the SS, regions important as sites of opiate action and binding, in association with dependence development measured by an objectively quantifiable change. Supported by USPHS DA-00710.

411 THE CHRONOPHARMACOKINETICS OF SECOBARBITAL IN FASTED AND NON-FASTED RATS. Alvin L. Sermons,* Fred H. Ross* and Charles A Walker. Florida A and M University, School of Pharmacy, Tallahassee, FL 32307.

The toxicity of secobarbital in rodents have been shown to vary significantly with the time of day. Male Sprague-Dawley rats weighing approximately 200 gm each were used in this study. All animals was anesthetized with ether and the aorta was permanently cannulated by the method of Popovic (1963). Following cannulation, the animals were adapted to a 12-hour light, 12-hour dark illumination cycle for three weeks at 23 ± 1° C. The control (non-fasted) and 24-hour fasted groups were injected with sodium secobarbital (80 mg/kg) intraperitoneally every four hours. Blood samples were collected at 30, 60, 120, 180 and 240 minutes following treatment. The blood levels of the drug were determined by the method of Baer (1965). Secobarbital concentrations peaked in both the fasted and non-fasted animals at 0600 hours and troughed at 1200 hours respectively. Blood levels differed significantly between groups. The fasted were lower than the non-fasted. Changes observed for the blood concentrations of secobarbital in both groups correlates positively with the chronotoxicity of secobarbital. The results of this study suggest that fasting can influence the blood levels and chronotoxicity of specific drugs. Fluctuation in the levels of the drug in the blood and daily variations in toxicity may suggest a biological rhythm in barbiturate drug metabolism. (Supported by a grant from National Aeronautics and Space Administration).

412 ROLE OF n.ACCUMBENS IN MORPHINE INDUCED LOCOMOTOR HYPERACTIVITY IN THE C57/bl MOUSE. Herman Teitelbaum, Paul Giammatteo* and G. Andrew Mickley. Physiol. Psychol. Div., Armed Forces Radiobiology Research Institute, Bethesda, MD 20014.

Mice of the C57/bl strain display locomotor hyperactivity which increases with increasing dose of morphine. A dose of 30 mg/kg of morphine produces a response that is the behavioral equivalent of the optimal dose of amphetamine (4mg/kg). Since it is known that 6-hydroxydopamine lesions of n.Accumbens block the response of amphetamine in the rat (Kelly et al., 1976) we compared the effects of lesions of posterior n.Accumbens and the bed nuclei of the stria terminalis (Group I) to the effects of lesions of the anterior olfactory nucleus and the anterior tip of n.Accumbens (Group II) on responses to both drugs.

The posterior n.Accumbens lesion was effective in completely blocking locomotor hyperactivity to amphetamine; it reduced the morphine response to half preoperative levels. The anterior lesion reduced the amphetamine response to half preoperative levels but had no effect on the response to morphine. The effects of posterior lesions were mimicked with bilateral microinjections of haloperidol into n.Accumbens. These results confirm the findings of Kelly et.al., 1976 showing that dopaminergic synapses in the n.Accumbens are necessary for amphetamine induced hyperactivity. The neural mechanism for morphine induced locomotor hyperactivity is not identical to that for amphetamine. Dopaminergic neurons of the n.Accumbens are involved in this response, but other neural elements are involved in the morphine response as well.

413 β-ENDORPHIN-INDUCED ALTERATIONS IN DOPAMINE (DA) AND SEROTONIN (5HT) METABOLISM IN DISCRETE REGIONS OF RAT BRAIN. G.R. Van Loon,* E.B. De Souza* and C. Kim* (SPON: Y. Israel). Depts. of Medicine and Physiology, University of Toronto, Toronto, Canada, M5S 1A8.

Interactions between brain monoamines and the effects of opiates have been demonstrated, although specific mechanisms remain to be defined. Endorphins have been characterized as peptides with opioid activity synthesized in brain and pituitary. It was clearly important to examine possible interactions between the endorphins and their behavioural effects, and brain monoamine metabolism.

Effects of acute intracisternal administration of synthetic human β-endorphin (15 µg) on DA and 5HT metabolism in discrete brain regions were investigated in adult male Sprague-Dawley rats. β-endorphin increased striatal concentrations of the DA metabolites 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) as well as producing catalepsy. All of these effects were inhibited by naloxone. Rates of pargyline-induced decline in striatal concentration of DOPAC and HVA were greater in endorphin-treated than in saline-treated animals, supporting the concept that β-endorphin increases striatal dopamine turnover. β-endorphin also increased the rate of decline in striatal DA following synthesis inhibition with α-methyl-tyrosine, further suggesting that endorphin increases striatal DA turnover. It is probable that this apparent increase in striatal DA turnover is compensatory since β-endorphin appears to inhibit neuronal release of DA. β-endorphin and probenecid interacted competitively to decrease the effects of each other to increase striatal HVA, and naloxone prevented this effect of β-endorphin.

In addition to the effects on striatal DA metabolism, β-endorphin increased concentrations of 5HT and its metabolites, 5-hydroxyindoleacetic acid (5-HIAA) in brain stem and hypothalamus and decreased 5-HIAA in hippocampus. β-endorphin increased in brain stem and hypothalamus and decreased in hippocampus the rate of pargyline-induced decline in 5-HIAA, and decreased the rate of pargyline-induced accumulation of 5HT in all brain regions. Thus, β-endorphin appears to increase 5HT turnover and release in brain stem and hypothalamus and decrease 5HT turnover and release in hippocampus, while also decreasing 5HT reuptake in these brain regions or increasing 5-HIAA egress from brain.

Acute administration of β-endorphin clearly alters brain DA and 5HT metabolism. The relationship of these changes in brain monoamine metabolism with β-endorphin-induced alterations in behaviour, pain threshold, thermoregulation, etc., remain to be defined.

414 THE EFFECT OF INTRAVENOUS ETHANOL ON VOLUNTARY ALCOHOL CONSUMPTION BY ALCOHOL-PREFERRING RATS. Marshall B. Waller, William J. McBride, Lawrence Lumeng* and Ting-Kai Li*. Institute of Psychiatric Research and Departments of Psychiatry, Biochemistry and Medicine, Indiana University School of Medicine, Indianapolis, IN 46202.

Sensory cues, a CNS pharmacologic effect or a combination of these factors appear to be the major determinants of ethanol (ETOH) self-selection in the free-fed unstressed rat. The present study examined the effect of intravenously administered ETOH solutions (w/v in saline) on the voluntary consumption of ethanol (10% v/v in water) by a line of rats genetically selected for alcohol preference (P-line). After a pre-infusion control period, a polyethylene cannula was implanted in the external jugular vein in male rats following the procedure of Pickens and Dougherty (1972). The animals were then divided into two groups. One group received 24 hourly infusions of ETOH daily to total 20-130% of their voluntary oral ETOH intake expressed as g of ethanol/kg of body weight/day. The other test group received 12 infusions each day to total 75-150% of the daily ETOH consumption, delivered only during the rat's dark cycle. Throughout the experiment, 10% ETOH and water were available ad libitum. When 75% or more of the ETOH usually ingested was infused intravenously, the amount of ethanol consumed orally changed dramatically. Voluntary consumption of ETOH in both groups decreased approximately 60% from 6.2 to 2.6 g/kg/d. Furthermore, the amount of ETOH infused correlated negatively with the amount of alcohol consumed orally. The r values are -0.55 for the 24 infusions/day group and -0.71 for the 12 infusions/day rats. The corresponding t values are 5.494 and 8.511 both significant beyond the 0.005 level. As alcohol intake decreased, the amount of water consumed orally increased from 5 to 30 times the volume (0.5-1.5 ml) ingested during the pre-infusion period. Thus, the total daily fluid intake was not compromised. Moreover, the total daily caloric intake remained stable throughout the experiment even though the amount of food eaten progressively declined. This suggests a voluntary compensation by the animals rather than an adverse effect of the alcohol. Finally, during a post-alcohol infusion period (saline infused), the amount of ETOH consumed orally returned to 80-100% of the pre-infusion level within 3-7 days; water intake, however, remained elevated. These results suggest that, although orosensory cues are present, the CNS pharmacologic effect provided by the infused ETOH was an important determinant of ethanol drinking behavior in these genetically selected alcohol-preferring rats. (Supported by Grant No. AA03243).

EPILEPSY

415 LESIONS OF THE INTERPEDUNCULAR NUCLEUS RETARD DEVELOPMENT OF AMYGDALOID-KINDLED SEIZURES IN RATS. Robert F. Ackermann , and Jerome Engel, Jr., Reed Neurological Research Center, UCLA School of Medicine, Los Angeles, CA 90024.

Effects of ventral tegmental lesions on electrical amygdaloid kindling were assessed in Sprague-Dawley rats chronically implanted with bipolar electrodes aimed at the central amygdaloid nucleus. Animals were divided into 3 groups and treated as follows:

(1) lesioned: radiofrequency lesions were made in the ventral tegmental area at the time of amygdala implantation.

(2) lesion controls: the lesioning electrode was only lowered and then withdrawn with no current passed.

(3) normal controls: no ventral tegmental treatment.

Following 2 weeks of daily handling, each animal was stimulated once a day with 60 cps, 400 uA current for 1 sec. until 3 consecutive stage 5 seizures were induced. Subsequently, the locus of the stimulating electrodes, and the locus and extent of the ventral tegmental lesions were determined with routine neurohistological procedures.

The mean number of stimulations to stage 5 seizures did not differ between the normal controls (x=4.0) and the lesion controls (x=5.0); therefore they were combined into a single control group. Animals lesioned in the interpeduncular nucleus (IPN) required significantly more stimulations to achieve stage 5 seizures (x=12.4); this effect was proportional to the extent of IPN damage. By contrast, animals lesioned elsewhere in the ventral tegmentum (medial substantia nigra, ventral tegmental area of Tsai, ventral raphe) did not differ from controls (x=4.5). The fact that lesions immediately rostral to the IPN were among those having no effect suggests that these results were due to disruption of intrinsic IPN structures rather than longitudinal fibers of passage.

These data indicate that, in rats, the development of amygdaloid kindled seizures is retarded by IPN ablation, suggesting that the IPN normally facilitates kindled epileptogenesis. At present, a mechanism for this facilitation is not obvious, but it is interesting to note that the IPN is rich in acetylcholine and enkephalin, and both substances are known to readily induce seizures.

416 EXCITATORY EFFECTS OF SODIUM VALPROATE ON SINGLE NEURONS IN RAT BRAIN. H.Blume, Y.Lamour*, E.Arnauld*, L.Renaud. Division of Neurology, Montreal General Hospital and McGill University, Montreal, Quebec, Canada.

Sodium valproate (N-Dipropylacetate) is now widely recognized as an anticonvulsant drug. It has also been associated with behavioral effects in the reduction of signs of morphine and alcohol withdrawal in human and animal studies. These pharmacological effects of sodium valproate have been ascribed to the increases in levels of GABA seen in many areas of the brain including the cerebral cortex. However, the precise mode of action of sodium valproate at the single neuron level has not yet been fully investigated. In order to observe the direct effects of this drug on neurons, extracellular recordings were carried out in rat cerebral cortex and hippocampus during application of sodium valproate by microiontophoresis.

Extracellular recordings were obtained from 50 neurons in the sensory-motor and parietal cortex and dorsal hippocampus in male Sprague-Dawley rats under pentobarbital anaesthesia. Recording electrodes of saline filled micropipettes were fixed to 7-barrel microiontophoresis electrodes filled with L-glutamate, GABA, acetylcholine (ACh), bicuculline, and sodium valproate (.5M, pH 8.0). 40 neurons displayed enhanced excitability of rapid onset and termination during ejection of sodium valproate at thresholds ranging from 0-15 nA negative current. Application of L-glutamate also showed enhanced excitability of rapid onset with all 40 of these neurons. The effects of sodium valproate were rarely seen without the simultaneous ejection of L-glutamate although only a small "priming" current was necessary. The sodium valproate and L-glutamate enhanced neuronal excitability in additive fashion. ACh also increased the excitability of over half the neurons tested. Sodium valproate increased the excitability of both cells sensitive and non-sensitive to ACh. However, the simultaneous ejection of sodium valproate and ACh did not give additive effects. GABA decreased the excitability of all neurons tested and antagonized the effects of L-glutamate, ACh and sodium valproate. An understanding of the significance of the reported findings, relative to previously observed behavioral and anticonvulsant effects of sodium valproate, awaits further in-vivo studies of single cell recording in conjunction with behavioral and epileptic animal models.

417 CHRONIC IRON-INDUCED EPILEPTOGENIC FOCI: AN ELECTROPHYSIOLOGICAL STUDY IN RATS. W.M. Boggs*, S.A. Reid*, G.W. Sypert, J.B. Munson, and L. J. Willmore (SPON: K.M. Heilman) VA Hospital and Dept. of Surgery and Neuroscience Univ. of Fla. Coll. of Med., Gainesville, FL 32610

Subpial injections of 5 ul of 100 mM $FeCl_2$, $FeCl_3$ or 0.9 NaCl were instilled into the sensorimotor cortex of Sprague-Dawley rats. Regular cortical electroencephalographic recordings through extradurally implanted screw electrodes revealed the following: 1) Both ionic salts of iron caused focal spiking activity within 48 hours, with spread of this epileptiform activity contralaterally; 2) Frequent and sustained bursts of epileptiform activity developed within 10 days; 3) Behavioral convulsions and electrocorticographic discharges continued to persist beyond 12 weeks in 94% of the iron-injected rats, and for as long as 31 weeks in one animal before being sacrificed; and 4) Four of the 14 animals injected with NaCl exhibited transient focal spike activity lasting less than 14 days. Preliminary electrophysiological data from continuing microelectrode recording of single cortical neurons reveal that most neurons within and immediately surrounding the site of iron injection ("focus") burst in synchrony with spiking activity. Neurons more distant from the focus appear to be unaffected by such spike activity and few neurons in any location seem to be inhibited during spiking. The similarities of these findings to pathophysiological changes in man suggest the applicability of this experimental model of focal epilepsy to the study of the disease in humans. (Supported by VA Hospital Medical Research Service.)

418 DECREASED SEIZURE SUSCEPTIBILITY IN RATS FOLLOWING LESIONS OF THE LATERAL MIDBRAIN TEGMENTUM. R. A. Browning, R. L. Simonton* and M. L. Smith*. Southern Illinois University School of Medicine, Carbondale, Ill. 62901.

In an attempt to localize the seizure antagonizing effects of norepinephrine (NE), seizure susceptibility was examined in rats after surgical interruption of the ascending noradrenergic (NA) pathways. Mechanical lesions designed to interrupt the dorsal noradrenergic (NA) bundle were placed bilaterally in the midbrain tegmentum of male Sprague-Dawley rats (300-400g). The lesions were produced by lowering a piece of stainless steel tubing (1mm diameter) into the brain at the level of the inferior colliculus according to the procedure described by Erinoff et al. (Proc. Soc. Exp. Biol. Med. 150, 748, 1975). Biochemical assessment of the lesion 28-35 days post-operatively revealed a 50-60% reduction in forebrain NE, with no significant alterations in forebrain dopamine or serotonin and no effect on spinal cord NE. Histological evaluation revealed a 0.5-1.0mm wide lesion tract, which passed through the midbrain at the level of the inferior colliculus damaging the following structures: lateral aspects of periaquaductal gray, dorsal NA bundle, lateral portion of decussation of the brachium conjunctivum, reticular formation, and medial edge of ventral NA bundle. All seizure testing was conducted at least 30 days after lesion placement. In contrast to our expectations, we found a significant ($p<0.05$) reduction in the percentage of lesioned rats exhibiting hindleg extension in response to maximal electroshock (150mA, 60Hz, 200mSec) as compared to sham operated controls. Moreover, the incidence of tonic extension in the pentylenetetrazol seizure test was found to be significantly decreased ($p<0.01$) by the lesion. However, no difference in the threshold for minimal electrochock seizures was detected between sham-operated and lesioned animals. Inasmuch as seizure facilitation has been consistently observed following widespread destruction of NE neurons with 6-hydroxydopamine, the present results cannot be attributed to the lesion-induced reduction in forebrain NE. It seems more likely that damage to structure(s) other than the NA neurons are responsbile for the seizure antagonizing effects of the lateral tegmental lesion. However, the precise anatomic and biochemical changes responsible for this effect remain to be elucidated.

419 KINDLING STIMULATION OF THE RAT HIPPOCAMPUS: ALTERED NEURONAL SENSITIVITY TO MICROIONTOPHORESIS OF ACETYLCHOLINE. James L. Burchfiel*, Michael S. Duchowny*, and Frank H. Duffy (SPON: M. BIBER). Dept. Neurol. and Seizure Unit, Children's Hospital Medical Center, Harvard Med. Sch., Boston, MA 02115.

The term "kindling" describes the phenomenon whereby repeated focal electrical stimulation induces electrophysiological and behavioral changes consisting of increasing duration and spread of afterdischarge (AD) activity and increasingly more widespread motor seizures. We have been exploring the hypothesis that the electrophysiological changes of kindling reflect altered neuronal responsiveness to neurotransmitter agents. Neuronal responsiveness to microiontophoresis of glutamic acid (GA):0.02M pH4.5, gamma-amino butyric acid (GABA): 0.1M pH4.0, and acetylcholine (ACH): 0.01M pH5.2 was assessed for CA1 pyramidal cells in adult male Sprague-Dawley rats anesthetized with chloral hydrate (400mg/kg IP). Kindling stimuli (0.1 msec bipolar squarewave pulses, 100 Hz frequency, 1 sec train) were delivered to the ipsilateral fornix. The major change seen after the induction of a hippocampal AD was a prolonged period of neuronal supersensitivity to ACH. ACH supersensitivity usually occurred at 40-60 minutes post-stimulus, and could still be observed at four hours. The period of ACH supersensitivity was often preceded by a period of ACH subsensitivity. A subsequent kindling stimulus delivered during the period of ACH supersensitivity resulted in a substantially longer AD. In contrast, re-stimulation before the onset of ACH supersensitivity resulted in no growth of the AD or an actual decrease in its duration. These effects were not observed for GA or GABA. These results suggest that kindling in the rat hippocampus may be a function of altered synaptic sensitivity to ACH.

420 KINDLING IN SENSORY THALAMUS AND NEOCORTEX. A PRELIMINARY STUDY. Donald Peter Cain and Marilyn Kilbreath Dept. of Psychology, U. of Western Ontario, London, Ontario N5A 5C2 Canada

The kindling response of a number of sensory and nonsensory areas of thalamus (lateral geniculate, medial geniculate, lateral posterior, and posterior nuclei), neocortex (areas 17, 18, 41), and midbrain superior colliculus, reticular formation) was studied. A total of 110 male hooded rats were implanted bilaterally with bipolar twisted nichrome electrodes and stimulated between 100 and 200 times through each electrode at the individually determined afterdischarge (AD) or aversive response threshold. Stimulation was delivered once daily and consisted of 1 sec of constant current sine waves at 60 Hz or 4 min of high frequency bursts of biphasic square waves. Currents were in the range of 2 to 200 μA. EEGs were recorded through both electrodes before and immediately after each stimulation. In no case did animals with electrodes in the superior colliculus or reticular formation show sustained AD or behavioral convulsions. A number of animals in each of the other groups showed either AD alone or behavioral convulsions that eventually generalized with associated AD. The proportion of animals showing AD or convulsions in each group was 20 to 60 per cent. The AD and convulsion manifestations differed markedly from those obtained from limbic areas in that AD was spikier and less rhythmic, convulsions required many stimulations to develop and were of abrupt onset and atypical in form, and often did not occur in response to each stimulation after they had appeared once or a few times. However, convulsion frequency increased gradually over time, and the resulting state of seizure susceptibility was permanent. These results suggest that much of adult mammalian brain, including primary sensory areas, is plastic and subject to seizure production if directly activated with electric current.

421 REDUCED POTASSIUM CURRENTS IN THE PRESENCE OF A PERSISTENT INWARD CURRENT LEADS TO BURSTING OF CAT SPINAL MOTONEURONS. Wayne E. Crill and Peter C. Schwindt*. VA Hospital and Depts. Physiol. & Biophys. and Med., Univ. Wash. Sch. Med., Seattle, WA 98195.

Voltage clamp studies of cat spinal motoneurons reveal a steady negative resistance 10-30 mV positive to resting potential. This negative resistance is caused by a persistent inward current (I_i) presumably carried by Ca^{++}. We have postulated that I_i is an important factor in pencillin-induced bursting in motoneurons since the underlying synaptic currents measured during voltage clamp are shorter than the prolonged bursts. This is in marked contrast to the large synaptic currents seen to underly strychnine-induced motoneuron bursting. In addition, I_i is necessary for penicillin-induced bursting since no bursting is observed when I_i disappears due to injury produced by electrode impalement. Thus, we have hypothesized that I_i can dominate neuron firing behavior if the repolarizing potassium and leak membrane currents (I_K and I_L, respectively) are decreased or if I_i is increased. Specifically, a relatively small decrease in potassium equilibrium potential (E_K) caused by the raised extracellular potassium accompanying intense neuronal activity may reduce I_K sufficiently to allow I_i to produce bursting. To test this hypothesis we have adopted the expedient of decreasing E_K (and, thus, I_K) by intracellular injection of the relatively impermeant cation tetramethylammonium (TMA). This agent appears simply to displace intracellular K^+ rather than to block K^+ channels in frog node of Ranvier or spinal motoneurons. After TMA injection sustained bursts of repetitive firing could be evoked by brief stimulation only after a decrease in I_K and a small decrease in I_L allowed I_i to become net inward over a certain range of membrane potential. The interspike plateau potential during bursting was well correlated with the steady current-voltage relation of the bursting cell. Both slow and fast components of the reduced K^+ currents were still present, and E_K remained negative to rest as indicated by spike afterhyperpolarization. Similar behavior could also be obtained by tetraethylammonium (TEA) injection which blocks the fast K^+ current in addition to decreasing E_K. It is concluded that a relatively small reduction of I_K in the presence of a normal I_i is sufficient to cause bursting. This may be one mechanism by which normal neurons are recruited into seizure activity. (Supported by VA Research Grant #MRIS 1610.)

422 ICTAL MECHANISMS AND CORTICAL AUDITORY PROCESSING. D.D. Daly, D.M. Daly, J.A. Wada*, M.E. Blaw. Dept. Neurology, UT Health Sci. Ctr., Dallas, Texas 75235, and Div. of Neurol. Sci., U. British Columbia, Vancouver, Canada.

Focal epileptic seizures disrupt function of the cortical area in which they occur; postictally, paralysis of cortical function persists for periods varying from minutes to hours (e.g. Todd's paralysis). Frequently recurring focal seizures may cause more enduring focal deficits in cortical functions. In previous reports, we have shown that sparse acoustic stimuli (SAS) provide a measure of cortical auditory processing (Neurosci. Abstr. 2:5, 2:6, 1976). We now report the use of SAS in the study of cortical ictal processes.

A 9 year-old boy developed partial seizures characterized by formed auditory perceptions (voices, sound of drums); music seemed to precipitate some seizures. Six months before study, he had had progressive inability to understand speech ("word deafness") without impairment of reading and writing; two weeks before study, aphasia evolved. Retrospectively, his parents recalled increasingly frequent, short intervals of altered responsiveness (brief seizures). Perception of SAS both monaurally and binaurally was profoundly altered although early click-evoked potentials (BSR) were normal, and he localized sounds correctly. Carbamazepine was added to his drug regimen. The frequency of seizures decreased associated with slow, steady improvement in comprehension and aphasia. After one month, his perception of SAS had improved significantly although during testing, short episodes of greater impairment intervened (brief seizures). In two months, aphasia had resolved and speech perception was virtually normal, paralleled by improved perception of SAS, even when best-performance testing time was not fixed to control for diurnal variation.

In contrast, studies of a patient during partial status epilepticus of mesial frontal origin and also during intoxication with phenytoin showed normal speech comprehension and sharply defined SAS identification functions (IF). Studies of another patient with focal seizures arising in visual area showed sharp IF except when ictal propagation to the other hemisphere impaired level of consciousness and caused transient fixed responses to stimuli.

Focal seizures in auditory cortex *alter* perception of SAS, whereas focal seizures elsewhere do not. In contrast, propagation of focal ictal discharge can *impair* perception of SAS. We conclude that in focal epilepsies serial SAS testing can provide a useful measure of recovery in function and a sensitive index of effective treatment.

423 CONVULSIVE DOSES OF PENICILLIN DO NOT REDUCE A MONOSYNAPTIC GABA-MEDIATED IPSP IN THE INTACT, ANESTHETIZED CAT. J. Davenport,* P.C. Schwindt* and W.E. Crill. VA Hosp. and Depts. Physiol. Biophys. and Med., Univ. Wash., Seattle, WA 98195.

A number of recent studies using a variety of model neural systems have shown that penicillin (PCN) can greatly reduce GABA-mediated IPSPs and hyperpolarizing inhibitory responses to externally applied GABA. It has been proposed that reduction of GABA-mediated inhibition may be the mechanism by which PCN causes seizures. To test this hypothesis in an intact mammalian system, we examined the effect of I.V.-administered PCN on the monosynaptic IPSP, believed to be GABA-mediated, evoked in Deiters' neurons by stimulation of the anterior vermal cerebellar cortex.

Ten cats were anesthetized with pentobarbital (6) or α-chloralose (4). The cortical EEG was continuously monitored to indicate the effectiveness of incremental PCN doses causing progressively increased EEG activity, interictal spiking, and seizures. We specifically considered the possibility of a progressive decline of IPSP amplitude in parallel with the development of abnormal EEG activity as predicted from the above hypothesis. Intracellular recordings with KCit. filled microelectrodes were obtained from 105 Deiters' neurons. PCN doses ($\geq 2 \times 10^5$ IU/Kg) sufficient to cause frequent interictal spiking or seizures were associated with spontaneous high frequency firing of Deiters' neurons, "depolarization shifts," and large, spontaneous IPSPs. We found that in normal cells the IPSP may decrease over time concomitant with a decrease of resting potential and input resistance, probably due to injury from impalement. Therefore, we closely monitored these quantities and to ensure the stability of the IPSP before evaluating the effects of PCN. Our data are based primarily on 5 cells which fulfilled the above criteria and were held for 9-53 minutes. Although the IPSPs in these cells varied considerably with each stimulus, no consistent change in mean IPSP amplitude could be detected after single or multiple doses of PCN; in particular, there was no consistent IPSP decrement as EEG or Deiters' cell activity progressively increased. Analysis of IPSPs in populations of neurons before and after PCN in 9 experiments also suggested that PCN caused no significant change in IPSP amplitude in the cell populations. These results cast doubt on the hypothesis that reduced inhibition due to PCN-GABA antagonism is necessary to cause seizures. It is possible that cortical GABA receptors are much more sensitive to PCN than those of Deiters' neurons. Alternatively, mechanisms other than reduced GABA-mediated inhibition may produce seizures at the brain PCN concentrations resulting from I.V. PCN administration. (Supported by VA Research Grant MRIS 1610 and NINCDS Grant NS05082.)

424 REDUCTION OF POSTSYNAPTIC INHIBITION BY PENICILLIN IN THE IN VITRO HIPPOCAMPAL SLICE. Raymond Dingledine and Leif Gjerstad*. Institute of Neurophysiology, Univ. of Oslo, Oslo, Norway.

Reduced synaptic inhibition may play a role in epilepsy by allowing the unrestricted expression of excitatory synaptic events. The epileptogenic agent Na benzyl penicillin has been found to reduce presynaptic inhibition in the spinal cord (Davidoff, Br.Res.,45:638,1972) and certain postsynaptic inhibitions in invertebrates (Wilson & Escueta, Br.Res.,72:168,1974; Hochner et al., Br.Res., 107:85,1976). The aim of the present study was to monitor IPSPs and EPSPs in a cortical pyramidal cell during the transition from a normal to an epileptic state. Intracellular recordings were made from CA1 pyramidal cells in transverse slices of guinea pig hippocampus maintained in vitro. Antidromic stimulation could elicit a pure IPSP, the transmitter of which is thought to be GABA. Subthreshold orthodromic stimulation yielded a mixed EPSP-IPSP, while stronger stimulation evoked a single action potential. Penicillin, applied as a small droplet (ca. 20 nl of 17 mM) near the recording electrode, quickly reduced the size of the IPSP, with recovery by 15-20 min. In parallel the response to suprathreshold orthodromic stimulation changed from a single action potential to a burst of spikes triggered from an underlying depolarizing potential. The membrane input resistance was not changed by penicillin. The IPSP reduction was shown to be due to a partial blockade of the IPSP conductance increase by comparing the voltage-dependent behavior of the IPSP before and after penicillin application. Penicillin also blocked the conductance and potential changes caused by iontophoretic GABA. Thus, penicillin appears to act directly on the pyramidal cell membrane, although it is not known whether the GABA receptor or iontophore is affected. Concurrent with the gradual reduction of the recurrent IPSP by penicillin, the mixed EPSP-IPSP elicited by subthreshold orthodromic stimulation was converted to a progressively larger and prolonged pure depolarizing potential. The initial rising phase of the EPSP was not altered by penicillin. This finding confirms the observation of Gjerstad et al (in Adv Epileptology, Meinardi & Rowan (eds), Swets & Zeitlinger, 1978), and is in accord with their finding that the presynaptic fiber volley and field EPSP are unchanged. Thus the processes underlying EPSP generation appear unaltered by penicillin. The timecourses of IPSP reduction and EPSP growth were similar, and the EPSP showed no further change after the IPSP was maximally inhibited. We conclude that the blockade of inhibition by penicillin may explain the enhanced response to weak orthodromic stimulation. We emphasize, however, that it is still unclear to what extent the removal of somatic inhibition contributes to the generation of intense burst discharges seen with stronger afferent stimulation.

425 ACUTE CARBON MONOXIDE HYPOXIA AND SEIZURES. Robert S. Dyer, Elizabeth Burden*, Karen Hulebak*, Nancy Schultz*, H. Scott Swartzwelder and Zoltan Annau. Neuroscience Prog., Nat'l. Ctr. Toxicol. Res., Jefferson, AR, and Dept. Environ. Health Sciences, Johns Hopkins Univ., Baltimore, MD.

Many attempts have been made to examine the consequences of exposure to various levels of CO hypoxia upon CNS function, yet disagreement still exists regarding appropriate methods for assessing toxicity. In the present report we describe attempts to develop a seizure model for assessing the neurobehavioral response to CO hypoxia. Exposure to CO is monitored according to the gas concentration, but the probable parameter of physiological significance is %HbCO. In the rat, exposure to a constant concentration of CO produces equilibration of HbCO in about 90 min. The %HbCO values for concentrations of 1000, 500, 250 and 0 ppmCO are about 55%,38%,22% and 0%. Rats were exposed to either 1000ppm or 0ppm CO for 2 hr and injected with either 30, 40 or 50 mg/kg pentylenetetrazol. No differences in seizure severity or duration were observed between the exposed and control groups at any dosage. In the second experiment animals were exposed for 2 hr to either 1000, 500 or 0 ppm CO and tested for 6 Hz electroshock responses. Again no differences were observed between exposed and control groups. Finally, animals were implanted with stimulating and recording electrodes in the dorsal hippocampal formation (HPC) and exposed to either 1000, 500, 250 or 0 ppm CO. HPC afterdischarge (AD) properties were studied. CO hypoxia did not significantly change the duration of the AD, nor did it significantly increase the duration of the postictal depression of the EEG. As concentration of CO increased, the spike frequency within the AD and the probability of a rebound AD decreased. Rebound AD's occurred in 100% of the 0ppm, 80% of the 250ppm, 60% of the 500ppm and 0% of the 1000ppm CO groups. The significance of the rebound AD's and their disappearance under hypoxia is not known. It may be pointed out that rebound AD's decrease in frequency with dosages of sodium pentobarbital as low as 10mg/kg. We conclude that the HPC AD model is the most reliable of those tested for studies of CO-induced hypoxia.

426 **ANTICONVULSANT ACTIVITY OF DIPROPYLACETIC ACID AND DIPROPYLACETAMIDE IN THE BABOON PAPIO PAPIO.** **C. L. Ehlers*, L. W. Mulbry* and E. K. Killam* (SPON: C. H. Sawyer). Department of Pharmacology, School of Medicine, UC Davis, Davis, CA 95616.**

The ability of dipropylacetic acid (DPA) and dipropylacetamide (DPM) to modify seizures induced by intermittent light stimulation (ILS) was assessed in 4 female and 3 male Papio papio. Whereas repeated oral doses of 100-200 mg/kg of DPA given over an 8-hr period, which produced blood levels of 19-44 ng/ml were not effective in modifying ILS-induced seizures, repeated doses of DPA (200-300 mg/kg) given over a 32-hr period produced blood levels of 62-372 ng/ml and were highly protective against ILS.

Similar results were obtained following the administration of DPM. Repeated oral doses of 200-400 mg/kg given over an 8-12 hr period produced blood levels of 18-91 ng/ml and caused a mild reduction in seizure activity, whereas repeated doses of 200 mg/kg given over a 36-hr period produced blood levels of 124-137 ng/ml and were completely effective in blocking ILS-induced seizures. Both agents produced a quieting effect upon behavior without severe depression.

Background EEG in response to DPA and DPM showed evidence of a striking increase in relative power in the 10-15 Hz range primarily in the parietal cortex.

427 CHANGES IN RETICULAR FORMATION NEURONAL RESPONSES TO SENSORY STIMULI INDUCED BY STRYCHNINE. C.L. Faingold and J.D. Stittsworth, Jr. Division of Pharmacology, Dept. Medical Sciences, Southern Illinois University, School of Medicine, Springfield, Illinois, 62708

Strychnine administration has been shown to enhance sensory-evoked field potentials in the brainstem reticular formation (RF). Response enhancement in the RF is considerably greater than that seen in primary sensory sites and occurs at a lower dose of strychnine than that which enhances the responses in other non-primary sensory sites (Faingold, Neuropharm. 16:73-81, 1977). This study was undertaken to elucidate the neuronal events associated with this response enhancement in the RF utilizing locally anesthetized, paralyzed cats. The response patterns of RF neurons to auditory, visual or somatosensory stimuli were characterized using poststimulus time histograms. Many neurons which were unresponsive to sensory stimuli before strychnine became responsive to the stimuli after strychnine administration (i.v. 0.025 mg/kg/min). Other neurons which were responsive to the stimuli became more responsive after strychnine administration. However, most of these neurons became temporarily unresponsive at the onset of strychnine-induced 10-20 Hz regular spiking in the EEG of the lower brainstem. At this time many of the neurons began to fire tonically at the same 10-20 Hz frequency. Sensory responsiveness returned and/or was enhanced when the EEG pattern either proceeded to the next stage of strychnine-induced activity (occasional high amplitude brainstem EEG spikes) or if the EEG recovered to normal. The doses of strychnine which produced these effects were considerably less than those which cause seizure generalization. With time, response patterns returned to those observed before drug administration. Strychnine-induced enhancement of the sensory response of RF neurons is quite extensive and very similar to that observed with pentylenetetrazol (Faingold and Caspary, Neuropharm. 16:143-147, 1977). In contrast, previous evidence indicates that these convulsants induce only minimal changes in sensory-evoked field potentials (Faingold, Neuropharm. 16:73-81, 1977) and single unit responses in primary sensory sites (Faingold and Stittsworth, Neurosci. Abs. 3:139, 1977). These data suggest that the enhancement of neuronal responses to sensory stimuli may be a general action of convulsant agents but may be a specific effect on non-primary sensory neurons such as those in the reticular formation.

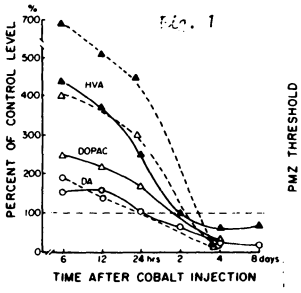
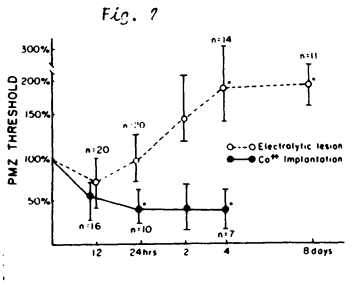
428 *METRAZOL (PMZ) THRESHOLD IN RATS WITH LESIONS OF THE SUBSTANTIA NIGRA (SN).* *R. G. Fariello and O. Hornykiewicz. Depart. of Neurology, University of Wisconsin, Madison, Wis. USA and Clarke Institute of Psychiatry, Toronto, Canada*

Three groups of preselected rats with a stable PMZ threshold for generalized convulsions (less than 20% variation in three tests in different days) were used for the study. Group A was injected with 2µg cobalt HCl in 0.6µl of saline in the left SN. Group B received left nigral electrolytic lesion and group C were sham operated. As we have previously reported (Shibuya et al, Exp. Neurol, 58, 486-499, 1978) such lesions induce changes in DA and metabolite content in the ipsilateral neostriatum. The time course and the magnitude of these changes are illustrated in fig. 1 where the continous line refers to group B and the dotted line to group A. Rats of the three groups were retested for PMZ threshold at various times after surgery. At the end of the experiments they were sacrificed and histologically examined and likewise the subjects that died during the experiments. PMZ threshold in group A and B changed as shown in fig. 2. Cobalt lesioned rats showed a steady decrease in threshold. Electrolytically lesiond rats showed changes in the opposite direction to DA changes in the neostriatum. Group C did not show variations. Cobalt caused a progressive necrotic lesion extending over time beyond the SN, whereas electrolysis induced a small stable lesion of the SN. It is therefore likely that the continous decay of the PMZ threshold in group A is unrelated to DA changes and linked to the epileptogenic action of cobalt on extranigral structures. Results from group B indicate that in rats increase of DA in the neostriatum is associated with decreased resistance to PMZ threshold and vice versa. The change in seizure susceptibility may be linked to the different functional state of the caudate nucleus.





429 CHOLINERGIC MODULATION OF INTERICTAL SPIKING IN KINDLED RATS J. Gregory Fitz* and James O. McNamara. Epilepsy Center, Durham VA Hospital, Duke Univ. Med. Center, Durham, N.C. 27705

Spontaneous interictal spiking (SIS) is the electroencephalographic (EEG) hallmark of epilepsy. Kindling is a recently developed animal model of epilepsy induced by periodic electrical stimulation of the brain. In response to successive stimulations there is a progressive intensification of stimulus induced epileptic activity. This culminates in a fully kindled seizure consisting of rearing, falling, and clonic limb movements. The goal of this study was to determine the role of muscarinic cholinergic synaptic mechanisms in the regulation of SIS in kindled rats.

Multiple depth electrodes were stereotaxically implanted into the brains of male Sprague-Dawley rats. Group I rats received no stimulations, Group II rats were fully kindled, and Group III rats were fully kindled and then treated with drugs known to affect the muscarinic cholinergic system. All kindled rats received hourly stimulations (400 µA, 1 sec duration) until a single fully kindled seizure was elicited. Thereafter, all animals were electroencephalographically monitored for > 1 hour per day for 7 days. A field effect transistor circuit eliminated movement artifact, and permitted quantitation of SIS in awake, unrestrained animals.

SIS was never observed in Group I animals. In Group II animals, SIS developed and declined in a highly reproducible temporal and spatial pattern. The frequency of SIS was maximal prior to completion of kindling, and disappeared 3-4 days after cessation of stimulation. In Group III animals: a) physostigmine (0.3 mg/kg IP) caused a 73% reduction in the frequency of SIS ($p < .01$) whereas saline had no effect; b) atropine (25 mg/kg IP) given to kindled rats with no SIS 7 days after kindling caused a rapid reactivation of SIS ($p < .001$); c) this atropine induced reactivation was reversed by physostigmine ($p < .005$); d) scopolamine (10 mg/kg IP) also reactived SIS, and e) neither atropine, physostigmine, scopolamine, nor saline caused SIS in control rats. Taken together, these results are consistent with the notion that muscarinic cholinergic synaptic transmission is capable of modulating SIS in kindled rats.

439 THE EFFECTS OF OPIATE-ANTAGONISTS ON THE SEIZURE PATTERNS OF AN ANIMAL MODEL OF EPILEPSY. H. Frenk, L. Pauly J. Diaz, and B. Bailey*(SPON: R. J. Schain). Dept. Psychology, Tel Aviv University, Ramat Aviv, Israel, Depts. Psychology, Neurology, Psychiatry, UCLA, Los Angeles, CA 90024.

Strains of the Mongolian gerbil (Meriones unguiculatus) which spontaneously exhibit severe generalized motor seizures have proved to be excellent models of epilepsy. Cortical EEG's recorded during these seizures show continuous hypersynchronous bursting of high amplitude similar to those observed in human grand mal seizures. Conventional anticonvulsants (i.e., phenobarbital, phenytoin) protect the adult gerbil from seizures.

Recent studies of endogenous opiate peptides in the brain have shown that these substances are potent neuromodulators and that alterations in these systems produce bizarre behavior such as prolonged muscular rigidity and catalepsy (Blum, et al, Science, 194, 1976). The findings that these peptides also cause pronounced and sustained epileptic electroencephalographic activity (Frenk,et al, Science, 200, 1978) have led some investigators to speculate that endogenous peptides may play a role in epilepsy. The purpose of the present study is to examine the effects of opiate antagonists upon the seizure behavior of gerbils.

Adult gerbils with reliable seizure behavior were treated with opiate antagonists in four separate experiments: 1) chronic administration of naltrexone, 10 mg/kg; 2) acute treatment with naltrexone, 10 mg/kg; 3) examination of a dose response curve of acute naltrexone injections (0.1, 1, 5, 10, 50 mg/kg); and 4) acute naloxone treatment in conjunction with phenobarbital (20 mg/kg) administration.

At all dose levels examined, neither opiate antagonist affected the intensity of the seizures, the duration of the individual seizures, or the latency for the animal to seize.

These data strongly suggest that endogenous opiate systems do not mediate the seizure phenomena of this model of epilepsy.

431 NEURONAL INTERACTIONS IN EXPERIMENTAL EPILEPTOGENIC FOCI. Richard N. Harner, Otto M. Sgro*, Department of Neurology, Graduate Hospital, University of Pennsylvania, Philadelphia, Pa. 19146

Large, extracellular units are recorded from a linear array of four insulated tungsten microelectrodes (impedance > 10 Megohms at 1 KHz) spaced at 100 micron intervals in the forepaw area of S_1 during 1-2/sec stimulation of the contralateral median nerve before and after topical application of Penicillin (100,000 U./ml) in rats anesthetized with 6 mg/100 g pentobarbital. Prior to penicillin, units had a post-stimulus latency of 6-18 msec. with infrequent and highly variable interactions between units recorded from nearby electrodes. After penicillin, latency and PST histograms showed (1) increased frequency and decreased variability of unit responses, (2) development of "tight connections" at latencies of 0.5-5.5 msec between nearby units and (3) bursts of unit activity at frequencies up to 500 Hz, correlated with the surface cortical potential. Nearby units may be heterogenous with respect to sensory modality, response to electrical stimulation, and burst response to Penicillin. Intensification and development of 3-6 msec interactions between nearby units produced by Penicillin suggests a possible role for long-loop and/or polysynaptic mechanisms in the epileptogenic process.

432 OPERANT CONDITIONING OF 12 - 16 HZ SENSORIMOTOR RHYTHM REDUCES MOTOR SEIZURES MORE THAN PSYCHOMOTOR SEIZURES. William J. Jackson, Arden V. Nelson*, and June O. Kearns*. Depts. of Physiology and Biomedical Engineering, Medical College of Georgia, Augusta, GA. 30901.

Four previously intractable psychomotor epileptics were compared to a group of previously intractable epileptics with focal motor or generalized convulsive disorders following 75 operant training sessions. The patients had learned to increase the density of 12 - 16 Hz activity recorded between Cz and either C3 or C4. All patients showed significant increases in the density of 12 - 16 Hz activity following training, but not all the patients realized improvement in their seizures as a result. Improvement was greater in the group with focal motor and generalized convulsions, with all of these patients showing some improvement in their seizure condition. Improvement included fewer seizures and sometimes less severe seizures. Only one of the four patients with temporal lobe foci showed significant seizure reduction following training, although the improvement in this one patient was substantial. One of the psychomotor patients reported increased numbers of seizures during training.

An additional factor involved the design of the devices which analysed the signal prior to feeding a cue back to the patients. Half of the patients in each of the two diagnostic categories were trained by use of one or the other of two signal analysis techniques. One signal analysis method utilized zero crossing techniques adjusted to trains of 12 - 16 Hz activity. A feedback cue was provided to the patients when at least 5 of the previous 8 zero crossings were within the 12 - 16 Hz band. The other method of signal analysis utilized eliptic filters to separate the 12 - 16 Hz band from the 0.2 - 40 Hz band. A computer then compared the two bands and a feedback cue was provided the patient if the power within the 12 - 16 Hz band was at least 20% of the power within the 0.2 - 40 Hz band for the previous second. Good learning curves were achieved using both devices. Each has its own sets of advantages and disadvantages, but the zero cross system is less expensive. (Supported by NIH-NINCDS Contract No. NO1-NS-6-2340)

433 ANTICONVULSANT ACTIVITY OF DIPROPYLACETIC ACID (DPA) IN EPILEPTIC FOWL. D.D. Johnson, H.L. Davis* and R.D. Crawford*. Depts. of Pharmacol. and Animal & Poultry Science. Univ of Sask. Saskatoon, Sask. Canada S7N 0W0

The seizure process in epileptic fowl is sensitive to the anticonvulsant actions of phenobarbital (Pb), phenytoin (Ph) and primidone (Pr) but not to ethosuximide. With Pb and Ph anticonvulsant activity occurred within the range of plasma concentrations achieved in the control of grand mal seizures in humans. Although Pr itself had anticonvulsant activity, metabolically derived Pb contributed to the anticonvulsant effect. This data indicates that epileptic fowl represent a potential pharmacological model of grand mal epilepsy. To further characterize this model, dose-response studies have been conducted with DPA, an agent whose major clinical value appears to be in absence seizures although it appears to have some efficacy in other epilepsies. DPA in doses of 25, 50, 75, 100 and 125 mg/kg were administered (i.v.) to groups of 8 epileptic chickens using a cross-over experimental design. Seizure susceptibility in response to stroboscopic stimulation was determined 1, 3, 6, 12 and 24 h later and compared to that in a control group treated with saline. At 1 h DPA 125 mg/kg produced complete protection and statistically significant protection occurred with all doses above 25 mg/kg for a 3 h period. No anticonvulsant effect was observed at 6 h. Only a minimal amount of sedation occurred at the highest dose level.

434 TRIMETHADIONE REDUCES POSTSYNAPTIC POTENTIAL AMPLITUDES IN NEURONS OF THE ABDOMINAL GANGLION OF APLYSIA. W.M. King* and N.R. Kreisman (SPON: P.S. Guth). Dept. of Physiology, Tulane U. Sch. Med., New Orleans, LA 70112.

Trimethadione (TMO) is the prototypical anticonvulsant agent effective in suppressing petit mal epilepsy. To gain some insight into its mechanism(s) of action at a cellular level, we have investigated the effects of TMO on synaptic transmission between identified neurons in the abdominal ganglion of Aplysia californica.

Simultaneous intracellular recordings were made from the cholinergic interneuron L10 and two monosynaptically connected follower neurons, L5 and R16, which receive an ipsp and epsp, respectively. We found that TMO (1-10 mM) reduced the amplitudes of both psp's as well as L10's action potential in a dose-dependent manner. In control observations, however, it was noted that activation of an unidentified neuron or set of neurons ("interneuron II") produced effects similar to those of TMO on both L10's action potential and its followers psp's. This observation, coupled with an earlier finding that TMO increases "interneuron II" activity (Kreisman et al. Comp. Biochem. Physiol., in press), implies that the effects of TMO on synaptic transmission from L10 may be the consequence of actions at other sites.

In order to avoid the problem of recruited synaptic input as well as to assay TMO's effect on presynaptic functions, we examined the cholinergic epsp produced in R15 by stimulation of the right connective. A 1 per sec. train of stimuli to the right connective produces an initial depression of epsp size followed by facilitation and post tetanic potentiation (PTP) (Schlapfer et al. Brain Res. 76:267-280, 1974). We found, that TMO (1-10mM) produced a dose-dependent decrease in the size of all epsps of a train without affecting the relative degree of depression, facilitation, or PTP. Simulation of "interneuron II" input to R15 by stimulation of the branchial nerve prior to the train did not alter the amplitude of any of the epsp's in the train, essentially ruling out any influence of "interneuron II". Bath application of acetylcholine (ACh) was conducted in the presence and absence of TMO to test for a possible postsynaptic site of action. TMO in doses up to 10mM had no effect on the depolarization produced in R15 by ACh.

These results are consistent with a presynaptic action of TMO leading to reduced transmitter release. The mechanism of the reduction in transmitter output will be the subject of further investigation. (Supported by grants from NIH NS-12419 and the Schleider Foundation.)

435 COMPUTER-ASSISTED ELECTROMICROPHYSIOLOGY OF THE DEVELOPMENT OF PENICILLIN INDUCED FELINE GENERALIZED EPILEPSY. George Kostopoulos*, Pierre Gloor, Andrea Pellegrini* and Jean Gotman*. Dept.Neuro.& Neurosurg.McGill Univ.MNI, Montréal,Canada H3A 2B4.

In acute preparations of 42 awake, immobilized cats we studied the activity of neurons located in the deep layers of the medial suprasylvian gyrus. The EEG was recorded by the extracellular microelectrode and at the point where it entered the cortex. Recordings lasting 3-5 min were stored on tape in regular intervals during the time in which the cortical response to single medial thalamic volleys was transformed from spindles (initially) to spike wave bursts(SW) (1-2 hours after penicillin administration). Analysis of data included unit-EEG correlations, wave-unit correlations and laminar profiles using a PDP-12 computer. Our results reaffirm the important role of synchronization of neuronal discharges in rhythmical EEG phenomena. Statistically appreciable neuronal excitation was often associated with negative waves of type I spindles (of Spencer and Brookhart, 1961) but very rarely with those of type II spindles. During SW, neuronal excitation coincided with the first part of the large negative-going transient of the "spike" while an increasing inhibition during the "wave" was the most characteristic phemomenon of this form of epilepsy. During either of the above conditions the increased probability of neuronal discharge was associated with transients which connect negative and positive peaks of biphasic surface EEG waves, and especially when the positive wave came first as is more often the case in SW than in spindles.

Observations like the above in conjunction with previous studies from this laboratory provide clues which may explain how thalamocortical volleys responsible for the production of spindles can produce SW under conditions of altered neuronal excitability induced by penicillin.

436 LOCAL CHANGES IN PO_2 INSIDE AND SURROUNDING EPILEPTOGENIC FOCI PRODUCED BY PENICILLIN OR FREEZING. Norman R. Kreisman, Thomas J. Sick* and D. Woodrum Pierson*. Dept. Physiology, Tulane U. Sch. Med., New Orleans, LA 70112.

It is well known that generalized epileptiform activity is accompanied by increases in brain blood flow and oxygen consumption. However, little is known about local changes in these parameters in the vicinity of focal epileptogenic lesions. Local changes in PO_2 were recorded with polarographic microelectrodes from two separate loci in the superficial layers of the bullfrog telencephalon. The first polarographic microelectrode was placed inside the boundaries of the region which was to become the epileptogenic focus and the second was placed 2-3mm adjacent in the same hemisphere or in the homotopic region of the opposite hemisphere. The ECoG was recorded from bipolar electrodes on each hemisphere. After placement of all electrodes focal epileptiform activity was initiated by topical application or microinjection of Na penicillin G. An increase in local PO_2 consistently occurred within seconds in all recorded areas and preceded the onset of ECoG signs of epileptiform activity in the primary focus in 4 of 13 experiments. Paroxysmal ECoG spike onset occurred within 5 min in the treated hemisphere and was associated with phasic decreases in PO_2 which were superimposed upon the initial PO_2 increase. The PO_2 decreases began simultaneously with each interictal discharge but outlasted the discharge by 30-60 sec. As the frequency of interictal discharges increased, the phasic PO_2 dips summated, driving the PO_2 level down toward 0 mm Hg. Similar PO_2 changes were recorded adjacent or homotopic to the focus but the onset of paroxysmal discharges and associated PO_2 decreases were absent or delayed. The onset of paroxysmal discharges in regions adjacent to the focus may have been the result of contamination by diffusion of penicillin. In order to avoid complications of penicillin diffusion, experiments were repeated with epileptiogenic foci produced by focal freezing. An increase in PO_2 was observed in adjacent and homotopic points but epileptiform activity and transient PO_2 dips were confined to the region of the freezing focus.

We interpret the increase in PO_2 to represent an increase in local blood flow, and the superimposed phasic PO_2 decreases to represent increases in O_2 consumption. Further study is required to elucidate the mechanism of the increase in blood flow. This blood flow increase in the "surround" may serve to aid in restricting the epileptogenic focus by preventing accumulation of diffusing metabolites. (Supported by USPHS grant NS 12419.)

437 CORTICO-CAUDATO-THALAMIC INTERACTIONS IN EXPERIMENTAL FOCAL EPILEPSY. John A. Kusske. Div. of Neurological Surg., UCI-Irvine, and VA Hospital, Long Beach, CA 90822

To study the interaction of corticothalamic, corticocaudate and caudatothalamic networks during the propagation of seizures neuronal activity has been recorded from the anterior sigmoid gyrus of cats with a tungsten microelectrode placed 1-2 mm from the site at which 0.03 to 0.05 ml of tungstic acid gel was injected subpially to produce acute recurring model seizures. Two microelectrodes were also placed in the head of the ipsilateral caudate nucleus, the lateral most being positioned in a site somatopically related to the cortical focus; a fourth electrode was placed in the ipsilateral ventral anterior thalamus. Both multineuronal unit activity and slow waves were recorded on magnetic tape; the time course of cortical and subcortical events was studied by transcribing the magnetic tape records on paper by means of a Honeywell Visicorder. Frequency spectra were computed, using a PDP-12 computer, on each channel of data. Initially burst firing patterns and large field potentials were recorded at the focus; these events were followed by field potentials in the thalamus and both caudate sites at latencies appropriate for multi-synaptic transmission. An increase in the rate of unit discharge in the lateral caudate was evident with each burst recorded at the focus; this was not apparent in recordings from the medial caudate. Recurring seizures, with propagation of afterdischarge to all recording sites, characterized the final maturation stage of the models. Frequency spectra derived from the four recording sites demonstrated sequential, progressive involvement at each location. There was spread of afterdischarge from the cortical epileptogenic focus to the thalamus and then to both caudate recording sites; delays ranged from 5-10 sec before there was an increase in the energy levels in the caudate nucleus following thalamic activation; usually there was an abrupt rise at both sites simultaneously. This study suggests that cells in the caudate nucleus which are somatopically related to the cortical focus can be driven by rapidly discharging cells in the seizure focus. Even though cells in lateral caudate are readily activated by hypersynchronous cortical neuronal activity it is apparent, here at least, that thalamic activation must occur before seizure afterdischarge can be recorded in the caudate nucleus.

438 ELEVATED AMINO ACIDS IN AN AUDITORY NUCLEI OF EPILEPTIC RATS. Hugh E. Laird and Ryan J. Huxtable* Depts. Pharmacol and Toxicol. and Pharmacol., Colleges Pharm. and Med., Univ. Ariz., Tucson, AZ 85721

There are several reports associating deficiencies in glutamic acid, γ-aminobutyric acid and taurine with experimental and human epilepsies. Recently, van Gelder (In: Taurine and Neurological Disorders, pg. 387, Raven Press, 1978) has suggested that a loss of taurine accompanied by an alteration in the glutamine/glutamate balance in the brain are causative factors in some types of epilepsy. Brain amino acid analyses in our laboratory on the genetically seizure susceptible rat (GS), indicate that this theory is not a general explanation of the CNS biochemical defect of epilepsy. GS rats show lower thresholds for seizure in the inferior colliculus (IC) than do non-GS rats of the same strain (Laird & Huxtable, Neurosci. Abst. 3:42, 1977), whereas no difference in cortical thresholds were found between the strains.

Table I shows selected and total amino acid concentration in the IC and cortex (C) of GS and non-GS rats. The concentration of the amino acids are uniformly higher in the IC of GS subjects whereas there is no difference in amino acid levels in the C. Also, if amino acid ratios are compared in IC and C of GS and NGS rats there are no differences in ratios between these rat strains in either brain area. These data do not support the suggestion that epileptogenesis is the result of loss of neuronal taurine in conjunction with a derrangement in the glutamine/glutamate balance.

TABLE I

Brain Amino Acid Concentrations (μmoles/gm)

	Inferior Colliculi		Cortex	
	GS (n=12)	NGS (n=10)	GS (n=11)	NGS (n=9)
Tau	2.25(0.45)	1.94(0.07)	5.60(1.05)	5.96(0.87)
Asp	3.49(0.80)	2.94(0.94)	3.56(1.59)	3.61(0.64)
Gln	2.35(0.55)	1.99(0.52)	2.46(0.58)	2.38(0.48)
Glu	6.36(1.41)	5.33(1.56)	11.32(3.90)	10.70(1.80)
Gly	1.57(0.44)	1.33(0.47)	0.70(0.29)	0.70(0.22)
GABA	2.94(1.41)	2.75(1.33)	1.50(0.65)	1.72(0.69)
other amino acids	2.50(0.38)	2.20(0.34)	3.56(0.51)	3.63(0.56)
TOTAL amino acids	21.46(1.83)	18.48(1.55)	28.70(3.38)	28.70(3.23)

439 EFFECTS OF ANESTHETICS AND ANTICONVULSANTS ON THE ACTION OF KAINIC ACID INFUSED INTO THE RAT HIPPOCAMPUS. Mark F. Nelson, Robert Zaczek* and Joseph T. Coyle. Dept. Pharmacology, Johns Hopkins Univ. Sch. Med., Baltimore, MD 21205

The injection of 2 µg of the potent excitatory neurotoxin, kainic acid (KA) (Coyle and Schwarcz, Nature 263:244, 1976), into the hippocampus causes degeneration of the intrinsic neurons while sparing cholinergic and adrenergic afferents. During the 4-6 hrs. after injection, the rats exhibit epileptiform behavior with dystonic posturing (DYS), hyperactivity (HA) and generalized convulsions (CNV). The effects of various anesthetics and anticonvulsants on the behavioral and neurotoxic actions of a threshold dose of KA (0.5 µg) injected into the hippocampus were examined.

After anesthesia with Equithesin [EQ; 40 mg/kg pentobarbital (PB) plus 200 mg/kg chloral hydrate (CH)] rats exhibited DYS and HA; 4 days after the injection glutamate decarboxylase specific activity (GAD-A) was reduced to 80% of control. After ether anesthesia, rats displayed DYS, HA and CNV, and GAD-A was reduced significantly further to 65%. Similarly, treatment with the short-acting anesthetic, hexobarbital, potentiated the epileptiform behavior and the neurotoxic action of KA. In contrast, 6 hr. anesthesia with EQ prevented the appearance of DYS, HA and CNV upon awakening and significantly limited the fall in GAD-A to 90%. Anesthesia with PB alone (65 mg/kg) provided some protection while CH alone (400 mg/kg) was ineffective against KA. Pretreatment of ether-anesthetized animals with the anticonvulsants diazepam (10 mg/kg), phenobarbital (50 mg/kg), phenytoin (50 mg/kg), or carbamazepine (75 mg/kg) attenuated the epileptiform behavior and reduced the fall in GAD-A as compared to rats anesthetized with ether alone.

The protective effect of non-sedative anticonvulsants and the lack of such an effect with CH suggests that sedation is not the fundamental factor altering the action of KA. Rather, the ability of drugs to limit neuronal excitation is more likely the primary mechanism. Hippocampal kainate injection may offer an animal model for temporal lobe epilepsy. (Supported by USPHS Grants NS 13584, RSDA KO2-MH 00125, The McKnight Foundation and a Pharmaceutical Manufacturer's Association Fellowship).

440 INTRINSIC NEURONAL MEMBRANE ABNORMALITIES IN HUMAN EPILEPTIC FOCI AS INFERRED FROM EFFECTS OF FOCAL COOLING. George A. Ojemann, William H. Calvin and Arthur A. Ward, Jr. Dept. of Neurological Surgery, University of Washington, Seattle, WA 98195

Focal cortical cooling has been used as a technique for studying neuronal membrane abnormalities in animal models of epilepsy (Reynolds, Ojemann & Ward, Exp. Neurol. 46:583, 1975). Compared to normal cortex, intracellular recordings from bursting neurons in epileptic foci demonstrate a more rapid rate of action potential (AP) widening with cooling, and a tendency to decreased bursting (normal cortical neurons become burstier with cooling). The rate of widening of the rising and falling phases of the AP with cooling differed in the alumina and penicillin models of epilepsy. In the penicillin model, the rising phase widens more rapidly than the falling; the alumina model shows the reverse. These data were interpreted as suggesting different neuronal membrane changes in the two models: abnormalities of passive Na+ exchange and Na-K pumping in the penicillin focus; altered K+ flux (and accelerated pumping) in the alumina focus.

The present study is directed at determining whether either of these models fits human epileptic foci. Although intracellular recording during cooling in man is not presently feasible, extracellular microelectrode recordings can be obtained from human epileptic foci in patients undergoing craniotomy and cortical resection (Calvin, Ojemann & Ward, EEG 34:337, 1973). The changes in bursting and AP width in units that can be followed through a cooling cycle are likely to be independent of geometric changes that might interfere with extracellular recordings. These were obtained with tungsten microelectrodes; focal cooling to temperatures of 26°-30°C was accomplished through a silver footplate attached to a heat pipe; temperature was monitored by a thermistor advanced in parallel with the microelectrode.

Recordings during cooling of bursting neurons in human epileptic foci have been obtained from seven patients at the time of writing this abstract. These neurons show the tendency to decreased bursting with cooling characteristic of the epileptic models rather than normal cortex. But the average rate of AP widening has been close to that of neurons in normal cat cortex. Most commonly, the falling phase of the AP has widened substantially more rapidly than the rising phase similar to neurons in alumina foci, and qualitatively different from neurons in penicillin foci. This finding suggests that intrinsic neuronal membrane abnormalities in human epileptic foci are qualitatively similar to those of the alumina focus, modelled as involving alteration in K+ flux.

441 POSSIBLE STRUCTURAL CORRELATES OF SPONTANEOUS SEIZURES IN MONGOLIAN GERBILS. L. Paul* I. Fried*, K. Watanabe*, J. Diaz, and A. B. Scheibel. Depts. of Psychology, Neurology, Psychiatry and Anatomy, UCLA, Los Angeles, CA 90024.

The Mongolian gerbil (Meriones unguiculatus) has been proposed as a model for the epilepsies (Loskota, et al, Epilepsia, 15, 1974) and strains of seizing and non-seizing gerbils have been established by several laboratories. Structural changes in the hippocampus of human temporal lobe patients have been reported (Scheibel, et al, Epilepsia, 15, 1974) and putative changes in hippocampal structures in kindled rats are presently under investigation in our laboratory. Following our experience in these areas, Golgi studies were performed on perfused and immersion-fixed brains of adult gerbils with known seizure histories.

Although our studies must be considered preliminary, several types of changes present in the actively seizing group seem worthy of description. 1) Mossy tufts of dentate granule cell axons appear enlarged in size and increased in number, most obviously at the transitional zone between CA3 and CA4. The tufts in non-seizing animals ranged in size from 2 to 7 micra, while those in seizure-prone gerbils were as large as 11 micra. 2) In many animals, the parent axons showed frequent beading. 3) Hippocampal pyramids in CA3 showed swelling of the cell body and proximal segment of the apical dendrite with patchy or even complete spine loss of many basilar shafts.

Selected electron microscopy studies are currently underway in our laboratory to confirm these changes.

442 INCREASED SEIZURE SUSCEPTIBILITY IN ADULT MICE FOLLOWING NEONATAL TREATMENT WITH GLUTAMATE OR ASPARTATE. William J. Pizzi, June E. Barnhart* and James R. Unnerstall*. Neuropsychology Lab, Northeastern Illinois Univ., Chicago, Il. 60625

Neonatal administration of the amino acids glutamate (GLU) and aspartate (ASP) has been shown to be neurotoxic in a variety of mammals. This report presents data demonstrating that neonatal administration of GLU and ASP can produce adult mice that have an increased susceptibility to pentylenetetrazol (PTZ) induced seizures. Evidence is presented to show that these seizures are of greater intensity than those seen in controls and are independent of the characteristic obesity seen in GLU- and ASP-treated animals.

Neonatal mice were given subcutaneous doses of GLU, ASP or bacteriostatic saline from days 2-11 after birth according to a dose schedule which started at 2.2 mg/g b.w. and increased to 4.4 mg/g b.w. by the last day of injection. The dose of PTZ which induced seizures in 50% (CD_{50}) of the species of mouse (Ha:ICR) used in this study was determined on a population of normal controls. GLU- and ASP-treated mice were challenged at various stages during development with the CD_{50} of PTZ.

Obese GLU-treated males and females ($p < 0.001$) showed an enhanced susceptibility to PTZ ($p < 0.01$, chi square). An analysis of the severity of seizures showed that both male and female GLU-treated groups experienced seizures that were more severe ($p < 0.002$, Mann-Whitney U). A second group of GLU-treated mice were allowed to become obese and then reduced in weight to within 11% of a control group before being challenged by PTZ. These animals demonstrated the same pattern of behavior with both GLU-treated males and females showing increased seizure susceptibility ($p < 0.01$ & $p < 0.02$ respectively, chi square), and increased severity of seizures ($p < 0.002$, Mann-Whitney U). A third experiment was conducted on GLU-treated and ASP-treated mice just prior to their becoming obese (equated weights). Again, these animals showed greater seizure susceptibility ($p < 0.05$ GLU-treated, chi square; $p < 0.002$ ASP-treated Binomial test), and seizures were of greater severity than controls ($p < 0.02$ GLU-males and $p < 0.002$ GLU-females, Mann-Whitney U). All probability values are two-tailed.

Whether this preparation will serve as a useful model of convulsive disorders will most likely depend upon the elucidation of the particular mechanism underlying the lowered seizure threshold. The mechanism is far from clear and could involve any of the following: a) permanent disruption of the blood-brain barrier; b) endocrine dysfunction; c) impairment of GABA synthesis; d) neurodevelopmental abnormalities; e) lowered metabolic efficiency.

443 CONVULSANT ACTION OF HYPOGLYCEMIA: CORTICAL DISINHIBITION. W. Raabe. Dept. Neurol., VA Hospital, Minneapolis, Minn. 55417.

Hypoglycemia is a well known cause of convulsions. However, the detailed mechanism of the convulsant action of hypoglycemia is not clear. Since neurons derive their energy supply solely from oxygen and glucose, it was a surprise to find that hypoglycemia produced a neuronal dysfunction, e.g. seizures, at a time when the overall energy state in the CNS was normal. Since hypoglycemia increases cerebral ammonia concentrations prior to convulsions, it was suggested that the effects of ammonia, abolition of postsynaptic inhibition, initiate hypoglycemic convulsions.

The effects of insulin-induced hypoglycemia (IIH) and i.v. ammonium-acetate (AA) on cortical postsynaptic inhibition and cerebral ammonia-concentration were studied. Pentobarbital anesthetized and artificially respirated cats were used. Extracellular recordings were obtained from pyramidal tract cells. Cortical postsynaptic inhibition was measured as the efficacy of recurrent postsynaptic inhibition of pyramidal tract cells to suppress antidromic action potentials of pyramidal tract cells. As soon as the efficacy of inhibition was abolished the widely exposed cortical hemispheres were frozen with liquid nitrogen. Cerebral ammonia concentrations were determined with the Conway microdiffusion method.

IIH (100 I.U. insulin/kg i.p. or i.v.) abolished action potential suppression by cortical postsynaptic inhibition as the first sign of neuronal toxicity. This disinhibition occurred at blood glucose levels of 47-54 mg% and cerebral ammonia concentrations of 416± 75 S.E. nmol/gm wet weight. Although cerebral ammonia-concentrations during IIH-induced disinhibition were slightly increased when compared to values obtained from sham animals (284± 55 S.E. nmol/gm) the difference was statistically not significant. Intravenous infusion of AA (1.1-2.8 mmol/kg) abolished action potential suppression by cortical postsynaptic inhibition at cerebral ammonia-concentrations about three times higher (742± 80 S.E. nmol/gm) than in sham-operated animals.

IIH abolishes the efficacy of cortical postsynaptic inhibition like ammonia does. The effect of IIH occurs independent of IIH-induced increases of cerebral ammonia concentrations. IIH-induced cortical disinhibition occurs at blood glucose levels known to produce preconvulsive changes in the EEG. Cortical disinhibition may account for the convulsant action of hypoglycemia.

444 SEIZURE ACTIVITY OF ANTIBODIES TO G_{M1} GANGLIOSIDE PURIFIED BY AFFINITY CHROMATOGRAPHY. Maurice M. Rapport, Sahebarao P. Mahadik, and Stephen E. Karpiak. Div. Neurosci., N. Y. State Psychiatric Inst. and Depts. Biochem. and Psychiat., Columbia Univ. Coll. Phys. & Surg., New York, N. Y. 10032.

We have previously shown[1] that a single intracortical injection of antiserum against total brain ganglioside into the sensorimotor cortex of rats will induce recurrent epileptiform seizure activity lasting as long as several weeks. The specificity of the antibody was established by showing that removal of anti-G_{M1} ganglioside antibodies by absorption of the antiserum with small quantities of pure G_{M1} ganglioside eliminated the biological activity. However, in view of the variability in both titer and avidity of antibodies in individual antisera, the reproducibility of the reagent can only be assured by demonstrating the effectiveness of pure antibodies. Very highly purified antibodies to G_{M1} ganglioside were prepared from two different antisera by affinity chromatography on G_{M1}-containing gels[2]. Intracortical injection into the sensorimotor cortex of 6.5 and 6.8 µg, respectively, of protein purified by affinity chromatography from these two antisera resulted in the onset of epileptiform discharges within 1 to 5 hrs. With native antisera, induced discharges were not seen earlier than 24 hours after injection. Intensity of response with purified antibody was greater than with antiserum judging by the increase in spike amplitude and discharge frequency. No convulsions were seen. We also observed that unilateral injection of purified antibody into the ventral hippocampus through a bipolar electrode cannula induced epileptiform activity within 30 min. Discharges were sustained (3 to 5/sec) and lasted for the duration of the experiment (6 to 8 hrs). Injection of antiganglioside serum into an identical preparation usually was followed by the following sequence over a 5 to 6 hr. period: depression of EEG activity, return to normal EEG patterns, then infrequent discharges of low amplitude and low frequency. It is concluded that pure anti-G_{M1} antibody is able to induce seizure activity without participation of other exogenous substances present in the antiserum and should be a reproducible agent. The fact that it is more reactive than antiserum suggests that there are factors in serum that inhibit the epileptiform activity of the anti-G_{M1} ganglioside antibody. Supported by NIH Grant NS-13762.

445 ALTERED PHOSPHORYLATION OF CORTICAL MEMBRANE PROTEINS AFTER ECS. M. V. Reddy*, Y. H. Ehrlich, L. G. Davis, J. Daugherty* and E. G. Brunngraber. Mo. Inst. of Psychiatry, Univ. of Mo.-Columbia, St. Louis, Mo. 63139.

Seizure activity has been often related to changes in the levels of cAMP in the brain. Previous findings in our laboratory have indicated that such changes are accompanied by alterations in the phosphorylation of specific membrane-bound proteins, presumably of synaptic origin (Brain Research Bull. in-press). In the present study, the effects of electroconvulsive shock (ECS) on this enzymatic activity have been investigated. Rats (120-140 gms) were sacrificed by body immersion in liquid N_2 during the tonic (9-11 sec after the shock) and clonic (28-32 sec) phases of electroshock-induced convulsions and after recovery (2 min and 4 min). Controls were fitted with the same ear-clip electrodes but were not shocked. Membrane fractions were prepared from the cortices of frozen rats as described (Pharm. Biochem. Behav. 6: 169, 1977). Endogenous phosphorylation reactions were carried out by incubating the membranes for 10 sec with gamma-^{32}P-ATP (Neurochem. Res. 2: 533, 1977) and the reactions were stopped by solubilizing the membranes in a detergent (1% SDS). Incorporation of radioactive phosphate from ATP into specific protein components was determined by autoradiography of reaction products separated electrophoretically in gradient (7-18%) polyacrylamide gel-slabs. Over twenty specific protein bands that incorporate radioactive phosphate under these assay conditions were identified in the preparations. Of these, the phosphorylation of one group of bands, designated H (MW 15-20K) demonstrated temporal relationships with the treatment. Compared to the above controls, phosphate incorporation into H increased in membranes from shocked rats, peaked at the clonic phase and then gradually decreased. Examination of cytosol fractions from the same animals did not reveal such time-dependent changes. The possibility that phosphorylation of membrane-bound proteins is involved in mechanisms underlying seizure activity will be discussed. Supported in part by a grant from the Epilepsy Foundation of America and by intramural funds from the Missouri Institute of Psychiatry.

446 AMYGDALOID KINDLING AND CENTRAL ENZYME ACTIVITY. D. Peter Reedy*, Edith G. McGeer, William A. Staines*, and Michael E. Corcoran. Division of Neurological Sciences, University of British Columbia, Vancouver, Canada.

Intermittent application of localized electrical stimulation to the amygdala or certain other areas of brain results in the development of generalized convulsive seizures (kindling). In an attempt to identify possible neurochemical correlates of kindling, we measured the regional activity of neurotransmitter-synthetic enzymes in the brains of amygdaloid-kindled rats and of yoked control rats that either received nonepileptic low-frequency stimulation of the amygdala or carried amygdaloid electrodes and were handled but not stimulated. In addition to measuring the activity of enzymes involved in the synthesis of GABA, glutamate, acetylcholine, catecholamines, and taurine, we also measured the regional high-affinity uptake of glutamate in kindled and control rats. All rats were killed 24 hours after the fifth fully generalized seizure in the kindled group.

The results were negative: There were no changes in enzyme activity or glutamate uptake that were reliably related to amygdaloid kindling. The mechanisms underlying the lasting increase in seizure susceptibility produced by kindling thus may not be expressed at the levels of enzyme activity or uptake of glutamate.

447 HISTOPATHOLOGY OF FERRIC-INDUCED EPILEPTOGENIC FOCI: A GOLGI SURVEY IN CATS. S.A. Reid*, W.M. Boggs*, G.W. Sypert and L.J. Willmore. (SPON: F.A. King). Dept. of Neuroscience, Univ. of Fla. Coll. of Med., Gainesville, FL 32610

Domestic cats were rendered epileptic via sub-pial injection of 20 microliters of saturated ferric choloride ($FeCl_3$) solution into the regions of either the left sigmoid or marginal gyri. Serial EEG's, recorded from a permanent montage of bone screw electrodes, confirmed the development of focal epileptiform activity which continued unabated until the animals were sacrificed six months later. Brain tissue was prepared for histopathological evaluation using the tungstate modification of the Golgi-Cox method. The cortical region exposed to $FeCl_3$ was compared to the homotopic contralateral cortex. Changes noted in the $FeCl_3$ exposed cortex include: 1) striking neuronal depopulation; 2) a relative increase in astrocytic forms; 3) segments of poor impregnation; 4) reduction of dendritic branching; 5) dendritic nodulation and swelling; and 6) marked loss of dendritic spines. These pathological changes are similar to those observed in human epileptic foci obtained at neurosurgery. Hence, this study suggests that sub-pial injection of ferric chloride solution in cats may be an accurate model of human focal epilepsy. (Supported by VA Hospital Medical Research Service.)

448 GABAergic AXON TERMINALS DECREASE AT EXPERIMENTAL SEIZURE FOCI IN MONKEY CEREBRAL CORTEX. C. E. Ribak, A. B. Harris, L. Anderson*, J. E. Vaughn and E. Roberts. Division of Neurosciences, City of Hope National Medical Center, Duarte, CA 91010 and Department of Neurological Surgery, University of Washington, Seattle, WA 98195.

Using an immunocytochemical method for the localization of the GABA synthesizing enzyme, GAD, GABAergic nerve terminals were found to be distributed homogeneously in all layers of normal monkey sensorimotor cortex. This distribution in the neocortices of both Macaca mulatta and M. fascicularis was similar to that previously described in rat neocortex where GAD-positive terminals arising from aspinous and sparsely-spinous stellate neurons made symmetric synapses with all cortical somata and formed extensive pericellular plexuses with the somata of pyramidal neurons in layers III and V. GAD-containing axon terminals in monkey neocortex also formed symmetric synapses with somata and dendrites suggesting that they arise from the same types of stellate neurons.

In order to determine if GABAergic neurons are altered at seizure foci, specimens were obtained from the sensorimotor cortex of five monkeys made epileptic by either intracortical injections or subarachnoid applications of alumina gel. EEG tracings from these monkeys were normal initially, but changed as epilepsy developed. Electrocorticography verified epileptic foci prior to fixation. Frozen sections of the specimens were incubated in GAD immunocytochemical reagents and examined by light microscopy. At low magnification, sections at sites of alumina gel (A) displayed a staining intensity for GAD which was lower than both (B) ipsilateral sections further away from the alumina gel and (C) control sections from contralateral homotopic cortex. Sections from these sites (A, B and C) taken from each of the subjects were examined at high magnification, and the numbers of GAD-positive terminals were counted in 38 contiguous 100 μm^2 areas from the bottom of layer VI to the middle of layer V. The mean numbers of GAD-positive terminals per 100 μm^2 for sites A, B and C were 5.8, 11.4 and 16.7, respectively. An analysis of variance and a comparison of means by the Newman-Keuls method showed that the differences among these mean values were all highly significant ($P<.01$). These results indicate a numerical decrease in GABAergic axon terminals at sites of seizure foci (A and B), and this decrease may be due to a selective loss of GABAergic, cortical neurons. Such a loss of GABAergic inhibition at seizure foci could be responsible for the observed epileptic activity.

449 EFFECT OF PHENYTOIN ON THE ACTION POTENTIAL OF A NEURON IN THE LAMPREY SPINAL CORD. Michael E. Selzer. Dept. Neurol., Sch. Med., University of Pennsylvania, Philadelphia, PA 19104.

Dorsal cells are primary sensory neurons within the spinal cord of lampreys. They receive no synaptic input and are easily impaled under direct microscopic vision. Conventional techniques were used to stimulate these cells through intracellular microelectrodes, and record their resting membrane potentials and action potentials in various bathing solutions. The action potentials were abolished in 10^{-7}M tetrodotoxin and greatly reduced or eliminated by replacing Na^+ with choline. Removal of Ca^{++} and addition of 1mM Mn^{++} did not reduce the action potential. Thus the action potential of dorsal cells is generated by increased Na^+ conductance. A total of 146 dorsal cells were studied in normal lamprey solution (N = 45), in phenytoin (PTN) 20 uM/ml (N = 60) or in washout (N = 41). PTN did not significantly affect the average resting membrane potential (50.9 mV) or the input resistance (21.9 megohms). It did reduce the maximum rate of rise of the spike (from 110.7 to 50.6 V/sec.), the spike overshoot (from 40.9 to 29.5 mV), and the spike undershoot (from 15.8 to 12.3 mV). PTN increased the spike width, and both the current and voltage thresholds for spike initiation. Most of these changes were at least partially reversible, although both the drug effect and the washout effect were usually not maximal after more than 1 hour of perfusion.

The results are best explained by the hypothesis that PTN partially blocks the sodium conductance increase of the dorsal cell action potential. The long delay in onset cannot be explained by diffusion time from the bath to extracellular space, and suggests the possibility that PTN requires diffusion into the cell or partitioning into the membrane for its effect.

450 CEREBROSPINAL FLUID AND REGIONAL BRAIN KINETICS OF γ-HYDROXYBUTYRATE. Jack S. Shumate* and O. Carter Snead. Dept. of pediatrics and Medicine, USAF Med Ctr., Keesler AFB, Ms 39534.

Gamma hydroxybutyrate (GHB) is a naturally occurring metabolite of gamma-amino butyric acid (GABA) which possesses the ability to precipitate profound electroencephalographic (EEG) and behavioral changes in animals. These changes closely resemble human petit mal epilepsy and can be aborted by anticonvulsant drugs used specifically for these types of seizures (Godschalk et al, Neurosci. Lett. 3:145, 1975). The present study was undertaken to ascertain the time relation between the administration of an epileptogenic dose of GHB and its appearance in spinal fluid, plasma and specific areas of brain. In addition, the relationship of these kinetics to the EEG and behavioral effects of the drug were studied. GHB was administered to dogs intravenously in varying dosages with continuous EEG and temperature monitoring. Dosages of GHB in excess of 500 mg/kg produced ataxia, stupor and myoclonic jerks with occasional spiking and paroxysmal slow waves on the EEG. In addition there was a mild hypothermia produced by the GHB. These changes were evident within 15 to 20 minutes of administration. Single pulsed doses of 500 mg/kg of GHB sodium in an aqueous solution were then administered to dogs intravenously and timed serum, CSF, and brain samples obtained for determination of GHB concentration. Regional brain distribution of GHB was determined 60 minutes after the pulse dose. All assays for GHB were done by a modification of the gas liquid chromatographic method of van der Pol et al (J. Biopharmacokinet. Biopharm. 3:99, 1975). Brain and plasma concentration of GHB peaked within ten minutes of administration at 120 mcg/gm and 3000 mcg/ml respectively. The CSF concentration of GHB peaked at 180 minutes post infusion at 170 mcg/ml. The highest concentration of GHB at 60 minutes post infusion was in the white matter of temporal lobe at 100 mcg/gm. The amount of GHB in the frontal and temporal lobes exceeded that in thalamus, cerebellum, caudate and pons. These results demonstrate that the behavioral and EEG effects produced by GHB can be correlated with the concentration of this substance in brain as well as plasma. Further an active uptake of GHB into brain with subsequent passive diffusion into spinal fluid is suggested by our data. Finally, the low concentration of GHB in subcortical structures suggest that these areas are inordinately sensitive to GHB, since the GHB-induced EEG changes have their origins in subcortical areas (Snead et al, Neurology 26:51, 1976).

451 HIPPOCAMPAL AFTERDISCHARGES AND SODIUM PENTOBARBITAL. H. Scott Swartzwelder and Robert S. Dyer. Psych. Dept. American Univ., Washington, D.C. and Neuroscience Prog. Nat'l.Ctr. Toxicol. Res., Jefferson, AR.

Because of its apparent sensitivity to a variety of toxicants, the hippocampal formation (HPC) is a potentially useful structure for studies of neurotoxicity. In work reported at this meeting this year and last year we have characterized some of the normal properties of afterdischarges (AD's) elicited by stimulation of the HPC of the rat, and shown how these properties are altered by exposure to toxicants. The present experiment was performed to provide a standard of comparison for previous and future studies. Sodium pentobarbital (SP) was used because of its well known effects upon the central nervous system. The influence of various dosages of SP upon the ictal and postictal manifestations of HPC AD's was explored. Twelve hooded male rats were implanted with bipolar stimulating and recording electrodes in the dorsal HPC. AD thresholds were determined by a method similar to that described by Pinel (1972), and the properties of the threshold AD were measured. Testing occurred on alternate days. On test days the animals were injected, 30 min before testing, with either 0,10, 20 or 30 mg/kg SP. Each animal received each concentration once, but the order of presentation was counterbalanced across animals. At 10 mg/kg there was a small decline in AD duration, and a decreased incidence of rebound AD's. At 20 mg/kg there was an increase in threshold for producing an AD, a large drop in the number of AD's followed by a rebound AD, and a further decline in AD duration. At 30 mg/kg the threshold increased further and the spike rate during the AD declined significantly. Using the Pinel method of threshold determination instead of the Racine method increases the probability that threshold AD's will not be followed by depression of electrical activity. About 90% of threshold AD's determined by the Racine method are followed by depressions. In this study only 50% of threshold AD's determined by the Pinel method were followed by a depression at the 0 mg/kg dosage, and this incidence was reduced further to less than 10% at the 20 mg/kg dosage. These results provide a profile of the effects of a CNS depressant upon AD activity. The most sensitive measures of AD activity in this study were AD duration and incidence of rebound AD's.

452 POSTICTAL EXCITABILITY AND POSTICTAL DEPRESSION IN THE HIPPOCAMPAL FORMATION. Steven T. Wegner*, H. Scott Swartzwelder, Craig T. Johnson*, and Robert S. Dyer. Towson State Univ., Baltimore, Md. and NCTR., Jefferson, ARK. (SPON: ZOLTAN ANNAU)

Afterdischarge (AD) and postictal depression (PID) resulting from electrical stimulations of the hippocampal formation (HPC) depend upon the properties of the eliciting stimulus. Stimulation at 400% of threshold produced short ADs and long PIDs compared to those elicited by stimulation at 115% of threshold. It is not yet known to what extent the PID of the HPC EEG is an accurate reflection of depressed HPC excitability. If PID duration accurately reflects depressed excitability then high intensity stimulation should be followed by a longer period of inexcitability than low intensity stimulation. On the other hand, if depression of excitability is better reflected by duration of the AD, then low intensity stimulation should be followed by a longer period of inexcitability than high intensity stimulation. The purpose of the present experiment was to determine the excitability of the HPC after an AD and it's relationship to AD and PID duration. Male hooded rats were each implanted with a bipolar electrode for stimulation and recording in the right dorsal HPC. Animals were then divided into 3 groups, matched according to their threshold values. Two days later ADs were induced at stimulus intensities of 115% threshold for group 1, 200% for group 2, and 800% for for group 3. Postictal excitability was assessed by introducing a stimulus 115% of threshold within 2 sec of AD termination, and once every 30 sec thereafter until a second AD was elicited. As expected, high intensity stimulation produced short AD durations and long PID durations. Animals receiving high intensity stimulation also required fewer postictal stimulations to elicit a second AD than did animals receiving low intensity stimulation. These results indicate that the duration of the PID following HPC AD is not positively correlated with the time it takes for a subsequent near threshold stimulus to elicit an AD. The significance of the postictal EEG flattening for HPC electrical excitability therefore remains to be determined.

453 ALTERED PROTEIN SYNTHESIS WITHIN A RECURRENT SEIZURE FOCUS IN THE ALBINO RAT. L.J. Willmore, A.J. Dunn, J.J. Rubin*, and G.W. Sypert, VA Hospital and Departments of Neurology, Neuroscience and Div. of Neurosurgery, Univ. of Fla. Coll. of Med., Gainesville, FL 32610

Intracortical injection of microliter quantities of isotonic ferrous or ferric chloride into rat sensorimotor isocortex will induce a focus of recurrent seizure discharge. Electroencephalographic recordings with platinum needle electrodes confirm the presence of an active epileptiform discharge in experimental animals. Histological assessment after transcardiac perfusion with neutral buffered formalin shows an epileptic cortical focus containing a meningocerebral cicatrix, neuronal ferrugination and astroglial proliferation accompanied by moderate neuronal loss.

Six groups of 10 each of 200-300 gm albino rats were prepared with a single 5 ul injection of 100mM ferric chloride. Each of 5 animals from each group was injected with [^{3}H]lysine, 1 uCi/g body weight. At 30 minutes the brain was removed and a 3mm core was punched perpendicular to the pial surface at the site of focal epileptiform discharge, from the contralateral homotopic cortex and from the cerebellum. Tissue processed for liquid scintillation counting showed increased total uptake of [^{3}H] in the actively discharging epileptic focus, but the relative incorporation of [^{3}H]lysine into protein was decreased. Animals not developing epileptiform discharge showed diminished uptake of [^{3}H] without alteration in relative incorporation of [^{3}H]lysine into protein compared to control.

We propose that active epileptiform discharge results in alterations in either blood-brain barrier and/or focal blood flow while inhibiting cellular protein synthesis. Altered uptake of [^{3}H] in the developing or inactive epileptic focus and remaining brain may indicate a generalized change in uptake of amino acids during the process of epileptogenesis in the rat isocortex. (Supported by VA Hospital Medical Research Service.)

454 MEDIAL FOREBRAIN BUNDLE LESIONS PROLONG AMYGDALAR AFTERDISCHARGE WITHOUT CHANGING THE ONSET OF BEHAVIORAL SEIZURES IN THE KINDLED RAT. W.C. Wooten*, J.E. Walker*, and I.L. Crawford. Southwestern Regional VA Epilepsy Ctr. and Univ. Texas Health Sci. Ctr. at Dallas, TX. 75235

Brief, daily electrical stimulation of the amygdala develops sequential stages of epileptiform activity that progresses from partial complex seizures to generalized convulsions. The kindling effect occurs concomitant with trans-synaptic changes in electrophysiological responsiveness, yet it has not been determined whether kindling is dependent on specific pathways and neurotransmitters. We studied the effects of directly reducing forebrain monoamine levels on amygdaloid kindling by making electrolytic lesions in the posterior medial forebrain bundle (MFB).

The left MFB was lesioned (5 mA, 10s) and bipolar electrodes were implanted in the ipsilateral basolateral amygdala of albino male rats. Control rats were implanted with electrodes but were not lesioned. After 5 days recovery the rats were stimulated once daily (400 μA, 1s, 60 Hz). Afterdischarge, a proposed electrophysiologic index of the kindling process, was recorded from the stimulation electrodes in each rat. The maximal seizure stage of kindling, characterized by the onset of a bisymmetrical clonic-tonic motor convulsion, was attained by day 7 ($\pm$ 0.3 days, SEM) in the non-lesioned rats. A similar number of days (7.8 $\pm$ 0.5) were required to develop fully expressed seizures in lesioned animals; however, stereotypical seizure behavior was attenuated, particularly in its early stages of development. 24 hrs after the third maximal seizure, tissues from the frontal cortex, hippocampus, and caudate-putamen were sampled on the lesioned and unlesioned sides of each rat brain. Norepinephrine, dopamine, and serotonin were assayed by a fluorometric method. The concentration of dopamine was significantly less ($p < .001$, N=8) on the lesioned side (756 $\pm$ 158 ng/g/wet wt) compared to the contralateral side (7540 $\pm$ 610 ng/g). Norepinephrine and serotonin levels were reduced 25% to 40% and 40% to 60%, respectively in tissues from the lesioned side. The average duration of afterdischarge was significantly ($p < 0.02$) longer for rats with MFB lesions (49.5 $\pm$ 4.5s) than for non-lesioned control animals (28.8 $\pm$ 3.2s).

The data supports the concept that monoamines influence the duration of afterdischarge. Our results also suggest that the temporal sequence and behavioral expression of kindled amygdaloid seizures are independent of intact monoamine pathways in the medial forebrain bundle. Reduction of forebrain monoamines levels may dissociate electrophysiological events from kindled seizure behavior. (Supported by a grant from the Epilepsy Foundation of America and by the VA Medical Research Service).

EVOKED POTENTIALS AND EEG

455 EVOKED POTENTIAL CORRELATES OF CONCEPTUAL TEMPO IN ADOLESCENCE.[1] Ernest S. Barratt, James H. White*, and Perrie M. Adams. Dept.of Psychiatry and Behavioral Sciences, Univ. of Texas Medical Branch, Galveston, Texas 77550

Performance on the Matching Familiar Figures Test (MFFT) was used to assess the conceptual tempo of adolescent males and females between the ages of 13 and 16. Those subjects scoring at the low end of the distribution (N=33) were classified as reflective (low error/long latency ratio). Those scoring at the high end of the distribution (N=28) were classified as impulsive (high error/short latency ratio). Those subjects in the middle of the distribution of ratios were classified as moderates (N=14). Auditory evoked potentials recorded from the vertex were found to be significantly lower in amplitude for the N100 and N100-P180 components for the reflective subjects. In addition, the reflective subjects demonstrated a significantly greater tendency to show a reduction in the P100-N140 component of the visual evoked potential across increasing flash intensity. The impulsive subjects showed a tendency to augment (increase in amplitude) across intensity levels. These findings were taken as further evidence in support of a hypothesized difference in central nervous system processes as the basis for the observed range in conceptual tempo.

[1]This research was supported in part by a Grant from the Office of Naval Research, Physiology Branch.

456 IDENTIFICATION OF VOLUME-CONDUCTED EARLY EVOKED POTENTIALS IN THE SOMATOSENSORY SYSTEM OF CAT. Philip C. Bechtel* and Robert J. Sclabassi. Biomedical Engineering Program, Carnegie-Mellon University, and Department of Neurological Surgery, University of Pittsburgh, Pittsburgh, PA 15213.

Early volume-conducted (far-field) evoked potentials have been observed in the somatosensory system of the rat, cat and human. Ambiguities have existed in identifying these components and their origins. This study demonstrates the components (some not previously reported) and clarifies their origins in the cat.

Evoked EEG activity was recorded at multiple cranial epidural locations using screw electrodes and selected points along the neuraxis using needle electrodes. All were referenced to a frontal screw. Filter bandpass was 1-3000 Hz (-3 dB). Using a photoelectric stimulus isolation unit, constant current impulses (width .1 msec) were applied directly to the exposed sciatic nerve unilaterally via platinum electrodes. Computer-generated stimuli were randomly produced (mean rate 2 per sec, minimum interstimulus interval 100 msec). Each stimulus epoch lasted 60 sec with 4 to 8 epochs per run. Averaged evoked potentials were computed using cross-correlation techniques.

Selective enhancement of the early components was achieved by variation of recording electrode positions along the neuraxis. The earliest component occurred at 1.5 msec and disappeared with section of the sciatic nerve proximal to the point of stimulation. The second component appeared at 3.5 msec; it was removed by section of the nerve both above and below the stimulation site. Lesions of the somatosensory system at higher levels were also performed and their effects on the form and latency of subsequent components were evaluated.

The initial primary negative displacement in the cortical somatosensory evoked potential in cat appears to be a resultant complex produced by the distributed volume-conducted components. Further, these results establish a basis for evaluating the functional and anatomical interaction of the somatosensory system. While subserving a localizing capability, they provide an objective view of this system as a continuum from the periphery to the cortex.

457 INCENTIVE-RELATED CORTICAL UNIT ACTIVITY DURING THE M-WAVE AND CNV. E. H. Boyd, E. S. Boyd and L. E. Brown*. Dept. of Pharmacology and Toxicology, University of Rochester, School of Medicine and Dentistry, Rochester, NY 14642.

When squirrel monkeys (Saimiri sciureus) have learned that two tone cues (a warning cue followed in 1 sec by an imperative cue) signal the availability of a food reward if they bar-press within 1 sec, a short latency (150-200 msec to peak), short duration surface-negative waveform, the M-wave, develops in post-arcuate and post-central cortex following the cues (Boyd et al., EEG Clin. Neurophysiol. 42: 341, 355, 364, 1977), as well as a longer latency, surface-negative potential, sustained during the interstimulus interval. Since this sustained potential resembles the contingent negative variation (CNV) evoked in humans and in rhesus monkeys performing in a similar paradigm, it has been called a CNV (Boyd et al., submitted for publication). In the squirrel monkey, both the M-wave and the CNV reflect the conditioned, positive incentive value of the cues. Investigation of the activity of single cortical neurons in relation to the M-wave, the CNV, and the behavioral paradigm, compared to activity during a baseline period, has revealed at least six categories of units (Boyd and Boyd, Fed. Proc. 37: 617, 1978). We report here that the changes in activity of some, but not all, cortical neurons whose activity changes during the M-wave or CNV, reflect, like the M-wave and CNV, the conditioned, positive incentive value of the cues, in that 1) these changes were greater for trials in which the monkey responded correctly, and was rewarded, than for trials in which the monkey failed to respond; 2) they were greater for trials early in the session than for trials late in the session, after the monkey had consumed a number of pellets; and 3) they were greater when the food reward was of a more preferred flavor than when the reward was of a less preferred flavor. (Supported in part by USPHS BRSG, to the University of Rochester.)

458 NEUROMAGNETIC SEGREGATION OF FUNCTIONALLY DIFFERENT NEURAL POPULATIONS IN THE HUMAN VISUAL CORTEX. D. Brenner, L. Kaufman*, S.J. Williamson*. Neuromagnetism Lab., Dept. of Physics and Psychology, N.Y.U., N.Y., N.Y. 10003.

Magnetic fields associated with current flow in the human visual cortex were measured at various positions on the scalp with a high resolution superconducting detector. Spatio-temporal mapping of the steady-state visually evoked field revealed the existance of at least two populations of cells that respond differently to grating stimuli. Because of the detectors high resolution, the two populations can be studied separately merely by repositioning the probe.

Responses from the two areas were studied as a function of the spatial and temporal frequencies of the grating as well as the area of retinal stimulation.

Comparisons with evoked potentials have been made.

459 EFFECTIVENESS OF THE WIENER FILTERING METHOD OF IMPROVING EVOKED POTENTIAL ESTIMATION. E. Carlton* and S. Katz. Medical University of South Carolina, Charleston, South Carolina 29403.

Two recursive and two a posteriori Wiener filters were applied to somatic evoked potentials from monkeys anesthetized with N_2O (70%) delivered by face mask. Sterile stainless steel electrodes were aseptically inserted into the skull overlying the cortical forelimb and hindlimb projection areas. A reference electrode was placed in the nasal bone. Bipolar stimulating electrodes were placed on the skin over the median or radial nerves in the forelimb and the peroneal or posterior tibial nerves in the hindlimb. Square wave pulses having a duration of 0.1 - 0.3 msec were routinely delivered at a frequency ranging from one every 3-5 sec. The cortical evoked responses produced by stimulation of the peripheral nerves were amplified, filtered (0.1 - 500 Hz), and recorded on analog tape for subsequent playback and analysis on a LSI-11 computer.

Effectiveness of the Wiener filtering method of improving evoked potential estimation was ascertained by comparing filtered and unfiltered averages of the same and greater numbers of sweeps. The different filters were found to be effective in different ways. Both a posteriori filters gave smoother averages in fewer sweeps than produced by unfiltered averaging. However, high frequency transient components were suppressed by both a posteriori filters. The recursive filters had opposite effects from each other. One enhanced all components present in the unfiltered averages, while the other produced flat averages. Components not yet apparent in unfiltered averages were clearly delineated in averages produced from the same number of sweeps by one method of recursive Wiener filtering. The recursive Wiener filter which emphasized evoked potential components may be particularly useful in distinguishing evoked potentials produced under different experimental conditions.

460 FUNCTIONAL POWER SERIES ANALYSIS OF VISUAL EVOKED EEG SUGGESTS PARALLEL LINEAR AND NONLINEAR PATHWAYS. Richard Coppola*. (SPON: S.A. Cohen), *Biological Psychiatry Branch, NIMH, Bethesda, MD20014*

Visual evoked potentials (VEP) are clearly nonlinear in nature since in many cases a sine wave modulated light stimulus produces its major EEG response at twice the frequency of stimulation. It has previously been shown that nonlinear analysis may be applied to the human VEP by collecting VEPs to white noise modulated light (Trimble, Neurosci. Abstracts, 2:241, 1976). In that study, no significant contribution to the VEP from kernels higher than second order was noted.

In the present study an attempt is made to elucidate the mechanisms contributing to transient and steady state VEPs. EEG in response to three types of visual stimulation was recorded in a group of normal volunteers: 1) white noise modulated light (WNML) 2) sine wave modulated light (SML) in one Hz steps from 1 to 20 Hz and 3) half second light flashes at several intensities. Functional power series analysis was performed on the WNML data to yield first and second order Wiener kernels, i.e., the linear and nonlinear kernels. Frequency response characteristics for the SML EEG were obtained by spectrum analysis. The response amplitude at the fundamental and first harmonic were plotted versus stimulation frequency. Because in some cases the harmonic response is larger than the fundamental a single frequency response characteristic is not possible. Having obtained the system kernels, the prediction of the system response to any temporally modulated light signal is possible. In this case, the linear and nonlinear kernels give the fundamental and harmonic response. The frequency characteristics computed in this way agree favorably with the spectrum analysis of the SML data. The complete predicted response also agrees favorably with the actual steady state VEP (SSEP). Using this method of analysis the variation in wave shape of the SSEP is seen to be a function of the differential gain and latency of the linear and nonlinear parts. The kernels may also be used to predict the transient visual response (averaged VEP). The different responses seen to increasing intensities of stimulation seem to be related to the different gains of the linear and nonlinear components of the response revealed by this type of analysis.

Although the addition of the linear and nonlinear parts is intrinsic to the form of the functional power series, the comparison to actual responses in terms of wave shape suggests that parallel linear and nonlinear pathways might exist in the visual system and that a combination of the potentials due to each pathway may account for the variation in frequency and intensity response seen in VEPs.

461 CONTRIBUTION OF THE SPEECH MUSCULATURE TO APPARENT HUMAN EEG ASYMMETRIES PRIOR TO VOCALISATION. Merlin W. Donald and Barry H. Brooker. Queen's University, Kingston, Ontario, Canada.

The origins of slow surface EEG asymmetries preceding speech have remained unresolved because of conflicting claims regarding the importance of myogenic artifact at the electrode sites commonly used in these studies. This study reports an attempt to quantify the contribution of the major muscles involved in articulation to the EEG electrode sites used in previous speech potential studies. The procedures used by previous studies claiming slow wave asymmetries of neural origin were replicated. Twenty-eight female, right-handed college students served as subjects. The first experiment replicated the procedures and analysis of McAdam and Whitaker (Science, 1971; 172: 499-502), involving bilateral scalp recordings over inferior frontal and other relevant scalp loci. Tongue glossokinetic activity was recorded at the cheek. Off-line backward averages were triggered by the subjects' self-paced vocalisations (voice key). The second experiment was a more extensive study of the relationships between various parts of the speech musculature and averaged inferior frontal slow potentials. The design included repetitive, as well as variable vocal responses, under both language and non-language conditions. Temporalis, masseter, obicularis and myelohyoid muscles, as well as tongue movement activity, were monitored and averaged along with the anterior scalp sites.

Results

Three different procedures were used in quantifying the slow potential amplitudes, each indexing a different point in time prior to vocalisation. Averaged glossokinetic potentials were significantly correlated with the inferior frontal slow potentials but not with the vertex (C_z) recordings. Other muscles involved in articulation also showed significant correlations with averaged inferior frontal steady-potential shifts, depending on their timing relative to vocalisation.

Significant left-right differences between some of the speech and non-speech conditions did occur at inferior frontal electrode sites, confirming in principle previous claims, of EEG hemispheric asymmetries related to speech. However, these effects were reduced to statistical non-significance by analysis of covariance using the averaged muscle potentials as covariates. Since the muscle averages far exceeded in amplitude the inferior frontal averages, it appears likely that the apparent EEG asymmetries were myogenic in origin, suggesting that previous reports of EEG asymmetries preceding speech reflected a combination of several myogenic confounds.

462 FAR-FIELD POTENTIALS FROM TRIGEMINAL NERVE STIMULATION. Michael Feely*and Chi-ming Huang* (SPON: Susan Hoppe), Depts. of Neurosurgery and Physiology, Col. of Medicine, Univ. of South Alabama, Mobile, AL 36688.

Electrical stimulation of the infraorbital nerve in the cat resulted in a series of minute evoked potentials at the vertex detectable by computer averaging. The waveform of these potentials is similar to the auditory brainstem evoked response and the somatosensory far-field response; i.e., it is multicomponent, the amplitudes are of the order of 0.5 μV, the latencies are within 8 msec. The anatomical origins of these evoked potentials were first investigated by mapping with bipolar electrodes in the brainstem area near the trigeminal complex. Surgical lesions in the trigeminal afferent pathway were also attempted. Results indicated that: (1) The primary generator loci of the far-field potentials were within the trigeminal complex with main contribution coming from the spinal trigeminal and the principal nucleus. (2) The earliest electrical activity detectable in the thalamus had a latency of >10 msec. (3) These potentials were not affected by flaxedil. However, myogenic potentials were recordable at a latency of 7-10 msec but were abolished following administration of flaxedil. It was concluded that the multi-component far-field potential in this study was due to neural activity generated by the brainstem trigeminal structures. The relevance to clinical studies in trigeminal neuralgia will be discussed.

463 EEG CORRELATES OF "COGNITIVE" ACTIVITIES

A.S. Gevins, G.M. Zeitlin*, J.C. Doyle*, R.E. Schaffer*, C.D. Yingling, and F.C. Callaway. EEG Systems Lab, UCSF Sch. Med., San Francisco, CA 94143

As a prerequisite to possible clinical use of the EEG for the assessment of subtle patterns of cortical dysfunction, two studies were conducted. Study 1 used a battery of relatively complex sensory - "cognitive" - motor tasks. Study 2 employed simpler tasks without overt continuous motor activity, and controlled for gross sensory and task-load related differences.

In Study 1, 23 subjects performed two to three 1 min replications of reading (RE), writing from memory (WR), Koh's block design (KB), mental paper folding (FO), fixation on a spot (FO), eyes closed (EC), and several control tasks. In Study 2, thirty subjects (21 were retained based on behavioral analyses) each performed thirty 5-15 sec replications of mental rotation of block structures (BR), serial addition of a column of decimal digits (AR), substitution of letters with subsequent word recognition (LE), and fixation on a spot (EO).

In each study EEGs from F4, F3, C4, C3, P4, P3, O2 and O1 were Fourier-analyzed, and measures based on estimation of spectral intensity in the theta, alpha, $beta_1$ and $beta_2$ bands were retained.

Pattern recognition was performed using a nonlinear, two-layered algorithm.

Task-to-task discrimination, strong in Study 1, was weak in Study 2 (Table I), suggesting that sensory-motor and arousal-related factors can be more prominent in EEG signals than factors relevant to the "cognitive" processes under study.

Other conclusions which followed from these studies were: (1) When decreased arousal can be ruled out, increased theta band spectral intensity, accompanied by decreased alpha and beta band intensity, may reasonably be associated with use of an underlying cortical region; (2) changes in alpha band spectral intensity are less important in distinguishing complex tasks; and (3) intertask differences in patterns reflecting asymmetry were smaller than in other topographically-organized patterns.

464 TRANSIENT NEURONAL DYSFUNCTION FOLLOWING MECHANICAL HEAD INJURY IN CATS EVALUATED WITH EVOKED POTENTIALS.

Richard P. Greenberg, Marti S. Hyatt* and Donald P. Becker. Div. of Neurosurg., Medical College of Virginia, Richmond, VA 23298.

In an animal model of head trauma based on the fluid percussion mechanical brain injury model of Rinder and Olsson (Acta Neuropath. 11:183-200, 1968), multimodality evoked potentials were recorded to evaluate cortical and brainstem function immediately after brain injury and serially thereafter. Detailed physiological and pathological correlates of pressure transients from 0.4 - 5.0 ATM have been made in this model and found to be reproducible. Injury forces between 1.5 and 2.5 ATM consistently produce the appearance of coma in the cat for up to 16 hours, thereafter the animals recover without detectable physiological or pathological evidence of brain injury. Above 2.5 ATM the neurological and pathological findings increase directly with the magnitude of injury force.

Visual, auditory and somatosensory cortical and brainstem responses, multimodality evoked potentials (Greenberg et al. J. Neurosurg. 47:150-177, 1977) were recorded in cats (respiratory function was controlled and B/P, ICP and EEG monitored) within minutes after impact and continuously for 3 hours after injury forces from 1.7 - 4.1 ATM. Animals receiving mild injury, < 2.0 ATM, demonstrated transient loss of cortical function. Above 2.0 ATM both cortical and brainstem evoked potentials were transiently absent. The EEG although abnormal was present throughout the period of evoked potential recording. Time to recovery of the evoked potentials following impact increased directly with the magnitude of peak pressure. At 2.0 ATM cortical and brainstem potentials returned to 50% of baseline by 40 minutes after injury. At injury forces of 3.0 ATM or greater neither somatosensory nor auditory brainstem potentials recovered by 3 hours. However, visual evoked potentials did recover within 1 hour of impact at 3.0 ATM or more. Overall the somatosensory evoked potential was most sensitive to mechanical brain injury recovering more slowly than either the visual or auditory evoked potentials.

The appearance of coma following 1.7 - 2.0 ATM injuries coincided with cortical dysfunction as the brainstem evoked potentials were unchanged from baseline. (Supported in part by NIH grant NS 12587 and a Southern Medical Association Training Grant).

465 RECOVERY CYCLES OF SCALP-RECORDED EVENT-RELATED POTENTIALS FOLLOWING HEMI-RETINAL STIMULATION.

Richard L. Horst* and Emanuel Donchin. Dept. of Psych., Univ. of Ill., Champaign, Ill. 61820.

Checkerboards flashed to the upper hemi-retina elicit event-related potentials (ERPs) which, over the first 75-200 msec, are composed of several components differing in latency, polarity, and scalp distribution. Moreover, the same stimulus flashed to the lower hemi-retina elicits ERPs in which the components are opposite in polarity and, in some cases, different in scalp distribution from corresponding components in the upper hemi-retina ERP. Jeffreys and Axford (Exp. Brain Res., 1972, 16:22-40) have attributed these ERP differences to activity occurring in the different areas of visual cortex to which the upper and lower hemi-retina are known to project.

If checkerboards presented to upper and lower hemi-retina engage different neuronal populations, then two successively presented checkerboards should interact more if presented to the same rather than to different hemi-retinas. Thus measuring the "recovery cycle" of the ERP elicited by the second of two hemi-retinal checkerboards can serve to test Jeffrey's formulation. Furthermore, a determination of the extent to which the three distinct ERP components within a given hemi-retinal ERP show different recovery cycles, will help in assessing the functional significance of these components.

Checkerboard patterns, 25 msec in duration and subtending 3^0 x 6^0 of visual angle, were tachistoscopically presented, with no overall luminance change, to either the upper or lower hemi-retina. Each of the possible stimulus pairs -- upper-upper, upper-lower, lower-upper, and lower-lower -- was presented at 8 inter-stimulus-intervals (ISIs) ranging from 50 to 800 msec. Single stimuli were also presented to either the upper or lower hemi-retina. On each trial, subjects reported whether a single stimulus, a pair of "same" hemi-retinal stimuli, or a pair of "different" hemi-retinal stimuli had occurred. EEG was recorded from 7 evenly spaced mid-line electrodes, each referred to the linked earlobes.

The data indicate that the ERP elicited by a checkerboard presented to a hemi-retina is largely unaffected by the preceding presentation of a checkerboard to the other hemi-retina. However, the amplitude of this ERP is quite depressed if the same hemi-retina has been stimulated prior to its presentation, the amount of amplitude depression depending on the time interval between the two stimuli. Moreover, the recovery of the various components within a given hemi-retinal ERP occurred at different rates with increasing ISIs. These data are consistent with the suggestion that the components both within and between hemi-retinal ERPs are manifestations of distinct brain processes.

466 THE COMPARATIVE EFFECT OF ISCHEMIA ON CAT VISUAL, AUDITORY AND SOMATOSENSORY CORTICAL AND BRAINSTEM EVOKED POTENTIALS.

Marti S. Hyatt,* Miles L. Saunders,* Richard P. Greenberg, and Donald P. Becker. Div. of Neurosurg., Medical College of Virginia, Richmond, VA 23298.

Observations on the behavior of individual evoked potential modalities either visual, somatosensory or auditory in response to brain ischemia have been reported by others. Some of these authors found a progressive loss of amplitude and waveform as well as a delay of latency of the evoked potentials with increasing degrees of ischemia (Chang. J. Neurophys. 13:305-318, 1950; Meldrum et al. Brain Res. 13:101-118, 1969, etc.). Others noted an ischemic threshold above which the evoked potential remains unchanged while below this level the evoked potential rapidly disappears (Branston et al. Exp. Neurol. 45:195-208, 1974). A comparative study of the behavior and sensitivity of the visual, auditory and somatosensory cortical and brainstem evoked potentials following progressive ischemia has not been reported. Therefore, we recorded multimodality evoked potentials in cats subjected to stepwise decreases of systemic blood pressure and measured the ICP, CPP and CBF to evaluate the comparative response of each evoked potential modality to the ischemic insult. An assessment of the relative sensitivity of the cortex and brainstem to ischemia was also made with evoked potentials.

An aortic reservoir was utilized for controlled stepwise decreases in systemic blood pressure. Each animal had respiratory function controlled and its ICP, CPP, EEG and CBF (hydrogen clearance technique) measured throughout the experiment.

Somatosensory cortical and brainstem potentials were the most sensitive of the modalities to ischemia, progressively declining and finally disappearing at a mean CPP of 45 mmHg and CBF of 24 ml/100 g/min. The sequential nature of the waveform deterioration was similar for all modalities and progressed from afterwaves to primary complex with increasing levels of ischemia. Auditory cortical and brainstem potentials were the most resistent to ischemia often peristing at a CPP of 30 mmHg, a level at which both visual and somatosensory potentials had disappeared. (Supported in part by NIH grant NS 12587 and a Southern Medical Association Training Grant).

467 TEMPERATURE INDEPENDENT ALTERATION OF BRAINSTEM AUDITORY EVOKED RESPONSES BY ENFLURANE. Timothy A. Jones, James J. Stockard, and Kenneth R. Henry. Dept. Animal Physiol. UCD, Davis CA 95616

Temperature profoundly alters latencies of far field recorded brainstem auditory evoked responses (BAERs)[1]. Few drugs (if any), have been shown to have temperature independent influences on the latencies of BAERs. Enflurane (2-chloro-1,1,2-trifuoroethyl difluoromethyl ether) was found in the present study to have potent influences on BAERs in contrast to other general anesthetics, anticonvulsants, and tranquilizers tested to date.

Cats were anesthetized with and equilibrated at enflurane concentrations producing relatively flat background EEG tracings accompanied by large amplitude spike-wave paroxysms. Tympanic, esophageal, and rectal temperatures were monitored and strictly controlled in order to assess the temperature independent effects of enflurane. The same animals were curarized (awake) and stabilized at normal (38.6 to 38.9°C depending on animal) and reduced (37.5 to 37.6°C) temperatures. End tidal CO_2 concentrations were maintained between 4 and 5%.

Enflurane produced latency shifts (slowing) in positive peaks II through V($p<.001$), with the largest changes occurring in later waves. In addition, enflurane reduced the amplitude of waves PIII, PIV and PV relative to PII ($p<.001$). In curarized animals, reducing temperatures to 37.6°C was sufficient to produce latency shifts approaching those induced by enflurane alone, however, no decrease in relative amplitudes accompanied the shift. This latter finding may prove useful in distinguishing enflurane and temperature effects.

Many drugs modify systemic temperatures through central and/or peripheral actions and, therefore, will influence BAER latencies indirectly by that means. To our knowledge, this is the first evidence for the existence of a drug which is capable of altering BAER latencies through means other than hypothermia.

468 EFFECTS OF SPINAL CORD LESIONS ON SOMATIC EVOKED POTENTIALS ALTERED BY INTERACTIONS BETWEEN AFFERENT INPUTS. S. Katz, H.F. Martin, J.G. Blackburn*, R. Simpson*, and E. Carlton*. Medical University of South Carolina, Charleston, South Carolina 29403

In cats anesthetized with alpha-chloralose, somatic evoked potentials (SEP) were recorded in response to electrical stimulation of surgically isolated peripheral nerves. Selected surgical lesions were made at T_9-L_1 spinal cord and were histologically verified. Two stimulus magnitudes were used to activate peripheral nerves, one only exciting the large fibers and another exciting the small fibers as well.

Control SEPs were recorded in response to stimulation of both large and small fibers of the radial nerve. The later components (latencies greater than 40 msec) of this SEP are suppressed when evoked 100 msec after application of a conditioning stimulus (CS) to the large fibers of either peroneal nerve. Evidence indicates this interaction occurs supraspinally. Bilateral transection of the dorsal columns and spinocervical tracts eliminates these effects. Increasing the CS intensity to include small diameter fibers again resulted in reduction of the later components of the SEP. This interaction was largely eliminated if the transection was extended to include mid-lateral cord tracts.

These results suggest that the SEP can be influenced by small fiber afferent activity conducted in mid-ventrolateral spinal cord in the absence of the dorsal columns and spinocervical tracts. Alterations in the forelimb-evoked SEP by a conditioning hindlimb stimulus is a sensitive indicator of spinal cord integrity. This method may be used to assess whether low spinal injury spares ventrolateral columns.

469 EVOKED POTENTIAL INDICES OF HABITUATION AND GENERALIZATION. Andrea L. Megela and Timothy J. Teyler. Sect. Neurobiol. Behav., Cornell Univ., Ithaca, N.Y. 14853 and Neurobiol. Div., Northeast. Ohio Univ. Col. Med., Rootstown, Ohio 44272.

This study was designed to investigate whether scalp-recorded evoked potentials exhibit habituation and generalization, forms of neural plasticity related to behavioral learning.

Auditory and visual evoked potentials were recorded in a habituation/generalization paradigm from left hemisphere frontal, temporal and occipital scalp placements in 26 normal, right-handed adults. Stimuli were either loud and soft tones or bright and dim flashes of light. These stimuli were presented in series of repetitive (habituation) stimuli of one intensity which were interrupted in random, unpredictable positions by test (generalization) stimuli of another intensity. Evoked potential averaging was performed on a stimulus-by-stimulus basis across series. Changes in the amplitudes and latencies of the N1P2 and P2N2 components across the repetitive stimuli were examined according to the defined operational criteria of habituation (response decrement as a result of repetitive stimulation) and generalization (similarity of responses to test and repetitive stimuli). Direction and degree of intensity generalization of habituation were analyzed according to the differential predictions made by the dual-process and stimulus comparator models of habituation.

Auditory evoked potentials showed decreases in amplitudes and latencies in response to both loud and soft repetitive stimuli at all three electrode sites, but most consistently at the temporal. Visual evoked potentials exhibited decrements in response to repetitive bright and dim light flashes at frontal and temporal sites but not at the occipital. Both auditory and visual evoked potentials habituated in response to repetitive stimuli in a manner consistent with the operational definition of habituation. These results indicate that evoked potentials can be used as electrophysiological indices of learning in humans.

For both modalities of stimulation, intensity generalization of habituation occurred in the manner predicted by the dual-process theory of habituation: Less intense generalization stimuli evoked less response recovery above the habituated level than more intense generalization stimuli.

470 PERIPHERAL VERSUS CENTRAL PROCESSES AS REFLECTED BY AUDITORY EVOKED FREQUENCY FOLLOWING AND BRAINSTEM RESPONSES. T. Mendelson*, J. Gardi*, A. Ortiz* and A. Salamy (SPON: N. Peterson). Brain-Behavior Research Center and Letterman Army Medical Center, Sonoma State Hospital, Eldridge, CA 95431

Developmental studies of the brainstem auditory click-evoked response (BSER) in humans have shown that the P1 (VIII nerve) component attains adult latency within a few weeks of birth, whereas P5, believed to represent summated activity from the region of the inferior colliculus, does not mature until after the first year. The differential rates of maturation have been presumed to reflect separate peripheral and central processes (EEG clin. Neurophysiol. 40:418, 1976). The tone-evoked frequency following response (FFR) has been investigated in efforts to provide frequency-specific information on auditory function. Recent findings by Gardi (manuscript in preparation) have suggested that the FFR is generated primarily by the cochlea and cochlear nucleus and is mediated along the apical regions of the basilar membrane; thus it reflects peripheral activity. In this investigation FFRs were recorded from 22 neonates and 10 normal-hearing adults in an attempt to assess the level of maturity of peripheral structures in the neonate. FFRs were recorded to 10 msec duration tones of 250, 500 and 1000 Hz presented monaurally at levels ranging from 65dB HL downward to threshold. Electroencephalic activity was recorded from vertex to ipsilateral ear and summated on line. Responses were evaluated to determine amplitude, waveform configuration and threshold. Easily identifiable FFRs were obtained from all subjects at 65 dB HL. Neonatal responses were similar in configuration to those of the adults; responses at 250 and 500 Hz were of greater amplitude than those at 1000 Hz. Neonates typically gave responses which were somewhat smaller in amplitude and approximately 15 dB higher in threshold than those of adults. In both groups, response amplitude decreased as a function of stimulus intensity. The recording of essentially mature FFRs from neonates confirms that peripheral mechanisms in audition are highly developed at birth. This supplements the contention that the developmental trend witnessed for P5 of the BSER must represent a process which is not primarily peripheral.

471 ELECTROPHYSIOLOGICAL PREDICTORS OF THE ROTATIONAL DIRECTION IN RATS. Michael S. Myslobodsky, Yehuda Shavit* and Jeffrey Rosen* Psychobiol. Res. Unit, Dept. Psychol., Tel-Aviv Univ., Ramat-Aviv, Israel.

A general principle of the rotational behavior states that normal rats or animals with lesions in the nigrostriatal dopamine (DA) system circle away from the more active side of the brain. An increase in DA content was found to correlate with the side contralateral to the preferred direction (Life Sci. 18: 889, 1976). The present study was designed to compare bilaterally recorded secondary components of the visual evoked potentials (i.e. slow negative wave, sensory afterdischarge) and Metrazol-induced wave-spike afterdischarges with rotational side preference as assessed in the rotometer. 80% of naive undrugged rats displayed reliable interhemispheric asymmetry of the secondary components of the visual evoked potetials. The unilateral facilitation of these components was associated with corresponding unilateral synchronization of the EEG which displayed a 40% increase in the duration of spindles in the 6-8 Hz frequency band. The rats with reliably asymmetric EEG and evoked potentials showed rotation after intraperitoneal amphetamine (1.5 mg/kg) administration in the direction opposite to the side with more suppressed electrocortical activity. Electrocortical asymmetry was emphasized and sometimes reversed after subconvulsive (10-20 mg/kg) and convulsive (20-40 mg/kg) intraperitoneal Metrazol (1% solution) injections which transformed sensory afterdischarges into wave-spike complexes. With the convulsive dose of Metrazol the asymmetry of wave-spike discharges was observed during the recovery phase after a generalized electrographic fit. Administration of amphetamine on the background of the Metrazol effect elicited the rotational behavior in the direction away from the hemisphere with more suppressed wave-spike activity. A decrease of the synchronized and hypersynchronized electrocortical (evoked and spontaneous) activity over the hemisphere opposite to the preferred rotational side is believed to reflect the higher DA content in the more active nigra. These findings will be discussed with respect to the DA nigrostriatal participation in the control of seizure activity.

472 AMPHETAMINE-INDUCED ALTERATIONS OF EVENT-RELATED SLOW POTENTIALS IN THE RAT ARE DEPENDENT ON DOSE AND CORTICAL AREA. James H. Pirch. Department of Pharmacology and Therapeutics, Texas Tech University School of Medicine, Lubbock, Texas 79409.

Amphetamine alters event-related slow potentials recorded from the rat cortex in response to a warning stimulus which is always followed by food reinforcement (Pharmacol. Res. Comm. 9: 669, 1977; Pharmacol. Biochem. Behav. 6: 697, 1977). The present experiments were conducted to investigate the effect of d-amphetamine on slow potentials (SPs) associated with operant performance. Two seconds after the onset of a 20 msec auditory warning stimulus a retractable lever began to move into the chamber. Once the lever was activated (1.9 sec after extension was initiated) the rat had 2 sec to press for a food pellet. The lever was inactivated and retracted either at the end of this 2-sec period or after a lever press. Cortical slow potentials were recorded by means of d.c. amplifiers and permanently implanted silver-silver chloride electrodes in contact with the brain or dura via agar-saline pools. In some rats an "active" surface electrode was located 2-3 mm anterior to the bregma and 2-3 mm lateral to midline while a "reference" was placed 2-3 mm anterior to the parietal-interparietal suture and 3 mm lateral to midline (A-P recordings). In others, surface electrodes were located at the same anterior and posterior sites while a depth electrode (1-1.5 mm below surface) was placed approximately 1.5 mm lateral to each surface electrode, thereby allowing surface-to-depth recording (S-D recordings). After conditioning, the warning stimulus elicited negative SPs in the A-P recordings and surface-negative SPs in the anterior and posterior S-D recordings. Posterior S-D SPs were generally smaller than anterior S-D SPs. SPs were averaged with a computer and peak amplitudes (μV) and areas (μV sec) were obtained from control and drug sessions (40 trials per session presented at variable intervals of 18-70 sec). Amphetamine (0.25 to 1.0 mg/kg) caused a dose-related depression of SP amplitudes and areas in A-P and anterior S-D recordings. Peak amplitudes of posterior S-D SPs were slightly depressed. However, the areas of posterior S-D SPs were enhanced by some doses during the same time that anterior S-D SPs were markedly depressed. These results show that the effects of amphetamine on cortical event-related slow potentials in the rat depend upon dose, cortical area and method of analysis. Amphetamine and other drugs may prove useful in the elucidation of mechanisms of generation of event-related slow potentials. (Supported by USPHS MH29653 and by the Tarbox Parkinson's Disease Institute at Texas Tech University School of Medicine.)

473 SELECTIVITY OF ATTENTION TO MULTI-FEATURE GRATINGS: EVOKED POTENTIAL AND BEHAVIORAL MEASURES. Fred H. Previc,* M. Russell Harter,* and V. L. Towle* (SPON: R. G. Eason). University of North Carolina, Greensboro, N. C. 27412.

The mechanisms underlying selective attention to four gratings, varying in spatial frequency (0.83 vs 3.33 c/d) and orientation (vertical vs horizontal), were explored using visual evoked potentials (VEPs). The problem investigated was whether the facilitory effects of attention on VEP amplitude to gratings of varying spatial frequency and orientation will be specific to 1) those gratings with either feature identical to those of the attended grating (feature-specific attention), or 2) only that grating identical to the attended grating (pattern-specific attention). The four gratings were stroboscopically presented sequentially (about 1/780 msec) in random order. Selective attention was manipulated by requiring the subject to give an RT response to one of the four gratings. The results indicated that the specificity of the facilitory effects of attention depended on which point in time after stimulation the VEP amplitude was measured. Between 175 and 225 msec post-stimulus, the facilitory effect occurred when the flashed grating had either feature in common with the attended grating (feature-specific attention). After 225 msec post-stimulus, the facilitory effect occurred primarily when the flashed grating had both features in common with the attended grating--that is, was identical to the attended grating (pattern-specific attention). The behavioral measure of attention (median latency of less than 375 msec) also reflected a pattern-specific attention effect and was most related to the effects of attention on VEP amplitude measured at 375 msec post stimulus. Both the VEP and behavioral RT measures indicated facilitation was greater when the flashed grating had the same spatial frequency, as compared to same orientation, as the attended grating. These results were related to information processing and neurophysiological models of spatial vision.

474 LINGUISTIC PERFORMANCE IN THE CONTEXT OF LANGUAGE NEURO PHYSIOLOGY. Armando F. Rocha* and E. Françozo* (SPON: C. Timo-Iaria), Dept. of Physiol. and Biophysics, UNICAMP, Campinas 13100, SP . BRASIL

The purpose here is to study the neurophysiological correlates of the intonational system of Portuguese, by means of recording the scalp Evoked Potentials (EP) during speech recognition. Intonation,in Portuguese as in many other languages, renders Given&New information in a sentence.New is the information the speaker (S) expects the hearer(H) not to have present at the moment of communication.Given&New, in Linguistics, are related to the concept of theme(the structure of the communicative act as related to the discourse framework). Also, the notion of Communicative Dynamism,assuming the sentence as a continuum between two extremes,the topic and the comment(G&N and the thematization structure), was considered.A 3 minute tape was presented twice, with an interval of 30 min.,to right-handed people,and was composed by:i)a short text (from a newspaper)read with no Intonation Emphasis(IE)so as to allow us to study the intonational pattern H imposes on the test,and ii)a set of 25 sentences,in which IE varied according to a) different sentences and b)different intonational patterns of the same sentence,in order to reveal the patterns S imposes upon H.The linguistic performance was tested by asking H to point to the IE in a written copy of the tape.Our results clearly indicate that 1)both in the text and in sentences,the underlined words evoked easily recognizable EEG configurations;2)in the text, all thematic words induced EEG modifications,even if not chosen by H as IE, and the EEG pattern remained similar for the words well uttered and sharply changed with hesitation,stuttering,etc;3)changes of IE and the type of information in the same sentence were accompanied by correlate EEG changes;4)for a fixed position of IE in different sentences there was a fixed relation for the EP onset,accompanied by modifications in the EP pattern; finally 5)there was a high correlation between the EEG pattern and the linguistic performance,both regarding success and failure.Our work demonstrates that language neurophysiology and that relevant questions regarding linguistic knowledge can be studied with the aid of the EEG,and the results also support our theoretical model of language performance, presented elsewhere. In this context,both experimental and theoretical language neurophysiology can be realized.

475 RELATIONSHIP BETWEEN EVOKED POTENTIALS AND PSYCHIATRIC SYMPTOMS. Richard A. Roemer and Charles Shagass *. Eastern Pennsylvania Psychiatric Institute and Temple University Health Sciences Center, Philadelphia PA 19129.

We have reported a number of evoked potential differences between different psychiatric populations. The clinical populations in these studies were derived from discharge diagnoses arrived at by two senior psychiatrists. The question examined here deals with the extent to which symptom patterns, indicated by the Brief Psychiatric Rating Scale (BPRS), are associated with alterations in evoked potentials. BPRS ratings and evoked potential records were obtained during the second week of hospitalization while patients were free of medications. Stimuli were pseudorandomly presented left or right median nerve shock (LSEP, RSEP), clicks (AEP), or checkerboard pattern flash (VEP). Recordings were obtained from 14 scalp and one EOG lead.

The BPRS ratings of 150 hospitalized psychiatric patients were subjected to principal component factor analysis with varimax rotation. Individual factor scores were computed for each of the resulting 8 components in the factor structure. The resultant arrays for the 150 patients were subjected to a hierarchical cluster analysis to identify the "natural" ordering of the rating profiles. Three age and sex matched groups of 29 patients each were derived from the respective thirds of the original 150 patients. This provided three patient groups, each group composed of patients with mathematically similar BPRS ratings. The first and third groups tended to reflect symptomotology associated with psychoses.Composite evoked potentials for each stimulus mode and lead location were computed for each of the three groups and statistically compared.

The key findings were with LSEP and RSEP recordings. EP differences were observed during three time periods: 1) 40-50 msec; 2) 70-110 msec; 3) 200-300 msec post-stimulus.

The nonpsychotic group 2 had lower amplitudes than the other two groups over the contralateral hemisphere during the 40-50 msec period and higher amplitude responses during the 200-300 msec period over most of the scalp. Group 1 differed from group 3 with lower amplitudes during the 70-110 msec period over the contralateral posterior scalp.

Previously, the EPs of nonpsychotic inpatients were shown to be essentially like those of nonpatient controls; by inference, the second group, defined by BPRS rating profiles, appears to be a nonpsychotic subpopulation and their EPs appear similar to those of controls. Consequently, the results appear to be in accord with our previous reports comparing nonpatient controls and psychiatric populations.

476 POWER SPECTRAL DENSITY METHODS FOR THE DETECTION OF WEAK EVOKED POTENTIALS. Bernard Saltzberg. Information Analysis Section, Texas Research Institute of Mental Sciences, Houston, TX 77030.

Coherent averaging is frequently inadequate for the detection of weak evoked potentials because of the waveshape and/or latency instability of the evoked responses. Waveshape and latency of the evoked potential is commonly state dependent and therefore constancy of response may be limited to a single state which persists over a time period so brief that it is not possible to present a sufficient number of replications of the stimulus to make averaging an effective detection procedure. In some experimental designs averaging as a detection method is precluded because the stimulus events are spontaneous and therefore knowledge of stimulus timing is not available to accomplish coherent addition. The alternative to averaging in these circumstances is based on the morphology of high resolution power spectral densities from which the presence of evoked responses can be inferred. Aperiodicity of the signal background is required in order for the power spectral density to unambiguously reveal the presence of evoked responses. Noninvasive detection of spontaneous deep brain electrical spikes which produce weak scalp evoked potentials is an especially useful application of the proposed approach.

477 EFFECTS OF TRIETHYLTIN INDUCED NEUROPATHY ON BRAIN STEM AUDITORY EVOKED POTENTIALS IN RATS. S.N. Shah*, R.C. Johnson*, A. Amochaev* and A. Salamy, Langley Porter Neuropsychiatric Institute, UCSF, Brain-Behavior Res. Ctr., Sonoma State Hosp., Eldridge,CA 95431

In a recent study we reported that the latencies of the brain stem auditory evoked potential (BEP) increased when myelination was impaired in the developing rat (Exptl. Neurol. 58:111, 1978). During maturation, however, changes in structural, metabolic and functional processes occur in parallel. Thus, the demonstration of a correlation between myelin content and electrophysiological parameters is not necessarily indicative of a causal relationship. In the present study we therefore examined the effects of demyelination induced by triethyltin (TET) intoxication on the BEP in young adult rats. Two groups of Sprague-Dawley rats (average body wt. 200g) drank either normal tap water or water containing TET (20mg/liter) for a period of 12-15 days. At the end of this treatment period, BEPs to auditory stimuli were recorded as described earlier (Exptl. Neurol. 58:111, 1978). An average of 400 BEPs was summated with a computer of average transients and written out on an X-Y plotter. The peak latencies were then computed from these tracings. Immediately after testing the animals were sacrificed, brains removed and weighed. Two hemispheres were dissected and one from each rat was frozen immediately, later lyophillized for lipid analysis. The remaining hemispheres from three or four rats of each group were pooled and myelin and synaptosomes prepared using discontinuous sucrose gradient procedure. Results of these experiments showed that the rats receiving TET water had a lower body wt, increased brain wt, as well as an increase in moisture content of brain tissue. The lipid content per g of wet brain and the amount of myelin recovered was reduced in TET treated rats. But the amount of synaptosomes recovered remained normal. The decrease in myelin content in CNS of TET treated rats was accompanied by not only a significant increase in the latencies of all BEP components, but also an increase in the difference between the latencies of waves IV and I. The latencies of the BEPs and the amount of myelin recovered became normal within 15 days when TET was removed from drinking water. These results indicate that when the myelin content of CNS is reduced, there is an increase in the latencies of the BEP and vice versa. Since the synaptosomal content of CNS remained unaltered in TET treated rats, it is reasonable to suggest that BEP latency changes are associated with alteration in the CNS myelin and may serve as a measure of myelin defect.

478 THE UNCONDITIONED FELINE SENSORIMOTOR RHYTHM AND AUDITORY INFORMATION PROCESSING: AVERAGED EVOKED RESPONSE AND SPECTRAL STUDIES. J. Marc Simard*, Calvin C. Turbes and Gerald T. Schneider* (SPON: James Maskin). Creighton University School of Medicine, Omaha, NE 68178

Electroencephalographic activity (EEG) was recorded from the sigmoid gyrus, the nucleus accumbens and the basolateral amygdala in freely moving cats using telemetric methods. Free field auditory stimulation consisted of 10 ms bursts of a 2 KHz tone, repeated every 10 sec for 20 min, each day for 5 consecutive days. Cats were rerun using the same paradigm one month later. (Amphetamine was administered between runs.) Ten sets of data were thereby obtained for each cat. All data were analyzed digitally. For each set of data, amplitude spectra of the sigmoid EEG were computed for the 500 ms immediately preceding each of the 120 auditory stimuli. The statistical parameters of each of these groups of spectra were then used to sort each set of responses into 2 classes: responses associated with high prestimulus SMR; responses associated with low prestimulus SMR. The subcortical responses were sorted according to the concurrent classification of the sigmoid response. For each set of data, the average response in each class for the 3 brain areas was computed. In addition, the average of the power spectra of each response period and the power spectrum of the averaged evoked response (AER) for each class of each set for the 3 brain areas were computed.

Visual analysis revealed a high degree of stability, over the 1 month course of the experiments, of certain components of the AER's consistently associated with high SMR. Generally, differences between the 2 classes of responses were greatest for those responses obtained from the sigmoid gyrus, while lesser, though still distinct and stable differences between the classes were observed from the subcortical sites. Quantitative analysis of the P250-350 wave of the sigmoid AER's sorted for high SMR indicated a close relationship between the amplitude of this wave and the average power of the SMR preceding the response to the stimulus: in 3 of the cats, positive correlation coefficients of .94-.97 ($P<.01$) were obtained for this relationship. The spectral analyses demonstrated the absence of coherence between the SMR and the AER, thereby excluding the high amplitude, highly synchronous SMR as a direct contributor or contaminant of the AER.

The significance of these data in a re-evaluation of current theories on the SMR will be discussed.

479 INTERACTION BETWEEN SPATIALLY SEPARATE PERIPHERAL NERVE FIBERS AS MEASURED BY ALTERATIONS OF THE SEP: A FUNCTION OF ALGEBRAIC ADDITION OF WAVE COMPONENTS. R.K. Simpson, Jr.,* E.H. Carlton*, and S. Katz (SPON: L.D. Middaugh). Dept. of Physiology, Medical University of South Carolina, Charleston, South Carolina, 29403.

Interaction between spatially separate peripheral nerves in monkeys anesthetized with 70% N_2O and 30% O_2, was investigated using as measurement, alterations of the somatosensory evoked potential (SEP). The SEP's from forelimb peripheral nerve stimulation were observed 100 msec after a stimulus was applied to a hindlimb peripheral nerve and compared to control forelimb SEP's. The resultant alterations were consistently demonstrated in forelimb SEP early wave components (within 40 msec.). Interaction observed by this study demonstrated different SEP alterations than those seen using cats anesthetized with chloralose. This may reflect fundamental differences in CNS structure or mechansims responsible for interaction. In this study, decreased amplitudes of negative potentials and enhanced amplitudes of positive potentials occured. Hindlimb SEP's, recorded from the forelimb receiving area, resulted in long duration, long latency, positive potentials. This SEP when algebraically added to the control forelimb SEP, corrected for the 100 msec delay, resulted in duplication of the SEP derived from interaction. These data suggest that interaction between spatially separate peripheral afferent inputs may be due to the algegraic summation of voltages. A physiological mechanism for interaction is suggested by this study based on the observation that later wave components of one SEP may influence early wave components of another SEP when these potentials occur at the cortex simultaneously. This is further supported by previous investigations showing a correlation between different components of the SEO and activation of different diameter peripheral nerve fibers. The observed interaction may take place as a result of summed electrical events occuring at the postsynaptic level. A simple model fitting the observed SEP alterations and established theories of SEP wave formation would be that of inhibitory potentials invluencing excitatory potentials of neurons in the upper cortical cell layers. This could occur as a result of activity from late arriving small fiber systems affecting the activity of earlier arriving large fiber systems in an inhibitory manner. This may be reflected in the observed alteration of the SEP. (Supported by NINDS grant P-5P81-NS-11066).

480 SINGLE-TRIAL AND SMALL-N VERTEX BRAIN POTENTIALS RELATED TO SENSORY THRESHOLD AND RELATIVE DURATION ESTIMATE FOR TWO MODALTIES IN HUMANS. Hilton Stowell. Sensory Neurophysiol., Rivers Lab, CSH, GA 31062.

For psychophysical correlates single-trial and small-n records of event related brain potentials (ERBP) have advantages over conventional averages. This study is part of a plan to evaluate the functional significance of the vertex component of somatosensory and acoustic ERBP for sensoriperception, with reference to exogenous and endogenous aspects of central processing. Vertex-focussed ERBP may confound activity from both "nonspecific" thalamic nuclei and specific contra- and ipsilateral cortex. Moreover, the relationship of P200 phenomena to the vertex component is unclear. Also, there is evidence for the functional importance of amplitude changes in the vertex component for pain perception in man.

Intrasubject studies of a small sample, using self-administered and exogenously administered stimulation with control of subjective expectancy and attention, suggest that the vertex component (80-400 ms after stimulus onset; 50-200 ms after stimulus offset) of somatosensory and acoustic ERBP is an indicator of subjective readout on (a) sensory detection threshold; and (b) discrimination of relative stimulus durations (off responses); also that this component is unlikely to reflect only stimulus/sensory-nonspecific, endogenous variables, since the vertex scalp electrode, during intermodality stimulation, seems to differentiate either the spatial or the temporal patterns of cerebral activity, or a combination of both, with respect to input modality.

The single-trial data of this study are "raw" ERBP. That is to say, they have not been subjected to adaptive filtering, template matching, or any processing other than the usual on-line amplifier bandpass and filter time constant used for small-n averaging.

This work was supported by the Research Section of PERT, Division of Mental Health and Mental Retardation, Dept. of Human Resources, Central State Hospital, Milledgeville, GA 31062.

481 STUDIES ON BRAIN RHYTHM INTERRELATIONS (THETA, SENSORIMOTOR [SMR] AND 40 Hz) IN THE SIGMOID GYRUS, NUCLEUS ACCUMBENS AND AMYGDALA OF THE CAT. Calvin C. Turbes, J. Marc Simard*, Gerald T. Schneider*, Dept. Anat., Sch. Med., Creighton Univ., Omaha, NE 68178; and R. John Morgan, Colorado State Univ., Ft. Collins, CO 80521.

Recordings are made on cats with chronic electrode implants and using radiotelemetry and hardwire methods. Analog data are collected on FM tape and analyzed digitally using Varian V-72 minicomputer. The discrete time data are transformed using a Fast Fourier Transform (FFT) algorithm. Spectral estimates are plotted sequentially out to a frequency of 50 Hz.

Special consideration is given to these CNS rhythms as they relate with normal behavioral states and altered behavior induced by d-amphetamine and l-amphetamine.

Spectral analysis of auditory evoked potentials during normal behavior and d-amphetamine and l-amphetamine altered behavior is compared with ongoing spectral arrays of the same experimental states. These data indicate that amphetamine altered cerebral cortical activity resulted in changes in the averaged auditory evoked potentials and the spectral profiles. These changes and how they relate to deficits in auditory information processing are discussed.

Long term ongoing spectral arrays show that amphetamine induced behavior shows dissociation of rhythmic activity at the cortex and these subcortical nuclei. There is also a "fixation" of rhythmic processes at the cortex and the subcortical areas that deviates from the rhythmic activity of normal behavior.

482 WAKEFULNESS-SLEEP MODULATION OF THE THALAMIC MULTIPLE UNIT ACTIVITY IN HUMANS. Francisco Velasco, Marcos Velasco, Carlos Cepeda*, Héctor Muñoz* and Xavier Almanza.* Sci. Res. Dept., Natl. Med. Ctr., IMSS and Service Neurol. Surg., General Hosp. SSA, México, D.F.

This is a study of the changes in spontaneous and evoked multiple unit activities from different thalamic nuclei during wakefulness and sleep of Parkinsonian patients with implanted electrodes as part of their surgical treatment of tremor:

Spontaneous multiple unit activity (number of units /min) of all studied thalamic nuclei (VPL, VL and NcM) showed large variations according to the state of wakefulness and sleep: It was high during distraction and paradoxical sleep, it was moderate during quiet wakefulness and attention and was low during habituation and slow wave sleep (stages I, II, III, IV). In contrast, multiple unit activity evoked by single shock stimulation of the median nerve (number of units/0.2 msec) and recorded from VPL nucleus (mean latency of 18 msec) showed no significant changes during various states of wakefulness and sleep.

483 CEREBRAL POTENTIALS PRECEDING SPEECH PRODUCTION. Donald H. York and Thomas W. Jensen. Dept. of Physiology and Communication Disorders Unit, University of Missouri, Columbia, MO 65212.

Earlier studies have examined the EEG for hemisphere assymetries during vocalizations. Other studies have looked at computer averaged slow waves which precede speech. The present study addressed the question of whether there are potentials preceding speech which are utterance specific. If such potentials can be demonstrated, do they represent a cortical program for the vocalization?

Experiments were conducted on 26 female subjects, mean age 23.6 years, who were right-handed and not taking any medications. Standard EEG electrodes were placed at the midline intra-aural position (Cz) and on the left mastoid process. A ground electrode was placed on the right forearm. Electrodes were connected to a preamplifier and then averaged in a computer of average transients (CAT1000). A stimulator provided timing pulses to one oscilloscope which served as a visual target for the subject to start a vocalization. It was also used to trigger the averager at various times preceding the vocalization. The initial run (control) consisted of the subject fixating on the oscilloscope screen, at a precise point where a black arrow was placed, while 100 sweeps were obtained in three groups of 33 sweeps. A short break inbetween was undertaken to minimize fatigue. The subsequent runs consisted of the subject voicing a mono-syllablic production when the oscilloscope trace reached the arrow. Various time periods preceding the vocalization were examined for consistencies in the topology of the averaged waveforms. At least five utterances were evaluated on each subject. Recordings of EMG from muscles overlying the larnyx were also obtained during vocalizations and always occurred after the time period over which EEG signals were averaged. The results demonstrate that consistent waveforms between subjects for certain vocalizations were obtained only during selected time periods preceding the vocalization. A most interesting observation was the production of a waveform "identical" to a voiced waveform by thinking the word, but not voicing it. The potential for such studies in speech pathology is presently being explored.

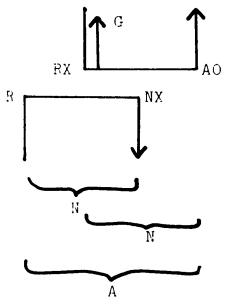
EXTRAOCULAR MOVEMENT

484 LATENT EVENTS PRIOR TO HUMAN SACCADES. B.D. Adams* and P.E. Hallett. Dept. of Physiology, Univ. of Toronto, Toronto, Canada.

The purpose of this study was to examine some timing parameters of the human saccadic oculomotor system. Targets were presented as blue-green oscilloscope dots (100 x foveal threshold) which stepped horizontally to one of 6 or 8 randomly selected positions in the range ± 12 degrees. The subject's left eye was monitored in the dark by a special near infra-red tracking device, the right eye being occluded by an eyepatch. Seven subjects were asked to perform two tasks - to follow the target with their eye (normal saccade N) or to make an equal and opposite eye movement (anti-saccade A) - and feedback of latency and error was given automatically (Hallett, Vision Res., in press). "Reflex" responses to the target (direction errors) occurred in only 5% of A trials. The mean A latency was typically prolonged and had a larger standard deviation than the N. Reaction times N or A, or differences such as A-N, vary considerably from subject to subject. However, the regression line of A on N is simply $A = 2.01N - 143$, with $r^2 = .98$ and $\sigma(A) = \sqrt{2}\,\sigma(N)$. This implies that the definition of the A goal occurs a fixed time in advance of the missing N saccade.

The diagram symbolically interprets the regression equation $A = 2N - 143$ as two identical overlapping processes, each of mean duration N, where R is the retinal image step and NX would be the start of the cancelled reflex saccade. Event AO is the observed anti-saccade, which originates, not from a fictitious retinal input RX, but more plausibly from an internal redefinition of the goal at some fixed time G in the overlap region.



Similarly, we interpret the experiments of Lisberger et al. (Vis.Res. 1975) as showing that cancellation of a saccade occurs a fixed time prior to the missing saccade. 'Fixed time' in the present context could be 'fixed place' neuroanatomically.

485 MODIFICATION OF THE PATTERN OF SACCADIC EYE MOVEMENTS FOLLOWING ABLATION OF THE MONKEY SUPERIOR COLLICULUS. Joanne E. Albano and Robert H. Wurtz, NIMH, Bethesda, Md. 20014.

A striking aspect of the ongoing behavior of the alert rhesus monkey is the high frequency of eye movements and fixations that are made as he surveys his visual environment. EOG recordings in normal monkeys with head restrained show that while viewing a complex visual field animals display a repertoire of large and small saccadic eye movements; the smaller eye movements of less than 15 degrees predominate. Some of these smaller eye movements take the form of a glance where the intervening fixation may be no longer than the latency for a saccade of the same size. When in the dark, the alert animal no longer executes the smaller eye movements or glances with such high frequency but the rate at which larger saccades occur is the same as in the light, suggesting that the smaller eye movements are visually-elicited.

Two monkeys were studied: one with a unilateral and the other with a bilateral ablation of the superior colliculus made under visual inspection. There is a selective reduction in the frequency of the smaller saccades and glances made in the damaged visual field. This effect is limited to saccades made in the lighted environment; there is no major change in the frequency of saccades made in the dark. This effect is not a result of a simple sensory or motor loss, since these animals could perform detection and saccade tasks to points within the central 15 degrees.

While performing a visual fixation task normal monkeys are readily distracted by an irrelevant and unrewarded stimulus onset and movement occurring in the peripheral visual field. This distraction is expressed by either a glance or less frequently by a saccade toward the stimulus. If the stimulus is presented repeatedly or predictably the animal no longer glances at the stimulus. Following ablation of the superior colliculus, monkeys are no longer distracted by onset and movement of a stimulus in their damaged field although the unilaterally lesioned monkey continues to be distracted by a stimulus in the visual field contralateral to the remaining superior colliculus.

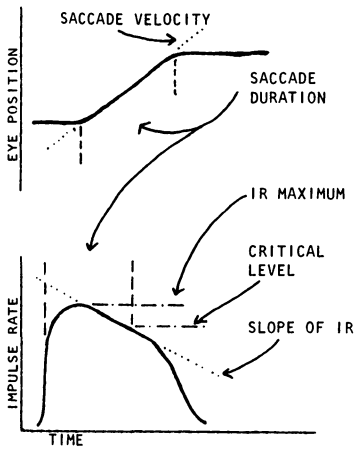
Previous experiments on visual-oculomotor function following ablation of monkey superior colliculus concentrated on a learned saccade task and found only increases in saccadic latency or slight errors in saccadic accuracy in the central visual field. Our observations suggest that in a more complex visual environment the consequence of colliculus ablation is to dramatically modify the normal pattern of visually elicited saccadic eye movements.

486 FINE STRUCTURE OF SACCADE BURST UNITS IN THE MACAQUE BRAINSTEM. S.M. Blair*, R. Eckmiller and M. Gavin*. Dept. of Physiology-Anatomy, University of California, CA 94720.

Single unit recordings from the brainstem of the alert macaque show a population of neurons whose bursts are closely correlated with saccadic dynamics.

Juvenile macaques were allowed to make random saccades, or were trained to execute a stereotyped series of saccades in the horizontal meridian. Neuronal discharges were recorded along with vertical and horizontal electro-oculograms. For units which burst in relation to saccades we determined the time course of the impulse rate (IR) in each burst in relation to the dynamic properties of the accompanying saccade.

We identified a class of neurons that began firing about 12 msec before each saccade, and stopped firing about 2.5 msec after completion of the saccade. During the last 2/3 of the burst the IR showed a near linear decrease with a slope varying from 127 to 1270 ips/sec. This slope varied inversely with velocity of the saccade. The duration from onset of burst to the time when IR fell to a constant critical level was correlated with duration of the saccade. Maximum IR occurred in the first 1/3 of the burst, was nearly constant for all saccades in the "on" direction, but was inversely correlated with the slope of the last 2/3 of the burst.



These findings are consistent with a view which links the dynamics of the saccade to the time course of IR in the bursting unit, but separates these from the neural input which initiates the saccade. Such an interpretation implies that saccadic dynamics are due in part to a neural input, available when the saccade starts, which codes the position in which the saccade will end.

487 CONNECTIONS OF A VERTICAL EYE MOVEMENT AREA IN THE ROSTRAL MESENCEPHALIC TEGMENTUM OF THE MONKEY. J.A. Büttner-Ennever* and W. Lang*
(SPON: M.E. Anderson). Brain Research Institute, University of Zürich, 8029 Zürich, Switzerland.

Recent anatomical and physiological studies indicate that not only the interstitial nucleus of Cajal (iC), which lies caudal to tractus retroflexus, but also the rostral interstitial nucleus of the medial longitudinal fasciculus (rostral iMLF), lying rostral to tractus retroflexus, is involved in the generation of vertical eye movements. On the other hand our results suggest that nucleus Darkschewitsch does not participate in oculomotor control. The neural connections of iC and rostral iMLF were studied using anterograde ([^{3}H]proline and [^{3}H]leucine) and retrograde (horseradish peroxidase) tracer substances in macaque monkeys.

HRP studies revealed that both cell groups send fibers to the oculomotor nucleus but the projections from rostral iMLF were mainly ipsilateral while those of iC were mainly contralateral. The anterograde tracer experiments revealed that these efferent fibers supply the trochlear and oculomotor nuclei, bilaterally, with the exception of the subgroups of the oculomotor nucleus which receive an input from the abducens nuclei, that is the medial and inferior rectus divisions. The contralateral terminal labelling after an injection of [^{3}H] amino acids into iC and rostral iMLF arose from fibers that crossed within the posterior commissure, and also included rostral iMLF, iC and its adjacent reticular formation. Control injections in n. subfascicularis, the fields of Forel, the hypothalamus, the red nucleus and the n. Darkschewitsch labelled of none of the above structures. Long pathways which descend within the ipsilateral MLF were shown to originate from both iC and rostral iMLF. Both cell groups receive vestibular afferents, although the pontine reticular formation, a center for vertical and horizontal gaze projects only to rostral iMLF.

Rostral iMLF and iC certainly subserve different functions, but there are some striking similarities in their anatomy. These results emphasize their importance in the control of vertical eye movements.

488 THE ROLE OF VELOCITY STORAGE IN VISUAL-VESTIBULAR INTERACTIONS IN HUMANS AND MONKEYS. Bernard Cohen, Volker Henn*, Theodore Raphan, and Victor Matsuo*. Depts. of Neurology, Mt. Sinai Sch. of Med., CUNY, New York, N.Y. 10029, and Univ. of Zurich, Zch, SW

In the monkey a velocity storage mechanism in the VOR is important for production of optokinetic nystagmus (OKN), optokinetic after-nystagmus (OKAN), and vestibular nystagmus, and provides a focus for visual-vestibular interactions (Raphan, Cohen & Matsuo, 1978). The purpose of this study was to compare OKN, OKAN and per- and post-rotatory nystagmus in humans and monkeys and to determine the role of velocity storage in producing visual-vestibular interactions in man. As previously reported the gain of OKN in humans is 0.8-1 to 60-90°/sec. Similar gains were found for rotation in light, but for rotation in darkness vestibular gains were lower, varying between 0.35-0.75. In the monkey gains for rotation in dark and light are close to 1 to 180-240°/sec. During OKN in the monkey eye velocity rises rapidly and then slowly reaches peak values. In humans eye velocityrises immediately and there is no slow rise to a steady state value. OKAN in monkeys saturates at 90-120°/sec; in humans OKAN is weak and saturates at about 20°/sec. Rotation in light is followed by a decrease in intensity of after-nystagmus in both humans and monkeys. Consistent with saturation levels of OKAN, after-nystagmus could be reduced by 90-120°/sec in monkeys, but only by about 20°/sec in man. Visual fixation during OKAN and post-rotatory nystagmus causes a loss of activity responsible for the nystagmus. In the monkey fixation times of 2-3 sec abolish OKAN and 5-8 sec abolish vestibular nystagmus. In humans, the effect of visual fixation was much less than in the monkey; even 30 seconds of fixation failed to block the reappearance of vestibular nystagmus in darkness. Perception of motion was affected by visual fixation to a much greater extent than nystagmus. Evidence for velocity storage is the presence of OKAN, and the ability to reduce post-rotatory nystagmus by stored activity associated with OKN. In monkeys the visual system is capable of powerfully activating velocity storage to reduce after-nystagmus. The visual system has much less access to this storage mechanism in man. The response can be modeled using a similar scheme to that in the monkey. The model indicates that direct pathways from the visual system to the oculomotor system are more important for mediating OKN in man than in monkey and that the integrator plays a relatively minor role. Consequently the velocity storage integrator seems to be more closely related to enhancing the low frequency characteristics of the VOR than in supporting ocular following. It could also be important in mediating the perception of motion.

489 ASYMMETRIES IN BINOCULAR COUNTERROLLING IN HUMANS DURING DYNAMIC ROTATION. Shirley G. Diamond*, Charles H. Markham, Norman E. Simpson* and Ian S. Curthoys*. Dept. Neurol., Sch. Med., UCLA, Los Angeles, CA 90024.

Seven subjects ranging in age from 18 to 66 years underwent 360° rotation about a naso-occipital axis at a constant velocity of 3°/sec in a specially constructed rotating chair. Subjects were securely held by a series of straps. The head was stabilized by means of a bite bar adjustable to permit precise horizontal alignment of the centers of the two pupils. A camera was mounted on the chair and rotated with the subject. A line etched on the view finder passed through the centers of both pupils, enabling verification of pupil alignment during rotation. Photographs of the whole upper part of the face were taken at each 10° of rotation. Most subjects were given 4 trials, with rotations beginning left ear down or right ear down in random order.

Dual projectors were used to measure counterrolling. The first projector contained a slide of the eyes taken while the subject was upright (0°). The second projector contained the film strip of the eyes at each 10° of rotation, and was fitted with horizontal and vertical adjustments and a calibrated rotating device. The image from the second projector was aligned and rotated until it was exactly superimposed on the image from the first projector. Repeated interruption of one light beam induced apparent motion of the iris when superimposition was not precise. The extent to which the second image had to be rotated to achieve superimposition was the measure of counterrolling at that position. This measurement system has a mechanical accuracy of one minute of arc; practical accuracy is between 15 and 30 minutes. Right and left eye in each trial were measured independently.

Results showed the extent of counterrolling was greater than most earlier studies have indicated. Mean range of counterrolling (maximum on one side to maximum on other side) was about 20° with individual means varying from 9° to 35°. Each subject showed a high degree of consistency from trial to trial.

Although mean range of counterrolling was 20°, this was not distributed symmetrically around the upright position. Maximum counterrolling when subjects were right ear down averaged 12° and left ear down averaged 8°, regardless of which direction was presented first. The two eyes did not counterroll in perfect conjunction, sometimes being as much as 4° different. The downward eye almost invariably rolled more than the upward eye. Amount of counterrolling appears to decrease with age.

490 VELOCITY CODED NEURONS: A NEW CLASS OF PRE-MOTOR NEURONS IN THE PRIMATE OCULOMOTOR SYSTEM DURING PURSUIT Rolf Eckmiller and Manfred Mackeben*. Smith-Kettlewell Institute, San Francisco, CA 94115

Initially, Duensing and Schaefer(Arch.Psychiat. Z. ges.Neurol.196:402,1957)working with rabbits, and since then several authors working with monkeys described neurons in the reticular formation, which were only "loosely coupled" with eye movement(EM) parameters. Therefore, they were not considered in the description of oculomotor functions.

We found a population of such neurons in a circumscribed region 0.5 to 1.5 mm caudal to the abducens nuclei and discovered that they reveal their correlation with EMs only during pursuit. Single unit recordings were made in 2 Java monkeys trained to pursue a light spot(4 min.of arc in diameter), which was sinusoidally moving in the horizontal plane. EMs were recorded form both eyes simultaneously as DC-EOG using 3 implanted electrodes. During spontaneous EMs this neural activity was only loosely related to large saccades and to far eccentric eye positions. However, during pursuit EMs these neurons showed a good correlation with eye velocity. The neural activity was characterized by the following features:
a) impulse rate IR during spontaneous EMs was zero or very low and irregular in the range of ± 10 deg.
b) IR of neurons caudal to the right abducens nucleus increased with pursuit velocity to the right and vice versa for neurons located on the left side.
c) IR_{max} during sinusoidal pursuit(f= 0.1 to 1.5 Hz) in the on-direction typically did not exceed 100 impulses per second. d) IR_{max} during sinusoidal pursuit occurred in the phase range of ± 30 deg. around the maximum stimulus velocity v_{max}(in comparison, IR_{max} of motoneurons during sinusoidal pursuit lagged 40 to 80 deg. behind v_{max}). Therefore we suggest to designate this class of neurons as velocity coded (VC) neurons.

We assume that these VC-neurons provide the velocity component for the activity of motoneurons(dur. pursuit).

491 VISUAL RESPONSES OF OMNIPAUSE NEURONS IN THE AWAKE CAT. C. Evinger*, C.R.S. Kaneko, and A.F. Fuchs. Dept. Physiol. and Biophysics, and Regional Primate Center, Univ. WA., Seattle, WA 98195.

Omnipause neurons (OPN) in the cat cease their tonic discharge just before and during all saccadic eye movements made in either the light or dark. In addition, microstimulation near OPN suppresses all saccades, but does not interrupt smooth eye movements. Models of saccade generation propose that OPN inhibit neurons that exhibit a burst of activity during saccades and thereby control saccade duration. However, we have shown that OPN are excited by visual stimuli and it is not clear how this response fits into models of saccade generation. To understand the role of the visual input, we tested these neurons with a variety of visual stimuli. Stimuli were presented at locations within the visual field of alert cats trained to track or fixate a moveable target spot.

Omnipause neurons respond with a transient burst of activity to changes in luminance. Movement of a 45x55 deg striped background (0.6 cycles/deg) at velocities ranging from 1 deg/sec to step changes elicits an excitatory response regardless of the direction of movement. Turning a full field light stimulus either on or off evokes a brisk excitatory response. The cells respond over a four log unit range of light intensity with latencies ranging from 35 msec (0 log units) to 94 msec (4.0 log units).

The receptive fields of OPN were mapped with a 2 deg light spot. The spot was maintained at different constant positions on the visual field by using eye position to control spot position. With these techniques, each OPN studied (N=20) had a receptive field within which either a 2 deg spot displacement or turning the spot on and off elicited a vigorous discharge. The strongest response usually occurred for stimuli within 5 deg of the area centralis; however, significant responses occurred over a larger area ranging from 20 to over 40 deg in diameter for different neurons. The receptive fields showed no evidence of inhibitory areas. The strength of the visual response was inversely proportional to receptive field size.

In one cat visual stimuli were presented during saccades to test their effect on saccade properties and OPN activity. Visual stimuli triggered to occur during a saccade appeared to interrupt some saccades in midflight. During the interruption, the OPN resumed its tonic firing. Nevertheless, our data do not suggest an obvious role for the visual response of OPN in the generation of saccades.

492 RAPID CHANGE IN GAIN OF VESTIBULO-OCULAR REFLEX IN CHICKENS. Alan E. Green* and Josh Wallman. Biology Department, City College of City University of New York, New York, N.Y. 10031.

The vestibulo-ocular reflex (VOR) helps stabilize the visual world by means of eye movements that compensate for rotations of the head. If the horizontal movements of the visual world relative to the head are reversed, as by wearing reversing prisms, the normal VOR destabilizes the visual world, since the eye movements produced now increase, rather than decrease, retinal image slip. In this situation, the amount of eye rotation for a given head rotation (that is, the gain of the VOR) is gradually reduced, thereby improving visual stability. This adaptive plasticity of VOR gain has been shown in humans, monkeys, cats, rabbits, and goldfish. There is evidence for involvement of the cerebellum in this gain plasticity. Since at hatching chicks have apparently normal visual function, and the cerebellum is relatively immature, we were interested in whether there is a post-hatching developmental change either in VOR gain, or in the degree of plasticity of VOR gain.

Eye position and head position were measured with the magnetic field-search coil technique. The VOR gain (eye velocity/head velocity) was measured in the dark. Reversed movements of the visual field relative to the head were produced by rotating the animal sinusoidally in the horizontal plane (0.25 Hz, 7° peak-to-peak), while a surrounding vertically striped cylinder rotated in phase with the animal, but with twice the angular amplitude. This simulates the effect of reversing prisms without restricting the visual field.

Normal VOR gain was about 0.4 in two-week-old birds (n=4), but only 0.24 in two one-day-old chicks. After two hours of sinusoidal rotation in the reversed visual movement situation, the gain was reduced to about 0.1. The time constant of this gain reduction was approximately one hour. The gain reduction could be reversed with a similar time course by rotating the birds within a stationary visual field. VOR gain was higher at higher frequencies (0.5 Hz and 1 Hz) and showed less change as a result of the reversed visual experience. These results suggest that this form of motor learning is present at hatching and improves with age. The rate of the VOR adaptation to reversed visual movement seems more rapid than reported for other species.

493 AFFERENTS TO THE MEDIAL PONTINE RETICULAR FORMATION AS DEMONSTRATED BY HORSERADISH PEROXIDASE (HRP) RETROGRADE TRANSPORT. R. W. Greene*, M. Schulder* and G. B. Stanton* (SPON: A. I. Kobrine). Armed Forces Radiobiology Research Institute, Bethesda, MD 20014 and Howard University, Washington, D.C. 20059.

Projections have been demonstrated from the superior colliculus (SC) to the caudal pole of the contralateral nucleus reticularis pontis caudalis (RPC) using anterograde degeneration techniques (Kawamura et al., Exp. Br. Res. 19:1, 1974). In order to identify the cells of origin to this projection, the floor of the IVth ventricle was exposed by aspiration of the midline cerebellum and HRP was pressure-injected through micropipettes into the RPC and the VI nucleus. Control injections were made in the rostral part of the nucleus reticularis gigantocellularis (RGc) and anterior to the VI nucleus.

Injection of the RPC and the VI nucleus produced labeled cells bilaterally in the deep and intermediate layers of SC but none in the superficial layers. Labeled neurons in the contralateral SC were most numerous in the rostral half (12 large and 14 medium-sized neurons/60 µm section). Moreover, labeling intensity of the large cells was greatest in the medial third of SC which suggests that these soma have the largest number of axon terminals within the injection site. On the ipsilateral side labeled neurons were few and faintly labeled. No projections from the SC to the VI nucleus were seen following HRP studies by Maciewicz et al. (Br. Res. 123:229, 1977). Furthermore, our control injections resulted in relatively few labeled cells in SC, confirming the localization of terminals of SC-RPC projection to the caudal pole of the RPC.

Another major projection to the RPC was from the vestibular nuclei. Cells were most numerous in the ipsilateral medial, inferior, and ventrolateral vestibular nuclei, but were also seen in these nuclei on the contralateral side. Other nuclei labeled by injection in the RPC include on the ipsilateral side, the nucleus of the field of Forel, the nucleus of Darkschewitsch, the interstitual nucleus of Cajal, the mesencephalic reticular formation and the spinal nucleus of V. Nuclei labeled bilaterally include intermediate sized cells in the caudal part of the nucleus of III, the pontine raphe nuclei, the pontine lateral tegmental fields, the RPC and the RGc.

These results demonstrate that the cells of origin of the SC-RPC projection are the large and intermediate sized neurones in the deep and intermediate layers of the SC.

494 VERTICAL OCULOMOTOR DEFICITS FOLLOWING MLF LESIONS IN MAN AND MONKEY ARE SIMILAR. D. Guitton and T. Kirkham*, Montreal Neurological Institute, McGill University, Dept. Neuroophthalmol., 3801 University St., Montreal, P.Q. Canada H3G 1Y6.

Fibres of the monkey medial longitudinal fasciculus (MLF) can be grouped into two categories: (1) horizontal burst-tonic fibres that discharge with adducting saccades and have quantitatively similar characteristics as medial rectus motoneurones; and (2) vertical tonic-pause fibres that pause for vertical saccades and carry the full vertical vestibulo-ocular reflex, and a portion of both vertical pursuit and hold signals (King et al., J. Neurophysiol. 39:1135, 1976). Lesions of the MLF in monkey have revealed oculomotor deficits compatible with the elimination of these signals (Evinger et al., Exp. Brain Res. 28:1, 1977). In man, the syndrome of internuclear ophthalmoplegia (INO) has been associated with lesions of the MLF. The well documented horizontal oculomotor deficits are similar to those produced in monkey (Kirkam, T. and Katsarkas, A., Ann. Neurol., 2: 385, 1977).

In the present work we have examined vertical deficits. Vertical eye movements in INO patients have been recorded using the eye coil in magnetic field technique. An annular ring, with an embedded coil of fine wire, was held to the eye by suction and subjected to vertical and horizontal magnetic fields. The results are compatible with observations in monkey. Patients with presumed MLF lesions showed: (1) normal vertical saccades; (2) deficits in vertical pursuit and in the ability to hold the eye in an eccentric up or down position. We have not examined vertical VOR. However, we have measured optokinetic afternystagmus (OKAN) following the induction of vertical optokinetic nystagmus (OKN) with a 110°x110° moving bar pattern. OKAN is linked to activity in the vestibular nuclei (Waespe, W. and Henn, V., Exp. Brain Res., 27:523, 1977) and for vertical eye movements should be carried by the vertical tonic MLF fibres. Patients with INO had deficient OKN and this is compatible with deficient pursuit. OKAN was abolished.

In summary, vertical and horizontal oculomotor deficits associated with presumed lesions of the MLF in humans are compatible with recent neurophysiological and anatomical data obtained in monkey.

495 QUANTITATIVE STUDY OF HUMAN SMOOTH PURSUIT TRACKING Michael J. Iandolo, A. Terry Bahill and B. Todd Troost, Biomedical Engineering Program Carnegie-Mellon University Pittsburgh, PA 15213

Random target movements with statistical properties approximating gaussian white noise were used to quantify human smooth pursuit system tracking behavior and to nullify the effects of the learning process. Bandlimited gaussian white noise and variations of Pseudo Random Binary Sequences (PRBS) were employed as the target waveforms. Because the power spectrums of the waveforms are flat from zero hertz to any predetermined frequency, the full frequency range of the smooth pursuit system can be characterized with these stimuli using a short test run.

Bandlimited gaussian white noise waveforms were discarded because the subjects found them to be too confusing. This confusion resulted in an increased number of saccades.

With the binary states of the PRBS corresponding to positive and negative velocities, a controllable, constant speed waveform was generated in which the direction of movement changed at random intervals. Because the smooth pursuit branch is a velocity sensitive mechanism, a complete test of the system would need to contain more than one velocity. Therefore another variation of the PRBS was implemented in which the target velocity was a random variable and the intervals at each velocity were constant. By using PRBS, some parameters can be easily constrained i.e. target velocities, target range and acceleration, so that system nonlinearities can be reduced. With these target waveforms, the system transfer functions were computed.

Also investigated was the interaction between horizontal and vertical eye movements using predictive (single sinusoids) target waveforms in one direction and random (PRBS) target waveforms in the orthogonal direction. It was found that the two channels of the system were independent with some crosstalk.

Eye movements were recorded with an infrared photoelectric measurement system. To eliminate head movement artifact, the subject's head was restrained. The target waveforms were generated in a digital computer and converted into an analog voltage. The target was a small phosphorescent dot located on a large oscilliscope screen.

496 NECK POSITION MODULATES VESTIBULAR EYE NYSTAGMUS PARAMETERS. David W. Jensen. Dept. Neurosciences, UCSD, La Jolla, CA 92093.

Neck proprioceptive stimuli alter the eye nystagmus caused by a unilateral injection of 0.3cc of 2% Lidocaine HCl into the middle ear cavity of guinea pigs. Eye position was measured with Ag-AgCl ball electrodes chronically implanted into holes in the left and right orbital crests that communicated with the orbits. Electrode signals were differentially amplified and displayed on a D.C. recorder. The electrooculogram (EOG) was calibrated by either comparing a videotaped record of eye position during nystagmus with concommitant EOG amplitude, or by measuring saccadic EOG amplitudes and the magnitude of the associated horizontal voluntary head movements. Four parameters of nystagmus were measured as a function of maintained horizontal or vertical neck position: frequency of beating, mean eye position, mean slow phase velocity, and direction of beating. Direction of beating was measured by videotape analysis. Neck proprioceptive stimuli were delivered by moving the body about the fixed head. Vision was unobstructed in normal laboratory illumination.

The Lidocaine treatment produced a conjugate horizontal eye nystagmus within 5-40 minutes in all animals screened for normal vestibular reflexes. Vertical neck position did not alter this nystagmus. For a right-beating nystagmus (left ear block), a left (horizontal) neck deviation produced tonic increases in frequency and in mean slow phase velocity and a maintained left eye deviation, when compared to the situation with no neck deviation. Right neck deviation produced tonic decreases in frequency and in mean slow phase velocity and a smaller left eye deviation. The direction of beating was not changed. These effects were present in all 17 animals studied and were proportional to the amount of neck deviation imposed (maximum = 90° deviation). These influences persisted after a dorsal hemisection of the spinal cord just above C-1 (1 animal); after bilateral fastigial nuclear lesions (2 animals); and nodulectomy with extensive damage to the uvula and lobule VIIIb (1 animal). In two animals the entire vestibulocerebellar cortex was removed, along with the posterior vermis and postero-lateral hemispheres. Both these animals displayed a rightward eye deviation with right neck deviation, while all other neck-eye nystagmus influences remained as described above.

In conclusion, neck proprioceptive information via the ventral funiculi integrates with eye nystagmus activity in a spatially specific manner. The vestibulo-cerebellum does not participate in neck effects on mystagmus beat frequency or mean slow phase velocity. However, certain parts of the cerebellum, probably the flocculi, are involved in controlling the magnitude and sign of the gain of neck controlled mean eye position during nystagmus. Funded by a NASA grant to T.H. Bullock.

497 CONNECTIONS OF FELINE OMNIPAUSE NEURONS. C.R.S. Kaneko and A.F. Fuchs. Dept. of Physiol. and Biophysics and Regional Primate Center, Univ. WA, Seattle, WA 98195.

Omnipause neurons (OPN) are tonically active and pause before and during all saccadic eye movmeents. Because of this activity pattern, OPN have been implicated in the control of saccades. However, neither the afferent inputs nor the target neurons of OPN have been studied in detail. Therefore, we have begun experiments in Ketamine anesthetized cats which are sufficiently anesthetized to allow both surgical procedures and microstimulation but still make the saccades necessary to identify OPN.

Eye movements were measured by an X-Y photodiode which detected the light emitted by an LED affixed to the cornea. Stimulating electrodes were placed in the superior colliculus (SC), cerebellar vermis (CbV), fastigal nucleus (FN), and vestibular nerve (VN) since stimulation at these sites evokes eye movements, and in the optic chiasm (OX) to further evaluate our recently demonstrated visual input to OPN. The OX electrode was adjusted to record the maximal evoked response to a flash of light. The SC electrode was first placed 1 mm ventral to the area in which the maximal OX or flash evoked response was recorded and then adjusted to evoke eye movements at minimal currents by stimulation. The FN electrode was also placed to evoke eye movements. The VN electrodes were placed bilaterally on the 8th nerves which were exposed by ventral approach through the bullae. The CbV electrodes were placed on lobules 5 and 6 after exposing the lobules by partial craniotomy.

Neither FN or CbV stimulation resulted in OPN responses to single or multiple shocks with currents up to 1.5 mA. Similarly, ipsilateral or contralateral VN stimulation never resulted in a response in OPN even at current intensities which were sufficient to evoke a twitch of the globe and were several times threshold for the vestibular field. Optic chiasm stimulation produced a long latency (range 6-12 msec) excitation which was presumably polysynaptic since it was highly variable and did not become more stable with increasing current or multiple shock stimulation. As shown in the monkey, SC stimulation resulted in a short latency excitation (1-2 msec) and/or a longer latency inhibition with increasing current strength or multiple shocks. The inhibition occurred even at current strengths too low to evoke discernible eye movements and was proportional in duration to the number of stimuli.

Although the description of OPN afferents is probably incomplete the above data show that many structures believed to be associated with saccade generation do not project directly to OPN. Our preliminary microinjections of tritiated amino acids into the functionally identified OPN nucleus have suggested candidate target areas for OPN projections. Further anatomical analyses and evaluation of OPN efferents using microstimulation techniques should supply a broader basis for assessing OPN function.

498 LATE BURST PURKINJE CELL ACTIVITY IN THE VERMIS DURING EYE MOVEMENTS. Manabu Kase* and Hiroharu Noda. (SPON: S. Hagiwara). Brain Research Institute, Depts. Physiol. Anat., Sch. Med., UCLA, Los Angeles, CA 90024.

Single unit activity recorded from Purkinje cells in the vermis (lobules VI and VII) of the monkey during saccadic eye movements and fixation was analyzed.

The majority of saccade-related Purkinje cells were characterized by saccade-onset related bursts which continued throughout the duration of saccade. During fixation, the Purkinje cells fired continuously at a relatively high rate, which in some cells was a linear function of eye position.

In addition, we discovered that other Purkinje cells showed an increase in activity which was time locked with the end of saccades. When present, this increased activity (late burst) appeared regardless of the direction of the saccades. The late burst was not due to visual inputs, since it persisted even in complete darkness and Purkinje cells exhibiting late burst did not respond to visual stimuli. The burst started immediately prior to the end of saccade (average 21 msec) and lasted for approximately 150 msec. There was no relation between the durations of the burst and the saccade. The peak activity in these Purkinje cells appeared within 40 msec after the end of saccades and usually attained frequencies up to 2-4 times the level of background activity. In some cells the late burst was preceded by a slight decrease in activity which started with the onset of the saccades.

It is known from the literature that the impulses of Purkinje cells are the sole output signal from the cerebellar cortex and exert a powerful inhibitory action on postsynaptic cells. The late burst of these Purkinje cells indicates that the vermis sends inhibitory impulses which are time locked with the end of saccades. As a function of the vermis, therefore, we suggest that it helps control the terminal stage of saccades and participates in the mechanism concerned with holding a new eye position after a saccade. 499 FIRING PATTERNS OF CENTRAL VESTIBULAR NEURONS DURING ADAPTIVE MODIFICATION OF THE VESTIBULOCULAR REFLEX BY REVERSING PRISMS. Edward L. Keller and Wolfgang Precht*. Dept.Elect.Eng. and Computer Sci., Univ. of Cal., Berkeley, CA 94720 and Dept.Neurobiol., MPI for Brain Res., Frankfurt/M., FRG.

It has been reported that prism modification of normal image motion on the retina during head movement results in adaptive changes in the vestibuloocular reflex (VOR). The cerebellar flocculus has been suggested as the site of the synaptic modification implied by these adaptive behavioral changes. Since the flocculus does not project directly to oculomotor neurons, these supposed synaptic modifications would have to be expressed through other neuronal pools more directly connected to motoneurons. In the present study we looked for possible changes in vestibular nucleus neuron (Vn) discharge patterns induced during adaptive prism modification of VOR. We recorded in alert cats the response of a large sample of Vn to horizontal sinusoidal oscillations of the head in darkness over a frequency range from .025 to .25 Hz. In the same animals on random days a similar sample of Vn were recorded after the cats had been force rotated in the horizontal plane at a frequency of about 0.1 Hz while viewing a highly structured visual field through reversing prisms. Gain of the VOR was monitored during the forced rotation and neural recording was begun when it had adaptively decreased by more than 50%. In each animal a similar pattern of changes in the population of prism adapted Vn responses was observed. There was a small, but highly significant, shift toward lower gains (the ratio of peak unit modulation to peak head acceleration) of the overall sample of Type I cells. This shift was observed almost exclusively in the lower gain, large phase lag (re. head acceleration), Type I units. Small phase lag Type I units were relatively unmodified. Since the small phase lag cells have been shown in a number of other studies to be predominately monosynaptically connected to the vestibular nerve, this result suggests that second order Vn are relatively unaffected by prism adaption. Among Type II units, on the other hand, there was only a small shift toward lower gains, but this was accompanied by large (up to 90 deg.) phase shifts. This result suggests that adaptive changes in the VOR may be mediated through Type II units, which are known to provide commissural inhibitory pathways to Type I units.

500 IS THE INTERSTITIAL NUCLEUS OF CAJAL A PREMOTOR CENTER FOR VERTICAL EYE AND HEAD MOVEMENTS? W.M. King, W. Precht* and N. Dieringer*. Max Planck Institute for Brain Res., Frankfurt/M, W. Ger.

The interstitial nucleus of Cajal (INC) may be a premotor center for vertical and rotatory eye and head movements. Anatomical studies suggest that INC cells receive inputs from the vestibular nuclei, superior colliculi and cortical frontal eye fields (FEF), structures which play roles in eye and head movement. Other studies show that INC cells project monosynaptically to extraocular and neck extensor motoneurons. However, it is not known if any one INC cell projects both to neck and eye motoneurons, or if all INC cells receive similar synaptic inputs. Initially, we used intracellular recording techniques in nembutal anesthetized cats to determine the synaptic inputs to INC cells, and to test each cell for antidromic activation from the cervical spinal cord.

Stimulation of the contralateral (V_c) or ipsilateral (V_i) VIII nerves evoked characteristic field potentials centered in the INC. Most INC cells (68%) were disynaptically excited from V_c (EPSP latency 1.8 $\pm$ 0.6 ms) and inhibited from V_i (IPSP latency 2.1 $\pm$ 0.8 ms). Acute bilateral lesions of the medial longitudinal fasciculus rostral to the abducens nuclei abolished the field potentials and intracellular responses. Electrical stimulation of the FEF underlying the cruciate sulcus and in the depth of the presylvian sulcus excited 56% of the units tested (EPSP latency 2.6 $\pm$ 1.1 ms). 37% of these units received vestibular input, and 51% were antidromically or synaptically activated from the spinal cord. We were unable to demonstrate synaptic inputs from either superior colliculus or optic chiasm.

These results demonstrate differences among INC cells according to their connections. Can these differences in connectivity be related to differences in discharge pattern? In the second part of our study, we recorded extracellularly from INC cells in Ketamine anesthetized cats during spontaneous or induced eye movements. Unit firing was correlated with the left superior and lateral rectus EMG. Single unit response to electrical stimulation was used to determine connectivity. Preliminary results revealed two groups of INC cells: Group A exhibited a burst-tonic discharge pattern similar to the discharge pattern of oculomotoneurons. All Group A cells received a vestibular input and were polysynaptically excited from the FEF. In contrast, the discharge pattern of Group B cells was unrelated to the EMG, and no Group B cell was activated by vestibular stimulation. Group B cells were orthodromically excited by FEF stimulation, and antidromically activated from the spinal cord. Our results suggest that Group A cells are premotor to oculomotoneurons, and Group B cells are premotor to neck extensor motoneurons. However, other functionally significant groups of cells may exist within the INC.

501 INTERACTION OF THE EYE MOVEMENT AND LOCOMOTORY CONTROL SYSTEMS. Jose R. Latimer, A. Terry Bahill, and B. Todd Troost. Neurological Control Systems Laboratory, Biomedical Engineering, Carnegie Mellon University, Pittsburgh, PA 15213.

There have been many studies of eye movements and of locomotion, but none were found on the effects of locomotion on the eye movement system. Human locomotion is usually guided by input from the visual system. To facilitate the information processing of this system, the eyes must be moved so that the foveae of the eyes are aimed at certain specific points. The head oscillates up and down, from side to side, and back and forth while walking. Thus, the head does not provide a stable platform for the eyes, and compensatory eye movements must be made in order to fixate the eyes on target while walking. Head turns of about one-half a degree, head sways of two cm, and compensating eye movements of $\pm$ five degrees were measured.

Inputs from at least three sensory systems are integrated to guide the eye movement control system: the visual system, the vestibular system, and the proprioceptive system. Normal human eye movements used while walking were studied with the feedback loops of each system "opened". A homeomorphic model of the human eye movement control system as used for while walking was developed. It incorporates the sampled data visual feedback aspects of the saccadic control system, the vestibular-ocular control system, the proprioceptive control system, and the sixth order nonlinear extraocular Reciprocal Innervation Plant (RIP). As a first step in intergrating these various models the nonlinear RIP model was linearized. Of the various methods for doing this, one of the best was by changing the nonlinear force-velocity relationship into a time varying relation. This allowed the use of canned computer programs to analyze and simulate the plant so as to correlate the input-output relation of the RIP and the behavior of our complex model. The model was justified qualitatively by comparing the shapes of the human and model movements, quantitatively by constructing Main Sequence diagrams plotting velocity versus magnitude and duration versus magnitude for both head and eye data from the human and model data, analytically by performing a sensitivity analysis to find which parameters are most important, which require further study, and which can be ignored, and heuristically by simulating movements that the model was not designed to do.

502 EYE MOVEMENTS IN PARALYZED CATS. R.A. Linsenmeier* and B. Gevene Hertz* (SPON: C. Enroth-Cugell). Biomedical Engineering Center, Northwestern University, Evanston, IL. 60201.

Most quantitative experiments in visual neurophysiology require stability of the eyes. We have found, however, that relatively large eye movements occur under some experimental conditions, even in paralyzed cats.

Experiments were performed on cats anesthetized with urethane and paralyzed with gallamine (Flaxedil, 50 mg/kg-hr). Small mirrors were glued to the corneae, and a laser beam was directed off these mirrors onto a screen. We obtained a record of eye position as a function of time by plotting the reflected beam.

Eye movements before the experimental manipulations were small--about 0.14 degrees in 10 minutes. However, when bicuculline (0.3 mg/kg), strychnine (0.1-0.4 mg/kg) or methoxamine (Vasoxyl, 0.25 mg/kg) was then given intravenously, or when the animals were made hypoxic by respiring them with 5% O_2, eye movements were larger. The displacement in eye position was 0.5 to 2.0 degrees within 5 minutes of the manipulation. The eyes slowly returned to their initial positions following hypoxia and bicuculline, but did not return after methoxamine or strychnine. Unilateral cervical sympathectomy reduced only those movements of the ipsilateral eye caused by bicuculline and strychnine. It did not prevent movements associated with any of the agents tested.

503 SACCADIC AND VESTIBULAR VELOCITY COMMANDS: DO THEY ADD? G. Mandl and D. Guitton. Aviation Medical Research Unit, McGill University, 3655 Drummond St., Montreal, Canada H3G 1Y6.

Microelectrode recordings from the medial longitudinal fasciculus and vestibular nucleus of alert monkeys have suggested that the vestibulo-ocular reflex (VOR) is mediated by cells whose discharges pause during quick phases. This implies that there should be no linear addition of slow and quick phase velocities during head rotation. Consequently, the characteristics of vestibular quick phases, and saccades with head fixed, should be identical. This prediction has been confirmed in the monkey (Ron et al., Vision Res., 12: 2015, 1972). Recent experiments with cats by Haddad and Robinson (Neurosci. Abs., 3, 155, 1977) indicate that the velocity of quick phases with respect to the head is actually faster than the velocity of saccades.

The present experiments were undertaken to re-investigate the differences between spontaneous saccades and vestibular quick phases. Three normal cats were studied. Their heads were firmly attached to a turntable while eye movements were recorded with an implanted scleral coil in a magnetic field. Measurements were obtained both in the light and in the dark under the following conditions: (1) head stationary with the animal performing spontaneous eye movements; and (2) head and body oscillated sinusoidally at a peak-to-peak amplitude of 40°, and peak velocities ranging from 25°/sec to 75°/sec. VOR gain was 0.85-0.95. Saccade and quick phase amplitudes ranging from 2°-20° were plotted against: (a) peak velocities; and (b) durations. Regression lines were fitted to these data. Covariance analysis revealed no statistically significant differences between saccades and vestibular quick phases. This lack of linear addition would be consistent with the presence of VOR-mediating tonic-pause cells in the cat. However, the interaction between quick and slow phase may depend on visual context. This is implied by the experimental results of Bizzi et al. (Exp. Brain Res., 16: 492, 1973), who have shown that linear addition does occur during visually triggered eye-head movements in the monkey.

504 THE EFFECT OF ANESTHESIA ON PONTOMEDULLARY RETICULAR BURST INHIBITORY NEURONS RELATED TO NYSTAGMUS. Charles H. Markham, Shozo Nakao* and Ian S. Curthoys* (SPON: Thomas L. Babb). Dept. Neurol., Sch. Med., UCLA, Los Angeles, CA 90024.

Nystagmus is a sensitive indicator of arousal state and in this study we sought to identify the neural mechanisms responsible for this sensitivity. Under halothane anesthesia cats received a unilateral labyrinthectomy. Bipolar stimulating electrodes were placed on the damaged labyrinth. The activity of the ipsilateral abducens and oculomotor nerves was recorded in the orbit. Stainless steel crews over the frontal and parietal cortex were used to record EEG activity. After removal of the midline cerebellum extracellular recordings were made from reticular neurons in the vicinity of the contralateral abducens nucleus. Halothane was discontinued and Flaxedil and extensive local anesthesia were maintained for the rest of the experiment. Efficacy of anesthesia was assured by continuous monitoring of blood pressure, pupillary size and EEG.

Unilateral labyrinthectomy results in long-lasting horizontal nystagmus with the slow phase to the ipsilateral side. When cats so prepared are paralyzed with Flaxedil, it can be observed that the ipsilateral abducens nerve shows rhythmic discharges corresponding to each slow phase. Each discharge slowly increases in amplitude and is abruptly terminated under influence of a small group of burst inhibitory neurons (BINs), largely located caudal to the contralateral abducens nucleus (Hikosaka & Kawakami, 1977). Each BIN fires in bursts 50-100 msec long, reaching a maximum discharge rate of 200-800/sec. These cells are identified by their location, firing pattern as described above, and by their failure to fire when the direction of nystagmus is reversed by electrical stimulation of the damaged labyrinth.

For most BINs during nitrous oxide anesthesia (80% N_2O, 20% O_2) the maximum firing rate during the burst decreases, the number of bursts per second decreases, whereas the duration of each burst increases. These changes occur at about the same time, as soon as 20 sec after anesthesia onset, as the first detectable slowing of the EEG. These changes in BIN activity are accompanied by progressive rounding of the end of the abducens slow phase discharge.

Hikosaka and Kawakami have shown BINs have a major role in horizontal nystagmus; we have shown the activity of these cells is quickly affected by the relatively weak nitrous oxide anesthesia.

505 VELOCITY STORAGE DURING VERTICAL NYSTAGMUS. Victor Matsuo*, Bernard Cohen, Volker Henn*, Theodore Raphan, and Vianney deJong*. Depts. of Neurol., Mt. Sinai Sch. of Med., CUNY, New York, N. Y. 10029 and University of Zurich, Zurich, Switzerland.

Velocity storage plays an important role in producing horizontal nystagmus induced by optokinetic and vestibular stimulation in the monkey (Raphan, Cohen & Matsuo, 1978). Experiments were done to determine the function of velocity storage in producing vertical nystagmus. Vertical OKN was induced by rotating an optokinetic drum around monkeys lying on their sides. Vestibular nystagmus was induced both by rotating monkeys lying on their sides about a vertical axis, and by horizontal axis rotation (pitch). Regardless of the stimulus, upward nystagmus saturated at lower velocities than downward nystagmus, and neither reached the levels attained during horizontal nystagmus. The difference between upward and downward nystagmus was similar to that reported for vestibular nystagmus in man and other species, and was particularly apparent during OKN. Maximum downward slow phase velocities during upward OKN were less than 30°/sec, while upward slow phases of downward OKN could be 60°/sec or more. Saturation values of OKAN were similar to those of OKN. The addition of a rotating gravity vector during pitch caused nystagmus to be prolonged indefinitely. This is similar to effects during barbeque rotation.

The presence of OKAN indicates that velocity storage occurs for nystagmus in the vertical as well as in the horizontal plane. After-nystagmus following rotation in light was also weaker than after rotation in darkness, indicating that velocity storage during OKN had reduced the post-rotatory response. Reduced storage for upward nystagmus was reflected in a reduced ability to counteract post-rotatory downward nystagmus. Presumably during pitch the velocity storage integrator is continuously activated by the action of the rotating gravity vector on the labyrinth. The data suggest that the organization of the vertical and horizontal systems producing nystagmus is similar, but that there are differences in coupling to the velocity storage mechanism. Different coupling coefficients could also account for the observed differences between upward and downward nystagmus.

506 PGO BURST NEURONS: EVIDENCE FOR PGO WAVE GENERATION. Robert W. McCarley, John P. Nelson, J. Allan Hobson. Lab. of Neurophysiol. Harvard Medical School, Boston, Mass. 02115.

PGO waves are the prominent monophasic potentials seen in Pons, lateral Geniculate body (LGB) and Occipital cortex just before (transition, T) and during desynchronized sleep (D). As a first step in defining the neuronal network involved in the chain of events leading to PGO wave generation, it is of particular importance to identify the set of neurons forming the last link of this chain, that is to identify a set of output neurons for PGO wave generation.

We now report on a class of neurons, PGO burst neurons, which satisfy the following correlational criteria for output cells for PGO wave generation: high discharge coherence with PGO waves (discharge bursts associated with most waves - range 60-93% for these 23 cells); high discharge specificity (relative absence of discharge at other times - range 79-99% for these cells); and a fixed phase lead and stereotyped discharge pattern (these cells discharge in bursts of 2-6 spikes, the first occurring with minimal variability 12 msec before PGO wave onset, 45 msec before PGO wave peak). These cells discharge single spikes in relationship to some eye movements and to startling stimuli during wakefulness (W).

In a series of explorations from A4 to P8, such neurons were recorded only at midbrain sites in close approximation to the brachium conjunctivum, an area in which there is HRP evidence of projection to LGB. However, we were unable to elicit antidromic activation from LGB. Orthodromically activated bursts could be elicited consistently by stimulating through LGB leads which gave the best PGO wave recordings. The evoked bursts were state-dependent, with a single spike at 37-70 msec in W contrasted to a typical burst at 25-30 msec latency in D. Another state-dependent result was that PGO waves could be evoked consistently in D by stimulation in the opposite LGB. Burst cell discharge had the same phase relation to the evoked PGO waves as to spontaneous PGO waves, and it is thus probable that these cells also act as output generators for evoked PGO waves.

In contrast, recent experiments intended to record cells in the nucleus abducens and praepositus hypoglossi (histology pending) have yielded a number of units whose discharges are highly correlated with eye movements and which show marked modulation in association with PGO waves, but not in the fixed, specific pattern of PGO burst neurons.

We postulate that PGO burst neurons are output cells for PGO wave transmission from brain stem to forebrain.

507 NEURONS IN THE OCULOMOTOR, TROCHLEAR AND ABDUCENS NUCLEI PROJECT CAUDALLY IN THE MLF TO THE PREPOSITUS NUCLEUS. R. A. McCrea and R. Baker. Dept. Physiology & Biophysics, New York Univ. Med. Ctr., 550 First Ave., New York 10016.

Previous studies have shown that neurons in the oculomotor nucleus (Oc.n.) project to the abducens nucleus (Abd.n.), reticularis tegmenti pontis and cerebellum. In addition, neurons from the Abd.n. project to the Oc.n. and the cerebellum. Electrophysiological evidence has demonstrated that these neurons are not motoneurons. We now report that there are neurons in each of the oculomotor nuclei which project via the medial longitudinal fasciculus (MLF) to levels caudal to the Abd.n. and terminate in the prepositus nucleus. Following extracellular HRP injections in either the prepositus or the caudal MLF of the cat, labelled neurons are found bilaterally throughout the Oc.n. and Abd.n. Labelled cells are also observed in the rostral ipsilateral troclear nucleus. Many labelled neurons are also found in close proximity to each of the ocular nuclei as well as around, and within, the MLF. Most of the neurons were either small or medium sized, but a few large cells were always labelled.

The pathway from the ocular nuclei to the prepositus nucleus was demonstrated electrophysiologically by recording intra- and extracellularly from neurons in the Abd.n. while electrically stimulating the prepositus and Oc nuclei. Neurons in the Abd.n. which were antidromically activated following stimulation of the prepositus were not activated by stimulation of the VIth nerve or inferior cerebellar peduncle. Several of these neurons were stained by intracellular injection of HRP. Surprisingly, 36% of the caudally projecting Abd.n. neurons were antidromically activated following stimulation of both the prepositus and Oc.nuclei. Collision studies demonstrated that the axons of these neurons collateralized, one branch ascending and the other descending in either the ipsi- or contralateral MLF. In another set of experiments, neurons in the prepositus nucleus were recorded intracellularly while stimulating the Oc.n. Many of these cells were antidromically activated. In nearly all neurons, monosynaptic EPSPs were recorded following stimulation of the ipsilateral and, in most cases, the contralateral Oc.n. These data suggest the existence of reciprocally organized excitatory loops between the prepositus and each of the ocular nuclei. Given the wide profile of eye movement responses observed in the prepositus nucleus and that expected to be found in the neurons of the individual ocular nuclei, we propose that the aforementioned intrinsic pathways may be utilized to coordinate horizontal with vertical eye movements. 508 EFFECT OF PROLONGED OPTICAL REVERSAL OF VISION ON THE VESTIBULO-OCULAR REFLEX: SOME NEUROPHYSIOLOGICAL OBSERVATIONS. F. A. Miles and D. J. Braitman.* Lab. Neurophysiol., NIMH, Bethesda, MD 20014.

The vestibulo-ocular reflex (VOR) undergoes adaptive gain changes when the visual input associated with head turns is disturbed by reversing prisms. Single unit recordings were undertaken in the vestibular nerve and flocculus of 7 awake rhesus monkeys: 4 were normal and 3 had worn left-right reversing prism spectacles so that their horizontal VOR gain was low (<0.2) or even reversed. Animals were seated in a primate chair which could be oscillated about a vertical axis (providing controlled vestibular stimulation), and their heads secured to it through a platform which could be tilted 25° forward or backward. 437 semicircular canal fibers were analyzed, each being assigned to a given canal on the basis of its response to oscillation and tilting. Cosine functions relating oscillation sensitivity to tilt angle were constructed for individual fibers from each canal to determine apparent canal orientations and allow estimation of fiber sensitivities to sinusoidal oscillations when canal alignment was optimal. Statistical analyses revealed no significant differences between normal and low gain animals in the sensitivity, phase or resting discharge rate of their semicircular canal fibers. We conclude that VOR gain changes are not mediated by vestibular efferents. The discharge characteristics of 532 flocculus Purkinje cells were examined for vestibular and oculomotor relationships: 44% were related to gaze velocity during horizontal tracking, 23% to vertical tracking, 15% to eye position, 6% to miscellaneous combinations of head and eye movement, 4% to saccadic eye movements only and 8% were unresponsive. The discharges of horizontal gaze velocity neurons were examined during sinusoidal tracking both when the head was stationary--to provide a measure of "eye velocity" sensitivity--and when the head was moved exactly in concert with the target--to provide a measure of "head velocity" (vestibular?) sensitivity. Assessed in this way in the normal monkey, head and eye velocity signals were of similar strength (correlat^{n} coef. = 0.87; regression line has a slope not significantly different from 1 and an intercept not significantly different from zero). In the low gain animals, eye velocity signals were significantly greater than head velocity signals (correlat^{n} coef. = 0.72; slope of the regression line = 0.67 with an intercept not significantly different from zero). Such a shift in the weightings of the head and eye velocity signals in low gain animals is not consistent with the view that the flocculus is the site of modifiable elements subserving VOR gain changes. We suggest that such changes in the floccular output are more probably a secondary consequence of it receiving a modified input. However, since the signals carried by the flocculus changed less than the VOR, flocculus Purkinje cell discharges would be responsible for some of the observed reduction in the VOR gain.

509 PURKINJE CELL ACTIVITY IN THE MONKEY FLOCCULUS DURING SMOOTH PURSUIT EYE MOVEMENTS. Hiroharu Noda and David A. Suzuki*. Brain Research Institute, Depts. Physiol. Anat., Sch. Med., UCLA, Los Angeles, CA 90024.

The activity of Purkinje cells in the flocculus was studied in alert monkeys that were tracking a small, colored spot moving in straight lines at various orientations on a tangent screen. Target movement was either as a sine wave or as a composite of sinusoids of different frequencies; the latter was employed in order to eliminate the predictability of a pure sine wave. Activity in Purkinje cells of the flocculus was studied in association with the three paradigms of smooth pursuit in darkness, tracking in the presence of a black and white random dot background, and fixation during movement of the random dot background.

During smooth pursuit eye movements, modulation of simple spike activity was observed in Purkinje cells. In a portion of this population, this modulation was clearly related to eye movement velocity, but in many cells, peak activity did not occur in phase with maximum velocity. A phase difference of about 45° was typically observed between peak activity and the point of peak velocity. Interestingly, a 45° phase shift was also commonly observed in Purkinje cells classified as position coded, indicating that the output of these Purkinje cells in the flocculus may reflect the integration of eye position and velocity information.

In Purkinje cells exhibiting both smooth pursuit related discharge modulation and saccade related suppression of simple spike activity, suppression appeared to be relatively potent. Saccadic pauses were observed even during the high frequency, maximal Purkinje cell discharge associated with pursuit in the preferred direction. It appears that signals related to saccades reach the flocculus independent of eye position and/or velocity information and act to disinhibit cells upon which floccular Purkinje cell axons terminate.

In a small sub-population of the cells exhibiting smooth pursuit modulation, cellular activity was also correlated with background movement during fixation. A 180° phase difference was observed between unit activity associated with tracking and with background movement, indicating that information concerning retinal image motion also reaches the flocculus. To be noted, however, is the observation that in the majority of cells exhibiting smooth pursuit modulation, the modulation occurred regardless of the presence or absence of the background, implicating the primacy of eye movement signals to these cells in the flocculus. To different degrees, therefore, oculomotor and visual information aid the flocculus in its role in the control of eye movements. (Supported by NIH Grant EY01051)

510 VOR GAIN CHANGES PRODUCED BY TARGET ROTATION WITHOUT HEAD MOVEMENT IN GOLDFISH. J.O.Schairer*& M.V.L.Bennett (SPON: R.Babb). Dept. Neurosci., Albert Einstein Coll. of Med., Bronx, N.Y.10461.

Goldfish can be trained to change the gain of their vestibulo-ocular reflex (VOR) over the course of a few hours (Neurosci. Abs. 3:157, 1977). Training the gain to increase towards two consists of sinusoidally rotating a restrained goldfish in the center of a cylindrical, vertically striped drum which is rotated equal and opposite to the fish. In order to assess the effect of visual stimulation alone on VOR gain, the striped drum was rotated sinusoidally with an amplitude of 20 deg and a period of 8 sec around stationary fish. The VOR gain was measured by rotating the fish at the same period and amplitude in the dark. Fish were not rotated in the light during the experiment. Nine fish underwent this "stripes only" treatment for times varying from two hours to six hours. In every fish the gain increased. The mean initial gain (±S.D.) was 0.67 ±0.13 and the mean final gain was 0.99 ±0.14. For comparison six fish that were trained for two hours to increase their gain towards two, increased their gains from 0.77 ±0.05 to 1.40 ±0.07. Four fish that were run for two hours in the stripes only condition increased their gain from 0.72 ±0.08 to 0.95 ±0.09. The peak amplitude of the slip (the difference between the drum velocity and slow phase eye velocity with respect to a non-rotating frame of reference) in both conditions dropped: from 10.1 ±0.9 deg/sec to 6.3 ±2.2 deg/sec for the fish which underwent the stripes only condition and from 12.3 ±2.5 deg/sec to 3.8 ±2.2 deg/sec for the fish trained towards two. Thus the greater effectiveness of training towards two does not appear to be simply due to greater slip.

An optokinetic stimulus drives goldfish vestibular neurons in such a way that a stationary visual scene improves their response to long constant velocity rotations (Dichgans et al., Br. Res. 18:319, 1973). Thus when the striped drum is rotated around a fish, it sees slip in one direction while its vestibular neurons are responding as if it were rotating in the other direction. This pairing of slip and activity of vestibular neurons is what occurs when the animal is being trained towards two with rotation. The similarity may explain why the VOR increases with the visual stimulus alone.

511 THALAMIC UNITS DETECTING ABSOLUTE SPACE POSITION OF VISUAL TARGETS. John D. Schlag and Madeleine Schlag-Rey. Dept. Anat. and BRI, Sch. Med., UCLA, Los Angeles, CA 90024.

Saccade neurons of the cat's thalamic internal medullary lamina (IML) fire before and during eye movements in specific directions. The same IML neurons can also respond phasically (On and Off) and/or tonically to the presentation of visual stimuli. Visual stimuli are effective only when they are so placed that, should a targeting saccade occur, it would be oriented in the unit's preferred direction for producing saccadic bursts. These results, already reported, imply that visual responses correspond to the detection of targets for orienting eye movements. If there is a spatial coding in these responses, is it exclusively based on retinal coordinates?

Microelectrode recordings were made in the IML of alert cats with the head fixed and facing a tangent screen on which dim light patterns were projected. Stimulus and electrooculographic (EOG) coordinates were continuously monitored. Tested with 1-deg. targets on which fixation was conditioned, the EOG measurements were consistent within a ± 1-deg. range. Maps of receptive fields were determined for individual cells. While the animals fixated in various directions, stimuli were systematically presented at sites on the screen corresponding to equivalent positions within the receptive field. For most IML neurons tested in this manner, On-responses were absent or much weaker when stimuli were offered in the hemispace opposite to the side of receptive field location. The effect of absolute spatial location was even clearer for tonically activated units. Those with a small central receptive field fired continuously only when the animal fixated a stationary target or tracked a moving target within a circumscribed area of the screen. Thus, the adequate stimulus location was defined in terms of head-body coordinates during fixation. Units with a large receptive field started to discharge profusely when stimuli reached, moved in, or appeared in an hemispace, whether the target was fixated or not. The competence of this type of cell was limited to a half visual space around the animal, in which the cells hardly ever failed to notice visual events. In most cases, the frequency of firing increased gradually as the stimulus moved far away from the center of the screen. Thus some IML neurons receive information on the orientation of the eyeball but this information appears at the cell output only in presence of a visual target. This interpretation is supported by the finding, in the IML, of pure fixation units and eye position units which could provide the adequate inputs to explain the properties described. The data provide a basis for models assuming spatial visual coding referred to non-retinal systems of coordinates (Supported by USPHS grant NS-04955).

512 FIRING CHARACTERISTICS OF UNITS IN CAT SUPERIOR COLLICULUS DURING TRACKING. Madeleine Schlag-Rey and Carol K. Peck. Dept. Anat. and BRI, Sch. Med., UCLA, Los Angeles, CA 90024.

In alert cats, cells of the superficial and intermediate layers of the superior colliculus (SC) respond profusely to moving visual targets over a wide range of velocities (see Peck and Schlag-Rey's abstract, this meeting). Some cells are activated only when something moves in the visual environment. We have tried to determine the parameters responsible for this activity during eye tracking, the head being fixed.

The moving target was a dim, blue 1.5°-circle projected on a tangent screen. Stimulus velocities ranged from 3 to 400°/sec. Tests were run with single ramps, sinusoidal and sawtooth movements with various amplitudes and directions. The sawtooth motion was effective in inducing the cats to bring their gaze exactly on the linear path of the moving target. Stimulus and electrooculographic (EOG) coordinates were continuously recorded. Calibration adjustments afforded EOG measurements consistent within ± 1 deg. The cats were not reinforced for tracking but prior conditioning had given them an incentive to explore their visual environment.

All cells analyzed had a preferred direction. 1. When the cats were fixating a point on the path of the target and the target was moving in the preferred direction, the firing rate gradually increased as the target approached the point of fixation of the gaze. At some distance past this point, while the target moved away, the firing rate started to decrease. This was shown by synchronizing rasters of unit activity on the time when the target met the eyes. This pattern of response was condensed over a shorter time interval as stimulus velocities were higher, suggesting a rather constant relationship with the target position in the receptive field. 2. During pursuit episodes in the preferred direction, when eye velocity matched target velocity, the rate of discharge remained constant; some cells fired intensively whereas others were silenced. 3. When the cats approximated a smooth pursuit by a succession of small catching-up eye movements, velocity errors of opposite signs were associated with increased activity (eyes lagging) or decreased activity (eyes catching up). These changes followed the eye movements. They could be due to changes in the virtual movement of the target or to a proprioceptive input interacting with the visual input. However, predictions of unit activity based solely on the effect of virtual movement are contradicted by results obtained when the target moved in the null direction. These observations support the hypothesis that visual activity of SC neurons is better understood in terms of the information needed for tracking than perception of movement (Supported by USPHS grant 04955).

513 INNERVATION OF EXTRINSIC OCULAR MUSCLES. Marjorie D. Shaw* and Keith Alley. Case Western Reserve University, Cleveland, Ohio 44106.

The oculomotor system provides an excellent model for the study of developing motor systems in mammals. As a basis for such an analysis, we are charting the basic innervation patterns of the extrinsic ocular muscles. Neonatal and adult rabbits are being used to follow the development of motoneuron pools, and adult cats and rabbits to localize the primary sensory neurons.

Horseradish peroxidase injected into specific eye muscles was retrogradely transported to cells in the brainstem and trigeminal ganglion. Even at birth, the motoneurons of the rabbit oculomotor nucleus are segregated into distinct subpopulations, similar to those described in cat and monkey. Injections of tritiated amino acids into motor nuclei have been shown to label motor terminals intensely, and are being used to confirm such projections.

The peroxidase-filled cells of the trigeminal ganglion are presumed to represent the cell bodies of primary sensory neurons to the eye muscles. No peroxidase labelled cells could be detected in the mesencephalic nucleus after eye muscle injections, in contrast to previous reports in the literature, even though labelled cells were numerous after injection into the masseter. To document our presumption that the ganglion cells supply sensory receptors to the eye muscles, we are injecting tritiated amino-acids into these neurons, to label their endings via fast axonal transport. (Supported by NIH grants NS 12781, NS 00147 and NSF fellowship.)

514 IDENTIFICATION AND LOCALIZATION OF MOTONEURONES INNERVATING THE CAT RETRACTOR BULBI MUSCLE. Robert F. Spencer. Dept. of Anat., Med. Coll. Virginia, Richmond, VA 23298.

The retractor bulbi (RB) muscle is an extraocular muscle which is divided into four slips that are closely associated with the lateral rectus (LR) and medial rectus (MR) muscles. In the present study, motoneurones innervating the four slips of the cat RB muscle have been identified by retrograde intraaxonal transport of horseradish peroxidase (HRP).

Following injections of HRP into all four slips of the RB muscle, motoneurones were found distributed throughout the rostral-caudal extent of the ipsilateral abducens nucleus, overlapping the distribution of LR motoneurones and abducens internuclear neurones. The RB motoneurones accounted for approximately 30% of the total number of neurones in the abducens nucleus. HRP-labelled motoneurones were also found in the ipsilateral accessory abducens nucleus, situated considerably ventral and lateral to the abducens nucleus, and in the ipsilateral oculomotor nucleus, overlapping the distribution of MR motoneurones. Injections of HRP into individual slips of the RB muscle also resulted in labelled motoneurones in the abducens, accessory abducens, and oculomotor nuclei, though in fewer numbers than when all four slips were injected. There was no apparent topographical organization of neurones innervating individual slips within any of these nuclei. Light microscopic examination of semithin sections revealed the RB motoneurones to be circular to pyriform in shape, ranging from 32 - 52 μm in mean diameter. Examination of ultrathin sections by electron microscopy showed these motoneurones to be cytologically similar to LR and MR motoneurones.

The results indicate that RB motoneurones comprise a more homogeneous population of neurones than LR or MR motoneurones. This is consistent with the reported physiological homogeneity of RB motor units, in contrast to the heterogeneity of LR motor units. The results also indicate that a single muscle may be innervated by neurones located in more than one motor nucleus. This finding suggests that functional differences may exist between motoneurones in different motor nuclei that innervate the same muscle.

515 OCULAR MOTOR ABNORMALITIES IN TRAINED MONKEYS WITH FLOCCULAR LESIONS. David S. Zee, Atsumi Yamazaki* and Gundez Gucer. Dept. Neurol., Johns Hopkins University, Baltimore, Md. 21205.

Eye movements were recorded (search coil technique) in three trained juvenile macaques with bilateral lesions of the cerebellar flocculi and paraflocculi. One monkey with histologically verified total flocculectomy showed: 1) decreased smooth pursuit (gain (eye vel/targ vel) = 0.65), 2) decreased ability to cancel the vestibulo-ocular reflex (VOR) using fixation of a small target moving with the head (gain (eye vel/head vel) = 0.4), 3) inability to hold eccentric gaze (gaze-paretic nystagmus) with a time constant of centripetal drift of 2 secs, 4) increased VOR gain in darkness (35%), 5) impaired suppression of the VOR when rotating with an optokinetic (OK) drum fixed to the chair (gain = 0.95; preop = 0.35), 6) abnormal OK nystagmus with a slow rise to maximum eye velocity (time constant $>$ 15 secs; preop $<$ 7 secs) and decreased steady state gain (eye vel/drum vel = .85), however, the time constant of OK after nystagmus in darkness was unchanged, 7) downward beating vertical nystagmus, 8) rebound nystagmus in primary position after prolonged eccentric gaze and 9) post-saccadic drift (glissades). These abnormalities partially recovered in several months.

A second monkey with a presumed complete ablation showed similar but less marked abnormalities. A third monkey had an asymmetrical partial lesion and showed a transient ipsilateral deficit in smooth pursuit, OK nystagmus, cancellation of the vestibulo-ocular reflex and holding eccentric gaze.

These results directly implicate the flocculi (and possibly paraflocculi) in a variety of retinal image stabilizing reflexes. Smooth pursuit and cancellation of the VOR using fixation were comparably affected by flocculus ablation although other cerebellar structures must also be important since the defects were partial. OK nystagmus was also impaired, the dynamic more than the steady state response. This finding may reflect a loss of the normal smooth pursuit contribution to the intact monkey's nystagmus response to OK stimulation. During rotation with a chair fixed OK drum, suppression of the VOR was markedly impaired. This finding correlates with reports of impaired suppression of caloric-induced nystagmus in flocculectomized monkeys. Gaze holding was also impaired and suggests the flocculus acts to increase the time constant of the brain stem neural integrator that holds positions of gaze. Downbeat and rebound nystagmus as well as abnormal pursuit and gaze paretic nystagmus are features of the human ocular motor cerebellar syndrome which suggests that floccular damage may contribute to its production.

FEEDING AND DRINKING

516 THE EFFECTS OF KNIFE CUTS ON EATING ELICITED BY NORADRENERGIC STIMULATION OF THE HYPOTHALAMUS. Paul F. Aravich*, Anthony Sclafani, and Sarah F. Leibowitz. Dept. Psychol., Brooklyn Coll. of CUNY, Brooklyn, N.Y. 11210 and Rockefeller Univ., New York, N.Y. 10021.

The present experiment examines the interrelationship between three hypothalamic manipulations known to increase feeding: first, norepinephrine (NE) injections into the paraventricular nucleus (PVN) which elicit feeding in satiated rats; second, PVN injections of the presynaptically-acting tricyclic antidepressant protriptyline which elicit feeding through activation of endogenous NE stores; and third, bilateral parasagittal knife cuts between the medial and lateral hypothalamus which cause hyperphagia and obesity.

Male rats received either large parasagittal knife cuts rostro-lateral to the PVN or sham knife cut surgery. Following recovery a second surgery was performed on all animals during which a unilateral drug cannula aimed at the PVN was implanted. Possible disruption of efferent fibers mediating the noradrenergic feeding response was assessed by examining the effectiveness of postsynaptic receptor stimulation through l-norepinephrine bitartrate injections (20, 40, and 80 nmoles in .5 microliters of saline). Disruption to afferent noradrenergic fibers mediating this feeding response was appraised by examining the effectiveness of the presynaptically-acting drug protriptyline hydrochloride (100 nmoles in .5 microliters of water).

The results of the experiment indicate that, while the knife cuts increased daily food intake, they did not block NE or protriptyline induced eating. Histological examination revealed that the drug cannulae for all animals were in the region of the PVN. The knife cuts, on the other hand, extended rostro-caudally from the anterior preoptic region through most of the mamillary region. They were 4 to 5mm in height and extended dorsally above the cannula tips and ventrally to the base of the brain. In the medio-lateral plane the cuts were located just medial or just lateral to the fornix.

These findings appear to demonstrate that the NE-elicited feeding response can be disassociated from the hyperphagia syndrome produced by parasagittal hypothalamic knife cuts. Furthermore, it would appear that neither the afferents or efferents responsible for NE-elicited eating have been transected by these particular cuts. To further explicate the fiber systems responsible for noradrenergic feeding, an additional study designed to examine the effects of coronal knife cuts anterior and posterior to the paraventricular region is being conducted.

517 EFFECTS OF CERVICAL VAGUS NERVE STIMULATION ON LPA-LH-MFB SINGLE UNIT ACTIVITY. F.C. Barone, M.J. Wayner, U.H. Aguilar-Baturoni and R. Guevara-Aguilar. Brain Research Laboratory, Syracuse University, Syracuse, New York, USA and Departamento de Fisiologia, Facultad de Medicina, U.N.A.M., Mexico.

The whole left cervical vagus nerve was stimulated in female rats. Data collected from those animals which displayed a constant bradycardia effect at a stable threshold were used for analysis. Recordings were made from neurons in both the ipsilateral and contralateral hemispheres during vagus nerve stimulation. The polarity of rectangular pulses used to stimulate the vagus nerve during brain cell recording was the opposite to that which elicited the largest bradycardia response at the lowest threshold. Following a 3 minute baseline period of data collection on a unit under study, a train of pulses 0.5 m seconds in duration, was applied to the vagus nerve for a period of 4 seconds. Each subsequent 4 second pulse train was separated by at least 3 minutes. Both frequency, 10 to 100 Hz, and voltage, 1 to 20 volts, of the vagus nerve stimulation were varied in a random manner for units under study. The graphical output in spikes per second were used to evaluate the effects of vagal nerve stimulation on central neural activity. Frequency response relationships were established for most of the lateral preoptic-lateral hypothalamic-medial forebrain bundle (LPA-LH-MFB) neurons which were affected by vagus nerve stimulation. Four types of neuronal responses were observed due to vagus nerve stimulation. Cells studied would exhibit increases or decreases in discharge rate as stimulation frequency was increased, or increases or decreases in discharge rate as stimulation frequency was decreased. In all cases, when increasing or decreasing the stimulation frequency increased or decreased the unit discharge rate, increasing the stimulation voltage facilitated further the same effect. Eighty-two percent of the cells studied in the LPA-LH-MFB area exhibited significantly altered discharge rates due to vagus nerve stimulation. Of these 33 percent increased discharge rate when vagus stimulation frequency was increased (22 percent) or decreased (11 percent). Sixty seven percent of the cells affected decreased discharge rate when vagus stimulation frequency was increased (44 percent) or decreased (22 percent). None of the cells sampled from some other areas of the brain responded significantly to vagus nerve stimulation and indicated a somewhat specific effect due to vagus nerve stimulation in this area.

518 THE EFFECT OF HYPOPHYSECTOMY (HYPOX) AND ADRENALECTOMY (ADX) ON DIURNAL FEEDING AND DRINKING RHYTHMS IN THE RAT. Larry L. Bellinger, Fred E. Williams* and Lee L. Bernardis. Dept. Physiol., Baylor Coll. of Dentistry, Dallas, TX 75246 and Dept. Surg. and Path., S.U.N.Y., Buffalo, N.Y. 14215.

Hypox alone has been shown (Bellinger and Mendel, Can. Fed. Biol. Soc., in press) to alter the normal diurnal feeding rhythm of rats. Corticosterone rhythms also appear to be closely aligned to feeding patterns in the rat (Bellinger et al, Neuroendocrin. 22:216. 1976). This study was undertaken to first, confirm our earlier findings that Hypox alone would alter the diurnal feeding rhythms of rats and secondly, to observe if the modified patterns could be attributed to a loss of corticosterone rhythm. Hypox (n=14), Adx (n=16) and non operated control (CON) (n=14) male Sprague-Dawley rats of the same age were purchased from Simonsen Lab., Gilroy, Ca. The animals were housed individually under a L:D of 12:12. The animals were allowed 13 days to adjust to their new environment. At the end of this period the amount of food and water consumed during the light phase and dark phase was recorded on each rat for six days. No one was allowed in the animal room except to measure food and water consumption. There was a significant difference in the % of food the groups consumed during the dark and light phases over the six day period [H(2)= 21.2; P<0.001]. The Hypox rats ate a significantly lower % (z= 5.2; P<0.001) of their food at night compared to the CON (77.2 $\pm$ 1.5% vs 87.0 $\pm$ 0.6%). The % of food the Adx rats consumed during the dark (86.9 $\pm$ 1.1%) did not differ from the CON but did differ (z=4.9; P<0.001) from the Hypox rats. The Hypox rats showed a large day to day variation in the % of food consumed during the light and dark phases (χ^2=172.9; P<0.001) while the CON showed little variation (χ^2=30.4; P>.99). There was also a significant difference in the % of water the groups consumed during the dark and light phases [H(2)=52.8; P<0.001]. The Hypox group drank a lower % (z=5.1; P<0.001) of their water at night compared to the CON (74.2 $\pm$ 2.3% vs 86.3 $\pm$ 1.5%). The Adx rats consumed a larger % (91.3 $\pm$ 1.4) of their water at night than either the CON (z=4.3; P<0.001) or the Hypox rats (z=6.6; P<0.001). These data show that Hypox can somewhat alter the normal diurnal food and water intake rhythms in rats. However, it should be noted that the Hypox rats still consume a large % of their food during the dark phase and thus appear to be still strongly influence by the photoperiod. The data further reveal that Adx does not cause an alteration of the normal food intake rhythm but does appear to slightly enhance the % of water the animals will consume during the dark phase.

519 EFFECT OF EPI- AND SUBTHALAMIC LESIONS ON SOMATIC AND ENDOCRINE PARAMETERS IN WEANLING AND MATURE RATS. Lee L. Bernardis and Larry L. Bellinger, Depts. Surg. and Path., SUNY at Buffalo, Buffalo, N.Y. 14215, and Dept. Physiol, Baylor Coll. Dent., Dallas, Texas 75246.

Weanling rats received bilateral electrolytic lesions in the zona incerta (ZIN); sham-operated animals served as controls. The animals were maintained for 30 days postoperatively and trunk blood was collected at sacrifice. Two experiments were performed several months apart. The data show that ponderal and linear growth, food and water intake and water/food intake ratio and pituitary weights were significantly reduced in the ZIN-lesioned rats. Body composition and circulating glucose, growth hormone and insulin were normal, however. The findings are surprising since previous reports indicate that ZIN lesions in mature rats do not cause alterations in food intake and body weight. This is possibly so since in the present studies the rats were in a state of rapid growth and thus more sensitive to the disruptive effects of the lesions. The above changes-growth retardation in the face of normal body composition and growth hormone levels-are similar to those reported for the weanling rat dorsomedial syndrome and point to an extrapituitary origin of the alterations. The changes observed may be related to the mesencephalic reticular formation that could bring to bear its influence on the subthalamus, into which it extends as the ZIN.

Weanling and mature (220 gm) rats received bilateral electrolytic lesions in the medial habenula (HAB); Sham-operated rats served as controls. The animals were maintained for 43 postoperative days and trunk blood collected at sacrifice. Both weanling and mature rats showed no significant changes in any of the parameters except for a slight reduction of linear growth in the weanling rats and of water intake in the mature rats. The lack of profound changes in the HAB-lesioned rats is surprising since this area has been described as exerting an influence in thyroid control and of playing a role in thermoregulation as well as serving as an important link between olfactory sensor information with motor areas of the brain. HAB lesions of long standing have also been reported to bring about obesity. The HAB are linked to the brain via the fasciculus retroflexus of Meynert and could thus come under the influence of the forebrain reticular formation. This has been described as a pathway through which primitive aspects of brain function are influenced by the viscera.

NIH-HD 03331 and NSF-PCM 76-8[illegible]81.

520 SHORT AND LONG TERM EFFECTS OF KAINIC ACID INJECTIONS INTO THE LATERAL HYPOTHALAMUS. Michael Britt* and Darryl B. Neill* (SPON: David Freides). Department of Psychology, Emory University, Atlanta, GA 30322.

Electrolytic lesions of the lateral hypothalamus (LH) have indicated the importance of LH structures in the control of food and water intake. However, damage to the monoaminergic fibers passing through the LH duplicates many of the effects of LH electrolytic lesions. This experiment assessed the effects of LH injections of kainic acid, which appears to damage neuronal somata while leaving fibers of passage intact.

Rats receiving kainic acid injections (0.4 µl/0.2 µl; pH4) were compared with those receiving:electrolytic lesions (2 mA, 15-20 s), saline (0.2 µl), lactic acid (0.2 µl; pH4), or sham surgery. The latter three groups showed no significant internal differences and will be collectively referred to as controls.

Postoperatively, both kainic-injected (KI) and lesioned (EL) rats were aphagic (food intake $\leq$ 2 g/day) for equivalent periods. Hypophagia, however, was much shorter for KI than EL rats. The duration of adipsia ($\leq$ 4 ml/day) was shorter for KI than EL rats. Controls showed no aphagia or adipsia. Whereas EL rats were hunched and inattentive, KI rats retained normal posture and were hyperactive to many stimuli. Locomotor activity on the 2nd postoperative day was severely depressed in EL rats but only moderately depressed in KI rats. By the 4th postoperative day, KI and control rats were equally mobile and both more active than EL rats. Neither KI nor EL rats increased food intake above baseline levels following intraperitoneal (IP) administration of 2-deoxy-D-glucose (750 mg/kg), nor did either group show normal increases in water intake in response to IP injections of hypertonic saline (2 M).

Spectrophotofluorometric measurement of neocortical and striatal norepinephrine, dopamine, and serotonin content showed no differences among control and KI groups, indicating no damage to monoaminergic fibers of passage. Electrolytic lesioning depleted monoamines. Examination of nissl-stained sections revealed kainic-induced cell loss apparently limited to the LH. 521 ADULTLIKE DRINKING BEHAVIOR IN SIX AND TEN DAY OLD RATS. John P. Bruno* (Spon. Elliott M. Blass) Dept. Psychology, Johns Hopkins Univ., Baltimore, MD 21218.

The demonstration of alternate patterns of ingestion in suckling rats would be of interest. It would permit direct analyses of the ontogeny of adultlike feeding and drinking behaviors. Accordingly, the capacity of infant rats to ingest in a manner other than suckling was investigated.

Pups were individually placed on a paper towel that was saturated with either milk, water, or hypertonic saline (1M). Rats were tested at 35°C. This high temperature is necessary for the elicitation of the consummatory response. Six and ten day old pups were randomly assigned to one of the following conditions: 1) nondeprived (pups remained with the mother until tested); 2) nondeprived + NaCl (1M, 2% BW, s.c.); 3) 4 hr. deprived (pups were removed from the mother for four hours prior to testing); and 4) 4 hr. deprived + NaCl (1M, 2% BW, s.c.). Subjects from each treatment condition were allowed to consume either milk, water, or hypertonic saline during a 20 minute test.

There were four major findings. First, nondeprived and deprived pups consumed little of any fluid: milk intake: 1-2% BW, water and saline intake: .5-1% BW. Second, acute cellular dehydration increased intake of all fluids. Third, acute cellular dehydration differentially affected water intake, increasing it to 6-7% BW. In fact, dehydrated rats drank more water than milk. This is a reversal of the preference exhibited by both nondeprived and deprived pups. The response to dehydration was selective, since dehydrated subjects still consumed only very small amounts (1-2% BW) of the saline solution. This selectivity is important as it is a major defining characteristic of adult drinking behavior. Finally, there were no age-related differences in the responses of six and ten day old pups.

These findings demonstrate that adultlike drinking behavior can be elicited by cellular dehydration in rats as young as six days of age. This demonstrated ability now permits a detailed investigation of the earliest forms of ingestive behavior leading to an appreciation of how they become expressed under natural conditions.

522 BLOCK OF CHOLINERGIC INDUCED THIRST AFTER OBSTRUCTION OF ANTERIOR VENTRAL THIRD VENTRICLE OR PERIVENTRICULAR PREOPTIC ABLATION. James Buggy, Dept. Physiol., Sch. Med., Univ. S. Carolina, Columbia, SC 29208.

A cholinergic coded circuit in the limbic system mediating thirst behavior has been postulated in the rat since cholinergic brain stimulation at a variety of limbic sites induces water intake. Drinking normally observed after cholinergic stimulation is blocked by atropine pretreatment at any of several circuit sites yet ablation of these same sites is without effect. This result and the fact that many positive sites are located near the cerebral ventricles suggests that the injected chemicals may have acted at one or more distant sites after spread through cerebral ventricles. To assess this hypothesis, drinking after lateral preoptic or lateral ventricle injection of carbachol was measured before and after placement of cold cream plugs obstructing cerebral ventricles. Plugs obstructing the anterior ventral portion of the third ventricle at the preoptic level nearly abolished drinking while plugs that did not prevent cerebrospinal fluid circulation through this region did not alter the drinking response.

Since the ventricular obstruction experiment suggested that cholinergic induced thirst involves activation of neurons near the anterior ventral third ventricle, the effect of preoptic-anterior hypothalamic periventricular ablation was next determined. Drinking responses to lateral preoptic injections of carbachol were monitored before and after the periventricular ablation or a sham ablation. Post lesion drinking tests were delayed until ad lib water intake recovered to normal after transient adipsia. Drinking after carbachol injection was virtually abolished after periventricular preoptic ablation but unchanged after the sham lesion procedure. The failure of drinking after cholinergic stimulation when cerebrospinal fluid circulation through anterior-ventral third ventricle is impaired or when surrounding tissue is ablated suggests that cholinergic stimulation arouses drinking through an action on the preoptic periventricular region.

It is interesting to note that plug and lesion experiments implicate the same region in angiotensin induced thirst. However, studies with pharmacological blockers show that the cholinergic blocker atropine does not affect angiotensin thirst while angiotensin antagonists or the dopamine blocker haloperidol blocks angiotensin but not cholinergic thirst. Moreover, angiotensin results in water plus NaCl solution intake while carbachol increases water intake only. Thus, while angiotensin and carbachol may both act in the same region, they apparently involve separate systems. Supported by Iowa Medical Research Council and Univ. S. Carolina funds.

523 CHANGES IN SERUM CORTICOSTERONE, FREE FATTY ACIDS, AND GLUCOSE ASSOCIATED WITH EATING, CONDITIONED CUES, AND VENTROMEDIAL HYPOTHALAMIC LESIONS. Gary D. Coover, Stephen L. Welle* and Robert P. Hart*. Dept. Psych. Northern Illinois Univ., DeKalb, IL 60115.

Male hooded rats were fed once daily for 14 days with 1-hr access to food mash (40% ground Wayne Lab Blox) and water. Feeding times each morning varied between 9 a.m. and 1 p.m. Feeding was always associated with the stimuli (CS) of the experimenter entering the animal quarters for the first time that day (Exp. 1) or placement of the rat's cage into a sound-attenuating chamber (Exp. 2). The CS-feeding interval varied each day, between 0 and 10 min. On the 15th day the rats were decapitated either before (Time 0) or after 10, 20, or 40 min of feeding or CS presentation. Blood serum was analyzed fluorometrically for corticosterone and colorimetrically for free fatty acid (FFA) and glucose concentration.

Both experiments confirmed (Coover, Sutton, & Heybach, J.c.p.p., 1977, 91, 716-726) that normal rats exhibit a decline in corticosterone level when they are fed, from a baseline of over 20 µg/100 ml (at Time 0) to less than 10 µg/100 ml after 20 min, and that corticosterone level exhibits a conditioned decline of equivalent rate for the first 10 min. However, the rats did not exhibit conditioned changes in serum FFA or glucose. During feeding, glucose levels increased from a baseline of about 100 mg/100 ml to levels well above those found in ad lib fed rats by 10 min, and then declined toward ad lib levels by 20 min. FFA levels fell by about 50% during feeding in the first 10 min.

In Exp. 2, 39 of the 77 rats received bilateral electrolytic lesions of the ventromedial hypothalamus (VMH) 9 days before the initiation of the feeding-conditioning regimen. The VMH rats exhibited body wt. gain and eating pattern and preference signs of the VMH syndrome during the first 8 postsurgical days, but they did not, by the end of the conditioning phase, weigh more, or eat more vigorously, than the controls. Their baseline (Time 0) serum concentrations of corticosterone, FFA, and glucose did not differ from control values, and their FFA responses to feeding and CS presentation were normal. However, their corticosterone response to feeding was very small, levels remaining elevated at over twice those of the controls at 20 min, and they did not exhibit a conditioned decline. Also, serum glucose declined more between 10 and 20 min after the initiation of feeding. Most important of all, the VMH rats did exhibit a decline in glucose level after 20 min of CS presentation. The results confirm recent findings of metabolic imbalance in VMH rats and suggestions (e.g. Powley, Psych. Rev., 1977, 84, 89-126) that VMH rats have abnormal conditioned responses to food cues.

524 EQUIVALENCE OF INTRAVENTRICULAR p-CHLOROPHENYLALANINE AND PHENYLALANINE IN PRODUCING HYPERPHAGIA AND OBESITY IN RATS. Donald V. Coscina, Juri V. Daniel*, Peter Li* and Jerry J. Warsh. Sects. of Biopsychol. and Neurochem., Clarke Inst. Psychiat., and Depts. of Psychol., Psychiat., and Pharmacol., Univ. Toronto, Toronto, CAN.

Recent work from Hoebel's lab (Science 192: 382, 1976) shows that intraventricular (i.v.) infusions of p-chlorophenylalanine (pCPA) can induce transient hyperphagia and bodyweight (BW) gain in rats. Since the time course of this effect was shown to parallel that of maximal depletions in brain serotonin (5-hydroxytryptamine or 5HT), it was suggested that central 5HT neurons might normally serve to inhibit feeding. Problematic to this interpretation are many previous reports in which depletions of rat brain 5HT by midbrain raphe lesions fail to elicit overeating or BW gain. Since control infusions of a pCPA congener were not studied despite the large quantities (2-4 mg) of drug required to generate hyperphagia, a non-specificity of this pCPA action remains to be discounted. Accordingly, we compared the efficacy of i.v. pCPA to that of its parent amino acid, phenylalanine (PA), in modifying ad lib food intake. For all experiments, single-housed adult (225-283 g) female Wistar rats were used. Under Nembutal anesthesia, separate groups of 4 rats received stereotaxically-placed i.v. infusions of 2, 3, or 4 mg d,l-pCPA methyl ester HCl or 2, 3, or 4 mg d,l-PA methyl ester HCl in 20 µl saline (10 µl/lateral ventricle infused 1 µl/min; infusion needle left in situ 5 min after each infusion). Compared to additional groups of normal or saline-infused controls, daily intake of Teklad 4%-fat pellets and attendant BW gain reliably increased in both magnitude and duration as a function of dosage. However, this effect was equivalent for pCPA and PA (see table). Assays of endogenous forebrain 5HT, norepinephrine (NE) and dopamine (DA) in these and additional rats sacrificed at the peak of their hyperphagia showed no reliable depletion of any amine irrespective of drug injected or time at which animals were sacrificed. Therefore, we find no evidence that the transient "obesifying" effect of central pCPA infusion relates specifically to brain 5HT depletion.

Group	Dose	$\bar{X}$ daily eating above controls	$\bar{X}$ daily BW gain above controls	Days post-injection
pCPA	4 mg	16.2 g	.9 g	7-36
	3 mg	11.0 g	.6 g	2-31
	2 mg	9.0 g	.2 g	1-12
PA	4 mg	16.2 g	1.2 g	1-40
	3 mg	10.0 g	.9 g	1-28
	2 mg	10.0 g	.4 g	1-10

525 ANOREXIA AND BODY WEIGHT LOSS CAUSED BY INTRAVENTICULAR GLYCEROL INFUSIONS. John D. Davis and David Wirtshafter, Dept. Psychol., Univ. of Illinois, Chicago, Ill. 60680.

Food and water intake and body weight were measured in rats before, during and after 7 days of continuous infusion of glycerol into the lateral or third ventricle of the brain. Unincumbered infusion was achieved by means of a subcutaneously implanted Alzet osmotic pump which was connected to a ventricular cannula by a polyethylene tube. The pump delivered fluid to the ventricular space at a rate of 1 µl/hr. During the first day of glycerol infusion at a rate of 54 µg/hr into the lateral ventricle food and water intake and body weight were significantly reduced. After the initial anorexia food and water intake recovered toward normal levels, but body weight gain was inhibited during the period of glycerol infusion. At the termination of the infusion period food and water intake continued to increase and the animals recovered their normal rate of body weight gain of about 2.5 gm/day. Infusion of glycerol into the third ventricle at a rate of 27 µg/hr completely abolished food and water intake for a period of 3 days after which food and water intake began to recover. This infusion rate led to a loss of 130 gm in body weight during the 7 days of glycerol infusion when compared to the body weights of rats receiving intraventricular normal saline at a rate of 1 µl/hr. Infusion of glycerol at rates of 13 and 7 µg/hr inhibited food intake in a dose related fashion, and led to body weight losses of 100 gm and 70 gm respectively during the 7 day infusion period. When glycerol was infused at a rate of 7 µg/hr into the third ventricle or at a rate of 54 µg/hr into the lateral ventricle food and water intake during the light phase of the light-dark cycle were unaffected. Inhibition of ingestion occured only during the dark phase of the cycle. This differential effect of glycerol on the diurnal feeding pattern of the rat, and the fact that the food to water intake ratio was normal at these infusion rates indicates that glycerol induced anorexia was not due to a toxic effect of glycerol. Rather, these results together with those previously reported by Wirtshafter and Davis (Science 198:1271, 1977), suggest that glycerol plays a regulatory role in the feedback system responsible for the control of food intake and body weight.

526 DEPLETION OF CENTRAL CATECHOLAMINES BY CHEMICAL LESIONS THAT CAUSE OBESITY. Ralph Dawson, Jr.,*Michael Callahan,*and Joan F. Lorden (SPON: Lawrence Mays). Dept. Psychol. and Neurosci. Program, Univ. Alabama in Birmingham, Birmingham, AL 35294

In the mouse a single injection of goldthioglucose (GTG) can produce both severe obesity and disturbances in anterior pituitary function. The obesity syndrome which follows GTG injections is associated with hypothalamic damage; however, the precise anatomical substrate for the syndrome has not been established. Several investigators have proposed that the hypothalamic monoamine systems may be involved. Damage to monoamine-containing neurons could account for the altered secretion of prolactin and growth hormone in GTG-injected mice. In addition the catecholamines (CA) have been implicated in the elicitation and suppression of feeding behavior. A loss of CA fluorescence in the median eminence of GTG-treated mice has been reported; however, there have been no quantitative studies of regional levels of CA's following GTG injection.

In order to study the relationship of central CA's to GTG-induced obesity, we injected 50 female and 67 male C57Bl/6J mice 60-90 days of age with GTG (.8 mg/g body weight). An additional 23 females and 34 males received injections of physiological saline. The mortality rate for females receiving GTG was 37% and for males, 40%. After a 6 wk observation period during which the mice were weighed every 4 days, all mice were sacrificed by decapitation. The brains were dissected into hypothalamic and telencephalic sections and the pituitaries were removed from the base of the skull. The sections were analyzed for norepinephrine (NE) and dopamine (DA).

Substantial weight gain was observed in both male and female mice injected with GTG; however, 18% of the females and 30% of the males failed to show a weight gain which exceeded the range of the saline-injected mice of the same sex. No significant differences between GTG and saline-injected mice were observed in telencephalic NE or DA or hypothalamic DA. Hypothalamic NE was slightly reduced and a significant sex x injection interaction was obtained. Hypothalamic NE was reduced further in females than males. The correlation between hypothalamic NE and body weight in the GTG groups was not significant.

A large decrease in pituitary DA was observed in the GTG-injected mice of both sexes when compared with saline-injected controls. Furthermore, a significant negative correlation ($r = -.5$, $p < .001$) was obtained between pituitary DA levels and body weight change. These changes in CA levels may account for the adiposity of the GTG mouse. Recent evidence suggests that the development of obesity in the GTG mouse is pituitary-dependent.

527 HYPOSALIVATION IN RATS FOLLOWING VENTRAL MEDIAL HYPOTHALAMIC LESIONS. F.W. Flynn, D.L. Schirer and J.C. Mitchell*. Dept. of Psychology, Kansas State University, Manhattan, Ks., 66506.

Salivation was recorded for 6 normal and 6 rats with ventro-medial hypothalamic lesions. Salivation was quantified by inserting a cotton-tipped applicator into the rat's mouth for one minute. The difference in the pre-insertion weight and the post-insertion weight of the applicator reflected the amount of salivation. Measures were taken twice daily for 9 days during ad libitum food availability. Hypothalamic lesions resulted in the usual dramatic weight gain but were associated with a 50% reduction in salivation compared to normal animals (mean salivation measurement: normals = 11.7 mg; VMH = 5.6 mg).

On the 10th post operative day, animals were placed on a six hour food deprivation schedule (0900-1300 hours). Measures were taken for 20 days 1/2 hour into the deprivation schedule and immediately prior to the reintroduction of food into the food bin.

As in the ad libitum period, the VMH animals continued to display a statistically reliable lowered salivation (normals = 13.26 mg; VMH = 5.82 mg).

These results are contrasted with those of Rozkowska and Fonberg (1973) who found VMH animals to be hypersalivatory compared to normal animals. However, in their study, the animal's salivation was examined in a classical conditioning paradigm. Both findings are consistent with the view that VMH animals are hyperresponsive to appetive cues; both those that signal food, and those that signal an absence of food. Rather than a unidirectional effect, there is reduced salivation to the absence of food and heightened salivation to food.

Following these baseline measures, animals were given prostigmine, a parasympathomimetic agent that produces salivation. Animals were given subcutaneous injections of .10 mg/kg. On three test days salivation in VMH animals equalled normals.

In order to test both normal and VMH animal's responsiveness to natural food or taste stimuli, lemon juice, vanilla-glucose solution and wintergreen were introduced into the animal's mouth and salivation measured. The response to these stimuli will be discussed.

528 CALCITONIN AND FEEDING. William J. Freed, Mark J. Perlow, John Scott Carman*, and Richard Jed Wyatt. Laboratory of Clinical Psychopharmacology, SMR, IRP, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032.

Plasma calcitonin (CT) concentrations increase following a meal, and the administration of the gastrointestional hormones glucagon, gastrin, pancreozymin, and cholecystokinin. A series of experiments was performed to test the hypothesis that this feeding-induced increase in CT secretion plays a role in reducing subsequent food intake. In rats, a single s.c. injection of synthetic salmon calcitonin was found to inhibit 24-hr food intake (up to 58%, $p<0.005$) in proportion to the dose (12.5-50 U/kg). The decreased food intake was accompanied by a pronounced diuresis and increase in drinking--not observed in food deprived animals. In rhesus monkeys, a single injection of CT (30 U/kg) greatly suppressed feeding for 3 days and drinking for one day (both $p<0.01$). A retrospective study of humans demonstrated a 2% reduction in body weight ($p=0.03$) during the 12-36 hr following a single s.c. injection of CT (2 U/kg).

To test whether these effects were due to a direct action on the brain, CT was administered intraventricularly to rats. On a dosage basis these injections were approximately 75-fold more effective than s.c. injections in reducing feeding; amounts as small as 43 ng (0.2 U) significantly suppressed 24-hr food intake ($p<0.02$). Other experiments in 23½-hr food-deprived rats indicated that CT (12.5 U/kg, s.c.) effectively suppressed feeding only when administered several hours prior to 30 min of access to food; injections 1 hr before feeding were ineffective.

Thus CT reduces feeding, apparently through a direct action on the brain. Because this action does not seem to be manifest immediately, it is suggested that post-prandial secretion of CT acts on the brain to inhibit the ingestion of subsequent meals. Thus, when a meal is not eaten, the absence of the normally concomitant CT secretion may serve to enhance feeding during subsequent meals.

529 BOMBESIN SUPPRESSES FOOD INTAKE IN THE RAT. J. Gibbs, D.J. Fauser*, E.A. Rowe*, B.J. Rolls*, E.T. Rolls* and S. Maddison*. Dept. Psychiatry, Cornell Univ. Medical College and E.W. Bourne Laboratory, The New York Hospital, White Plains, N.Y. 10605, and Dept. of Experimental Psychology, Univ. of Oxford, Oxford, UK.

Bombesin (BBS) is a tetradecapeptide isolated from the skin of the frog Bombina bombina. BBS-like activity, as determined by radioimmunoassay, has been found in mammalian gut. Since BBS has several of the visceral gut actions of cholecystokinin (CCK), we tested BBS to determine if it also possessed the satiety action of CCK.

Eleven male Sprague Dawley rats were injected intraperitoneally with synthetic BBS (courtesy of R. de Castiglione, Farmitalia, Milan) or the synthetic C-terminal octapeptide of CCK (CCK-8, courtesy of M. Ondetti, Squibb Institute, Princeton) immediately before presentation of a balanced liquid food (25% EC 116, GIBCO) during the light phase following a 3-hr food deprivation. Drinking water was always available ad-libitum.

Both peptides produced a marked, dose-related suppression of food intake. CCK-8 was 5-10 times as potent as BBS, on a molar basis. Maximal suppression by each peptide occurred 15 to 30 minutes following injection. The lowest dose of BBS tested (2 μg/kg) produced a 15% suppression ($p<0.01$). The D50 was 8 μg/kg. BBS also suppressed consumption of solid food (n=20) and operant responding for pellets (CRF schedule, n=5) over a similar dose range in black hooded Lister rats.

BBS did not appear to suppress food intake by causing illness: (1) Rats did not appear ill after BBS injections. They began eating eagerly when food was presented, but stopped eating sooner and they exhibited the characteristic sequence of behaviors seen during normal satiety. (2) Rats maintained normal body weight gain over a 6-month period despite frequent BBS administration. (3) BBS did not alter rectal temperatures under typical test conditions. (4) BBS did not affect water intake when it was injected after minimal water deprivation.

Since circulating BBS-like radioimmunoassay activity rises rapidly following a meal in humans (V. Erspamer, personal communication), we suggest that BBS may play a role as a satiety signal.

This study was supported by USPHS NIH grant AM17240, NIMH RSDA 5 KO2MH70874, and the Medical Research Council of Great Britain.

530 THE ORGANIZATION OF FEEDING IN THE DEVELOPING RAT. W. G. Hall. North Carolina Div. Mental Health, Raleigh, NC 27611.

Neural mechanisms subserving components of the feeding system are present from birth in the rat. Diet infusions (made through oral cannulas) stimulate mouthing, licking and ingestion in deprived infant rats tested in an incubator. In addition, exposure to the taste and smell of food produces a profound, but general, increase in motor activity.

In fact, pups were found to be capable of independent ingestion when placed in a warm test container where diet was spread on the entire surface of the floor. The diets tested were milk, 10% sucrose, and a semi-solid chow mash. In a ½-hr test, deprived pups of 3, 6 and 9 days of age consumed 4.4, 8.6, and 6.4% body weight respectively of the milk diet; 5.3, 12.3, and 7.1% body weight of 10% sucrose; and 2.4, 4.8 and 4.0% body weight of the semi-solid mash. At each age, and with each diet, there was an increase in intake from 1 to 7 and 7 to 22 hr deprivation. There can be little doubt that the infant rat is capable of a regulated form of independent feeding.

Yet, detailed behavioral observations made every 30 seconds during oral-infusion and independent-feeding tests revealed: 1) that while components of feeding were present in the neonate they were not organized in the same way as in the adult; and 2) that the pattern of ingestion changed from one age to the next. Taste, smell, and stimulation from swallowing the diet produced vigorous head probing and mouthing, locomotion, rolling, and tumbling in 3-day-old pups. Tongue protrusion was noted, but with little licking. Food also stimulated an activation in 6-day-old pups, but their activity was directed toward the floor and corners of the test container. Probing and mouthing of the floor was frantic, and there was obvious licking of the floor; but these behaviors were nondirected. At 9 days of age, diet did not generate a difuse activation. These pups predominately fed, showing mouthing and licking which were directed and focused. This channeling of activity into appropriate output patterns is documented by the finding that when diet was made available on just 1/10th of the area of the floor 3- and 6-day-old pups consumed only a fraction (18%) of the volume they had ingested when diet was freely available over the entire area. In contrast, 9-day-old pups consumed almost as much diet from the localized source (71%), demonstrating that they could direct their ingestive behavior.

Thus, at birth, components of feeding in the rat pup are not yet organized into coherent patterns. At the start, feeding is under the control of deprivation. Gustatory and olfactory stimulation can excite or arouse pups, facilitating or energizing responses, but in a nonspecific fashion. By 9 days of age, feeding has become organized into a directed and specific form of behavior.

531 ALTERATIONS IN FEEDING BEHAVIOR FOLLOWING DORSAL BRAINSTEM LESIONS IN RATS. Jeffrey M. Halperin*, Yaakov Stern*, Barbara Burt*, Robert Farrell*, Constantine Pavlides*, Solomon S. Steiner and Steven J. Ellman. Dept. Psych., CCNY, New York, N.Y. 10031.

The present study examined the role of dorsal brainstem (DBS) structures in the regulation of feeding behavior by placing bilateral DBS lesions in ten rats, housed individually on a L-12, D-12 schedule. Following at least 15 days of adaptation to a sweetened milk diet, body weight, the volume of milk ingested, and the number and temporal distribution of licks were recorded for the light and dark period of each day during a seven day pre-lesion baseline and at least 21 days following the lesion. The meal pattern records were scored for meal size and meal frequency. Response to quinine adulteration was also measured for each animal.

Six rats had lesions in the pontine central gray area. These lesions impinged upon the dorsal tegmental nucleus, the locus coeruleus, the sub-coeruleus, and the trigeminal motor nucleus. Four rats had lesions ventral or lateral to these structures leaving the dorsomedial pontine tegmentum intact. Those rats with lesions in the pontine central gray, but not in other DBS loci, significantly increased their food consumption as measured by volume and number of licks. The hyperphagia was characterized by a significant increase in the number of meals; meal size remained unaltered. Interestingly, the hyperphagic rats did not gain significantly more weight than controls. The non-hyperphagic animals showed no changes in meal size or frequency. Quinine adulteration did not differentially reduce feeding between groups.

This experiment is being replicated using a solid food diet. Data, histological and neurochemical analyses are in progress. The data will be discussed in terms of 1) the similarities and differences of solid and liquid food diets in response to DBS lesions, and 2) the similarities and differences between the DBS feeding syndrome and hypothalamic hyperphagia.

532 VENTROMEDIAL HYPOTHALAMIC DESTRUCTION IN NEONATAL RATS: EFFECTS UPON GROWTH AND CONSUMMATORY BEHAVIORS. David L. Hill*, C. Robert Almli, David M. Williams* (Spon: M. M. Patterson). Dept. Psychol., Ohio University, Athens, Ohio 45701.

Neonatal rats (albino, male and female) at one day of age (24 hours of age) sustained bilateral destruction of the ventromedial hypothalamus (VMH). Body weight and body length (nose-anus) were measured daily, and the Lee Index of relative obesity was calculated each 10 days. At adulthood the rats were tested for water intake during food deprivation, and intake of quinine adulterated food was measured. The rats were on a high fat (25% Crisco by weight with powdered rat mash) diet from 25 days of age through completion of the study at 200 days of age.

Following VMH damage at one day of age, the rat pups displayed slightly attenuated growth for approximately 10 days when body weights were approximately 90% of control. Following this, the rats grew at an accelerated rate and surpassed control body weights by 70-80 days of age. Female VMH rats continued to be heavier than controls than were males throughout the measurement period.

Body lengths of the VMH pups were within the control range for the first 50-60 days of age. Thereafter, the brain damaged rats displayed attenuated body length increases, and were slightly stunted in linear growth for the remainder of their lives.

Lee Index, a measure of relative obesity, most clearly separated the brain damaged from control rats, as elevated Lee Indices became apparent when the rats were 60-70 days of age. The VMH rats had elevated Lee Indices for the duration of the study, and VMH males and females were similarily elevated.

The VMH rats were not hyperphagic during any period of development, however, they did display finickiness as evidenced by decreased quinine intake, and water intake during food deprivation was decreased.

The present results demonstrate that neonatal VMH damage produces relative obesity and finickiness, and the development of obesity awaits puberty. Thus, when rats sustain VMH damage at 1, 10, 25, or 40 days of age, body growth is within the normal range until puberty at 50-70 days of age, when important endocrinological alteration results in the manifestation of relative obesity. Growth hormone and gonadal hormone alteration are likely candidates for the etiology of VMH lesion induced obesity.

533 SOME PROPERTIES OF THE CENTRAL AFFERENT SYSTEM THAT CONTROLS SWALLOWING IN CATS. Charles H. Hockman, Ananda Weerasuriya* and Detlef Bieger. Sch. Basic Med. Sci., and Dept. Physiol. and Biophysics, Univ. Illinois, Urbana, IL 61801.

The swallowing apparatus may be conceptualized as a central afferent system that decodes sensory information and, when appropriate, sends commands to a swallowing center where they are elaborated upon and organized so as to produce swallowing through an effector system by the sequential activation of relevant muscles. The afferent system, organized in and around the nucleus of the solitary tract (NTS) in the dorsal medulla, receives inputs from the superior laryngeal (SLN) and glossopharyngeal (GN) nerves. In cats anesthetized with urethane, swallowing was induced by electrical stimulation of the SLN or GN, and monitored by means of a xylocaine-coated balloon in the oropharynx. The frequency-response curve for SLN-induced reflex swallowing shows a distinct bell shape with an optimal frequency range between 25 and 45 Hz. The limiting frequency was about 100 Hz. In the production of reflex swallowing, a type of spatial summation could be demonstrated between both SLNs and between ipsi- and contralateral SLN and GN. The swallowing response could be facilitated when one nerve (SLN) was stimulated immediately after cessation of stimulation of another nerve (contralateral SLN or ipsilateral or contralateral GN). Both types of facilitatory interaction were observed between contralateral nerves after a mid-sagittal cut just behind the obex: the point at which primary visceral afferents cross over to terminate in the contralateral NTS. Neither type of interaction was seen when both SLNs were stimulated at values above the limiting frequency. With continuous stimulation of one nerve, the response rate decreased, which could be reversed by switching the stimulation to another ipsi- or contralateral nerve. The response decrement could also be reversed by stimulating in the brain stem in and around the contralateral solitary tract. By partial hemisections and punctate electrolytic lesions, it was established that the region of the NTS essential for the elicitation of reflex swallowing lies at least 2.0 mm in front of the rostralmost point of the dorsal median sulcus. These results suggest that (a) the stimulus response relationship reflects input-output properties of the central afferent system; (b) the facilitatory interaction between contralateral nerves occurs at the level of second or higher order neurons of the central afferent system; (c) the neural substrates responsible for the response decrement are situated in a localized region of the central afferent system; and (d) the essential component of the central afferent system is located in and around the anterior region of the medial NTS. (Supported by the State of Illinois Dept. of Mental Health and Developmental Disabilities.)

534 THE THRESHOLDS FOR HYPERGLYCEMIA AND FEEDING TO GLUCOPRIVATION PRODUCED BY INTRAVENOUS 2-DEOXY-D-GLUCOSE. Thomas M. Hyde* and Richard R. Miselis. Dept. of Anim. Biol., Sch. Vet. Med. and Inst. Neur. Sciences, Univ. of Penn., Philadelphia, PA 19104.

Rats prepared with chronic intravenous (i.v.) catheters were tested individually in their home cages either for the hyperglycemic reflex or feeding in response to i.v. infusions of 2-deoxy-D-glucose (2DG), a glucose analogue which causes glucoprivation. Infusions for the feeding study were given to 34 rats in an intermeal interval 1.5 to 3.0 hours after the last spontaneous meal. In a similar manner 37 rats were studied for their hyperglycemic response to i.v. 2DG given during an intermeal interval but without food available 2.0 hours before and for the duration of blood sampling. For both studies a remote infusion and blood sampling technique was used to avoid stress and interference with spontaneous behavior. The threshold dose for hyperglycemia was between 40 and 80 mg of 2DG/kg of body weight and a dose response relationship was present. The threshold for the feeding response was between 25 and 50 mg/kg and was evident as an increase in the percentage of rats responding to a particular dose over the percentage of rats responding to the control infusion of isotonic saline. The percentage of rats responding increased in a dose response fashion. At all doses tested, rats that responded ate a normal sized meal which did not vary with dose. The threshold for feeding is at least the same if not lower than the threshold for hyperglycemia indicating a possible role for the glucoprivic control in normal feeding. Using doses of 2DG which produce feeding without triggering the hyperglycemic reflex is a physiologically meaningful way to study the glucoprivic control of feeding. Location of a site of detection of glucoprivation operating physiologically in the control of normal feeding will depend upon using the same low doses.

535 PLASMA ANGIOTENSIN II (AII) LEVELS AND THIRST. A. K. Johnson, J. F. E. Mann*, M. W. Houshk*, and D. Ganten*. Dept. Psychology, Univ. Iowa, Iowa City, IA 52242 USA, and Dept. Pharmacology, Univ. Heidelberg, Heidelberg, GFR.

Investigations of the hormonal basis of thirst leave no doubt that AII is a potent dipsogenic stimulus and that it acts on the brain to induce water intake. It is also clear that under normal conditions AII is not the sole stimulus for water intake and that to understand its role in the physiological control of drinking, the dynamics of the effector peptide, AII, must be characterized. We have determined plasma AII levels by radioimmunoassay following experimental treatments that induce thirst.

1) AII was infused intravenously into nephrectomized rats over a period of 60 min (n=30). Blood samples were taken at the end of the infusion. Results are given in the table:

Dose of AII (ng/kg/min)	1	25	50	100
Plasma AII (pg/ml)	121.6 ±13.4	187.9 ±21.6	394.6 ±42.9	843.0 ±86.9

2) Rats (n=28) were water deprived for 12, 24, and 48 hr. Plasma AII levels were 136.7 ± 8.6, 117.4 ± 16.1, and 399.6 ± 90.8 pg/ml, respectively (controls with ad lib water 50.2 ± 5.3).

3) Isoproterenol was injected subcutaneously (0.1 and 0.3 mg/kg) in rats (n=15). Plasma AII levels 60 min later were 619.2 ± 84.9 and 1001.0 ± 112.5, respectively, and in sham treated controls 71.5 ± 8.3.

4) The inferior vena cava was ligated in rats (n=48). One, 2, and 4 hr later plasma AII levels were significantly elevated to 881.6 ± 168.0, 749.0 ± 112.0, and 557.2 ± 101.7 pg/ml, as compared to the levels in sham operated controls (332.4 ± 30.2).

5) Subcutaneous injections of 20% polyethylene glycol (15 mg/kg) in rats (n=26) elevated plasma AII levels after 1, 2, 4, and 8 hr to 67.59 ± 11.75, 100.73 ± 17.93, 170.78 ± 18.21, and 349.21 ± 48.40 pg/ml. Saline injections (n=24) of the same volume, after the same time intervals, produced plasma AII levels of 41.3 ± 14.73, 27.04 ± 2.64, 47.04 ± 2.0, and 67.08 ± 7.49 pg/ml.

6) Rats (n=30) on a 1 hr daily feeding schedule with ad lib access to water were forced to eat a meal without access to water. One hour after access to the food, levels of plasma AII were elevated to 138.8 ± 11.45 pg/ml, whereas the level in control animals that had not eaten a dry meal was 91.5 ± 6.93 ($p < .01$).

The results of these experiments define the range of changes that occur in plasma AII levels after several thirst-inducing challenges and show that AII can act in some cases as a dipsogenic stimulus within the physiological range.

536 KAINIC ACID TOXICITY IN THE LATERAL HYPOTHALAMUS. K.M. Kantak, R.C. Cook*, F.C. Barone and M.J. Wayner. Brain Res. Lab., Syracuse Univ., Syracuse, NY 13210.

Bilateral infusions of kainic acid (KA, 3µg/0.5µl and 3µg/1.0µl) or 0.9% saline (Sal, 0.5µl and 1.0µl) into the posterior lateral hypothalamus were made. Within 30 min following KA infusions signs of autonomic and other effects were noted. These included exophthalamus, chromodacryorrhea, mydriasis, salivation, pulmonary edema, whole body tremors, tonic seizures and convulsions. The disturbances lasted for several hours post infusion and 50% of the animals died. The Sal infused animals did not show any signs of autonomic disturbance and had a 100% survival rate. Prior to and 11 days following the infusions animals were tested for salt arousal of drinking (1 hr test); post 24 hr water deprivation induced drinking (1 hr test); and post 24 hr food deprivation induced eating and drinking (3 hr test).

Following the infusions, KA treated animals (3µg/0.5µl) decreased water intake on post infusion days 1,2 and 3 relative to baseline and the Sal (0.5µl) control group. Food intake was significantly decreased in both groups on the first and second days post infusion. Thereafter food intakes were stable in both groups. Body weight in the KA treated animals decreased post infusion and returned to pre-operative body weight on day 9 post infusion but remained at a reduced level with respect to the Sal control group on post infusion days 1 through 11. Animals treated with 3µg/0.5µl KA failed to respond to salt arousal of drinking and post 24 hr food deprivation drinking. Following 24 hr water deprivation KA treated animals did respond but at an attenuated level with respect to the Sal control animals. There were no differences in post 24 hr food deprivation induced eating between groups.

There were no differences in post infusion food and water intakes, body weights, salt arousal of drinking, post 24 hr deprivation induced drinking, and post 24 hr food deprivation induced eating and drinking in animals treated with 3µg/1.0µl KA and 1.0 µl Sal.

These data indicate that the concentrations of KA were toxic in the lateral hypothalamus immediately following infusions. Of those animals which survived a concentration dependent effect on behavioral and physiological deficits was evident. That these effects are specific to the lateral hypothalamus remains to be determined.

537 EFFECT OF INTRAVENTRICULAR β-ENDORPHIN ON FOOD INTAKE IN RATS. Nancy J. Kenney, L. David McKay*, Stephen C. Woods*, and R. H. Williams*. Depts. of Psychology and Medicine, Univ. Washington, Seattle, WA 98195.

The recent discoveries that many endogenous peptides including cholecystokinin (CCK), somatostatin and β-endorphin are found in both brain and gut have made these compounds potential candidates for a role in energy balance regulation. Systemic administration of CCK or somatostatin previously have been reported to suppress food intake in food-deprived rats. On the other hand, central administration of somatostatin was found to have no effect on food intake in the rat or the baboon.

We examined the effect of low doses of β-endorphin, a morphine-like compound reported to produce analgesia and catatonia at high doses, on food intake of mildly deprived rats. Male Wistar rats were adapted to a feeding regimen on which they were deprived of food, but not water, for 6 hr during the light portion of the light-dark sequence. At the end of this period they were offered a liquid diet (50% sweetened condensed milk, 50% tap water) for ½ hr. At all other times the animals were maintained on dry pelleted lab chow. Animals were tested in blocks of three days consisting of a vehicle control day immediately before and after the β-endorphin test day. β-endorphin (200 ng/µl/rat) or isotonic saline (1 µl/rat) was injected into the lateral cerebral ventricle through a permanently implanted stainless steel cannula immediately prior to each test session.

Central administration of β-endorphin resulted in a significant and substantial increase of liquid-diet intake during the 30-min test session (average intake on control days 5.6 ± 1.0 ml vs. 10.8 ± 1.9 ml on the β-endorphin test day, $t(7)=3.0$, $p<.05$). The effect was limited to the 30-min test session with no treatment effects evident in the subsequent overnight food intakes. The effect appears to be centrally mediated; intraperitoneal injection of the same dose of the peptide had no effect on food intake under these conditions. Central injections of CCK (100 ng), substance P (200 ng) and neurotensin (100 ng) resulted in no change of food intake under identical conditions suggesting that the effect is specific to β-endorphin and not a general property of this class of peptides. These data, in conjunction with the finding that β-endorphin is endogenous to brain and gut, suggest the possibility that the peptide may play a role in the central regulation of energy balance.

538 NEUROLOGICAL SEPARATION OF FEEDING AND BEHAVIORAL ACTIVATION IN NEONATAL RATS. Carol L. Kornblith and W. G. Hall. Dept. of Psychology, U. North Carolina, Chapel Hill, NC 27514 and NC Div. of Mental Health, Raleigh, NC 27611.

When milk is delivered directly into the mouth of the infant rat via an intraoral cannula, significant ingestion occurs and is accompanied by a dramatic behavioral activation. The ingestion and activation occur when the pup is food deprived (22 hr) and tested in a warm, moist environment (33°C). Intact 3 day old pups allowed to ingest milk presented in discrete pulses consumed 60% of the injected diet (1.8% body weight) compared to 10% when nondeprived. The behavioral activation consisted of probing, mouthing, licking, swallowing, face grooming, rolling over, stretching, twitching, head waving and wall climbing (mean activity rating of 40). These results indicate the presence, at a very early age, of neuronal systems for both ingestive behavior and a primitive form of arousal. This activation may be an indication of one of the first reinforcers experienced by the infant rat.

As an initial step in describing the neurology of these responses, knife cuts were made at various levels of the neuraxis. Two day old pups were separated from their mothers, lightly anesthetized and given transverse knife cuts across the bottom half of the brain. The cuts were made at various anterior-posterior levels within a litter, ranging from the olfactory bulbs to the pons. Several hours before testing on the next day, the intraoral cannulas were implanted.

The 18 of 35 subjects with complete cuts could be divided into four groups. Both activity (ratings of 23-41) and intake (45-62% of injected diet) were normal in 4 of 5 subjects with cuts ranging from the anterior olfactory bulb to a line drawn through the middle of the caudate, the anterior commissure and in front of the supraoptic nucleus. Four subjects with cuts ranging from the supraoptic nucleus to a line running posterior to the thalamic reticular nucleus and behind the ventral supraoptic commissure were not activated (9-18) but had normal intake (37-78%). Six subjects with cuts extending from behind the ventral supraoptic commissure to in front of the substantia nigra were not activated (5-19.5) and had low intake (1-27%). The final group of 3 subjects had low activity ratings (5.5-21) and normal intake (37-41%). These cuts extended from the posterior substantia nigra through the interpeduncular nucleus.

Thus, the occurrence of behavioral activation seems to require an intact diencephalon, while cuts within the diencephalon decreased both activity and feeding. Interestingly, ingestion could still occur with cuts at least as far posterior as the interpeduncular nucleus.

539 VAGOTOMY FAILS TO BLOCK THE SATIATING EFFECT OF FOOD IN THE STOMACH. F. Scott Kraly and James Gibbs. Dept. Psychiatry, Cornell Med. Coll. and Bourne Laboratory, N.Y. Hospital, White Plains, N.Y. 10605

When rats eat after 3-hr food deprivation, pregastric food-contingent stimulation alone (during sham feeding) is not sufficient for normal satiety because meal size (MS) is abnormally large and the latency to rest (LR) in the behavioral sequence of satiety is abnormally long (Kraly, Carty & Smith, 1978). Thus, gastric and/or intestinal food-contingent stimulation is necessary to control normal MS and LR.

Combined food-contingent stimulation of pregastric and gastric sites is sufficient for normal MS and LR: Rats ($n=4$) equipped with a pyloric noose ate liquid food after 3-hr food deprivation. When the noose was open, ingested food accumulated in the stomach and entered the intestine in normal fashion. When the noose was open, rats ate a mean (± SE) MS of 4.2 ± 0.6 ml and displayed a postprandial satiety sequence with a mean LR of 11.1 ± 0.4 min. When the noose was closed, ingested food was trapped in the stomach and did not enter the intestine. When the noose was closed, rats ate a mean MS of 5.8 ± 1.9 ml ($p > .20$, open vs. closed noose) and displayed a postprandial satiety sequence with a mean LR of 10.9 ± 1.6 min ($p > .20$, open vs. closed noose). These results confirm the findings of Kraly and Smith (in press) and show that a satiety signal of gastric origin, when combined with pregastric stimulation by food, produces normal MS and LR.

Vagotomy does not block the ability of combined gastric and pregastric food-contingent stimulation to control MS and LR: Rats ($n=7$) with bilateral subdiaphragmatic vagotomy (with hepatic vagal branch intact), equipped with a pyloric noose, ate with the noose open or closed after 3-hr food deprivation. When the noose was open, vagotomized rats ate a mean MS of 4.4 ± 0.7 ml and displayed a postprandial satiety sequence with a mean LR of 10.6 ± 1.6 min. When the noose was closed, vagotomized rats ate a mean MS of 2.7 ± 0.8 ml ($p > .05$, open vs. closed noose) and displayed a postprandial satiety sequence with a mean LR of 16.8 ± 3.2 min ($p > .10$, open vs. closed noose). These results show that the satiety effect of gastric food-contingent stimulation is not dependent upon vagal mediation, and suggest that gastric distension is not the critical stimulus for satiety under these conditions.

540 THE BEHAVIORAL AND EEG RESPONSE TO KAINIC ACID INJECTIONS IN THE LATERAL HYPOTHALAMUS OF RATS. L. R. Leach*, I. Q. Whishaw* & B. Kolb (SPON: E. Davis). University of Lethbridge, Lethbridge, Alberta, Canada, T1K 3M4.

Bilateral electrolytic lesions of the lateral hypothalamus (LH) of rats cause transient aphagia, anorexia, behavioral depression, alterations in hippocampal and neocortical EEG, and chronic disturbances in water intake (Kolb and Whishaw, 1977). Electrolytic lesions destroy both axons passing through and neurons intrinsic to the LH. We used microinjections of the neurotoxin kainic acid (KA) to determine how destruction of neurons intrinsic to the LH might affect the ingestive and locomotor behavior and the EEG activity of rats. Rats with chronic EEG recording electrodes implanted in the hippocampus and neocortex, received bilateral .1 ug injections of KA (.5 to 4 ug/ul of CSF) in the LH. Following KA injection, a transient period of aphagia, adipsia, hypokinesia, poor postural support, ataxia, abnormal spike and slow wave activity in the hippocampus, and abnormal slow wave activity in the neocortex lasting 1 to 5 days was observed in all rats. The presence of abnormal hippocampal slow wave activity simultaneous with neocortical slow wave activity was associated with aphagia: all rats that exhibited both conditions of abnormal EEG activity were also aphagic. After 7 days the behavior deficits were not apparent, and after 15 days normal patterns of hippocampal and neocortical activity could be recorded from all rats. The effects of KA injections differed from previously reported effects of electrolytic LH lesions in the following ways: KA injections did not cause the chronic disruption of water intake regulation, the chronic decrease in frequency of atropine resistant hippocampal theta rhythm, or the appearance of atropine-sensitive hippocampal theta activity seen after electrolytic LH lesions. KA injections caused abnormal hippocampal spike and slow wave activity which electrolytic lesions did not. The results suggest that destruction of cells intrinsic to the LH contributes to the aphagia, behavioral depression, locomotor deficits and some transient abnormal EEG activity. However, chronic changes in water intake regulation and EEG activity observed only after electrolytic lesions are probably the result of damage to axons passing through the LH.

Kolb, B. and Whishaw, I. Q. Effects of brain lesions and atropine on hippocampal and neocortical electroencephalograms in the rat. Experimental Neurology, 56, 1-22, 1977.

541 THE EFFECT OF INTRACEREBROVENTRICULAR INFUSION OF SARALASIN ON DRINKING FOLLOWING CAVAL LIGATION, HYPERTONIC SALINE AND WATER-DEPRIVATION IN RATS. Maw-Chang Lee*, Terry N. Thrasher* and David J. Ramsay. Dept.Physiol., Sch.Med.,UCSF,San Francisco, CA 94143.

Ligation of the inferior vena cava in rats is known to be a potent dipsogenic stimulus (Fitzsimons,J.T.,Nature,204,479,1964). However, it is not clear to what extent the drinking is dependent on stimulation of the renin/angiotensin system. In the present series of experiments, the effect of central blockade of angiotensin with intracerebroventricular (IVT) infusion of saralasin(Sar^1-Ile^8-Angiotensin II) on drinking following caval ligation was investigated. Using similar experimental protocols, the effect of IVT administration of saralasin on drinking following hypertonic saline injection and 24-hour water deprivation was tested.

Inferior vena cavae of Sprague-Dawley rats of 260-360 gm were completely ligated above the renal veins under ether anesthesia. The rats then received an initial loading dose of 1 µl of either normal saline or saralasin (4 µg/µl) followed by infusions of the same solutions at 1.3 µl/h for 5 hours through chronically implanted lateral ventricular cannulae. Central administration of saralasin significantly reduced ($P<0.01$) the water intake during the 5 h after caval ligation from 1.47±0.38 ml/100 gm (n=6) in IVT saline controls to 0.28±0.18 ml/100 gm (n=8).

In a second group of 8 rats, the effect of saralasin IVT on drinking following 1.0 M NaCl (1% body weight, ip) was investigated. The saline was injected under light ether anesthesia 75 min following the commencement of IVT saralasin infusion. The rats receiving saralasin IVT drank 2.63±0.36 ml/100 gm (n=8) in the 90 min following hypertonic saline injection compared with 2.30±0.73 ml/100 gm (n=5) in IVT saline controls, intakes that were not significantly different.

Drinking following 24-hour water deprivation was measured in a third group of rats during IVT saralasin infusion. Access to water was allowed 75 min following the start of the IVT infusions of either saralasin or normal saline. Cumulative water intake following 10 min of water access was 1.96±0.31 and 1.19±0.36, and at 3h 3.30±0.26 and 2.38±0.46 ml/100 gm in rats receiving saralasin IVT (n=8) and saline IVT (n=7) respectively. Saralasin did not significantly affect either the latency or the total amount consumed.

These data show that the drinking following caval ligation drinking in rats is abolished by central blockade of the renin/angiotensin system. In contrast to this, drinking to hypertonic saline and to water deprivation was not affected by treatment with saralasin. It is concluded that drinking to caval ligation depends on the renin/angiotensin system, whereas drinking to hypertonic saline and dehydration does not.

542 SEROTONIN-NOREPINEPHRINE INTERACTION IN THE PARAVENTRICULAR NUCLEUS: ANTAGONISTIC EFFECTS ON FEEDING BEHAVIOR IN THE RAT. Sarah F. Leibowitz and Peter J. Papadakos*, Rockefeller Univ., New York, NY 10021.

The paraventricular nucleus (PVN) has been identified as the most sensitive brain area for the elicitation of feeding through direct α-noradrenergic stimulation. Studies described in this abstract provide evidence for an antagonistic action of serotonin in this region of the hypothalamus.

Brain-cannulated rats maintained on ad libitum lab chow pellets and water eat a meal of approximately 3 g after injection of norepinephrine (NE, 30 nmoles) into the PVN. Local injection of 5-hydroxytryptamine (5-HT, 13 nmoles in 0.02% ascorbic acid) immediately prior to NE consistently reduced this feeding response by 60-90%. This inhibition was dose-dependent and occurred reliably at doses as low as 0.5 nmole (88 ng free base). (Doses above 26 nmoles started to exhibit sedative properties and thus were not used.) This 5-HT effect was abolished, in a dose-related, competitive manner, by prior PVN injection of the 5-HT receptor antagonists methysergide (3-60 nmoles) and cinanserin (16-64 nmoles). It was unaffected, in contrast, by the dopamine antagonists haloperidol (1-14 nmoles) and pimozide (10-30 nmoles) and the cholinergic antagonist atropine (1.5-6 nmoles). Consistent with previous literature, preliminary studies with the phenothiazine fluphenazine (1.25-10 nmoles) and the β-adrenergic blocker alprenolol (100-400 nmoles) have indicated that these compounds may be effective in reversing 5-HT's receptor action in the PVN.

The 5-HT precursor, 5-hydroxytryptophan (5-HTP), produced the same inhibitory effect on NE-elicited eating (when injected 5-10 min prior to NE). It was approximately equipotent to 5-HT, with respect to both its threshold dose and its efficacy at maximum dose levels (10-20 nmoles). The inhibition produced by 5-HTP, in contrast to that of 5-HT, was prevented, in a dose-related fashion by PVN administration (30 min prior) of the nonspecific aromatic decarboxylase inhibitors Ro 4-4602 (1.35-135 nmoles) and MK 486 (2.4-40 nmoles). Similar to 5-HT, however, 5-HTP's action was blocked by the receptor antagonist methysergide.

These findings provide a preliminary basis for the hypothesis that NE and 5-HT interact, in an antagonistic fashion, in their effects on food intake. While the present evidence suggests that this antagonism may occur in the region of the PVN, further analyses will need to be conducted to establish the anatomical and pharmacological specificity of this phenomenon, its relation to noradrenergic stimulation versus a variety of other stimuli known to induce feeding, and its significance to brain serotonin mediation of anorectic drug action. (Research supported by NIH grant MH 22879, a Sloan Foundation Fellowship, and funds from Whitehall Foundation.)

543 SUPPRESSION OF FEEDING BEHAVIOR IN FOOD DEPRIVED MONKEYS BY LOCUS COERULEUS STIMULATION. K. Leverenz*, D.E. Redmond, Jr. and Y.H. Huang.

Norepinephrine has been found to have both stimulatory and suppressant effects on feeding behavior in non primate species. Lesions of the noradrenergic locus coeruleus (LC) have led to no consistent effects on food intake or body weight in rodents, but a recent study showed long-lasting hyperphagia, hyperdipsia, and weight gain in female monkeys after discrete bilateral LC lesions.[1] We have now studied the effects of intermittent electrical stimulation of the LC on feeding behavior in four adult female *Macaca artoides* implanted with LC electrodes.[2]

The monkeys were first acclimated to cable restraint and baseline feeding behaviors were studied under identical conditions to characterize feeding behavior during a 2 hour *ad lib* feeding period each day, after 22 hours with water but no food present. Total water intake, number of standard laboratory monkey biscuits grabbed, total biscuits wasted, total biscuits consumed, and the precise rate of biscuit grabbing were recorded. Biphasic square waves of electrical stimulation were delivered unilaterally to a bipolar locus coeruleus electrode at intensities from 0.15 to 0.65 mA, 0.5 msec pulse duration, 30-50 Hz frequency, for trains of 10 seconds each minute, with the parameters chosen to be below the threshold for typical observable behavioral effects of LC stimulation, previously described.[3]

Intermittent stimulation for 10 seconds/minute, beginning 5 minutes prior to and during the first 10 minutes of the feeding session had no effect on any overall measure of feeding or drinking for the entire 2 hour feeding session. No competing behaviors were elicited which would have prevented food grabbing, chewing, drinking, and swallowing, and all were sometimes observed to occur during stimulation. Stimulation did, however, produce a significant suppressant effect on spontaneous feeding behavior in 3 monkeys during the first ten minutes when intermittent LC stimulation was occurring at the beginning of each minute. The effect was reversed usually within 5 minutes of termination of stimulation, with a trend toward a post-stimulation increase in feeding. One monkey did not show this suppressant effect. Histological localization of the electrodes at the end of the study showed that the monkey without feeding suppression had an electrode placement anterior and outside the LC, while two of the other three electrodes were correctly located. One monkey's placement could not be verified. The specificity of these effects to LC-noradrenergic neurons require further study, but are consistent with the appetite suppressant effects of noradrenergic agonist drugs in humans and with other functions of the locus coeruleus we have proposed.

544 EFFECT OF ANTEROVENTRAL THIRD VENTRICLE (AV3V) LESIONS ON SCHEDULE-INDUCED POLYDIPSIA IN THE RAT. R. W. Lind and A. K. Johnson. Dept. Psychology, Univ. Iowa, Iowa City, IA 52242.

Periventricular lesions of the anteroventral third ventricle (AV3V) in the rat produce adipsia accompanied by a lack of compensating antidiuresis (Johnson & Buggy, Am. J. Physiol. 234: R122, 1978). In animals that recover from this acute adipsia, there are persistent deficits in drinking to angiotensin and hypertonic NaCl thirst challenges (Buggy & Johnson, Am. J. Physiol. 233:R44, 1977). To assess the effect of this lesion on secondary drinking (i.e., drinking not associated with a body water deficit) (Fitzsimons, Phys. Rev. 52:468, 1972), the AV3V was ablated in eight rats exhibiting schedule-induced polydipsia (Falk, Science 133:195, 1961) on a FT 60" schedule of food presentation. As compared with seven sham-operated controls, the lesioned rats drank significantly less ($p < .01$) in the polydipsia situation on the first day post-lesion. In animals (5 of 8) which were hypodipsic (<10 ml intake) in the home cage on the first night after surgery, a 74% decrease in schedule-induced drinking was observed. Controls showed no change in home-cage or schedule-induced drinking following surgery. This finding is consistent with the observation that prandial drinking, another form of secondary thirst induced by salivarectomy, does not enhance post-lesion water intake or recovery from adipsia. Thus, the AV3V lesion not only disrupts homeostatic mechanisms of thirst, but also reduces the animals' acceptance of water when water intake is under non-homeostatic control.

545 EFFECT OF 6-HYDROXYDOPAMINE LESIONS ON BODY WEIGHT IN GENETICALLY OBESE MICE. Joan F. Lorden. Dept. Psychol. and Neurosci. Program, Univ. Alabama in Birmingham, Birmingham, AL 35294.

Similarities between genetically transmitted obesity and hypothalamic lesion-induced obesity have suggested the possibility that the hypothalamus may be the locus of a genetic lesion responsible for obesity in obob and dbdb mice. In addition to obesity and concomitant metabolic changes, both obob and dbdb mice have numerous endocrine abnormalities, suggesting either anterior pituitary malfunction or a failure in hypothalamic control of the pituitary. No naturally-occurring hypothalamic lesions have been reported in either obob or dbdb mice; however, elevated levels of hypothalamic and telencephalic norepinephrine (NE) have been reported in both mutants when compared with lean littermate controls. Central catecholamines (CA) have been implicated in the control of food intake and body weight and are known to have an important function in the control of pituitary hormone release. To begin to assess the potential role of altered CA levels in the obesity syndromes of obob and dbdb mice, intraventricular infusions of 6-hydroxydopamine (6OHDA) were used to reduce CA levels in the brains of both mutants.

Female dbdb mice (C57Bl/Ks-db) and male and female obob mice (C57Bl/6J-ob) were obtained from the Jackson Laboratories, along with lean controls. Lesions were produced in both lean and obese mice by the infusion of 80 nmol (free base) of 6OHDA·HBr, dissolved in a .9% saline-.02% ascorbic acid vehicle. The 6OHDA was delivered in a 2 µl volume through a 30 gauge cannula, stereotaxically aimed at the third ventricle. Lean and obese control animals received 2 µl of the vehicle. All animals were weighed every four days. After 6 wk, all mice were sacrificed by decapitation and the brains assayed for NE and dopamine (DA). Blood samples were collected for determination of blood glucose.

The 6OHDA lesions had no significant effects on the body weights or blood glucose levels of lean mice of either strain. The lesions significantly reduced both body weight (-15%) and blood glucose (-24%) in dbdb mice when compared with vehicle-infused obese controls. Neither body weight nor blood glucose, however, was reduced to the levels of lean controls. In contrast, neither blood glucose nor body weight was significantly altered in obob mice of either sex by the 6OHDA infusion.

Assays of hypothalamic and telencephalic NE and DA showed that the 6OHDA infusions produced large decreases in the levels of both amines. The failure of the 6OHDA infusions to alter body weight in lean mice or obob mice was not due to a failure to produce a lesion. The results indicate that despite the similarities between the two syndromes, central monoamine systems play different roles in the development of obesity in these mutants.

546 DEPENDENCE OF THE CHOLECYSTOKININ SATIETY EFFECT ON VAGAL INNERVATION. Dennis N. Lorenz* and Steven A. Goldman* (SPON: Alan N. Epstein) Inst. Neurol. Sciences, U. Pa., Phila., Pa. 19104.

The intestinal hormone cholecystokinin has been implicated as a satiety signal specific for food intake (Smith, G.P. and Gibbs,J. Pharm. Biochem. and Behav. 3:135, 1975). Cholecystokinin must affect the brain either directly or indirectly to elicit satiety behavior, but its mechanism and site(s) of action are unknown. To investigate this mechanism, we tested the satiety effect of cholecystokinin in rats after selectively denervating portions of their viscera.

Holtzman albino male rats (300-450gm) underwent either a complete subdiaphragmatic bilateral vagotomy, including the hepatic branches, or section of the spinal cord between the 3rd and 4th thoracic vertebrae. All splanchnic afferents are believed to be located in the cord at this level. A third group of rats served as intact controls. The rats were tested daily after a 6hr food deprivation. Water was present at all times. At test time (1600hr), the rats were given Purina Pellets after an i.p. injection of either 1)cholecystokinin extract (20% pure); 2)the synthetically pure C-terminal octapeptide of CCK; or 3)the isotonic saline vehicle. Food was removed and weighed after the rats displayed satiety resting behavior.

The complete vagotomy group failed to suppress their food intake after the octapeptide and all but the largest dose of CCK (Table). All other groups suppressed their food intake. We conclude that some component of the subdiaphragmatic vagus is necessary for the cholecystokinin satiety mechanism, within our experimental paradigm; the splanchnic nerves are not required. The importance of the hepatic branches, as well as of the separate afferent and efferent projections of the vagi, in contributing to the cholecystokinin satiety effect, remain to be determined.

Food Consumed (Mean ± S.E.% of Saline Control)

547 SUBFORNICAL ORGAN: SITE OF PRESSOR AND DRINKING ACTIONS OF ACETYLCHOLINE. Michael L. Mangiapane and John B. Simpson, Depts. Physiol.-Biophys. & Psychol., Univ. Washington, Seattle, WA 98195

Iontophoretic and histochemical evidence indicates the presence of a dense cholinergic innervation of the subfornical organ (SFO), a circumventricular organ of the dorsal third ventricle. Simpson and Routtenberg have shown that the SFO is a sensitive site of dipsogenic action of acetylcholine (ACh; Brain Res., 1974) as well as of angiotensin II (A II; Science, 1973). The demonstration that SFO application of A II also elicits a pressor effect (Mangiapane and Simpson, Neurosci. Abstr., 1977) suggested that, like A II-induced drinking, drinking induced by SFO injection of cholinergic agonists also might be accompanied by a pressor effect. In unanesthetized, unrestrained rats prepared each with an SFO cannula and an aortic catheter, the SFO injection of carbachol induced within seconds a dose-dependent pressor effect which in all cases preceded onset of drinking. At 10^{-9} mols, the pressor response averaged 80 mm Hg, and decreased to 9 mm Hg at 10^{-13} mols. The pressor effect was not a consequence of drinking since it remained under chloralose anesthesia. Both responses were abolished by prior SFO injection of an equimolal quantity of atropine.

The effects of injection of ACh per se were next examined at three loci: SFO; adjacent ventral fornical commissure (VFC); and dorsal third ventricle (III V). Injection into SFO of 10^{-7}, 10^{-8}, and 10^{-9} mols of ACh elicited rapidly rising pressor responses of 37.1, 24.6, and 8.4 mm Hg, with concurrent intakes of 4.3, 1.0, and 0.5 ml H_2O, respectively. Injection of ACh at III V and VFC sites adjacent to SFO elicited significantly smaller pressor effects and provoked drinking only at the largest dose. At SFO, the mean latency for all doses, from offset of the 5 sec injection to onset of blood pressure increase, was 3.2±1.5 sec; indeed, 60% of responses commenced within 1 sec. Latencies to drinking were longer in all cases. At VFC and III V sites, latencies for both effects, if elicited, were significantly longer than at SFO. The extremely rapid onset of the SFO pressor effect suggested sympathetic participation in the response. Preliminary results indicate that the pressor effect of SFO ACh is sharply reduced following ip injection of 15 mg/kg phentolamine, whereas the drinking response is unaltered. These data: i)indicate the presence of a muscarinic cholinergic innervation of the SFO; ii)identify two functions of this innervation which are quite similar to those of SFO-injected A II; and iii)suggest that the ACh-induced pressor effect is at least partly sympathetically mediated.

548 ONTOGENY OF DRINKING TO ANGIOTENSIN II IN THE SUCKLING RAT. L.J. Misantone, S.E. Natale*, and A.N. Epstein. Dept. Anat. Hahnemann Med. Coll. and Inst. Neurol. Sci, Univ. of Pa., Phila., Pa. 19102.

Angiotensin II (AII) has been shown to be a potent dipsogen in all adult species tested. This study examined the ontogeny of the water drinking response to AII in the rat. One hundred ng. of AII (in 1 µl of a vehicle of 50% distilled water and 50% India ink) was injected into the anterior right lateral ventricle of unanesthetized suckling rats. Littermate controls that were matched for weight with the AII treated rats received 1 µl of the vehicle alone. Responsiveness to AII was evaluated by a modification of Wirth and Epstein's technique (1976 Amer. J. Physiol. 230: 188-198), which uses weight gain during the test period as a measure of water ingested by consumatory responding. To avoid confusion of drinking responses with eating, only pups that gained weight in the nursing period preceding testing were used in this experiment. Successful injections were confirmed by decapitating the animals immediately after testing, making a coronal section through the injection site, and noting the presence or absence of ink in the anterior ventricles.

While drinking to AII appeared in several of the pups tested at early ages (0-3 days), the first consistent and statistically significant differences from control in response to AII were seen at 4 days of age ($\bar{x} \pm$ S.E.: AII = 85mg ± 14, n = 16 vs. control = 25mg ± 4, n = 12). At 5 days the weight gain due to water drinking after AII was double that at 4 days (AII = 177mg ± 65, n = 13 vs. control = 17mg ± 9, n = 12). Responsiveness to AII at 6 days of age did not differ from that at 5 days. When 3% NaCl was substituted for water in 5 day old rats, no significant differences in drinking occurred. When Esbilac, a synthetic bitches milk, was offered to 5 day old AII treated rats, they drank significantly more than controls (AII = 318mg ± 23, n = 8 vs. 45mg ± 14, n = 8) and this milk intake was significantly greater than the amount of water drunk by the 5 day olds described above. It does not seem likely that this intake of more milk than water indicates a role for AII in control of suckling behavior rather than as a primary dipsogen, because 1 day old rats treated with AII did not differ from controls in the amount of Esbilac drunk. Perhaps this apparent preference for milk over water in 5 day old rats treated with AII is related to the fact that milk, rather than water, is the substance with which the suckling rat fills its needs for both water and food. (Supported by NINCDS 03469 and MH 28782).

549 SUBFORNICAL ORGAN EFFERENT AND SUPRAOPTIC NUCLEUS AFFERENT CONNECTIONS AND THEIR IMPLICATIONS IN THE CONTROL OF WATER BALANCE. Richard R. Miselis, Robert E. Shapiro* and Peter J. Hand. Dept. of Animal Biol., Sch. Vet. Med. and Inst. Neur. Sci., Univ. of Penn., Philadelphia, PA, 19104.

Angiotensin II (AII) is known to initiate physiological and behavioral responses which participate in homeostatic maintenance of body water balance. The subfornical organ (SFO), a circumventricular organ of the brain, is a receptor site for the dipsogenic action of angiotensin II (AII) (Simpson and Routtenberg, Sci. 181:1172, 1973). The efferent projections of the SFO are of interest since they may provide the necessary initial connections in a neuronal circuitry mediating the drinking response or other AII induced effects. An investigation of the afferent connectivity of the supra optic nuclei (SON), the brain's primary site of anti-diuretic hormone (ADH) production, might help illuminate the mechanisms of control of this final common path in the conservation of body water balance. To study these connections we applied the axoplasmic tracing techniques of anterograde autoradiography and retrograde horseradish peroxidase (HRP) histochemistry. As reported previously (Neurosci Abst. 3:484, 1977), the SFO projects to the nucleus medianus, the organum vasculosum of the lamina terminalis (OVLT) and to the SON bilaterally. The SFO projection to the SON was confirmed by injections of HRP into the SON and subsequent observation of labelled bipolar neurons 10-18µ in width in the SFO (Anat. Rec. 190:538, 1978). There are afferents to the SON from the OVLT and NM as well. These connections involve the SON in a circuit with structures known to be involved with drinking behavior. We now report additional forebrain projections to the SON from the circularis and paraventricular nuclei of the hypothalamus. These nuclei are moderately labelled with HRP reaction product granules suggesting light projections. The medial and triangularis nuclei of the septum, the nucleus of the diagonal band, the thalamic periventricular and parataenial nuclei also have retrogradely labelled neurons following HRP injections into the SON. However, the septal and thalamic nuclei, but not the hypothalamic nuclei, are also labelled when the HRP injections miss the SON and involve only the adjacent ventral lateral hypothalamus. The anatomical links demonstrated in these studies may subserve the physiological function of AII in the central control of water balance.

550 NALOXONE INHIBITION OF OVEREATING IN GENETICALLY OBESE MICE C57BL/6J ob/ob. Beatriz Moisset* and David L. Margules. Psychol. Dept., Temple University. Philadelphia, PA 19122.

The genetically obese mouse ob/ob shows a syndrome of marked hyperphagia, obesity, mild hyperglycemia and hyperinsulinemia. This syndrome is caused by a single autosomal recessive gene (Coleman and Hummel, Diabetologia 9: 287, 1973). Obese mice present pituitary levels of ACTH 14 times higher than lean controls at 16 weeks of age (Edwardson and Hough, J. Endocr. 65: 99, 1975). ACTH and β-endorphin are released concomitantly in the rat (Guillemin et al. Science 197: 1367, 1977) suggesting that the obese mouse may have abnormally high levels of β-endorphin in the pituitary. Intrahypothalamic injections of β-endorphin cause an increase in food intake in the rat (Grandison and Guidotti, Neuropharmacology 16: 533, 1977) suggesting that some forms of hyperphagia may be due to excessive production of β-endorphin. If this is so then the opiate receptor blocker, naloxone, would be expected to reduce food intake more markedly in obese mice than in lean controls. Food intake during the first hour after 20 hours of food deprivation was measured following injections of saline, 0.1, 0.25, 0.5, 1.0, 2.5 and 5.0 mg/kg s.c. of naloxone hydrochloride in C57BL/6J ob/ob and their lean littermates. Obese mice ate more than the lean littermates after saline injection (1.54 ±0.07g and 1.10±0.05g, respectively). Food intake was selectively depressed in ob/ob mice with doses of naloxone as low as 0.25 mg/kg. Lean mice also showed a reduction in food intake but this was significantly smaller at all doses, except for the lowest one. The present experiment suggests that β-endorphin may be involved in the regulation of food intake and that hyperphagia in the genetically obese mouse may be associated with excessive β-endorphin.

551 COMPARISON OF NOREPINEPHRINE AND OTHER SELECTED APPETITE STIMULANTS ON CIRCADIAN REGULATION OF FEEDING IN RATS. W.R. Pfister*, M.T. Lowy*, G.K.W. Yim. Dept. Pharmacol. and Toxicol. Purdue Univ., West Lafayette, IN 47907.

We have recently reported that chlordimeform (CDM), librium, clonidine, and cyproheptadine increase food intake in non-food deprived rats (NFD) (Yim et al., Fed. Proc. 37(3): 860, 1977). Increased consumption of milk induced by norepinephrine (NE) (Margules et al., Science 178: 640, 1972) and of dry food induced by theophylline (Sakata et al., Eur. J. Pharmacol. 19: 318, 1972) has been attributed to their ability to produce a phase shift in circadian feeding rhythm. This possibility was further explored by examining the effects of these agents on dry food intake when they were administered during the day vs at night. In NFD rats, NE (20 ug/5 ul; i.v.c.), clonidine (0.025 mg/Kg, i.p.), librium (40 mg/Kg, i.p.), CDM (10 mg/Kg, i.p.), theophylline (20 mg/Kg, i.p.), and cyproheptadine (10 mg/Kg, i.p.) increased daytime 3 hr food intake by 176, 293, 657, 570, 458, and 312 percent (control = 2.8 ± 0.5 g/Kg). With the exception of the 20% decrease observed with clonidine, 24 hr intakes were unaffected. In food deprived (FD) rats, the appetite stimulants increased 3 hr daytime food intake by 15-50 percent, except librium which decreased intake by 44 percent (control = 16.3 ± 2.5). In NFD rats tested at night, the same doses of NE, clonidine, CDM, theophylline, and cyproheptadine increased 3 hr food intake by 27-47 percent (controls = 7.3 ± 0.1 g/Kg). These results suggest that the increased daytime feeding induced by these agents (excepting librium) is not a result of their ability to produce a phase shift in the circadian feeding rhythm of the rat. Supported in part by grants from NIH (NS 12077, 5-R01CA17482-09 and EPA (R-803965).

552 THE ROLE OF SOMATOSTATIN (SRIF) IN THE CONTROL OF FEEDING. PART II: EFFECT ON FOOD INTAKE AS A FUNCTION OF METABOLIC CONDITION AND VISCERAL INNERVATION. M. Rezek, V. Havlicek, Sheu-Lun Lee* and H. Friesen*, Dept. of Physiology, U. of Manitoba, Winnipeg, Manitoba, Canada.

In Part I (Rezek et al., Federation Proceedings, 1978) we reported the differential effect of SRIF on food intake (FI) as a function of the dose and infusion site. Intraperitoneal infusions of 50ug and 100ug were strongly anorexigenic while the same doses of SRIF passed as a bolus through the hepatic-portal (HP) circulation produced a brief dose-dependent stimulation of FI. Present experiments examined the mechanism of this differential effect of SRIF on FI. It was found that HP infusions of SRIF retained their stimulating effect when administered during the period of nocturnal overeating or following cyclical food deprivation although the increases of the amount eaten were smaller than in the free-feeding animals or during the diurnal feeding period. On the other hand, stimulation of FI by HP bolus infusions of SRIF was reduced or eliminated in vagotomized animals, in reversibly diabetic animals (mannoheptulose-250 mg/kg) or following the infusion of endocrinologically less active analog of SRIF (Ala^8-SRIF). These results suggest that both the neural and endocrine components are necessary for the expression of this response. In contrast to the stimulating effect of HP bolus infusions of SRIF, the prolonged 3 hr SRIF infusions (300ug, 100ug/hr) produced a significant ($p < 0.05$) and long lasting suppression of FI without producing general behavorial depressions. This effect was preserved following repeated prolonged infusions of SRIF performed on alternate days or during the period of nocturnal insulin-dependent overeating. On the other hand, our preliminary results with the HP infusion of anti-SRIF serum (with binding capacity in excess of estimated endogenous content of SRIF) showed that following a temporary suppression (1st postinfusion hour) these infusions slightly facilitated FI as indicated by elevation of total daily intakes (11%).

553 GLUCOSE FAILS TO SUPPRESS 2-DEOXYGLUCOSE-INDUCED FEEDING WHEN INFUSED AFTER THE ONSET OF GLUCOPRIVATION. R.C. Ritter and M. A. Miller*. Dept. Veterinary and Comparative Anatomy, Pharmacology and Physiology, Coll. Vet. Med., WSU, Pullman, WA 99164.

Feeding in response to 2-deoxy-d-glucose (2DG) or insulin is presumed to be a response to ongoing cerebral glucoprivation. If ongoing glucoprivation is the adequate stimulus for 2DG- and insulin-induced feeding, then one might predict that (1) feeding should persist as long as glucoprivation persists and (2) the stimulus to eat should subside when glucoprivation abates. However, recent work from our lab (Am. J. Physiol. 1978) has shown that rats eating in response to 2DG or insulin stop eating within 2 hrs after injection, when other signs of glucoprivation are near maximal. Furthermore, if food is withheld for 6 to 8 hrs, until physiological signs of glucoprivation have disappeared, rats still eat significantly more than they do under control conditions. We have hypothesized that 2DG or insulin-induced feeding triggered by some persistent biochemical change which outlasts glucoprivation itself and which is not immediately reversed simply by restoring glucose availability postglucoprivically. If this hypothesis is correct, it should be possible to suppress 2DG-induced feeding by infusing glucose concurrently with 2DG but not by infusing glucose after 2DG-induced glucoprivation had been allowed to occur. Adult male rats implanted with chronic intracardiac catheters were infused with 2DG (200 mg/kg) or equiosmolal saline at 8 AM. When food was immediately available 2DG caused a significant increase in food intake (5.7 ± 0.5 g) over saline control conditions during a 2-hr test. If food was withheld for 7 hrs post 2DG, the rats still ate significantly more (5.6 ± 0.7 g) than under control conditions. Infusions of 4 cc of 12.5% glucose given over 15 mins at 5 min, 1, 2 and 3 hrs post 2DG suppressed feeding (1.4 ± .6 g) when food was returned 7 hrs post 2DG. However, when identical glucose infusions were made 4, 5, 6 and 7 hrs post 2DG, feeding in response to 2DG was not suppressed (4.7 ± 0.6 g). Our data show that (1) 2DG-induced feeding may occur after other signs of cerebral glucoprivation have vanished, (2) 2DG-induced feeding can be prevented by exogenous glucose only if glucose is infused in such a way that may compete with 2DG and prevent glucoprivation from occurring, and (3) glucose infusions made after exposure to and recovery from glucoprivation are insufficient to suppress the stimulus to eat. These data support the suggestion that 2DG-induced feeding is mediated by a biochemical change which persists after restoration of glucose availability.

554 ABLATION OF PERIVENTRICULAR TISSUE SURROUNDING THE ANTEROVENTRAL THIRD VENTRICLE (AV3V) BLOCKS DRINKING TO CAVAL LIGATION BUT NOT RENIN RELEASE. E.E. Shrager and A.K. Johnson (SPON: M.Z.M. Ibrahim). Dept. Psychology, Univ. Iowa, Iowa City, IA. 52242.

Lesions of AV3V periventricular tissue result in acute adipsia without aphagia; animals which regain ad lib water intake demonstrate chronic deficits in the drinking response to exogenous angiotensin II and/or hypertonic saline (Johnson & Buggy, Am. J. Physiol. 234:R122, 1978; Buggy & Johnson, Am. J. Physiol. 233:R44, 1977). Further, these animals do not become hypertensive or increase water intake following the Grollman procedure for 1-kidney hypertension (Buggy, Fink, Johnson & Brody, Circ. Res. 40:I-110, 1977).

Animals which have recovered from the acute effects of AV3V lesions drink normally in response to 24hr water deprivation but fail to increase water intake in the 4hr following vena caval ligation.

Determinations of plasma renin concentration (PRC) prior to and following water deprivation indicate that AV3V lesioned rats have significantly elevated basal PRC's despite concurrent hypernatremia. Nevertheless, following 24hr water deprivation, lesioned animals show further increases in renin release comparable to those demonstrated by sham-lesioned animals.

These results suggest that the failure of AV3V lesioned animals to develop renal hypertension and concommitant increased water intake is mediated not by a failure of renin release but rather, an inability to respond to increased circulating levels of angiotensin II.

555 CHOLECYSTOKININ ACTS AT A VAGALLY INNERVATED ABDOMINAL SITE TO ELICIT SATIETY. Gerard P. Smith and Brian J. Cushin*. Dept. Psychiatry, Cornell Univ. Med. College and E.W. Bourne Behavioral Res. Lab., The New York Hospital, White Plains, N.Y. 10605.

The intestinal hormone cholecystokinin (CCK) and its synthetic C-terminal octapeptide (CCK-8) have a potent satiety effect (Gibbs et al, 1973). The site where CCK acts to elicit this effect is unknown. Since the size and peptide nature of CCK and CCK-8 make it improbable that circulating CCK or CCK-8 acts directly on brain sites protected by the blood brain barrier, we have investigated the possibility that CCK-8 acts at a peripheral site innervated by the abdominal vagus. After overnight food deprivation, three groups of rats (intact n=8, bilateral vagotomized n=8 and unilateral vagotomized n=8) were administered CCK-8 (10, 20, 40, 80, 160 and 640 $U\text{-}kg^{-1}$, i.p.) 15 minutes before a test meal of 25% E.C. 116 liquid diet. The threshold dose for significant inhibition of food intake was 640 $U\text{-}kg^{-1}$ in bilateral vagotomized rats, 40 $U\text{-}kg^{-1}$ in unilateral vagotomized rats and 10 $U\text{-}kg^{-1}$ in intact rats. Since bilateral vagotomy (hepatic branch preserved) abolished the satiety effect of doses of CCK-8 < 640 $U\text{-}kg^{-1}$, we conclude that under these conditions low doses of CCK-8 act to elicit satiety at an extra-hepatic abdominal site innervated by the vagus nerve.

Supported by NIH Grants MH15455, AM17240 and MH00149.

556 ANTICIPATION OF 24 HR FEEDING SCHEDULES IN RATS WITH LESIONS OF THE SUPRACHIASMATIC NUCLEUS.
F. K. Stephan, J. M. Swann* and C. L. Sisk.
Dept. Psychol., Florida State University, Tallahassee, FL 32306.

Anticipatory wheel running in response to restricted feeding schedules was studied in rats with lesions of the suprachiasmatic nucleus (SCN) and in sham operated controls. Despite the absence of circadian periodicity in free feeding conditions, rats with SCN lesions anticipated restricted access to food at 24-hour intervals in the presence of a light-dark cycle and in constant light. Neither rats with SCN lesions, nor controls were able to anticipate feedings at 18-hour intervals. Adrenalectomy did not prevent anticipatory activity to a 24-hour feeding schedule in either group. These results suggest that circadian oscillators outside SCN can be entrained by restricted feeding schedules or, alternatively, that anticipatory activity is based on a clock which operates on the hourglass principle; i.e., a clock which requires daily resetting.

557 INTRAHYPOTHALAMIC INJECTIONS OF KAINIC ACID PRODUCE DEFICITS IN FEEDING AND DRINKING DURING ACUTE HOMEOSTATIC IMBALANCES.
Edward M. Stricker, Alissa F. Swerdloff* and Michael J. Zigmond. Departments of Psychology and Biological Sciences, University of Pittsburgh, Pittsburgh, PA 15260.

Large electrolytic lesions of the far lateral hypothalamic (LH) area of rats produce aphagia and adipsia. Even when voluntary ingestive behaviors return, after several weeks or longer, rats sustaining such lesions do not eat or drink normally in response to acute treatments producing severe glucoprivation or dehydration. It had been traditional to interpret these observations as indicating the presence of feeding and drinking centers within the ventral diencephalon. However, it is now known that LH lesions interrupt dopamine-containing neurons ascending from the mesencephalon to the forebrain, and that specific destruction of those neurons by intracranial administration of the neurotoxin 6-hydroxydopamine reproduces the severe initial impairments, gradual recovery of function, and residual deficits that characterize animals with LH lesions. These and other recent findings have shifted attention away from the hypothalamus in discussion of the central control of feeding and drinking, and suggested that LH lesions are effective because they disrupt nonspecific activational components of hunger and thirst (and other sensations) that are prerequisites for motivated consummatory behavior. In order to further examine this hypothesis we have studied the behavior of rats given intrahypothalamic injections of kainic acid, a rigid analogue of glutamate that appears to destroy neurons with cell bodies near the injection site while sparing fibers of passage. Kainic acid was dissolved in 0.9% NaCl (1.14 µg/.57 µl) and administered over 60 sec to 10 rats. Controls received an equivalent injection of vehicle. Rats given kainic acid showed a brief aphagia and adipsia (2-3 days) after which voluntary ingestive behaviors resumed. Nevertheless, feeding and drinking in response to acute regulatory challenges was greatly impaired in most animals. Of 10 rats given kainic acid that were tested, the rapid drinking response to acute cellular dehydration (1 M NaCl, 5 ml, i.p.) was found to be abolished in 4 animals and impaired in 5 others, the gradual drinking response to acute hypovolemia (30% PEG, 5 ml, s.c.) was abolished in 6 animals and impaired in 1 other, and the feeding response to acute glucoprivation (2-deoxyglucose, 750 mg/kg, i.p.) was abolished in all 10 animals. Control rats responded normally to these treatments. The concentration of dopamine and norepinephrine in whole brain was not significantly affected by kainic acid. The fact that functional deficits were obtained in the absence of damage to central catecholaminergic fibers suggests that cells in the LH area may indeed play a role in the control of ingestive behaviors.

558 THE EFFECT OF THE METABOLITE GLYCEROL ON FOOD INTAKE PATTERNS AND BODY WEIGHT IN RATS.
Alan J. Strohmayer* and Joel A. Grinker*. (SPON: Jeri A. Sechzer). Rockefeller Univ., New York, N.Y. 10021.

Levels of glycerol are correlated with adipose tissue mass and cell size. Glycerol has thus been proposed as a humoral signal to the brain representing the state of fat storage (Bray, 1976).

This study measured the effects of the infusion of near physiological doses of glycerol (12 and 24 mg/day) on body weight and 24 hour food intake patterns in six-month-old male Sprague Dawley rats. Using a computerized continuous data collection system, 24 hour feeding patterns (meal size, number, interval and duration) of 6 rats were monitored. Rats were initially adapted to the feeding chamber and to the powdered lab chow diet. Baseline food intakes and weight data were collected for 5 days on a 12 hour light/dark cycle. Rats were then implanted with Alzet Mini-pumps which delivered a continuous subcutaneous infusion of a glycerol solution at 1 µl/hour for 170 hours.

There were no changes in body weights over the 7 day infusion period. Total food intake during the light phase was decreased in a dose related fashion, while dark phase intake showed compensatory increases. The decrease in light phase intake was accomplished primarily by decreased meal frequency while meal size remained unchanged. These data suggest that the metabolic effect of glycerol interacts with circadian patterns of feeding in rats.

Other investigators have reported (Wirtshafter & Davis, 1977) that reductions in body weight following injections of glycerol are a function of both dose and time of administration. Additionally, (Kraly & Smith, 1978) have reported the magnitude of the satiety effect of cholecystokinin is also dependent on the time of administration relative to the light/dark cycle. These studies, in conjunction with the present study, suggest that the controls of food intake are altered with changes in photo period. Thus continuous analysis of 24 hour meal patterns may show a unique sensitivity to pharmacological and metabolic manipulations of feeding.

559 SEPARATE OSCILLATORS GOVERN ULTRADIAN ACTIVITY, FEEDING, AND DRINKING RHYTHMS AFTER SUPRACHIASMATIC NUCLEUS LESIONS.
Walter N. Tapp*, David C. Bird*, and Frank A. Holloway. Dept. Psychiatry and Behavioral Sciences, Univ. of Okla. Health Sciences Center, Oklahoma City, Ok 73190.

The suprachiasmatic nucleus of hypothalamus (SCN) appears to be a key element in the control of circadian rhythms in mammals. The presence of circa 8 h and circa 12 h rhythms in the locomotor activity spectrum of SCN-lesioned hamsters (B. Rusak, J. Comp. Physiol., 118:145-146, 1977) has been suggested to reflect mutual coupling of self-sustaining oscillators outside the SCN. It is not known if other functions exhibit such ultradian rhythms after SCN lesions or if such rhythms would be synchronized with activity.

Rats with bilateral, radiofrequency SCN lesions (n=10) were compared with unoperated controls (n=6) on activity, feeding, and drinking patterns. Both groups were maintained in constant dim red illumination. Control rats free-ran with periods ranging from 23.4 h - 28.7 h. In some controls the free-running period of activity, feeding, and drinking were different reflecting internal desynchrony.

Spectrum analysis revealed circa 8 h or circa 12 h (but not circa 24 h) components in the activity rhythms of most SCN lesioned rats. Food and water intake displayed similar circa 8 h or circa 12 h rhythms. The ultradian periods of feeding, drinking, and activity components were not always the same within individual lesioned rats. Ultradian feeding, drinking, and activity rhythms generally were not phase-coordinated.

The presence of circa 8 h and circa 12 h rhythms of feeding, drinking, and activity in SCN rats may reflect mutual coupling of oscillators outside the SCN. But the present results suggest that separate oscillators govern each function, interacting only weakly.

560 EFFECT OF THIRD VENTRICULAR INFUSIONS OF HYPERTONIC SOLUTIONS ON THIRST IN THE DOG. Terry N. Thrasher*, Richard G. Jones* and David J. Ramsay (SPON: I. Reid). Dept. Physiol., Sch. Med., University of California at San Francisco, CA 94143

A controversy exists with regard to the mechanism by which an increase in the effective osmotic pressure of extracellular fluid stimulates thirst. The osmometric hypothesis of thirst is based on Verney's (Proc. Roy. Soc. Lond. Ser. B, 135, 25-106, 1947) suggestion that increases in extracellular fluid osmolality cause withdrawal of water from sensitive receptor cells within the hypothalamus and lead to vasopressin release. Alternatively, Andersson and colleagues(Am.Scientist, 59, 408-415, 1971) have proposed the existence of receptors sensitive to the concentration of sodium in cerebrospinal fluid (CSF). As a test of the Andersson mechanism we infused 5 conscious dogs with hypertonic equiosmolar (1.7 Osm/L) solutions of NaCl, sucrose, glucose, urea or isotonic NaCl iv and measured the change in CSF sodium conc. at the thirst threshold or arbitrarily, after 45 min. Hypertonic NaCl or sucrose, which do not penetrate cell membranes, stimulated thirst and increased CSF sodium conc. by 1.6±0.3 and 1.2±0.3 mEq/L respectively. Hypertonic glucose or urea, which do penetrate cell membranes, did not stimulate thirst but did increase CSF sodium conc. by 1.4± 0.4 and 2.6±0.5 mEq/L respectively. Isotonic NaCl did not stimulate thirst or alter CSF sodium conc. significantly. Since all hypertonic solutions elevated CSF sodium conc., but only non-penetrating solutes stimulated thirst, these data indicate that an increase in CSF sodium conc. is not sufficient to stimulate drinking.

As a more direct test of the sodium receptor mechanism, we decided to increase the CSF osmolality by intracerebroventricular infusions of different solutes. Six dogs were prepared with chronic third ventricular cannulae. Each was infused with hypertonic, equiosmolar (0.2 Osm/L) solutions of NaCl, sucrose or glucose in artificial dog CSF for 45 min at 17 µL/min. The volume of water drunk during the infusion was measured and compared to the volume drunk during infusion of artificial CSF alone. Infusion of artificial CSF produced insignificant drinking. Infusion of hypertonic solutions containing NaCl or sucrose stimulated significant drinking amounting to 369±139 and 113±56 ml respectively. However, infusions of hypertonic glucose did not produce significant drinking. The only solutes which stimulated drinking were those which do not penetrate cell membranes and thus cause osmotic withdrawal of water. Furthermore, sucrose infused centrally initiated drinking without increasing CSF sodium conc. Therefore, we conclude that in the dog, thirst induced by increased extracellular fluid osmolality is mediated by an osmoreceptor mechanism.

561 RAPHE NEURON FIRING RATE AND SEROTONIN RELEASE VERSUS SEROTONIN BIOSYNTHESIS AS MODULATORS OF FOOD INTAKE IN THE RAT. Susan B. Weinberger* and Arnold J. Mandell. Dept. Psychiatry, Sch. Med., UCSD, La Jolla, CA 92093

In the search for understanding the role of the serotonergic neurotransmitter system in appetite regulation, earlier studies by several investigators have suggested a reciprocal relationship between food intake and brain serotonin levels. However, interpretation of such reports is made more complex by our recent finding that graded doses of tryptophan that more than doubled brain serotonin synthesis in the rat failed to alter food consumption. These data, along with other studies in our laboratory involving both quantitative microhistofluorescent examination of intracellular and extracellular single raphe cell body serotonin levels and regional brain patterns of tryptophan, serotonin, and 5-hydroxyindoleacetic acid (5-HIAA), have led us to the hypothesis that information encoded by firing rate and serotonin release, rather than by serotonin biosynthesis, may be the prepotent serotonergic factor in the modulation of appetite. Using a number of agents active on the serotonin system we have begun evaluating this hypothesis by studying the relative contributions of these variables to the control of food intake.

We have found that the serotonin uptake blocker fluoxetine produces a dose-dependent decrease in food consumption. Similarly chlorimipramine (CMI), which arrests raphe cell discharge and induces an increase in tryptophan hydroxylase activity, reduces food intake in rats food-deprived for 24 hours. However, CMI's dose-dependent reduction of appetitional behavior is partially reversed by tryptophan, which increases serotonin synthesis, when both drugs are administered simultaneously. Changes in patterns of the whole brain levels of tryptophan, serotonin, and 5-HIAA induced by these various drugs and combinations, along with the appetitional behavior data, suggest two possible mechanisms of serotonin's modulatory action on appetite: 1) the serotonin cells may act from outside the primary appetite informational circuit to modulate transmission along this pathway by altering the synthesis of serotonin, or 2) some serotonin cells may themselves be contained within the primary pathway for the neuronal representation of appetitional behavior and may modulate appetite by variations in neuronal discharge rate and neurotransmitter release without an increase in serotonin synthesis.

562 THE EFFECTS OF COPULATION ON FEEDING AND RELATED PROCESSES IN THE MALE. Freya A. Weizenbaum. Dept. of Psych., Va Polytech. Inst. & State University, Blacksburg, VA 24061.

Feeding behavior, body weight and carcass composition were monitored in males that copulated regularly (Group Sexual Activity [SA]) and in males that were not copulating (Group Sexual Rest [SR]). Sexually inexperienced males were screened for sexual vigor. The 12 males that were selected were divided into two groups, one group (Group SA) mated twice each week (1 ejaculation/test). The other 6 males comprised the second group (Group SR), which did not mate during the following 6 weeks. At the end of the 6 week period, body weight and carcass composition were compared. Group SA males had lower body weights and fat levels than the Group SR males. Examination of food intake patterns of the 2 groups revealed that food intake was depressed in Group SR males during the 24 hours following copulation. Since Group SR males were not permitted access to food during the periods when Group SA males were mating, but did not show a decrease in intake on those days, these findings indicate that the copulatory situation caused the change in feeding behavior body fat levels, and body weight.

In the second study the effect of the social component of the sexual situation was assessed. The overall procedure was the same as in the first study with one modification. Individual SR males were yoked to SA males, so that while each SA male was mated his yoked SR male was paired with an ovariectomized female. Both SR and SA males decreased food intake during the 24 hours after pairing with a female. These results suggest that the decrease in feeding was related to social aspects of the copulatory situation. However there were also indications that the effects of pairing a male with an estrous female were different from pairing with an ovariectomized rat. The SR males tended to show less of a decrement in feeding behavior than did SA males. The results of these two experiments suggest that social interactions can alter regulatory processes in the male. Other have shown that testosterone, (Science 189: 1104, 1975) a hormone which is known to alter food intake in males (J. Comp. Physiol. Psych. 90: 18, 1976), and testosterone-sensitive tissues (Physiol. Behav. 9: 401, 1972), are increased following exposure to females. The present studies extend the previous experiments concerned with the effect of the female on reproductive functions in the male because the present studies indicate that non-reproductive, testosterone-sensitive processes are also altered by exposure to female conspecifics.

563 REINSTATEMENT OF SPECIFIC COMPONENTS OF SUCKLING BEHAVIOR BY METHYSERGIDE IN YOUNG RATS. Christina L. Williams*, W. G. Hall, and Jay S. Rosenblatt* (SPON: B. R. Komisaruk). Inst. Anim. Behav., Rutgers Univ., Newark, N. J. and N. Carolina Dept. Mental Health, Raleigh, N. C.

Previous studies have demonstrated that suckling behavior of infant rats is not an unmodifiable reflex but that many of its components develop and change prior to weaning. Before 15 days of age pups will continuously suckle regardless of the amount of food in their stomachs, and thus cannot directly control their intake. After 15 days of age, pups will initiate suckling only after food deprivation and thus can control their food intake.

We have recently found that pharmacological manipulations of the serotonin system can alter the initiation component of suckling. For example, treatment with the putative 5-HT receptor blocker methysergide reinstates suckling in nondeprived pups older than 15 days. If suckling were a unitary behavioral system, then this pharmacological manipulation should similarly reinstate other components of suckling commonly displayed by pups younger than 15 days of age.

In order to test the effects of methysergide on the components of suckling involved in milk intake, we utilized an intraoral cannula which opens onto the back of the pup's tongue. With this technique, diet can be delivered to a pup while it is suckling from the nipples of its anesthetized dam. Saline- and methysergide-treated (20 mg/kg), 20-day-old littermates were tested in this manner.

We found that methysergide altered only some of the behavior patterns associated with suckling for milk. For example, all the drug-treated pups, but none of the saline controls, displayed the dramatic extensor reflex during milk ingestion which is normally shown only by pups younger than 15 days of age. Similarly, at the termination of milk intake, only the drug-treated animals could be induced to reattach by placing them at a nipple, a behavior normally shown only by pups less than 15 days of age. We found, however, that this dose of methysergide did not alter the pups' control of milk intake. Although pups younger than 15 days cannot control their intake, the drug-treated pups, like the saline-treated pups controlled their food intake, i.e. consumed moderate amounts of diet before leaving the nipple (Methy: 6.4± 0.6% body wt.; Sal: 6.8± 0.3%, n=8).

Thus, these data suggest that the neurochemical systems which control the initiation of suckling and the ingestive reflex may be different from those which control food intake and the termination of suckling or may be more refractory to manipulation by methysergide.

564 A Comparison of Ventral Noradrenergic Bundle and Ventromedial Hypothalamic Lesion-Induced Hyperphagia and Obesity. Robert M. Zacharko* and Thomas B. Wishart. Dept. Psych., University of Saskatchewan, Saskatoon, Saskatchewan, Canada S7N 0W0.

Gold (1970) reported that lesions restricted to the ventromedial nucleus (VMH) were ineffective in producing hyperphagia and obesity in rats. Gold argued that hyperphagia is produced only if the lesion extends beyond the VMH itself, and suggested a role for the ascending noradrenergic bundle (VNB) in mediating "satiety". Ahlskog (1973) subsequently reported that damage to the VNB with the catecholamine neurotoxin, 6-hydroxydopamine, produced hyperphagia and obesity in rats. In the present study we compared the ingestive behaviors of VMH and VNB animals under both drug and control conditions. Male rats were given lesions confined to the VMH (1 mA, 12 sec) or the VNB at the level of the oculomotor nerve (.8 mA, 5 sec). Immediately after surgery, rats with lesions of the VMH consume food so rapidly that gagging, retching and (sometimes) death ensue. If water, but not food, is available these animals will drink to the point of water intoxication death (Wishart and Walls, 1975). In marked contrast, VNB rats were observed to consume significantly less food and water than did controls during the first 3 hours after recovery from the anesthetic. However both VMH and VNB rats were hyperphagic and gained more weight than did controls during the first 10 days after surgery. VNB rats were hyperphagic only during the dark cycle whereas VMH rats overate during both light and dark phases. When these rats were switched to a 25% corn oil diet mixed with mash, the hyperphagic tendency of the VMH and VNB rats was maintained, but again VNB rats were hyperphagic only during the dark phase. The three groups of animals made equivalent adjustments to the alteration in caloric density of the diet. At the end of this phase the body weights of VNB, VMH and control rats were 474, 458 and 418 grams respectively. During the first 3 hours after d-amphetamine (2 mg/kg), VNB animals did not reduce food intake as much as controls while VMH rats reduced their intakes below that of controls. In rats with VMH lesions, feeding was suppressed significantly below that of either VNB or intact rats during the subsequent 21 hour interval. Under fenfluramine (2 mg/kg) all three groups consumed equivalent amounts during both the initial 3 and subsequent 21 hour periods.

Thus, while both VMH and VNB lesions eventually result in obesity, the onset of hyperphagia occurs sooner in VMH rats, suggesting that the etiologies of the syndromes are different. Further, d-amphetamine differentially affects the two preparations indicating a catecholaminergic alteration only in VNB rats. Serotonergic systems however appear functionally intact in both VMH and VNB animals.

INVERTEBRATE NEUROBIOLOGY

565 BURSTING IN APLYSIA CELL R15 IS MAINTAINED BY THE TEMPORAL PROPERTIES OF MEMBRANE CONDUCTANCE, NOT ITS NEGATIVE RESISTANCE. William B. Adams and Irwin B. Levitan. Friedrich Miescher-Institut, P.O.Box 273, CH-4002 Basel, Switzerland.

Steady-state current-voltage curves of the cell membrane of R15 reveal a region of negative slope resistance between -20 and -50 mV which, it has been suggested, produces an instability that maintains bursting activity. This hypothesis presupposes that the cell can actually "see" the negative resistance during normal activity, i.e. that a small depolarization increases the inward current, thereby further depolarizing the cell. We have found that this is not the case. Current-voltage curves measured at short times following application of a voltage-clamp have positive slope resistances over most of the operating range of the cell, except during times just preceding a burst. Our data suggest a mechanism for burst production that resembles the classical description of action potential generation: A conductance which allows an inward current flow is activated by depolarization and subsequently inactivated as a result of the depolarization produced during the burst. The conductance differs from the fast sodium conductance in that it is partially activated at the resting potential, is orders of magnitude slower and is not blocked by tetrodotoxin. The largest inward (negative) currents are found near the midpoint of the burst, as expected from the large values of dv/dt observed between action potentials. As the clamp is left on, the currents become less negative with little change in the shape of the i-v curve, indicating inactivation of the inward current. During the interburst, hyperpolarizing clamps elicit inward currents which do not change with time, suggesting that the inward conductance is inactivated. Depolarizing clamps at mid-interburst elicit large outward currents which then become more negative as the inward current turns on. The negative resistance that appears near the end of the interburst may accelerate the onset of depolarization, thus enhancing activation of the inward current.

566 BIOCHEMICAL AND PHYSIOLOGIC HOMOLOGY BETWEEN THE APLYSIA EGG-LAYING HORMONE AND A FACTOR FROM THE ATRIAL GLAND. S. Arch, T. Smock, W. Frost, and S. Naughton*(SPON: G. F. Gwilliam). Biological Laboratories, Reed College, Portland, OR 97202

The atrial gland is a specialized structure associated with the rostral portion of the Aplysia reproductive tract. Upon microscopic examination it appears to have a secretory function. Previous attention to this gland has not resulted in assignment of a specific role in reproduction. We have found that the gland contains a water-soluble substance that will cause egg laying when injected into mature animals. The activity of the substance is sensitive to enzymatic proteolysis. Heretofore, the only substance known to evoke egg laying in this animal was the egg-laying hormone (ELH) of the bag cell neuroendocrine organs associated with the central nervous system. Since ELH is also proteinaceous, the possibility that the atrial gland factor (AGF) and ELH are related molecules was investigated. Our biochemical studies show AGF to be stable to boiling for 10 min, to be insensitive to exposure to 1% sodium dodecyl sulfate, 6M urea, and 0.35% Triton X-100, and to be precipitable from neutral aqueous solution by addition of $(NH_4)_2SO_4$ to 40% final concentration. Gel filtration chromatography[2] shows the substance to have a molecular weight in the range 5000-8000. Gel isoelectric focusing of atrial gland homogenates shows the active substance to be located at two positions (pH 7.4 and pH 9.3). Thus, these investigations have shown AGF to have properties identical to those of ELH, with the exception that the neutral band of activity on isoelectric focusing is not found in the bag cells. Our physiologic studies have revealed identity of action of the two substances. Gel filtration purified samples containing egg-laying activity from both bag cell and atrial gland preparations stimulate the Aplysia heart in vitro, cause stereotypic egg-laying behavior, and markedly raise the threshold for elicitation of feeding activity. Moreover, extracts of the atrial gland cause clear and long-lasting changes in the electrical activity of at least 5 putative motor neurons in the buccal ganglion of Aplysia. This last result is consistent with the findings by D. Stuart (Caltech Ann. Report, Biology, p. 102, 1977) when ELH-containing preparations are applied to the same ganglion. In sum, the close correspondence between the molecular characteristics and physiologic actions of AGF and ELH suggest a striking homology between these substances derived from two distinct tissue types. Until further study reveals the physiologic regulation of AGF secretion the unique role assigned to the bag cell neurons in the control of egg laying must be considered to be in doubt.

567 INSIGHTS INTO THE MORPHOLOGICAL BASIS OF PRESYNAPTIC FACILITATION IN THE GILL-WITHDRAWAL REFLEX OF APLYSIA: ANALYSIS OF THE FINE STRUCTURE OF A MODULATORY SYNAPSE. C.H. Bailey,* E.B. Thompson, M. Chen,* and R. Hawkins. Division of Neurobiology and Behav., Depts. of Physiol. & Anatomy, Columbia Univ., College of P&S, New York, N.Y. 10032.

Hawkins et al. (1976,1977) have identified a group of neurons (L28, L29) in the abdominal ganglion of Aplysia which produce presynaptic facilitation of the EPSPs at synapses between the sensory and motor neurons of the gill-withdrawal reflex. It has been postulated that these facilitatory neurons may be serotonergic. The structure of the synapses made by these facilitating neurons on sensory neurons is interesting to study because the facilitators may produce their actions on transmitter release via a serotonin-stimulated second messenger (cAMP) that triggers a voltage sensitive Ca^{++} conductance (Klein and Kandel, 1978).

Whereas the structure of synapses mediating conventional synaptic potentials is well understood, little is known about the morphology of modulating synapses. In order to analyze the ultrastructure of both the conventional and the modulatory synapses of facilitatory neurons, we have injected L29 with horseradish peroxidase (HRP) to identify its neurites and synapses. L29 both makes and receives conventional synapses, which have active zones typical of Aplysia neurons. The most frequent vesicle type in the presynaptic terminals of L29 is relatively electron lucent and has a mean long axis of 68 nm ± 20 nm S.D. A subpopulation of vesicles (mean long axis 114 nm ± 29 nm S.D.) contains a small inner core of variable density. The morphology of the vesicles in L29 terminals is similar to that of vesicles in terminals of a serotonergic neuron (GCN) in Aplysia described by Schwartz et al. (1978). Both the serotonergic vesicles of the GCN and the vesicles of the facilitators resemble vesicles found by Bailey et al. (1976,1978) in terminals which synapse onto HRP-labeled sensory neuron processes.

The exact relationship of these facilitating synapses to the terminals of the sensory neurons can be further studied with double label experiments (Thompson et al., 1976, 1978) in which HRP is injected into the sensory neuron and ^3H-serotonin into the facilitator. These experiments would also provide a further test of the serotonergic nature of the facilitator.

568 THE SALIVARY BURSTER OF LIMAX MAXIMUS: A PRESUMPTIVE SENSORY-MOTOR NEURON. Barbara Beltz* and Alan Gelperin. Dept. Biology, Princeton University, Princeton, New Jersey 08540.

The salivary burster (SB) is an autoactive motor neuron which innervates the musculature of the salivary duct (Prior and Gelperin, J. Comp. Physiol. 114: 217-232, 1977). Feedback from salivary duct stretch modulates SB activity. Experiments reported here indicate that the SB itself is stretch sensitive. Sensory input from stretch sensitive processes is believed to modulate motor output at different branches of the same cell.

Microliter injections of saline are delivered into the salivary duct via a cannula placed in the lumen of the duct. These injections expand the duct less than the maximal amount of duct expansion measured in vivo. Salivary nerve activity is monitored while the duct is stretched by intralumenal saline injections.

In a preparation consisting of cerebral and buccal ganglia plus salivary nerves and ducts, a single stretch of the duct elicits a burst of activity from the SB with a fixed latency. This response persists during treatments which block chemical synapses in this preparation (.006 x Ca^{++}, 5.25 x Mg^{++} saline, cooling to 0°C).

When the salivary nerve and duct are severed from the buccal ganglion, so that the SB axon is separated from its cell body, the SB axon can still burst or fire tonically. In this isolated duct and nerve preparation, an injection of saline into the duct can modulate SB activity. The SB response to duct stretch in an isolated duct-nerve preparation is also unaffected by the treatments which block chemical synaptic transmission.

Another indication that the SB itself has the capacity to respond to duct stretch is the observation that in some preparations, in response to duct stretch, a single afferent spike is elicited in the SB before each SB efferent burst. This afferent spike phenomenon demonstrates that the SB does possess a region peripherally which is sensitive to duct stretch, and which can spike.

The stretch reflex which we have characterized is thought to be mediated by a single cell. We propose, therefore, that the SB is a neuron with both sensory and motor capabilities.

569 ANATOMY OF A COCKROACH EQUILIBRIUM RECEPTOR. Lisa P. Bennett and H. Bernard Hartman. Dept. Biol. Sci. Texas Tech University Lubbock, Texas 79409.

Insects are thought to lack a mechanism for directly detecting spatial orientation. Instead, light cues, proprioception, and differential limb loading provide them with an indirect means for deriving positional information. Recently, Fraser (Nature 268:523, 1977) has shown by behavioral means that the cerci of Periplaneta americana function in equilibrium reception. Physiologic experiments in our lab indicate that two rows of pendulous sensilla found on each cercus of the burrowing cockroach, Arenivaga, provide equilibrium information.

The plumb bob-like shape of the modified sensilla, tricholiths, is ideally suited for position reception. Tricholiths are composed of a large dense sphere located distally on a slender shaft, the shaft being elliptical in cross section. The sensilla, keeping a constant relationship with respect to the gravitational force vector, are deflected upon the insect's movement away from its primary orientation. Only one buttress hinges each sensillum, a condition which allows nearly universal movement of the tricholith. However, direction of movement is restricted by the eccentric placement of the shaft in its cuticular cup. Each row of tricholiths can only be deflected, then, in a direction away from the midline of the cercus.

The tricholith inserts into an innervated socket, and the movement of the sensillum elicits a neural response in the receptor cell. Four interneurons are responsive to equilibrium information, each interneuron being driven by afferents from a specific row of tricholiths. Polar plots of the interneuron responses mimic the quadrants of movement for the rows of tricholiths.

570 INTEGRATIVE FUNCTIONS OF PRIMARY SENSORY NEURONS IN THE BUCCAL GANGLIA OF THE OPISTHOBRANCH NAVANAX INERMIS. M. V. L. Bennett, D. C. Spray, M. E. Spira* D. H. Hall*, Div. of Cellular Neurobiology, Dept. Neuroscience, Einstein College of Medicine, Bronx, NY

Primary mechanosensory neurons of Navanax buccal ganglia innervate widely separate pharyngeal fields and make excitatory and inhibitory synapses on other sensory neurons and on buccal motoneurons controlling pharyngeal expansion. During high rates of discharge evoked tactilely or by electrical stimulation impulses may fail to invade the soma. Failures may occur at different distances from the soma in different branches. Studies with intracellular Lucifer Yellow CH or cobalt sulfide show that single sensory neurons can have one or several processes with branch points several cell diameters away which provides a number of possible sites of impulse failure. When failures occur impulses may or may not propagate between branches and summation of partial spikes can relieve block of propagation. Thus some information processing is possible within the single cells. The effects will depend on location of synaptic outputs and will also be modulated by synaptic inputs. Sensory PSPs are blocked by high Mg^{++}; IPSPs are inverted by Cl^- injection. Thus, chemical mediation is indicated. The buccal region innervated by a sensory neuron may have an excitatory or an inhibitory region neighboring or surrounding. Inhibitory fields generally are larger. Synaptic interactions between sensory neurons may mediate prolonged sensory firing observed after brief stimulation. Interplay of excitation and inhibition within the sensory pool may be responsible for patterning of motor activity. In any case the sensory neurons combine the functions of primary sensory elements and integrative interneurons. DCS is a McKnight Scholar.

571 DISTINGUISHING TWO TYPES OF INHIBITORY SYNAPSES FROM PACEMAKER NEURONS IN THE PYLORIC SYSTEM OF THE LOBSTER STOMATOGASTRIC GANGLION. M. Bidaut*, D.F. Russell and D.K. Hartline (SPON: T.H. Bullock). Biology Dept. B-022, UCSD, La Jolla, CA 92093.

The pyloric rhythm is driven by 3 synchronously bursting neurons, the single AB interneuron and the two PD motorneurons, all of which make inhibitory synapses with the set of "pyloric follower" motorneurons. D.V. Gassie and D.K. Hartline (in preparation) have shown that ipsp's from the AB neuron have a rapid time course, rising sharply and being of brief duration, whereas ipsp's from PD neurons have a much slower time course, rising slowly and having a rounded waveform. We report, additionally, that picrotoxin in low concentrations (e.g. 2-5 x 10^{-7} M) rapidly blocks the fast-rise ipsp's from AB without stopping the rounded ipsp's from PD's. Microelectrodes were inserted in PY and LP "pyloric follower" neurons while monitoring PD firing from the pyloric dilator nerves and AB firng from the stomatogastric nerve. In Fig. 1, the first two ipsp's (arrows) were purely from doublets of PD spikes, since the AB did not fire. The subsequent AB spikes (dots) evoked 1:1 fast-rise ipsp's. Under picrotoxin, the summed inhibition of a pyloric follower neuron became very smooth, even when the neuron was polarized to various levels of membrane potential. In Fig. 2, the first doublet of PD spikes evoked a discrete ipsp (arrow), but the subsequent AB spikes (dots) no longer evoked fast-rise ipsp's (nerve records in Fig. 2 are at lower gain).

A parsimonious working hypothesis is that the fast-rise ipsp's from AB would be due to (fast) Cl^- channels associated with a picrotoxin-sensitive receptor, whereas the rounded ipsp's from PD's would be due to (slow) K^+ channels associated with a picrotoxin-insensitive receptor. Supported by NIH NS13138 to D.K. Hartline.

572 INKING IN APLYSIA: QUANTITATIVE ANALYSIS OF THE IONIC MECHANISMS UNDERLYING THE SELECTIVE SENSITIVITY TO LONG DURATION STIMULI. J. Byrne, Department of Physiology, School of Medicine, University of Pittsburgh, Pittsburgh, Pa., 15261.

Many neurons have unique biophysical characteristics which contribute to their integrative action and firing behavior. But given such a high degree of differentiation, the question arises as to what extent a cells specialized biophysical features quantitatively contribute to the features of the behavior which that cell mediates. This question can be examined using inking behavior in Aplysia as a simple test system.

The release of ink occurs selectively to long lasting stimuli since the initial synaptic input to the ink gland motor neurons is ineffective in firing the cells (Shapiro et al., this volumne). As a result there is a several second silent period or pause before the cells fire in an accelerating burst of spikes which causes the release of ink. Voltage clamp experiments were performed to determine the quantitative extent to which the motor neuron ionic conductances account for the firing pattern and thus the features of the behavior. Using pharmacologic separation techniques four voltage dependent ionic currents have been analyzed including: inward Na^+ and Ca^{++}, outward fast transient K^+ and delayed K^+ currents. Equilibrium potentials, steady state activation and inactivation and the respective voltage-dependent time constants were analyzed using standard single and double pulse techniques. The features of the voltage-dependent conductances appear qualitatively similar to comparable currents examined in other molluscan neurons. Leakage, capacitance and synaptic currents were also analyzed. The total membrane current for a single cell was formulated in terms of a modified Hodgkin-Huxley (1952) model with lst order activation and inactivation kinetics. The model also incorporates the features of the electrotonic coupling between the 3 ink gland motor neurons. A computer simulation revealed the cells selective response to long lasting stimuli is due to the fast transient K^+ current shunting the initial excitatory input. The high resting potential (-75mV) of the ink motor neurons insures the steady state inactivation of the fast K^+ current is essentially removed at the resting level. Inactivation of the fast transient K^+ current by the synaptic depolarization and a late increase in synaptic input contribute to further depolarizing the cells leading to the generation of an accelerating burst discharge which in turn causes the release of ink. The results indicate the feasibility of quantitatively relating the features of individual ionic conductance mechanisms in individual neurons to the features of the behavior which those cells mediate. Supported by NIH grants NS13511 and NS00200.

573 MODULATION OF THRESHOLD IN THE ESCAPE BEHAVIOR OF THE COCKROACH PERIPLANETA AMERICANA. Jeffrey M. Camhi and Susan Volman*. Section of Neurobiology and Behavior, Cornell University, Ithaca, New York 14853.

The escape behavior of the cockroach Periplaneta americana is known to be evoked by gentle wind currents which excite filiform receptor hairs on the cerci (Camhi and Tom, 1978). The threshold for escape behavior was determined by directing controlled wind puffs at the cerci of restrained cockroaches which were free to make normal leg movements. The behavior consisted of anywhere from one rapid step to a prolonged running sequence, and generally resembled the escape behavior of unrestrained cockroaches (Camhi and Tom, 1978). As tested during, or within one second following, a bout of slow walking (stepping frequency 2-4/sec) the threshold was 1-5 millimeters/sec. This threshold generally did not increase during a period of up to four hours provided stimuli were presented no more often than once per two minutes, with several rest periods of 1/4-1/2 hr. This low threshold appears to be responsible for the fact that cockroaches escaped successfully from the predatory strike of a toad (Bufo marinus) by detecting the low-speed wind currents made by the toad's strike (Camhi, Tom and Volman, 1978).

Under certain conditions, the cockroach's threshold for wind-excitation of escape behavior was altered. Threshold was reversibly elevated when the insect groomed its antennae, when ambient illumination was reduced, and during prolonged periods when the insect did not walk. Threshold was also elevated, apparently irreversibly, when the cuticle was incised. The larger the incision, the higher the threshold. It was possible to record from the giant interneurons (GI's) of each connective with hook electrodes by making only a minimal ventral dissection. Thus the responsiveness of the GI's to wind could be tested during changes in behavioral threshold. The modulation of responsiveness of individual GI's could be studied by relying upon the known directional sensitivities of each of the GI's (Westin et al., 1977).

574 LEARNED MODIFICATION OF A MOLLUSCAN FEEDING RESPONSE PRODUCED IN THE ISOLATED CNS. Joseph Jin Chang and Alan Gelperin. Dept. of Biology, Princeton University, Princeton, N. J. 08540.

The terrestrial slug Limax maximus can show one trial food avoidance learning lasting three weeks (Gelperin, 1975, Science 189: 567). We have now produced an analogous form of learning in the isolated brain.

The preparation consists of the lips and central ganglia arranged so that chemical stimuli can be applied to the lips selectively. Adequate lip chemostimulation results in production of the feeding motor program (FMP), a stereotyped pattern of rhythmic, coordinated motoneuron activity recorded from buccal nerves (Gelperin, Chang and Reingold, 1978, J. Neurobiol., in press). The stimulus delivery system is sufficiently quantitative that successive 30 sec. stimuli delivered at 30 min. intervals elicit reproducible bouts of FMP.

A naive preparation of lips and CNS will give reliable bouts of FMP when given lip chemostimulation with standard extracts of attractive food plants such as potato, mushroom or carrot. Repellent plant secondary substances such as quinine, colchicine and nicotine sometimes elicit bouts of FMP, but also can terminate ongoing FMP set up by chemostimulation with attractive food extracts.

We have attempted to modify the responsiveness of naive preparations by pairing a positive chemical stimulus such as potato, carrot or mushroom extract with stimulation using a plant secondary substance such as quinine, colchicine or nicotine. During training the positive chemostimulus is closely followed by the negative chemostimulus for 2-4 cycles of pairing. During the subsequent testing two positive chemostimuli (the one used during training and a new one) are given alternately at 30 min. intervals. Responsiveness is scored in terms of number of bites, bite frequency and firing frequency of identified motoneurons during a bout of FMP.

We have been able by this procedure to produce selective depression of the in vitro preparation's responsiveness to an initially positive chemostimulus while maintaining its responsiveness to a second positive chemostimulus. Responsiveness to each of the three positive chemostimuli has been suppressed in different preparations. The response decrement lasts 6-10 hours. Of 43 preparations tested, 19 showed the learned suppression to a greater or lesser degree. Of these 19 preparations, 8 showed very clear and repeated suppression of response to the first positive chemostimulus while responding normally to a second positive chemostimulus. We have never observed suppression of responsiveness to the second chemostimulus while responsiveness to the first was maintained.

575 SIMULTANEOUS RECORDING OF ACTIVITY OF MOST (ALL?) OF THE LARGE NEURONS IN THE BARNACLE SUPRAESOPHAGEAL GANGLION. L.B. Cohen, A. Grinvald* and S. Lesher*, Dept. of Physiol., Yale Univ. Sch. of Med., New Haven, CT. 06510.

Changes in absorption of neurons stained with merocyanine-rhodanine type dyes were used to monitor action potential activity in ganglia from Balanus nubilus. A square array of 100 photodetectors (20th Century Electronics Ltd.), each 1.4x1.4mm, was positioned in the image plane of a 32X objective. The output of each detector was amplified and fed to a computer which sampled each channel every 0.6 msec during a recording period of 0.9 seconds. The images of the large cell bodies (40-100 μm diameter) often superimposed on several (2-6) detectors.

Stimulation of the ipsilateral connective via a suction electrode led to spikes in 9-15 neurons. About half as many neurons were active in response to turning off a light illuminating the median ocellus. This preliminary experiment illustrates the use of an optical method to locate neurons involved in behavioral responses. The signal-to-noise ratios obtained in these experiments were relatively large and therefore we feel that if other large neurons had been active, their activity would have been detected. This conclusion is, however, based on the untested assumptions that all cell bodies stain equally and that the action potential size was large in all neurons.

Yet another possible difficulty is pharmacological effects of the dyes. Suction electrode recordings from the connective and antennular nerve were used to monitor neurons that respond to turning off ocellar illumination. Since this off-response is polysynaptic, this pharmacological test was more stringent than those we had used previously and several dyes did have irreversible effects. However, using a concentration of 0.5 mg/ml, the sulfobutyl derivative of dye XVII led to reduced pharmacological action (but acceptable signal-to-noise ratios) and in some experiments the off responses before and after staining were similar. We plan to screen additional dyes trying to minimize pharmacological effects while maximizing signal size.

Since the barnacle ganglion has only 30-40 large neurons, the 100 detectors were relatively underutilized. We think that a recording with 100 detectors should be able to monitor activity from 100-200 individual neurons without ambiguity.

576 SYNAPTIC TYPES IN THE ABDOMINAL GANGLION OF APLYSIA CALIFORNICA, WITH SPECIAL REFERENCE TO SYNAPTIC-LIKE CONTACTS ON GLIAL CELLS. M. Colonnier, J.P. Tremblay and H. McLennan*. Dept. Anat., Laval Univ., Québec, P.Q., G1K 7P4 and Dept. Physiol., U.B.C., Vancouver, B.C., V6T 1W5.

The abdominal ganlion of Aplysia californica has been observed in preparations fixed by immersion in buffered formaldehyde and glutaraldehyde, either directly or after a survival of a few hours in artificial sea-water. In the neuropile, synaptic vesicles are of several sizes, may be round, oval or flat, and either clear or filled with different finds of dense material. The population of vesicles within a single profile may consist either of a homogeneous group of similar vesicles, or of various mixtures of 2 or 3 kinds of vesicles, in a continuous spectrum which has defied attempts at a rigorous classification. In profiles with mixtures of clear and dense-core vesicles, it is often only the clear vesicles which agglomerate towards the differentiated membranes. In such cases the dense-core vesicles lie as a peripheral halo around the clear vesicles. In other cases, both types of vesicles touch the presynaptic membrane. The differentiated membranes are characterized by a slight increase in density and by being regularly parallel to each other. Presynaptic densities are sometimes quite prominent but specialized dense cytoplasmic opacities have never been seen bordering the postsynaptic membrane. The interlemmal opacities vary considerably in density.

Four different types of zones can be defined on the basis of the number and type of vesicle-containing-profiles. 1) Some regions are formed mainly of medium to small neuronal processes, with very few vesicle-containing-profiles. 2) Others are made up of small processes, running in parallel and forming many contacts with each other. This type of zone is often surrounded and infiltrated by the processes of glial cells, forming glomeruli of different sizes. 3) The third kind of zone is still more densely filled with synaptic profiles contacting neuronal processes of all sizes. It most closely resembles mammalian neuropile. 4) The fourth type consists of islands of closely packed profiles containing large dense-core vesicles and only rarely forming synaptic contacts.

Synaptic-like contacts, characterized by the agglomeration of vesicles towards differentiated membranes, are present on glial cell bodies and processes in the neuropile. They are only rarely seen on the somata but in one case at least, three have seen on a single cross-section of a single soma.

In the subcapsular sinus, contacts are also found on small profiles identical to the many glial processes forming the loose meshwork typical of the region. Synapses are not present on the neuronal cell bodies. Supported by the M.R.C. of Canada.

577 FUNCTION OF MOLLUSCAN SALIVARY NEURONS DURING FEEDING. Jonathan Copeland* and Alan Gelperin (SPON: M. A. Lampert). Department of Biology, Princeton University, Princeton, New Jersey 08540.

The salivary burster (SB) is an autoactive motoneuron which initiates contraction of the salivary duct of the giant garden slug Limax maximus (Prior and Gelperin, J. Comp. Physiol. 114: 217-232). We have investigated the function of 5 other large buccal and cerebral ganglion neurons which each send a process into the salivary nerve of Limax. These neurons are the bilateral salivary neuron (BSN) and salivary neurons 1-3 (SN1, SN2, SN3), all found in each buccal ganglion, and the metacerebral giant cell (MGC), found in each cerebral ganglion. These neurons affect either salivary duct or salivary gland and are co-activated with motoneurons to buccal muscles during chemically elicited feeding in vitro.

BSN is a bursting neuron with processes in both ipsilateral and contralateral salivary nerves. Its burst rate is always slower than that of SB. Extracellularly recorded potentials indicate an effect of BSN on the salivary duct. Intracellular recordings from salivary gland cells indicate that BSN also innervates the salivary gland. Both EPSPs and action potentials occur in gland cells in response to BSN activation. BSN activity is increased during a feeding bout. As judged by extracellular recordings of BSN activity, stimulation of the serotonergic MGC inhibits BSN at low frequencies (1 spike/sec) and excites BSN at higher frequencies (10 spikes/sec).

SN1, SN2, and SN3 are large buccal neurons which also have an effect on the salivary duct. Both SN1 and SN2 receive EPSPs simultaneously with the firing of SB. These EPSPs rarely trigger action potentials. SN1 and SN2 produce a few action potentials during in vitro feeding. They receive unitary EPSPs from MGC. SN3, another slow bursting neuron, also has an effect on the salivary duct. SN3 is not affected by MGC stimulation.

Some of the salivary neurons are active in non-feeding periods. All are modulated during feeding. We have measured the amount of saliva secreted during non-feeding and feeding periods. Saliva is continuously secreted into the salivary duct during non-feeding periods. During feeding, however, the amount of saliva delivered to the salivary duct is greatly enhanced.

578 THE ROLE OF SEROTONIN IN PHASE SHIFTING THE CIRCADIAN RHYTHM OF THE *APLYSIA* EYE. G. Corrent* and A. Eskin. Dept. Biol., Rice Univ., Houston, Tx 77001. D. J. McAdoo. Marine Biomed. Inst., Galveston, Tx 77550.

In studying the reception of temporal information by the circadian pacemaker (CP) in the isolated eye, we discovered that a putative neurotransmitter, serotonin (5-HT), can phase shift the circadian rhythm of spontaneous optic nerve impulses (CAPs) from the eye. 6 hr. treatments of 5-HT (10^{-5}M) produced 3.1 ± .4 hr. (N=13) advance phase shifts when the treatment was administered late in the subjective day. At some other phases, 5-HT produced delay phase shifts. Phase shifts and inhibition of the CAPs were produced by concentrations of 5-HT as low as 10^{-7}M. Other putative transmitter substances, dopamine and acetylcholine, do not cause phase shifts in the rhythm at phases where 5-HT is effective. However, bufotenine (10^{-5}M), a 5-HT analogue, produced advance phase shifts when administered to the eye during the late subjective day. 5-HT is acting either directly on the cells housing the CP or on cells electronically coupled to it, since solutions capable of inhibiting secretion (HiMg-200mM, LoCa-.1mM) did not block the 5-HT phase shifts.

If 5-HT performs a neurotransmitter role in the eye, 5-HT must be present in the eye with some portion of it in a releasable state. The eye contains a substantial amount of 5-HT, 50ng 5-HT/mg retinal protein, as measured by gas chromatography-mass spectrometry. Depolarizing solutions with reuptake of transmitter inhibited (raised potassium, lowered sodium) caused from 30-48% decreases in the amount of 5-HT in eyes.

These results suggest that 5-HT is involved in the transmission of phase shifting information within the eye. Release of a transmitter substance does not appear to be necessary for phase shifting the isolated eye by light (Eskin, J. Neurobiol. 8: 273, 1977). 5-HT may be involved in mediating phase shifting in two other ways: extraocular entrainment of the eye by red light (Block et al., J. Comp. Physiol. 89: 237, 1974) and mutual coupling of the CP's in the two eyes (Hudson, Lickey, Soc. Neurosci. Abst. 3: 179, 1977). 5-HT is the first transmitter substance shown to phase shift circadian rhythms. As such, it is a natural marker that can be used for localization work and physiological studies.

579 PREY CAPTURE STRIKES OF THE PRAYING MANTIS: MOVEMENT AND ELECTROMYOGRAPHIC ANALYSES. Brian J. Corrette* (SPON: E.A. Maynard). Dept. Biology, Univ. of Oregon, Eugene, OR 97403.

Prey capture strikes of the praying mantis (Tenodera aridifolia sinensis) were analysed using several techniques of high speed photography. Although too rapid to be steered visually once released, strikes are not stereotyped. Movements of the coxa, femur (including trochanter), and tibia of the prothoracic legs during a strike can be divided into two phases termed the approach and the sweep. During the approach, the foreleg is promoted proximal to the prey by rotation about the articulation of the coxa in approximate synchrony with extension of the tibia. Variable extension or flexion of the femur also occurs during this time. Movements of the approach are variable in initial position, duration, and velocity, but the position of the coxa and femur at the end of the approach is highly correlated with pre-strike location of the prey relative to the prothorax. During the sweep, a rapid extension of the femur occurs simultaneous with a rapid flexion of the tibia, and the prey is grasped between spined surfaces of the femur and tibia. Promotion of the foreleg is slowed during the sweep by a rapid increase in rotational inertia due to extension of the femur. The velocity of sweep movements is variable, but their form and duration are relatively constant.

Proprioception from hairplates located proximal to the articulation of the coxa is important for coordination of the movements of the approach and the sweep. Removing these hairplates or reducing their stimulation by limiting movement of the coxa produces long duration strikes, and the sweep occurs at positions of the coxa and femur that are independent of prey location.

Myograms were recorded from muscles of the foreleg during high speed photography of strikes. Detailed analysis of these myograms is difficult as all muscles examined have a complicated innervation of slow and fast axons which often fire synchronously and at frequencies as high as 350 Hz, obscuring identification of individual potentials. During a strike, muscles are activated by loosely patterned bursts of slow followed by fast potentials. Overlap of agonist and antagonist bursts occurs during promotion of the coxa and rapid extension of the femur. Simultaneous onset of fast potentials in the extensor of the femur and the flexor of the tibia occurs during the sweep. Timing between fast activity of the promotor of the coxa and that of the sweep is variable and related to prey location.

580 FACILITATION AT THE NEUROMUSCULAR JUNCTION OF PHASIC AND TONIC AXONS INDEPENDENT OF FIBER TYPE IN LOBSTER MUSCLE. Walter J. Costello and Fred Lang, Boston University Marine Program, Marine Biological Laboratory, Woods Hole, Mass. 02543.

To gain perspective on the interaction between different types of nerve and different types of muscle, we studied the neuromuscular system of the closer muscles in the dimorphic claws of the lobster Homarus americanus. The closer muscle is innervated by two motor neurons - a phasic and a tonic. Additionally, it is composed of two types of fibers. In the cutter claw, the closer muscle consists of ≥ 60% fast fibers (2-4μm sarcomere length) and ≤ 40% slow fibers (>6μm sarcomere length). The closer muscle of the crusher claw contains only slow fibers (>6μm sarcomere length). With two populations of muscle fiber present, and two types of axon as well, the mutual effects of one upon the other could be examined among the various combinations of innervation. The degree of facilitation (Fe) was measured as a ratio of the height of the excitatory postsynaptic potential (EPSP) in the muscle fiber at 10 Hz stimulation to that at 1 Hz stimulation.

All possible combinations of innervation by the two motor neurons onto the fiber types were found except for one. The tonic axon was never seen to innervate fast fibers without the presence of the phasic axon also. The Fe of the synapses from both axons was inversely proportional to the height of the EPSP at 1 Hz stimulation. The Fe of an axon's synapse was highest when the EPSP elicited in the fiber at 1 Hz stimulation was at its lowest value. The Fe of the synapses was apparently independent of the type of muscle and the presence or absence of the other axon. The phasic axon formed synapses which facilitated poorly in both claws, on both fast and slow muscle. There was no significant difference ($p = 0.10$) between the Fe values of these synapses in the cutter or crusher closer muscles (ave Fe = 2.4 and 2.0, respectively). The tonic axon formed synapses with moderate-to-high degrees of facilitation in each claw (ave Fe = 6.4, cutter; 5.7, crusher). Likewise this was not significantly different ($p = 0.10$). From the evidence it appears that the muscle type is exerting little or no influence on the program of the neurons to specify the facilitatory characteristics of their synapses.

581 THE CRAYFISH THORACIC PHASIC FLEXORS: DIFFERENCES IN HOMOLOGOUS MOTONEURONS. R. L. Crabtree* and W. H. Evoy (SPON: S. W. Fox). Laboratory for Quantitative Biology, Univ. of Miami, Coral Gables, FL 33124

The deep flexor muscles of the crayfish are a complex series of four thoracic muscles which lie along the dorsal surface of the skeletal endophragmal shelf. The posterior portion of the deep flexors joins the phasic abdominal flexors via an inscription; the muscles contract during the rapid abdominal flexions of swimming and escape behaviors.

Ultrastructural studies revealed the deep flexors to be a homogenous population of typical crustacean phasic muscle fibers. Each fiber is innervated by three axons which reach the musculature through the ganglionic third roots of thoracic ganglia 1-3. Electrophysiological recordings of potential changes in the muscle fibers during stimulation of the third roots indicate that three synaptic potentials are present. One potential rapidly antifacilitates, even at stimulation frequencies of 1 Hz; one moderately facilitates; and the last is inhibitory. These results suggest that the thoracic muscles are innervated by neurons that are homologous to those found in the abdomen which innervate the phasic abdominal flexors: the motor giant, a non-giant excitor, and an inhibitor.

To examine the morphological characteristics of the thoracic motor neurons, the cells were filled intracellularly with cobalt sulfide, using the backfilling technique. In general, cells nearly identical to those previously found in the abdomen were located, further substantiating the homologous nature of the thoracic neurons. However, thoracic fast flexor motoneurons varied from those in the abdomen in: numbers, size, structure of the motor giant, and location of a posterior group of somata.

Fewer phasic flexor motoneurons per hemiganglion are found in the thorax. The first ganglion contains only three. Numbers increase in the two posterior ganglia. Soma size of the thoracic neurons is approximately 50% of corresponding abdominal neurons. These reductions may be related to the reduced musculature in the thorax.

No group of somata is located in the posterior ipsilateral portion of the ganglion. This group, found in the abdomen, appears to have shifted to a medial, posterior location in the thoracic ganglia.

Finally, the motor giant appears to have specialized branches in the ganglionic neuropile. These arborizations may be areas of synaptic contact to fibers contralateral to the motor giant axon, since the thoracic nerve cord connectives are split.

582 NEURAL CORRELATES OF AN ASSOCIATIVE BEHAVIORAL CHANGE IN HERMISSENDA CRASSICORNIS. T. Crow and D. Alkon*. Sec. on Neural Systems, Lab. of Biophys., NINCDS, NIH, MBL, Woods Hole, MA 02543.

The response of the nudibranch mollusk Hermissenda crassicornis to a light stimulus can be modified by stimulation of two sensory pathways, the visual and statocyst (primitive vestibular). This long-term behavioral modification, consisting of an increase in the animal's response latency to enter an illuminated area, is dependent on the association of light and rotational stimuli. The behavioral modification is now correlated with neural changes within these two sensory pathways.

Replications of previous behavioral results (Crow and Alkon, 1977) showed significant overall differences between an experimental group and two control groups ($p<.05$) that were trained in an automated apparatus for three consecutive days and then tested at the end of the training period. The experimental group received 50 trials each day of light (30 seconds) paired with rotation (30 seconds). Control groups received either 50 trials of light and rotation on independent random schedules or 50 trials of rotation presented randomly. The latency to enter the light was measured automatically for all groups at the termination of the third day of behavioral training. The experimental group latencies to enter the light were significantly longer than the latencies of the random control group ($p<.05$) and random rotation group ($p<.015$), while the respective control groups were not significantly different from each other.

Intracellular recordings were made from photoreceptors and statocyst hair cells in the isolated nervous systems of experimental and control animals following training and behavioral testing. Significant overall differences in the spontaneous firing frequencies of dark adapted Type B photoreceptors were found for experimental and control groups ($p<.01$). Type B photoreceptor activity was significantly elevated following training for the experimental group as compared to the random light and rotation control group ($p<.01$) and random rotation group ($p<.01$) while the two control groups were not significantly different from each other. Average firing frequency of statocyst hair cells following dark adaptation was less than 1/second for experimental animals. An overall (across experimental and control groups) significant positive correlation was found between the response latencies to enter the light after training and Type B photoreceptor activity in the isolated nervous systems ($p<.05$). This increase in Type B impulse activity may be related to long-lasting depolarization of Type B photoreceptors (Alkon and Grossman, 1977) and long-lasting inhibition of Type A photoreceptors during a light response (Alkon, 1976) found after stimulation of the isolated nervous system with light and rotation.

583 CENTRAL AND PERIPHERAL CONTROL OF COCKROACH GIANT INTERNEURONS DURING WALKING. Darryl L. Daley. Program in Neural and Behavioral Biology, University of Illinois, Urbana, IL 61801.

Within the ventral nerve cord (VNC) of the American cockroach, the giant interneurons (GI's) are morphologically divisible into dorsal and ventral groups of three each, and one smaller neuron associated with the ventral group. Control of the excitability of the dorsal and ventral groups has been investigated intracellularly in deafferented preparations and during tethered walking. Dorsal GI's are excited during walking while ventral ones are inhibited (Daley, Neurosci. Abst. 3:174, 1977). The origin of the descending excitation was investigated by first monitoring the activity of a GI found to be active during walking and then looking at its activity following a VNC cut anterior to the recording site. The results of these experiments suggest that the major source of walking-activated excitatory input is from thoracic nervous centers. During walking the mean firing frequency of all dorsal GI's increases as the speed of walking increases, suggesting that descending excitation may arise specifically from locomotor centers. To test whether the descending excitation resulted from sensory input concomitant with walking, the thoracic ganglia were deafferented. After deafferentation, the dorsal GI's were still excited during periods of leg motoneuron activity, clearly showing that the excitation originates in the thoracic locomotor centers, not from sensory input.

Walking-activated inhibitory input to ventral GI's was investigated by comparing sound responsiveness of individual GI's in animals which were resting to that of the same GI's during walking. This inhibition could result from either central descending pathways or peripheral sensory receptors activated during walking. To separate these alternatives, deafferentation and VNC lesioning experiments were performed. Deafferentation of thoracic and abdominal ganglia (only the cercal nerves were intact) guaranteed sensory input associated with walking was eliminated. Yet during leg motoneuron activity sound responsiveness of ventral GI's was reduced, demonstrating walking-activated central inhibition. To test for peripheral inhibition, central pathways were cut anterior to the recording site. The sound responsiveness of ventral GI's in tethered animals with these cuts was again reduced during walking, thereby establishing walking-activated peripheral inhibition.

Thus, the morphological division of GI's into dorsal and ventral groups appears to have a physiological correlate. While the primary source of excitatory input activating dorsal GI's during walking arises from a central source, ventral GI's receive inhibitory input from both central and peripheral sources.

This research was supported in part by NIH grant NS12142 to F. Delcomyn and HEW PHS training grant GM-1076 to the author.

584 INDUCTION OF BURSTING IN NORMALLY SILENT APLYSIA CELLS. Peter F. Drake* and Steven N. Treistman (SPON: Donald Keefer). Department of Biology, Bryn Mawr College, Bryn Mawr, PA 19010.

Cyclic nucleotides may mediate the longlasting effects of hormones and synaptic stimulation in the abdominal bursting cell R15 of Aplysia (Treistman and Levitan, Nature 261: 62, 1976; PNAS 73: 4689, 1976). This conclusion was reached through the use of phosphodiesterase inhibitors and other drugs which affect cyclic nucleotide metabolism. The question to which we addressed ourselves was this: Do phosphodiesterase inhibitors enhance conductances already known to be present in bursting cells or do they induce conductance changes in cells which normally do not show such conductances, as in non-bursting cells? The phosphodiesterase inhibitor, IBMX (10^{-4} M) induces synchronous bursting in the two silent metacerebal giant cells of Aplysia. Two classical techniques were used to detect and to block the involvement of a presynaptic cell: 1) hyperpolarization of the MCG cells, to uncover underlying postsynaptic potentials, and 2) perfusion with a modified solution of reduced Ca++ -- high Mg++ artificial sea water shown previously to block central chemical synapses (Weiss, Cohen and Kupfermann, Brain Research 99: 381, 1975). Both results implicate a postsynaptic locus in the induction of bursting. A dynamic current-voltage curve was also generated during the IBMX induced bursting. The result shows an increased anomalous rectification as a function of incubation time in ASW-IBMX.

Other drugs affecting cyclic nucleotide metabolism were utilized and their possible Ca++ ion artifacts investigated. These results will also be discussed. (This work was supported by NSF grant BMS 77-01548).

585 BAG CELL HORMONE ACTS DIRECTLY ON OVOTESTIS OF APLYSIA CALIFORNICA IN VITRO: BIOASSAY FOR RELATING RELEASE TO ELECTROPHYSIOLOGY. F.E. Dudek, K. Burke*, B. Soutar*, S.S. Tobe*
Erindale College and Department of Zoology, University of Toronto

The bag cells of Aplysia fire a characteristic train of action potentials to release a peptide hormone which triggers egg-laying. It has been hypothesized that the neurohormone acts directly on the ovotestis to initiate egg release. We have found that extracts of the parietovisceral ganglion (PVG) with the bag cells increase the rate of egg release from pieces of ovotestis in vitro at physiological concentrations and in a dose-dependent manner. Extracts of the genital or pleural ganglia do not increase egg release above control levels in artificial sea water (ASW), thus indicating that macromolecules associated with pigmented neurons do not cause egg release. Furthermore, microdissection experiments indicate that egg release activity is located primarily in the clusters of bag cell somata and the nearby connective tissue sheath. The number of eggs released by ovotestis in vitro for a particular dilution of PVG extract or in ASW alone increases as a function of the number of days since egg-laying; this is consistent with previous in vivo experiments. Therefore, hormone-induced egg release is a function of concentration of bag cell hormone and egg-laying history.

A. californica has a seasonal rhythm of egg-laying; more eggs are laid in fall than winter. Consistent with these in vivo observations, both PVG-induced and spontaneous (in ASW only) egg release from fragments of ovotestis in vitro are higher in fall than winter. However, the relative effectiveness of PVG extract at increasing egg release is similar during fall and winter, thus providing in vitro physiological evidence that egg-laying hormone is still present in the bag cells during winter, but eggs are not released from the ovotestis.

The logarithmic relation between concentration of PVG extract and relative egg release provides an improved bioassay for bag cell hormone. Preliminary experiments with the in vitro assay have confirmed that electrically-evoked afterdischarges of the bag cells cause secretion of egg-laying hormone in vitro. Future studies are aimed at understanding the relationship between temporal pattern of bag cell spikes during afterdischarge and rate of hormone secretion.

586 ROLE OF INTERNEURON II IN LONG-TERM SENSITIZATION OF SIPHON WITHDRAWAL IN APLYSIA CALIFORNICA. Lewis Eberly and Harold Pinsker.
Dept. Physiol. and Biophysics, Marine Biomedical Inst., UTMB, Galveston, TX 77550.

Aplysia show spontaneous, stereotyped contractions of the organs of the mantle cavity (gill, siphon and mantle shelf) at irregular intervals. A similar patterned behavior can also be triggered by a water jet stimulus to the siphon (Kupfermann and Kandel, 1969).

This behavior is mediated by a network of interneurons in the abdominal ganglion called Interneuron II (INT II) (Byrne and Koester, 1978). In freely-behaving Aplysia, occurrence of the behavior (INT II response) is associated with a burst of activity recorded by cuff electrodes on the siphon nerve which innervates siphon skin and musculature (Pinsker, Cobbs and Kanz, 1976). Plastic changes in latency of triggered INT II activity can contribute to short-term habituation and sensitization of the siphon withdrawal reflex (Kanz, Cobbs and Pinsker, 1978). We now report that long-term sensitization training modifies the probability of triggering short-latency INT II responses.

Long-term sensitization of siphon withdrawal (Pinsker, Henning, Carew and Kandel, 1973) is produced by a series of electric shocks delivered to the anterior mantle region over a 4-day period, and is associated with a dramatic and long-lasting increase in response duration. Associated with this behavioral change is a significant increase (from 60% to 85%) in the probability of triggering a short-latency (less than 5 sec) INT II response. Also, sensitized animals show a significant decrease in the latency of triggered INT II responses with repeated siphon stimuli, whereas controls show either no change or an increase. The greater frequency of occurrence and reduced latencies of triggered INT IIs in sensitized animals is presumed to play a role in the behavioral changes associated with long-term sensitization.

Triggered INT II responses play a significant role in siphon withdrawal for several reasons. (1) Spontaneous INT II responses lead to a nearly maximum siphon contraction. (2) About 60% of moderate intensity stimuli to the siphon trigger short-latency INT II responses. (3) Triggered INT II responses typically occur with latencies less than 3 sec. (4) Duration of siphon withdrawal is significantly longer when a triggered INT II response occurs than when it does not. Therefore, the modulation of excitability of the INT II network which occurs during long-term sensitization may represent a correlate of behavioral plasticity.

587 SEROTONIN, CYCLIC AMP, AND THE MODULATION OF EVOKED TRANSMITTER RELEASE AT THE CRAYFISH NEUROMUSCULAR JUNCTION. J. J. Enyeart* and S. D. Erulkar. Dept. of Pharmacol., Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA 19174.

In recent years evidence has accumulated suggesting that serotonin (5-HT) functions as a neurohormone in crustacea. When applied to the crayfish neuromuscular junction it produces separate pre- and postsynaptic effects. These include a marked increase in evoked transmitter release from excitatory nerve terminals (Dudel, Arch. Exp. Path. Pharmak., 249:518, 1965), as well as increases in muscle cAMP content and force of contraction (Battelle et al, Neuro. Abs., 2:774, 1976). Our experiments, performed on the abductor muscle of the dactyl in the first walking leg of the crayfish, were designed to determine whether the presynaptic modulatory action of 5-HT might be effected through a cAMP-dependent mechanism. Conventional intra- and extracellular recording techniques were employed to monitor responses elicited by stimulation of the excitatory motor nerve with a suction electrode.

The presence of a phosphodiesterase (PDE) inhibitor, i.e. Squibb 20,009 or papaverine (both 10^{-4} to 2×10^{-4} M), produced after a 30-60 minute delay a gradual increase in the amplitude of the excitatory postsynaptic potential (EPSP). This growth continued until a single stimulus induced contraction of the muscle fiber and dislodgement of the electrode. At this time the EPSP was frequently 50-100 times the control response. Statistical analysis indicated that this increase represented an enhanced quantal content. Results of similar experiments using focal extracellular recording techniques confirmed this finding.

In other experiments, the PDE resistant 8-benzylthio derivative of cAMP (4×10^{-4} to 1×10^{-3} M) produced 3-5 fold increases in the EPSP amplitudes. Neither cAMP nor its dibutyrl analogue had any effect at concentrations as high as 1×10^{-3} M.

A relationship between the cAMP and 5-HT induced effects was indicated. Alone, 5-HT (1×10^{-6} M) elicited a 3-5 fold increase in evoked transmitter release. Replacing this solution with one containing both 5-HT and a PDE inhibitor (5×10^{-5} M) produced a further 2-3 fold increase. By themselves, the PDE inhibitors at this concentration caused only a 0-0.3 fold increase in the response.

Focal extracellular recordings showed no change in the biphasic nerve terminal potential in the presence of 5-HT or PDE inhibitors. Neither was any increase in miniature end plate potential frequency or amplitude detected.

These findings indicate that procedures expected to increase levels of cAMP in crayfish motor nerve terminals also enhance evoked transmitter release. Furthermore, 5-HT may function by activating a presynaptic 5-HT sensitive adenylate cyclase. Evidence of a similar system in Aplysia has been reported (Shimahara et al, Brain Res., 127:168, 1977).

588 SYNAPTIC INTEGRATION BY CRAYFISH WALKING LEG MOTOR NEURONS W. H. Evoy and R. L. Crabtree*. Laboratory for Quantitative Biology, Univ. of Miami, Coral Gables, FL 33124

Input pathways and summation properties of identified motor neurons to the fifth walking leg have been investigated by intracellular recording and cobalt staining in the thoracic ganglia. Synaptic inputs to the anterior depressor of the coxopodite and the extensor of the meropodite of the leg are found in the fifth thoracic ganglion.

Proprioceptive inputs that originate in the MC_2 organ of the meropodite-carpopodite (MC) joint of the fifth leg were activated by electrical stimulation of the sensory branch. Intracellular recordings in motor neuron processes of that segment showed post-synaptic potentials with constant latency components in response to single stimuli. Both excitatory and inhibitory responses have been found.

Central nervous inputs to the walking leg motor neurons revealed by stimulation of fibers in the anterior nerve cord evoke repeatable changes in motor output that appear to be mediated by other interneurons. Intracellular recording and signal-averaging show a lack of constant-latency responses in the motor neurons in response to the stimuli, although depolarizations lacking discrete increments of potential are correlated with changes in spike frequency. Additional findings on interneuronal pathways in the thoracic chain will be presented.

Evidence for a discrete cellular or emergent network oscillatory system for the approximately one second cycle of forward walking is thus far lacking. Locomotor and postural behaviors appear to depend on complex interaction of interneuronal, motor, and sensory components.

589 SYNAPTIC ORGANIZATION IN THE CORPORA PEDUNCULATA OF THE HORSESHOE CRAB (Limulus polyphemus). Wolf H. Fahrenbach* (SPON: D. S. Rushmer). Oregon Regional Primate Research Center, Beaverton, OR 97005.

The large, hemispherical mass of the Limulus corpora pedunculata consists of two highly branched lobes connected to the protocerebrum by narrow stalks. About 10^4 afferent fibers, belonging to 5 types, enter through the stalks and make diverse, profuse, and often reciprocal contacts with several million Kenyon (intrinsic) cells and one another. The Kenyon cell axonal arborizations converge on a few hundred efferent dendrites. The five afferent fiber types can be characterized as follows: Type A - forms club-shaped core of glomeruli and circumglomerular annuli, contains small flat vesicles; presumptive inhibitory input; Type B - terminates with bushy endings in glomeruli, contains clear round vesicles, is presynaptic to Kenyon cells and to Type A terminals; presumptive excitatory input; Type C - terminates on other afferents, in glomeruli, and rarely on Kenyon cell bodies, contains angular (neurosecretory) granules; postulated to impart circadian rhythm; Type D - terminates on Kenyon cell somata and initial neurite segment (but not in glomeruli), contains dense-cored vesicles; Type E - terminates in peduncles on other afferents and Kenyon cell telodendria, contains dense vesicles. The C, D, and E afferents have reciprocal synaptic connections with Kenyon cell axon terminals. Glomeruli receive three afferent inputs of presumptive inhibitory, excitatory, and neuromodulatory nature. Numerical and directional details of the circuitry in the corpora pedunculata have been extracted by a combination of light and electron microscopy, serial sectioning, silver staining, and stereology. Kenyon cells, increasing in number up to about 1×10^8 in the adult, show minor variations in their dendritic pattern and have only one rare variant cell type. Interactions between them occur primarily at their axonal boutons as they crowd around efferent fibers. The latter have large receptive fields, some of their large somata are located within the confines of the corpora pedunculata, and they receive a highly convergent input from Kenyon cells. The corpora pedunculata appear to process primarily the voluminous chemosensory input from the appendages, an assumption that is supported by the major connections of the organ. 590 MECHANICAL AND ELECTRICAL ACTIVITY FROM THE PARASITIC FLUKE, SCHISTOSOMA MANSONI. R.H. Fetterer, Jr.*, R.A. Pax*, and J.L. Bennett. Departments of Zoology and Pharmacology, Michigan State University, East Lansing, Michigan 48824.

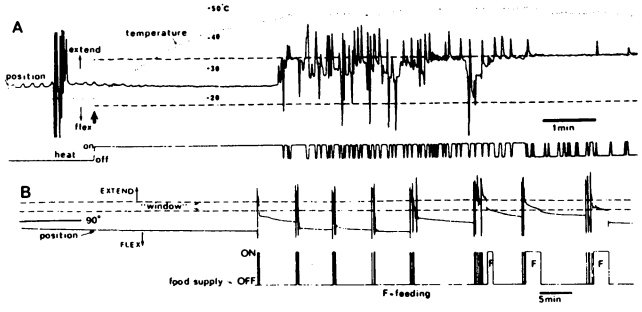
Parastaltic contractions and other muscular movements which appear to function in propulsion of the parasite through the mesenteric veins of its mammalian host can be observed in the blood fluke Schistosoma mansoni. Recordings of mechanical and surface electrical activity from the musculature of male parasites shows them capable of generating spontaneous contractions accompanied by large amplitude surface electrical activity. Isolated portions of the worm are capable of contractile activity. Putative neurotransmitters such as dopamine (10^{-4}M) and acetylcholine (10^{-4}M) inhibit spontaneous contractions and decrease the resting tension of the muscle. 5-Hydroxytryptamine (10^{-6}M) increases the rate of spontaneous contractions.

Upon penetration of the ventral tegument of an isolated male schistosome with a microelectrode a potential difference (-31.5±2.5 mV) can be recorded. Histological studies utilizing iontophoretic injection of horseradish peroxidase through the recording electrode indicate that the potential difference that is recorded exists across the tegumental membrane of the animal. Ion substitution experiments show that external potassium concentration has the greatest influence on both the tegumental membrane potential and the resting tension of the musculature. Spontaneous depolarizations of the membrane can be recorded and they appear to be correlated with contractions. Drugs such as carbachol and pentobarbital also eliminate the spontaneous depolarizations but do not greatly effect the membrane potential.

The above results indicate that rhythmicity is inherent in the musculature of S. mansoni and the nerve net of the animal has only a modulatory influence on contractions. In addition, movement of ions across the tegumental surface may play a role in electromechanical coupling. (This work was supported by grants from the Edna McConnell Clark Foundation, World Health Organization, and the National Institutes of Health.)

591 POSITION LEARNING IN BEHAVIORALLY APPROPRIATE SITUATIONS. R. Forman* and G. Hoyle, Dept. Biol., Univ. of Oregon, Eugene, OR 97403 USA. Supported by NSF Grant BNS-75-00463; PHS 5-T-32 GM07257.

We have developed a flexible paradigm which enables ability to learn to control an environmental variable to be tested in a wide range of situations. In some invertebrates the tests can be carried out whilst recording intracellularly from identified neurons. The intact or headless animal is secured to permit movement of only a single leg segment whose position is monitored. Upper and lower limits are set electronically to define a "window" of any angle and position within the movement range. The environmental variable is directly linked to the window limits. In one mode the animal must learn to hold the segment out of a broad window that includes its initial position; in another it must be moved into a narrow window away from its initial position and held there. We linked the former to temperature by placing a locust in a cool room and coupling the window to applied heat (starts at arrow in A). The animal tolerates a close heat lamp until its temperature dangerously exceeds the preferred range. It then makes many extension/flexion movements, locates the extension edge of the window, and learns to maintain a position at its edge, crossing the threshold at intervals to turn the heat lamp on and off to maintain a preferred temperature (36-38° C). The new position was retained for up to a few hours after the heat lamp was turned off. When linked to a device that brought food to the mouth, regular feeding was learned, the segment being brought to the edge of the window and very slowly through it (B). Feeding time increased to 2-7 min at an average interval of 45 min. All movements were voluntary. The insect is able to learn both a passive element (position) and dynamic ones (movement away from a position and back; also dwell time) in either extension or flexion ranges.



592 TEMPERATURE EFFECTS ON THE ELECTRORETINOGRAPHIC CIRCADIAN RHYTHM IN CRAYFISH. Beatriz Fuentes Pardo and Javier Ramos C.* Depto. de Fisiología, Facultad de Medicina, Universidad Nacional Autónoma de México, México 20, D.F. MEXICO

The effects of temperature in the circadian rhythm of response to light in crayfish Procambarus bouvieri have been examined. In order to obtain information about the role of this factor on the clock mechanism underlaying the circadian electroretinographic rhythm, we have obtained long-term records of the ERG in intact crayfish in conditions of controlled temperature and complete darkness except for the test light pulses. It was observed that the τ period of the free running oscillations tends to be almost invariable under different constant temperatures. A phase-response curve for two-minute pulses of stimulation, has been, however derived from experiments in which individual crayfish were treated with both, increments and decrements in temperature. The phase advance or delay was related to the point in the oscillation's cycle exposed to the temperature signal.

These results suggest that the circadian electroretinographic rhythm must be depending on thermolabile oscillators responsible for the described effects of temperature.

593 AXONAL TRANSPORT OF FOREIGN TRANSMITTERS IN AN IDENTIFIED NEURON OF *APLYSIA*. Daniel J. Goldberg and James H. Schwartz. Depts. Pharm. and Physiol., Div. Neurobiol. & Behav., Columbia Coll. Phys. & Surg., New York, N.Y. 10032.

One of the central tenets of neurobiology is that each neuron releases the same transmitter at all of its terminals. There are several steps at which this selectivity could be determined: uptake of transmitter or its precursor across the plasma membrane, synthesis of transmitter, and packaging of transmitter into appropriate organelles with transport of these organelles to the terminals. Using intracellular microinjection, we have been able to circumvent the first two processes and study packaging in the living cell.

The giant cerebral neuron (GCN) in the central nervous system of the sea hare, *Aplysia californica*, has been shown to use serotonin as its transmitter. Thus, GCN synthesizes serotonin from tryptophan, contains serotonin in high concentrations, and releases serotonin from its terminals. In addition, the application of serotonin mimics the effects of GCN stimulation on follower cells and muscle. Previous work in our laboratory has shown that when ^{3}H-serotonin is pressure-injected into the cell body of GCN it is packaged in characteristic storage vesicles and transported along the axons by fast transport. We have now found that other neurotransmitters, when injected into GCN's cell body, also undergo fast axonal transport. ^{3}H-Dopamine and ^{3}H-histamine both are transported in amounts and at velocities similar to ^{3}H-serotonin. With both substances, the radioactivity appearing in the axons has been analyzed and shown to be predominantly in the form of the injected transmitter. ^{3}H-D, L-octopamine is transported when injected in small amounts, but there is virtually no transport when larger amounts are injected. When unlabeled D, L-octopamine is injected together with ^{3}H-serotonin, the subsequent transport of the latter is partially depressed. ^{3}H-choline, when injected into GCN, is converted into ^{3}H-phosphorylcholine and ^{3}H-betaine; these substances move into the axons in substantial amounts but with the kinetics of diffusion. Finally, previous studies have shown that the precursor of serotonin, 5-hydroxytryptophan, and the metabolite of serotonin, tentatively identified as a glucuronide conjugate, are not transported. These compounds,like the choline metabolites, have no net charge.

We believe that the foreign transmitters are transported by virtue of their ability to be packaged by the serotonergic storage vesicle. We would suggest that a molecule must have a net positive charge to be packaged. D-octopamine, which does not occur naturally, may inhibit packaging when present at sufficiently high concentrations.

594 EVIDENCE FOR NEUROHORMONAL ACTIVATION OF GALACTOGEN SYNTHESIS IN THE ALBUMEN GLAND OF THE SNAIL, HELIX POMATIA. Esther M. Goudsmit, Dept. Biol., Oakland Univ., Rochester, Michigan 48063.

An investigation is under way to test the hypothesis that the reproductive cycle of pulmonate gastropods is regulated by neurohormones. A bioassay has been developed that utilizes organ culture to detect a precise metabolic response of a target organ, the albumen gland of the snail, H. pomatia, to the action of putative regulatory molecules. The albumen (egg white) gland synthesizes galactogen, a galactose homopolymer, in preparation for summer egg laying. Galactogen is the sole carbohydrate component of the albumen gland's secretory product, perivitelline fluid, which envelops each freshly laid egg. In autumn, the gland instead accumulates glycogen as a food reserve for winter hibernation. Thus a clear-cut biochemical manifestation of the seasonal cycles of reproduction and hibernation occurs. Albumen gland explants are easily maintained in culture and experimental activation of galactogen synthesis within the quiescent gland of a hibernating Helix provides a bioassay for regulatory molecules that turn on an essential element of the reproductive cycle.

Previous experiments indicated that albumen gland explants incubated in the presence of a Helix brain (nine circumpharyngeal ganglia) show a 2- to 10-fold increase in the specific activity of galactogen-^{14}C when compared with duplicate explants from the same gland maintained in the absence of brain (Goudsmit, J. Exp. Zool. 191:193, 1975). The brain-specific substance is released, during high-$[K^+]$ depolarization, by a $[Ca^{++}]$-dependent mechanism (Goudsmit, Brain Research, in press). Present results show that the brain-specific substance retains activity after exposure to 100°C for six minutes, but not after treatment with protease.

Galactogen-^{14}C synthesis can be stimulated 2- to 4-fold by incubation of albumen gland explants with 10^{-3} M concentrations of either the dibutyryl or 8-bromo analogue of 3'5' cyclic adenosine monophosphate (cAMP). Theophylline (10^{-3} M) enhances activation. Concentrations of cAMP below 10^{-5} M have no stimulatory effect. The amount of cAMP in a single Helix brain is only 20 picomoles (Levitan and Treistman, J. Neurobiol., 8:265, 1977), therefore it is unlikely that the brain-specific substance assayed in organ culture is cAMP itself.

Evidence thus far indicates that the galactogen-stimulating substance possesses properties characteristic of known peptide neurohormones.

595 HIGHER-ORDER CONTROL OF THE FEEDING MOTOR PROGRAM OF THE SNAIL HELISOMA TRIVOLVIS. Bonnie Granzow and Stanley B. Kater. Dept. Zool., University of Iowa, Iowa City, IA 52242.

Our previous work demonstrated that a bilaterally symmetrical pair of neurons in the cerebral ganglia have an excitatory influence over the feeding motor program of the buccal ganglia in Helisoma. This excitatory influence is manifested as an increase in the rate of alternating bursts in protractor and retractor motoneurons. There is a direct relationship between the frequency of action potentials experimentally evoked in an individual cerebral cell and the rate of the buccal motoneuron bursting (Granzow and Kater, Neuroscience 2:1049-1063, 1978).

Now we have found that these effects of cerebral cell activity can be mimicked by bath application of 5-hydroxytryptamine (the putative transmitter of these cells). We have obtained a dose-response curve which indicates that there is a direct relationship between the concentration of 5-hydroxytryptamine in the bath and the rate of bursting in buccal ganglia motoneurons.

In addition, we have found indications that increasing the frequency of firing in an individual cerebral cell produces qualitative changes in the composition of the motor output of the buccal ganglia; activity appears to be initiated in motoneurons which are quiescent at lower levels of cerebral cell firing. In particular, at least some protractor motoneurons remain quiescent at lower levels of cerebral cell activity.

Buccal neuron #4 which innervates the ipsilateral salivary gland fires non-rhythmically at low frequencies of cerebral cell firing and rhythmically (in phase with retractor motoneuron bursts) at higher levels of cerebral cell firing. Bath application of 5-hydroxytryptamine also changes cell #4's activity from non-rhythmical to rhythmical.

596 ALTERATIONS IN THE NERVOUS SYSTEM OF DROSOPHILA MELANOGASTER IN MUTANTS OF ACETYLCHOLINESTERASE AND CHOLINE ACETYLTRANSFERASE. Ralph J. Greenspan, James A. Finn, Jr.* and Jeffrey C. Hall*. Dept. of Biology, Brandeis Univ., Waltham, MA 02154.

Genetic variants deficient in the enzymes acetylcholinesterase (AChE) and choline acetyltransferase (CAT) have been obtained in Drosophila melanogaster and employed to study nervous system function and development in the absence of breakdown or synthesis of acetylcholine, a putative central nervous system transmitter. AChE-null mutations (of the Ace locus found by Hall and Kankel, Genetics 83, 517, 1976) and CAT-null mutations (defining the Cat locus) are lethal when homozygous, killing the animals late in embryogenesis but permitting apparently normal formation of the nervous system at a gross level. There is no detectable AChE histochemical activity in Ace$^-$ embryos and no detectable CAT activity by a radiometric assay in Cat$^-$ embryos.

Conditional mutants at the Ace and Cat loci have also been isolated. Conditional Ace$^-$ mutant adults paralyze at high temperatures tolerated by wild-type flies, and the mutation also has a temperature-sensitive lethal period during embryogenesis. Cat$^-$ temperature-sensitive mutations are lethal during embryonic, larval and adult stages, and CAT enzyme activity in these mutants is temperature-sensitive in an in vitro assay.

Analysis of the Ace$^-$ mutations for long term effects on localized parts of the nervous system has been carried out using genetic mosaics in which expression of the mutation is permitted in only a portion of the animal. These mosaics show histochemically null patches for AChE in limited portions of the cortex and neuropile of the brain and thoracic ganglion. Null patches have anatomical defects associated with them that appear to be condensations of the neuropile. In a dorsal brain mosaic,half of which is mutant, the null tissue has a degenerate appearance. Preliminary histological results of silver-stained mosaic brains support the observation of neuropile condensation. Some Ace$^-$ brain mosaics exhibit deficits in visually driven behavior, and an absence of the "off" transient of the electroretinogram correlates with mutant tissue in the first order optic lobe, the lamina.

AChE-null tissue is permissable in all cortical regions of the nervous system. These mutant patches are not usually very extensive, and bilateral mutant tissue for symmetrical structures is extremely rare and restricted mainly to the optic lobes. Null patches in the neuropile are less obtainable and these are completely restricted to the dorsal brain unilaterally, and the optic lobes. These results suggest there is no single focus for Ace$^-$ lethality and that the presence of the wild-type enzyme unilaterally is sufficient to compensate for the mutant tissue in most parts of the nervous system.

597 LASER PHOTOSTIMULATION OF INDIVIDUAL NEURONS IN THE CENTRAL NERVOUS SYSTEM OF THE LEECH AND BARNACLE. A. Grinvald* (SPON: C.R. MICHAEL) Dept. of Physiol., Yale Univ. Sch. Med., New Haven, CT. 06510.

A search for unidentified neuron(s) may become exceedingly difficult even in a simple nervous system, if many pairs of cells have to be impaled, or if the neurons are small. Such a search might be easier if it was possible to stimulate neurons with focal laser light; thus scanning of the laser microbeam over the ganglia may be used to find the neurons which are presynaptic to a given monitored neuron(s).

My preliminary experiments are an attempt to develop a general method, for non-pigmented neurons, by improving the original experiments of Arvanitaki and Chalazonitis (1953). They were carried out on the segmental ganglia of the leech, Macrobdella decora and the supraesophagel ganglia of the barnacle, Balanus nubilus. A neuron was impaled with microelectrode to monitor its electrical activity. The ganglion was then perfused with normal Ringer containing 10-100 µg/ml of a photoreactive compound (Indolenine tiobarbituric acid derivatives). The perfusion was changed back to a normal Ringer after ∿20 minutes. A 2 mW He-Ne laser was used to form a spot of light having a radius of only 1 µ which was positioned on the impaled neuron with the aid of 40X/.7NA Zeiss water-immersion objective using a vertical top illumination. A light pulse (.1-5 sec) then triggered fast photochemical reactions leading to a depolarization and subsequent firing. Reversible subthreshold depolarization was observed for P, T and N cells in the leech, when shorter light pulses were used.

The following results were obtained: (a) The low intensity of laser light has no effect on the electrical activity of the ganglia prior to the incubation with the photoreactive compound. (b) Staining of the neurons did not significantly alter the resting potential, the action potential size or shape, and I did not observe a modification of the synaptic inputs onto neurons. (c) In all cases it was possible to depolarize the selected neurons. (d) The effect of light is localized to the illuminated area. It seems that the in-plane resolution for stimulation is 4-6µ, and the depth of field is 5-10µ. Thus small neurons probably can be selectively stimulated. (e) With appropriate conditions photostimulation is usually "reversible" in that repetitive firing stopped after 1-150 seconds depending on the cell type, and recovery of the resting potential was observed. It is not yet clear if genuine membrane recovery occurs or ionic pumps are responsible for the repolarization. Improved performance may be achieved by a correct combination of beam intensity, pulse duration, and type and concentration of the photoreactive compound. Supported by a fellowship from Muscular Dystrophy Association.

598 POWER SPECTRA OF VOLTAGE NOISE IN STATOCYST HAIR CELLS. Y. Grossman* and Daniel L. Alkon*. (SPON: E.F. MacNichol). Sec. on Neural Systems, Lab. of Bio., NINCDS, NIH, MBL, Woods Hole, MA. 02543.

Power spectra (PS) and autocorrelation functions of voltage noise were obtained from hair cells in the statocyst of the nudibranch mollusc Hermissenda crassicornis under different conditions. Membrane potentials were recorded on FM Tape (DC-1000Hz) and digtized data were analyzed (0.1-100 Hz) off line on a Fourier Analyzer. Forty percent of the cells (N=20) from normal statocysts had a maximum peak of the PS at frequencies between 6-8Hz. Frequency of hair movement was previously shown to be about 7Hz for hairs experiencing the weight of the statoconia. The cells from statocysts containing only one statoconium (N=5) had a maximum peak at frequencies between 4.5-5Hz. For this type of cell frequency of hair movement was previously shown to be about 5Hz. For cells located in front of the centrifugal force vector rotatory stimulation shifted the noise PS to higher frequencies, increased noise variance and decreased the relaxation time constant (τ_r). The opposite effect occurred for cells located behind the force vector. Treatments such as hypertonicity (1600-2600 mOsmole), cooling (19 → 9°C), low extracellular Na^+, and perfusion with chloral hydrate (3-12 mg/ml), slowed or eliminated hair movement (Grossman et al., 1977). These treatments greatly reduced the noise variance, shifted the PS to the lower frequencies and increased the τ_r (Fig. 1). Current clamp control experiments indicated that these results cannot be accounted for by changes of noise filtering properties of the hair cell membrane during these treatments. These findings suggest that modulation of the voltage noise due to hair cell membrane conductance is caused by the movement of the hairs against the statoconia.

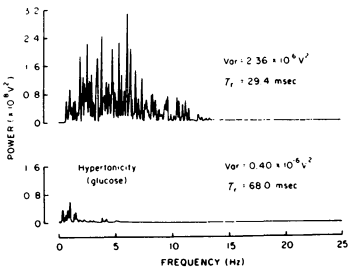

Fig. 1. Effect of hypertonicity on the power spectrum (PS) of a hair cell's voltage noise. Upper record shows PS before and lower record after treatment. Noise variance (var) was reduced, relaxation time constant (τ_r) was increased and the PS shifted to lowest frequencies.

599 PURIFICATION OF A NEUROACTIVE PEPTIDE FROM MOLLUSCAN BRAIN BY AFFINITY CHROMATOGRAPHY ON NEUROPHYSIN-SEPHAROSE. Anthony J. Harmar* and Irwin B. Levitan (SPON: B. Gähwiler). Friedrich Miescher-Institut, P.O.Box 273, CH-4002 Basel, Switzerland.

The mammalian posterior pituitary hormones oxytocin and vasopressin are members of a family of structurally related peptides, all of which possess a chain of 9 amino acid residues with a disulfide bridge linking cysteinyl residues at positions 1 and 6. Such hormones are present in the pituitary of all the (over 40) vertebrate species so far examined, but are commonly believed to be absent in invertebrates. However, this assumption may be incorrect, since:

1). Vasopressin and related peptides initiate or potentiate the "bursting" pattern of electrical activity in certain molluscan neurons.

2). Extracts of molluscan ganglia contain a protease-sensitive factor which has vasopressin-like effects on molluscan neurons.

We have purified a vasopressin-like factor from Helix brain by affinity chromatography on bovine neurophysin linked to Sepharose. The factor binds to neurophysin-Sepharose under conditions optimal for vasopressin binding (0.1 M ammonium acetate, pH 5.7), and like vasopressin may be eluted with 0.1 M formic acid. The purified material has vasopressin-like effects on the electrical activity of Helix cell F-1.

Labelled material, extracted from Helix ganglia following incubation with tritiated amino acids or with 35S-cysteine, can be eluted from neurophysin-Sepharose by 1 mM vasopressin, has a molecular weight of approximately 1000 daltons, and appears to be essentially homogeneous by 2-dimensional chromatography/electrophoresis. The radioactive peptide is distinguishable from all the known neurohypophyseal peptides by electrophoresis at pH 6.5. Physiological and structural studies on the labelled and unlabelled peptides are in progress.

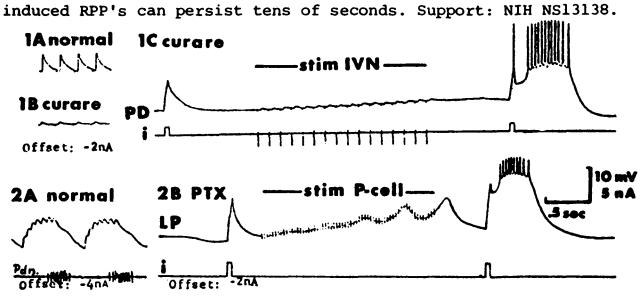
600 INDUCTION OF REGENERATIVE PROPERTIES IN NEURONS OF THE LOBSTER STOMATOGASTRIC GANGLION BY IDENTIFIED NEURAL INPUTS. D.K. Hartline and D.F. Russell. Biology Dept., B-022, UCSD, La Jolla, Ca 92093.

Several inputs induce a "regenerative plateau-potential property" (RPP) in specific neurons: (1) "ivn through-fibers" (IVN) in PD; (2) "hepatopancreas-duct nerve" units in PD and PE; (3) "P" units in LP and maybe other pyloric-follower [these also act as gastric rhythm command fibers]; (4) other "slow" inputs, producing no obvious PSP's, induce RPP's in pyloric-follower cells.

A single-fiber input can both evoke typical EPSP's and induce RPP's in a given postsynaptic cell; the EPSP may be blocked pharmacologically while the induction remains. In Fig. 1A, IVN stimulation evokes EPSP's in a PD; the PSP's are largely blocked by 5 x 10^{-4}M curare (Fig. 1B) yet IVN stimulation still strongly induces (enhances) an RPP in the PD (Fig. 1C).

RPP-inducing inputs may be organized into circuit loops, firing in coordination with a motor rhythm: In Fig. 2A P-cell inputs fire in bursts coordinated with the pyloric rhythm, causing EPSP trains in the LP. P-cell stimulation induces an RPP in LP even with the EPSP largely blocked by 5x10^{-6}M picrotoxin (Fig. 2B). P-cells may thus reinforce the pyloric rhythm by phasic induction, as well as by trains of EPSP's. In the gastric system, brief firing of Interneuron 1 (I1) appears to release a burst of firing in commissural ganglion neurons which then induces a brief RPP in the CP. This "central reflex" may help I1 "drive" CP bursts during the gastric rhythm, reinforcing the weak "direct" excitation of CP by I1.

Since regenerative properties can be induced by neural inputs, we speculate that changes in other cellular properties may also be neurally induced, e.g. (1) sensitivity to neurotransmitter; (2) voltage-dependent conductances (producing e.g. burst termination or phase-shifts in rhythmic patterns); (3) fast action potentials (e.g. in a "non-spiking" neuron to gate its output along an axon). Neural induction may contribute to theories of memory: e.g. induced RPP's can persist tens of seconds. Support: NIH NS13138.



601 SINGLE IDENTIFIED NEURONS PRODUCE PRESYNAPTIC FACILITATION OF THE GILL-WITHDRAWAL REFLEX BY INCREASING CA^{++} CONDUCTANCE IN SENSORY NEURONS OF APLYSIA. R. Hawkins, M. Klein,* and E.R. Kandel. Div. Neurobiol. & Behav., Depts. Physiol. & Psychiat., P&S, Columbia Univ., New York, N.Y. 10032.

Sensitization of the gill-withdrawal reflex in Aplysia is due to presynaptic facilitation at the excitatory synapses made by identified sensory cells on the gill motor cells. This facilitation can be produced in the isolated abdominal ganglion by stimulation of the connectives from the head ganglia. Klein and Kandel (1978) have found that connective stimulation produces 1) a small, long-lasting depolarization in sensory cells, and 2) an increase in the duration of the action potential in sensory cells in the presence of tetraethylammonium (TEA). This spike broadening has been shown to represent an increased Ca^{++} influx which leads to greater transmitter release from the sensory cells.

Hawkins et al. (1976, 1977) have previously identified two neurons in the abdominal ganglion (L28 and L29) which produce facilitation of the EPSPs at the sensory-motor synapses. We have now found that there are at least four other neurons which have similar inputs and are weakly electrically coupled to each other and to L29. We therefore propose to call the five L29-like cells L29A to L29E. Stimulation of a single L29 cell produces broadening of sensory neuron spikes in the presence of TEA, as well as a long-lasting depolarization in sensory cells. All L29 cells which have produced facilitation have also produced broadening of the sensory neuron spike, whereas other cells have not. As few as eight spikes in an L29 cell can cause a 100% increase in the duration of the action potential in a sensory cell. The spike broadening in sensory cells persists for several minutes, as does the facilitation produced by L29. Stimulation of one L29 cell can produce broadening in many (perhaps all) of the sensory cells, and two different L29 cells can produce broadening in the same sensory cell.

Thus, single facilitating neurons exert relatively widespread modulatory effects on the population of sensory neurons. Intracellular injection of electron dense marker into a facilitating neuron now allows a morphological analysis of how these widespread modulating effects are produced.

602 A NEW THORACIC LIMB INNERVATION PATTERN OF A DECAPOD CRUSTACEAN. Russell H. Hill* and Fred Lang. Boston Univ. Marine Pgm., Marine Biol. Lab., Woods Hole, Mass. 02543.

Experiments designed to study inhibition in the closer muscle of the claws and walking legs of Homarus americanus revealed that the inhibitory innervation differs from that previously described for the superfamily Nephropsidea. Earlier studies have suggested that the stretcher and closer muscles share a common inhibitory axon while the bender, extensor, and accessory flexor share another common inhibitor. The present evidence indicates that the stretcher and opener each receive a specific inhibitor while the closer muscle shares a common inhibitor with the bender and extensor. These conclusions rest on the following observations: 1) closer muscle tension from the slow closer excitor (SCE) was inhibited only when hyperpolarizing IPSP's were present in the closer, bender, and extensor muscles. 2) Inhibition of SCE tension was never observed with stretcher or opener IPSP's. 3) Each of three spikes recorded from the closer nerve could be identified as a response of the fast, slow, or inhibitory axon. Tension produced by SCE was inhibited only when the inhibitor spike was present. The appearance and disappearance of the inhibitor spike was always correlated with the presence or absence of IPSP's in the closer, bender, and extensor muscle fibers. 4) When the closer nerve was stimulated in the mid-propodite region, antidromically-evoked IPSP's were elicited in the bender and extensor. 5) Focal stimulation of nerve branches on the bender muscle resulted in inhibition of closer tension. 6) Stretcher and opener IPSP's were independent of each other and of those in the closer, bender, and extensor. 7) No IPSP's or EPSP's were seen in any of the antagonistic muscles concomitant with the IPSP's of the closer, bender, and extensor.

The hyperpolarizing IPSP's were found only in specific areas of each of the three muscles sharing a common inhibitor. Stimulation of the inhibitor had no apparent effect on tension or EPSP's produced by the fast closer excitor. In Homarus americanus a basis may exist for support of the much earlier proposal that antagonistic muscles are inhibited during contraction of agonists.

603 IONTOPHORETIC MAPPING OF ACETYLCHOLINE RECEPTORS ON THE SOMA, AXON AND IN TWO DISTINCT NEUROPILES OF A GIANT MOLLUSCAN NEURON. Philip. E. Hockberger and Michael B. Merickel, Neural and Behavioral Biology Program and Dept. of Physiol. and Biophysics, Univ. of Illinois, Urbana, IL 61801.

It is a well-established phenomenon that extra-synaptic receptors are found on the somata of molluscan neurons. There is, however, surprisingly little information on the distribution and properties of receptors on the axon, the region where the vast majority of synapses are known to occur. Specifically, we wished to determine whether receptors are localized to discrete regions, or whether they are more or less randomly distributed throughout the membrane.

We selected the gastroesophageal neuron (G-cell) in Anisodoris nobilis due to its accessible structure and because there is abundant information on its physiological and biophysical properties. The soma and axon are both large (approx. 350 um and 50 um, respectively), and consequently can be impaled with microelectrodes for intracellular recording and dye injection. In addition, the G-cell has two anatomically and physiologically distinct neuropiles (Gorman and Mirolli, J. Exp.Biol.53: 727-736, 1970) which can be readily investigated. The ability to directly visualize the G-cell axon and its neuropilar regions allows precise placement of the iontophoretic electrode.

Various technical and statistical considerations were incorporated into the analysis in order to normalize the ACh responses recorded distally from the iontophoretic locus. The results demonstrate that ACh receptors are localized within each neuropile but not on the axon adjoining them. Responses from the soma proper were less predictable, even though the axon hillock region was usually very responsive. All ACh responses were depolarizing and blocked by d-tubocurare (10^{-4}M), suggesting that the receptors are of the same type.

The demonstration that ACh receptors are localized to the neuropilar and somatic regions is very interesting, but not surprising, Most previous studies on molluscan neuron receptors have been based on the soma response characteristics only. Our results suggest that the lack of a somatic response to a putative neurotransmitter does not eliminate the transmitter from consideration. Additionally, it appears that molluscan receptors may not be as non-localized as previously throught. (Supported by RIAS grant #NSF SER 76-18255).

604 AXONAL ORGANIZATION OF THE DORSAL MESOTHORACIC NERVE INNERVATING THE DORSAL LONGITUDINAL FLIGHT MUSCLE OF DROSOPHILA MELANOGASTER Kazuo Ikeda and Takashi Tsuruhara*. City of Hope Natl. Medical Center, Duarte, CA 91010.

The arrangement of motor axons controlling the longitudinal flight muscle (DLM) was studied with light microscopic (K.I.) and electronmicroscopic (T.T.) methods. The six bilateral pairs of DLM fibers are referred to as 45-a through f from dorsal to ventral (Miller, 1950) and correspond to DLM 6 through DLM 1 in our previous report. These DLM fibers are innervated by five bilateral pairs of motor axons. Four of the five axons separately innervate muscle fibers f through c. The 5th axon innervates b and a commonly. The nerve containing these axons first bifurcates into medial and lateral branches at the ventrolateral surface of f so that the DLMs are innervated both on the medial and lateral sides. For a short distance proximal to the bifurcation, as well as subsequent ones, the axons were observed to lie in one plane parallel to the muscle surface. The medial branch made three major branches, i.e., anterior, central, and posterior. The anterior and posterior branches contained two axons innervating f and e. The central branch contained three other axons and further bifurcated, making anterior dorsal and posterior dorsal branches. The anterior dorsal branch contained two axons innervating the anterior portions of d and c. The posterior dorsal branch contained three axons, two innervating the posterior portions of d and c separately and one innervating b and a. The branches containing two axons (anterior and posterior for f and e, anterior dorsal for d and c) ran parallel to those muscle fibers along the border between them, then made many fine branches innervating their respective muscle fibers. The lateral branch bifurcated and innervated in a similar manner. Thus, particular sets of motor axons (f-e, d-c) run in close association with each other for fairly long distances so that activity in one axon might have an effect on the other. It is interesting to note that the amount of association of these axons correlates very well with the degree of interaction which is observed in the phase relationships between sets of muscle fibers innervated by these axons (Harcombe & Wyman, 1977; Koenig & Ikeda, 1977).

605 NEURONAL CIRCADIAN RHYTHM IN APLYSIA: TEMPERATURE COMPENSATION OF THE PHASE SHIFTING INDUCED BY A PROTEIN SYNTHESIS INHIBITOR. Jon W. Jacklet. Dept. Biol., Univ. at Albany, N.Y., 12222.

Anisomycin, a potent inhibitor of protein synthesis in eucaryotes, causes phase dependent shifts in phase of the circadian rhythm in electrical activity recorded from the eye of Aplysia in vitro (Science 198, 69). Delays in phase up to 15 hours or advances up to 5 hours are obtained depending upon the phase of the rhythm at which the 6 hour pulses of inhibitor (10^{-6}M) are given. Repeating these experiments at 12°, 15° and 17°C showed the effect of the inhibitor at these temperatures is the same: identical phase response curves (PRC's) are obtained. Thus, the inhibitor effects are temperature compensated as is the period length of the circadian rhythm over this range of physiological temperatures for Aplysia. This result supports the hypothesis that protein synthesis at the eucaryotic ribosome is a fundamental part of the rhythm generating mechanism. Similar studies on the circadian rhythm of Acetabularia (P.N.A.S. 73, 3216) by Karakashian and Schweiger using cycloheximide had shown that 5°C changes in temperature (20-25°C) produced quite dissimilar PRC's. The differences in temperature dependence of the PRC's in Aplysia and Acetabularia may be related to the differences in mechanisms for the rhythms or perhaps to differences in the inhibitors used.

Pulses of anisomycin applied to the Aplysia eye rhythm at 17°C near the critical point (circadian time 1-4) for cross over from delays to advances in the PRC produced unusual post-pulse periodicities of the rhythm. Initial delays of 8-10 hours were produced by the pulses but the next period of the rhythm after the initial delay was 50-53 hours (approximately double the normal period) before returning again to the normal period of 26 hours. The clock apparently skipped a beat. This behavior suggests a temporary state of desynchronization similar to splits in this rhythm previously induced by temperature and light pulses.

606 ACETYLCHOLINE FUNCTION IN THE NEMATODE ASCARIS. Carl D. Johnson* and Ira S. Kass* (SPON: P. Claude). Dept. of Zoology, Univ. of Wisconsin, Madison, WI. 53706

The role of acetylcholine in the nematode Ascaris lumbricoides is being investigated by combined techniques of biochemistry and pharmacology. As previously described, (Neurosciences Abstract #555, 1977)among the motorneurons in the body of Ascaris, choline acetyltransferase (CAT) is concentrated only in excitatory cells. Inhibitory motorneurons do not contain CAT. This result is obtained by measuring CAT in strips of hypodermis containing isolated pieces of identified motorneurons. The analysis includes five of the seven classes of motorneurons (Stretton, et al, PNAS in press). It has been extended to include at least five examples of each of 34 identified motorneurons in the animal. Of these 34, twenty have CAT, fourteen do not. There is a complete congruence of excitatory function and elevated CAT level.

Experiments to examine the pharmacology of motorneuron synapses are currently being performed. Each cell is separately stimulated and the effect of drugs on the post-synaptic response determined. Tubocurare ($3x10^{-5}$M) has been shown to block the responses of excitatory motorneurons, consistent with these cells being cholinergic. Excitatory motorneurons in both the ventral and dorsal nerve cords also synapse onto the dendrites of inhibitory motorneurons with output in the opposite cord. In preliminary experiments, these synapses are also blocked by curare.

Throughout the body of Ascaris, low levels of CAT activity were observed in strips of hypodermis which did not contain any nerve. In the anterior part of the first segment and in the tip of the head, this activity increases dramatically and obscures the expected elevated levels of CAT in excitatory motorneurons. The anterior 1mm of the animal (weighing 1mg out of a total 30gm) has about 50-100X as much CAT as the ventral and dorsal nerve cords. This CAT activity appears to be extraneuronal and its function is unclear.

We are also examining the distribution of cholinesterase activity with emphasis on distinguishing between multiple molecular forms. At least four forms of cholinesterase, separable by zone velocity sedimentation in sucrose gradients have been observed. These forms have similiar sedimentation coefficients and kinetic properties to separable forms of cholinesterase previously isolated from the soil nematode Caenorhabditis elegans. The two larger forms are distributed along the animals' length whereas the smaller forms seem to be concentrated in the head.

(Supported by NSF Grant BNS 76-09641 and a Postdoctoral Fellowship from the Muscular Dystrophy Association.)

607 NEUROTRANSMITTER MODULATION AND cAMP CORRELATES OF AFTERDISCHARGE IN NEUROENDOCRINE BAG CELLS OF APLYSIA. L. K. Kaczmarek, K. Jennings* and F. Strumwasser. Division of Biology, California Institute of Technology, Pasadena, CA 91125.

The neuroendocrine bag cells in the abdominal ganglion of Aplysia generate a long-lasting synchronous afterdischarge upon brief electrical stimulation of a pleurovisceral connective. Following their afterdischarge these cells become refractory to further stimulation. We find that synchrony, afterdischarge, and prolonged refractoriness are properties that can be expressed in the isolated asomatic neurites of the bag cells. We have distinguished two apparently independent types of refractoriness. The first (type I) is seen as a failure of action potentials generated in the tips of bag cell neurites to invade cell somata (Dudek and Blankenship, J. Neurophysiol. 40: 1312, 1977). This form of refractoriness may be prematurely induced by increases in temperature or by partial substitution of propionate for extracellular chloride ions. The second form of refractoriness (type II) controls the duration of afterdischarge in the neurites such that stimuli after the first afterdischarge (mean duration 30.2 min) produce only very short afterdischarges or fail to elicit an afterdischarge. We have found that the durations of the first and subsequent afterdischarges in each experiment are linearly related to the mean firing rate within 1 min of the onset of each afterdischarge. Type II refractoriness is sensitive to serotonin, dopamine, and the methyl xanthine phosphodiesterase inhibitors. Extracellularly applied serotonin and certain of its analogues suppress an ongoing afterdischarge while dopamine and the phosphodiesterase inhibitors, when applied at the end of the first afterdischarge generate a subsequent afterdischarges of long duration without further electrical stimulation. Moreover the mean duration of the subsequent afterdischarges induced by theophylline were found to be 7.5 times longer than those which could be generated by electrical stimulation at this time. None of these compounds influenced the degree of type I refractoriness. We have shown that both serotonin and dopamine increase cAMP levels in the pleurovisceral connectives (Cedar and Schwartz, J. Gen. Physiol. 60: 570, 1972) and in the bag cell clusters and that the occurrence of an afterdischarge is also associated with a specific increase in total cAMP in the bag cell clusters. cAMP levels peak 2 min after the onset of afterdischarge and thereafter decline to control values. Our data suggests that serotonin and dopamine may control bag cell afterdischarge and that activation of adenylate cyclase is linked to bag cell activity.

608 INCREASE IN PRESYNAPTIC CALCIUM CURRENT ASSOCIATED WITH PRESYNAPTIC FACILITATION MEDIATING BEHAVIORAL SENSITIZATION OF THE GILL WITHDRAWAL REFLEX IN APLYSIA. M. Klein,* and E.R. Kandel. Div. Neurobiol. & Behav., Depts. of Physiol. & Psychiat., Columbia Univ., New York, N.Y. 10032

Behavioral sensitization is an enhancement in the response to a constant stimulus after the presentation of a different (sensitizing) stimulus. Short-term sensitization of the gill-withdrawal reflex in Aplysia is due to a prolonged increase--lasting up to an hour--in transmitter release from the presynaptic terminals of sensory neurons in the abdominal ganglion. The presynaptic facilitation can be simulated with extracellular application of serotonin (5-HT) or with intracellular injection of cyclic AMP (cAMP) suggesting that the facilitation may be mediated by a 5-HT-sensitive adenylate cyclase in the presynaptic membrane (Kandel et al., 1976, Cold Spring Harbor Symp., Quant. Biol. XL:465). In the present study, we examined the hypothesis that presynaptic facilitation results from a cAMP dependent increase in the Ca^{++} current triggered by the action potentials in the sensory neuron.

The action potentials of sensory neuron cell bodies were found to have a Ca^{++} current contribution which is unmasked and enhanced when the K^+ current which normally terminates the action potential is blocked with 0.1m tetraethylammonium (TEA). In TEA the sensory neuron action potential (normally 2-4 msec) shows a slowly repolarizing plateau of about 50 milliseconds duration. This plateau behaves like a Nernst Ca^{++} electrode and serves as a good assay for changes in Ca^{++} current. Electrical stimulation of the neural pathway from the head that mediates sensitization, application of 5-HT or phosphodiesterase inhibitors (isobutylmethylxanthine or Ro-20-1724), as well as intracellular injection of cAMP all increase the calcium phase of the TEA action potential. There is also a strong parallel, both before and after sensitizing stimulation, between the duration of the calcium plateau of the action potential in the cell body of the sensory neuron and the transmitter released by its terminals as measured by the amplitude of the monosynaptic EPSPs evoked in the motor neurons by intracellular stimulation of a single sensory neuron.

These results are consistent with the idea that presynaptic facilitation consists of a cAMP-mediated increase in a voltage sensitive calcium current in the presynaptic terminals of the sensory neurons. This synaptic facilitatory action is novel in that it sometimes produces no change in the resting postential, is of long duration, and exerts its influence on a voltage sensitive conductance triggered by the action potential, rather than on the non-voltage sensitive conductances typical of synaptic actions.

609 CHARACTERIZATION OF THE CONCURRENT INTERVAL CORRELATION BETWEEN FIBERS OF THE BILATERAL PAIR OF DORSAL LONGITUDINAL MUSCLES IN DROSOPHILA. J. H. Koenig* and Kazuo Ikeda. (SPON: J. Holden). City of Hope National Medical Center, Duarte, CA 91010.

Simultaneous intracellular recordings were made from the 12 fibers comprising the bilateral pair of dorsal longitudinal flight muscles in Drosophila. Various analyses of this firing pattern have suggested there are two major influences determining interval size: (1) a common driving input which causes a positive concurrent interval correlation among the fibers of both sides and (2) an input involved in spacing out the firing times of the ipsilateral fibers. This second input would tend to obscure the influence of the first; therefore, a concurrent interval correlation analysis was performed which takes into consideration the influence of this second input, thus allowing a clearer visualization of the characteristics of the first.

Such an analysis reveals an interesting concurrent interval relationship between fibers of both the ipsilateral and contralateral sides. For example, if it is observed that three successive intervals of one fiber exhibit a long-short-long sequence, then the majority of the other fibers will also exhibit a long-short-long sequence. Furthermore, if the duration of the intervals of all the fibers (of both sides) are plotted successively by order of occurrence without regard to which fiber the interval represents, then the long-short-long sequence is observed as a progression of gradually decreasing and then increasing interval sizes.

The observations demonstrate an amazingly high concurrent interval correlation between both ipsilateral and contralateral fibers. Furthermore, the nature of this correlation suggests there is a periodicity to the common input driving this system which has an approximately 1 to 1 relationship with the motoneurons, that is, one period of the common input per one motoneuron interval.

610 ENDOGENOUS DOPAMINE IN THE LOBSTER STOMATOGASTRIC GANGLION AND A SINGLE, IDENTIFIED NEURON OF THE COMMISSURAL GANGLION. P.D. Kushner and J.K. Ono*. Dept. of Bio., U.of O., Eugene, Or 97403 and Div of Neurosci., City of Hope Med.Centr., Duarte CA 91010.

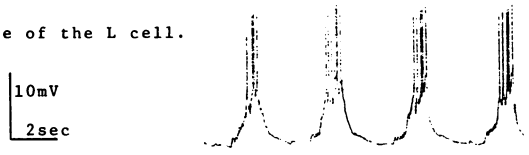
Catecholamines have been localized histochemically in particular nerves and ganglia of the stomatogastric system of spiny lobsters(Kushner and Maynard,'77). Dopamine synthesized from ^{3}H-tyrosine and ^{3}H-DOPA accumulates in those same structures (Barker, Kushner and Hooper,'78). Endogenous assays of dopamine were performed on nerves, ganglia and a single cell of the commissural ganglion according to the method of McCaman et al., '73.

Levels of dopamine found in the stomatogastric ganglion were 1.65 $\pm$ 0.89 pmole/gang. (n=8) and in the L cell 0.31 $\pm$ 0.17 pmole/cell (n=7). With a diameter of approx. 150 um the concentration of dopamine in this cell is estimated at 0.2 mM. Nerves, which in the histochemical assay had very low amounts of detectable catecholamines, gave low or no signal in this assay, although in the previous synthesis experiments there was significant accumulation of ^{3}H-dopamine. The commissural ganglion likewise gave no consistent signal but was found to possess a factor which inhibited the assay.

Significant values of endogenous dopamine in the stomatogastric ganglion confirm the dopaminergicity of the profuse neuropil histofluorescence. Endogenous dopamine values of the L cell of the commissural ganglion establish this cell as the first identified dopamine-containing neuron of arthropods.

The L cell has a constant position and axonal projection within the ganglion. From $CoCl_2$ backfills the cell does not have a process in the stomatogastric nerves (Kushner, submitted). Intracellular recordings have revealed the cell to fire tonically or to burst. Parameters involved in eliciting the tonic or bursting behavior are under investigation.

Burst mode of the L cell.



611 AXOTOMY OR PARTIAL AXOTOMY CAUSES A TRANSIENT INCREASE IN THE ELECTROGENICITY OF CRAYFISH NEURONS. John Y. Kuwada and Jeffrey J. Wine. Dept. of Psych., Stanford Univ., Stanford, CA. 94305.

Ionic channels are unevenly distributed in nerve cell membrane. It is not understood how regional variations in channels are produced and maintained, but under some circumstances the electrical properties of the membrane can be changed. For example, many invertebrate neurons have nonspiking somata and spiking axons. Pitman et al. (Science, 1972, 178, 507) recently demonstrated that nonspiking somata of cockroach motoneurons will support spikes following axotomy or implantation of colchicine; a finding that has been replicated in the locust (Goodman & Heitler, Soc. Neurosci. Abstr. 1977, #1357). We are assessing the effects of axotomy on the somata of neurons in the crayfish because: (a) trophic phenomena are sometimes unusual in this species, for example, distal portions of cut crayfish axons may live for many months and heal by fusion; and (b) in the experiments with insects entire limbs were removed or colchicine was applied to mixed nerves, so the possibility of changes caused by alterations in presynaptic elements could not be evaluated.

The first neuron chosen for study was the peripheral inhibitor to the fast flexor muscles of the crayfish abdomen. The inhibitor has many identified synaptic inputs, a known transmitter (GABA), a nonspiking soma, and an axon which runs in a pure motor root that contains only it and the axons of 6 to 10 fast flexor motoneurons. The main axon of the inhibitor or one of its axon branches can easily be cut through a small slit in the soft ventral cuticle of the abdomen; the axons of the other motoneurons are also cut, but no other neurons are injured. A homologous inhibitor on the other side of the ganglion serves as control.

In control neurons (either intact axon or acutely transected axon), a small (3 to 15 mV) passively conducted spike is recorded in the soma of the inhibitor following either orthodromic or antidromic stimulation. Two days after transection the membrane has changed so that overshooting impulses of up to 120 mV invade the soma. The soma membrane continues to support action potentials until about 2 weeks after axotomy, when spikes again fail to invade the soma. However, the amplitude of passively recorded soma spikes remains elevated for about 5 weeks, while the threshold for spike initiation to injected current is decreased for a similar period. The neuron's time constant increases to a peak about 3X normal and then declines with a time course roughly parallel to the changes in impulse amplitude. The same changes are produced when a single branch of the axon is cut. The implications of these results will be discussed.

612 NEUROTROPHIC INFLUENCES IN LOBSTER MUSCLE: CORRELATION BETWEEN OXIDATIVE CAPACITY AND PATTERN OF INNERVATION. Fred Lang, Mark M. Ogonowski*, W. J. Costello and B. Roehrig*. (SPON: J. Atema). Boston Univ. Marine Pgm., Marine Biol. Lab., Woods Hole, MA 02543

Muscle fibers from crustacean skeletal muscles have generally been characterized according to a dichotomy based on sarcomere length (SL). Fast fibers have short (2-4μm) SL while slow fibers have long (6-12μm) SL. However, we have observed that there is a striking heterogeneity in certain histochemical properties among fibers of a muscle which contains all long-sarcomere fibers. This variability is correlated with the pattern of innervation by the fast and slow motor axons.

The closer muscle of the crusher claw of the adult lobster (Homarus americanus) is composed entirely of long-sarcomere slow muscle fibers and is innervated by two motor axons, a fast and a slow. The majority of fibers (60%) are innervated by both axons while 15% are innervated solely by the slow axon and an equal amount solely by the fast axon. When conventional histochemical techniques are used to analyze the oxidative capacity of the fibers (as reflected by NADH diaphorase activity) there is a distinct staining pattern. Those fibers which receive both motor axons, or just the fast, have a low oxidative capacity while those receiving only the slow axon have a high oxidative capacity. When stained for myofibrillar ATPase activity, these tonic fibers all stain uniformly. Thus it appears that some properties of muscle fibers are correlated with the pattern of innervation by the motor axons while other properties are not correlated with this pattern.

During the early juvenile stages (2 weeks old) both claw closer muscles are virtually identical and each contains 30-40% fast muscle fibers and the remainder are slow (based on SL). The majority of fibers at this stage (> 90%) are innervated by both motor axons and these fibers have low oxidative capacity. Several molts later (4-8 weeks), the claws become asymmetric, with the fast fibers in one (the crusher) transforming into slow fibers. Whether the changes in oxidative capacity precede or follow the changes in innervation pattern is presently under investigation.

613 CALCIUM AND ENDOCRINE REGULATION OF GENITAL NEURON ACTIVITY IN APLYSIA. F. J. Lebeda, J. T. Haskins and J. E. Blankenship. Marine Biomedical Institute and Dept. Physiol. & Biophysics, Univ. Tex. Med. Br., Galveston, TX 77550.

During late winter and spring months neurons in genital ganglia from A. californica were typically silent and exhibited accommodation to maintained intracellular depolarization in vitro (Lebeda and Blankenship, Soc. Neurosci. 3:183, 1977). However, during the summer and fall, a period of more frequent reproductive activity (Strumwasser et al., Comp. Biochem. Physiol. 29:197, 1969) some of the genital neurons from these animals were spontaneously active and lacked the accommodation response. In contrast, genital neurons from the more regularly egg laying species A. brasiliana did not usually show accommodation and were often observed to have repetitive activity. Thus, the possibility that a hormonal-induced transition occurs between these two electrical states was considered and served as the basis for the following experiments.

First, a reversible transition from the silent, accommodating state to the repetitively firing, non-accommodating state in some genital neurons was seen after bag cell excitation in vitro. Stimulation of these neurosecretory cells releases egg laying hormone, which is assumed to be a low molecular weight polypeptide (Arch, Am. Zool. 16:167, 1976). Second, a similar transition in some cells was observed during exposure to homogenates of the atrial gland (a portion of the large hermaphroditic duct caudal to the spermathecal duct). Homogenates of this tissue have been shown by Arch (J. Comp. Physiol. 1978, in press) to stimulate egg laying in vivo. Although the perfusates collected after bag cell discharge and the atrial gland homogenates were able to release eggs in isolated ovotestis preparations, the latter were much more effective. In a third series of experiments a reversible transition between electrical states was observed when isolated ganglia were bathed in zero-calcium artificial sea water containing 0.5 mM EGTA.

The hypotheses presently being considered are that one or more hormones may be: 1) responsible for species differences in the typically observed genital neuron activity, 2) associated with the experimentally observed transition in the electrical properties of the genital neurons and 3) involved with alterations in calcium binding and/or conductance.

Supported by NIH awards NS05831 (FJL), NS05830 (JTH), NS70613 (JEB), and NSF grant PCM76-18936.

614 BIOCHEMICAL IDENTIFICATION OF SEROTONIN IN VITAL-STAINED NEURONS FROM LEECH GANGLIA. Charles M. Lent, Kent T. Keyser* and Joyce Ono. SUNY Stony Brook 11794 and City of Hope, Duarte, Cal. 91010.

Seven widely-scattered neurons in leech segmental ganglia fluoresce yellow following Falck-Hillarp treatment. The fluorescence in the two colossal (60-80 μm) Retzius cells (RZ) has been shown to be produced by serotonin (5-HT). The remaining five -- an unpaired medial (M) and paired ventro-lateral (VL) and dorso-lateral (DL) -- cells are much smaller (10-15 μm). The presence of 5-HT within these small cells is inferred because until recently, they have been unidentifiable in living ganglia. Neutral Red dye selectively and vitally stains these monoamine cells rendering them identifiable for cellular and biochemical studies.

We measured 5-HT in neural tissues from Macrobdella decora by an enzymatic technique (Saavedra, et. al, J. Pharm. Exp. Therap. 186:508, 1973) which is sensitive to 50 femptomoles of serotonin (50×10^{-15}). The serotonin content of stained and unstained ganglia ranges from 9 to 10.5 picomoles, while that of stained and unstained Retzius cells is from 0.3 to 0.4 p moles. The 5-HT content of neither RZ nor ganglia are significantly affected by the staining procedure. We dissected 18 individual VL cells ($\bar{x}$ diameter, 10 μm) and detected 5-HT in 17 at 0.2 ± 0.2 p moles. Unstained control cells had no measureable serotonin. We calculate the minimum concentration of 5-HT in these small VL cells as 100 mM -- a value exceeding the aqueous solubility of serotonin.

We have also measured the emission curves of each of the identifiable MA cells in the ganglia by microspectrofluorometry after Falck-Hillarp procedures. The emission spectra of RZ, VL, DL and M cells have very similar curves with peaks at 515 to 525 nm. Further, the fluorescence of each of these cell classes fades during exposure to U.V. We suggest from these data that all the fluorescent neurons within leech segmental ganglia contain genuine serotonin. (USPHS fellowship NS05343, J.O; NIH, BMS 75-00464, C.M.L.)

615 RESPONSE PROPERTIES OF PARTIALLY DEAFFERENTED SENSORY INTERNEURONS IN THE CRICKET, ACHETA DOMESTICUS. R.B. Levine. Dept. Biol., SUNY, Albany, NY 12222.

Sensory interneurons in the cricket receive a highly specific set of synaptic inputs from cercal sensory receptors. Both the receptor types which will innervate a given interneuron and their relative strengths must be specified during development. Part of this specificity may depend upon the presence of a normal balance of synaptic inputs during development. In order to investigate this possibility, crickets were reared with only one intact cercus throughout post-embryonic development, thereby partially deafferenting the sensory interneurons. The characteristics of remaining, untreated synaptic inputs were compared to the characteristics of these pathways in animals reared with both cerci intact, by recording intracellularly from identified sensory interneurons. Examples of the types of results which were obtained are presented below.

The medial giant interneuron (MGI) normally receives weak excitatory synaptic inputs from receptors on the cercus contralateral to its axon. The strength of this contralateral excitatory pathway was significantly enhanced in animals reared with only one cercus. This result is in agreement with the similar observation of Palka and Edwards (1974), who used extracellular recording techniques.

Normally, no clear membrane potential changes are observed in the lateral giant interneuron (LGI) upon stimulation of the contralateral cercus alone. The existence of contralateral inhibitory inputs, however, was demonstrated by their ability to reduce the amplitude of antidromically activated spikes which passively invade the dendritic area of the interneuron. In addition, the size of an independently evoked e.p.s.p. was decreased by concurrent sound stimulation of the contralateral cercal receptors. In unilaterally reared specimens the ability of this contralateral input to reduce the size of the antidromic impulse was significantly enhanced. Coincident with this apparent conductance change was a prominent membrane hyperpolarization. Sound stimulation of other contralateral cercal receptors caused a long latency e.p.s.p. which was never observed in control animals.

In summary, the results suggest that the strengths of synaptic inputs to sensory interneurons are not rigidly controlled during development, but can be altered. The results are consistent with the hypothesis that a normal balance of synaptic inputs is essential for the proper development of synaptic specificity.

616 SEROTONIN RECEPTORS IN HELIX AND APLYSIA: ANALYSIS BY ADENYLATE CYCLASE STIMULATION AND 3H-LSD BINDING. Irwin B. Levitan and Alan H. Drummond*. Friedrich Miescher-Institut, P.O.Box 273, CH-4002 Basel, Switzerland.

Serotonin stimulates adenylate cyclase activity in crude membranes prepared from Helix and Aplysia ganglia. Half-maximal stimulation is obtained with approximately 2 μM serotonin. The stimulation ranges from 20% to 50%, and is usually observed only in the presence of 0.1 mM GTP. A similar response can be obtained using membranes prepared from isolated Helix and Aplysia neuronal cell bodies. The extent of the stimulation by serotonin does not differ significantly among different identified Aplysia neurons. d-LSD, an antagonist which blocks electrical responses to serotonin in molluscan neurons, also blocks serotonin stimulation of adenylate cyclase in membranes from whole ganglia and from isolated cell bodies (Ki = 2-5 nM). In contrast, the pharmacologically inactive stereoisomer l-LSD is without effect on the cyclase stimulation.

3H-LSD binds stereospecifically to dopamine and serotonin receptors in Helix and Aplysia nervous system. Under appropriate conditions each receptor type may be studied individually, using this single radioactive ligand (Drummond, Bucher and Levitan, NATURE 272: 368-370, 1978). A detailed pharmacological analysis is currently under way to determine the relationship between the serotonin receptors labelled by 3H-LSD, those responsible for serotonin-stimulation of adenylate cyclase, and those mediating electrical responses to serotonin in molluscan neurons.

617 INDUCED L9 ACTIVITY PREVENTS HABITUATION OF THE GILL WITHDRAWAL REFLEX EVOKED BY SIPHON STIMULATION IN APLYSIA. Ken Lukowiak* (SPON: J.F. MacDonald). Dept. Physiol., McGill Univ., Montreal, Quebec, Canada, H3G 1Y6.

The effect of induced activity in central gill motor neurons L_7, LDG_1, and L9 on the gill withdrawal reflex and its subsequent habituation evoked by tactile stimulation of the siphon was studied in 20 preparations. Each preparation was tested for habituation at least 2 times: 1 series with L9 depolarized to produce 1-5 AP's/sec and one series with L9 free running. In most preparations L_7 or LDG_1 was also recorded from and depolarized on a 3rd series. Each habituation series was followed by a rest period of at least 3 hrs. The intensity of the tactile stimulus was 1 gm. The following results were obtained with L_7 and LDG_1 depolarization: 1) induced low level activity (1-3 AP's/sec, which does not elicit an observable gill withdrawal movement) resulted in an increased gill reflex amplitude but had little, if any, effect on the rate or degree of gill reflex habituation; 2) the synaptic input (as evidenced by the number of AP's evoked per trial) continued to decrement as in the control series. Thus, induced activity in L_7 or LDG_1 does not affect gill reflex habituation or the synaptic decrement associated with it. The following results were obtained with L9 depolarization: 1) induced activity in L9 also affected gill reflex amplitude, though not to the same extent as did L_7 or LDG_1; 2) induced activity prevented the occurrence of habituation of the reflex and in some cases resulted in reflex potentiation over the series; 3) in preparations already habituated, induced L9 activity brought about its reversal; 4) the synaptic input to L9 as well as to L_7 or LDG_1 continued to decrement even though the reflex no longer habituated. L9 activity can thus prevent habituation of the gill withdrawal reflex or bring about its reversal without affecting synaptic decrement. This property appears to be peculiar to L9 and not of central motor neurons in general. L9's affect probably occurs in the periphery and not in the PVG. L9 may be part of the CNS control system which exerts both facilitatory and suppressive control over the PNS and gill reflex behaviours.

618 PRESSURE INDUCED CONVULSIVE SEIZURES IN SQUID. Diana W. Mann. Institute of Marine Biomedical Research, University of North Carolina at Wilmington, 7205 Wrightsville Avenue, Wilmington, North Carolina 28403.

The effects of pressure on the nervous systems of terrestial vertebrates have been extensively studies. The complex of symptoms (culminating in convulsive seizures) seen under high pressure has been called the High-Pressure Nervous Syndrome (HPNS).

Lologuncula Brevis, a local species of squid, were compressed in natural seawater, hydraulically, in the high pressure aquarium system. These invertebrates exhibit a clear and reproducible pattern of HPNS symptoms: Pre-seizure abnormal activity includes rapid chromatophore flashing, waxing and waning of very fast fin movements, often with fibrillation, uncoordinated swimming, tentacle tetany episodes and "sinking spells". Most of these symptoms are also seen in very stressed animals at 1 atm. The seizure onset is sudden and consists of a sequential pattern of most of the following symptoms: fast jet swimming, loss of body position in space, tentacle tetany, inking and mantle contracture. The seizure may be followed immediately by death, or recovery of activity after a quiet post-ictal phase and/or additional seizures. Rapid decompression led to successful recovery in a few individuals.

Convulsion threshold pressures (P_c) ranged from 30 to 130 atms, depending on temperature, compression rate, and individual variability. Temperature was controlled to the selected value ± 0.5° C throughout each experiment and each animal was run within 1-2° of the ambient seawater temperature at the time of capture. Oxygen concentrations were essentially saturated.

At 18° C there was a significant compression rate effect. With fast compressions of 10 atm/min, P_c averaged 97 atm (N=8) in strong contrast to P_c=54 atm (N=8) at a rate of 0.5 atm/min. Preliminary data suggests that temperature alters the compression rate dependence of P_c. The positive slope of the P_c/logP relationship is opposite to that seen in vertebrates (see Brauer et al, J. Appl. Physiol. 38:220-227, 1975). The apparent compression rate effect is due to some interaction between time at pressure and the pressure magnitude as shown by fast compression and hold experiments.

619 *EFFECTS OF VARIOUS POLLUTANTS ON THE RESTING MEMBRANE POTENTIALS OF BLUE CRAB MUSCLE FIBERS.* *Luis A. Marco and Wallace E. Jenkins* Dept. of Psychiatry, MUSC, and VA Hospital, Charleston, SC 29403.*

As part of a larger study of heavy metal, herbicide, and insecticide pollutants, the effects of various concentrations of mercuric chloride ($HgCl_2$), Diquat, and Mirex on the resting membrane potentials (RMP) of adult blue crab (Callinectes sapidus) muscle fibers were investigated. Glass micropipettes filled with saturated solutions of KCl and conventional electronic equipment were used. Small bundles of 50-100 fibers from various walking leg muscles were laid on the recording chamber and stretched to approximately rest length prior to impalement. RMP in artificial normal sea water averaged -78 mV±4mV. $HgCl_2$ at concentrations of 50, 25, 15, and 5 ppm gradually lowered RMP to final values of (-) 13, 24, 48 and 62 mV respectively. $HgCl_2$ at 2.5 ppm did not alter RMP during 60 min. periods of exposure. The largest drops in RMP were reached after 30-35 min. of exposure to the poison. No further deterioration was observed beyond 35 min. This effect was irreversible despite several washes with normal sea water. The herbicide Diquat (ethylene-dipyridylium dibromide) did not alter the RMP at concentrations of 1 ppm, or 1, 3, and 44 ppt. The insecticide Mirex ($C_{10}Cl_{12}$) was also ineffective in lowering RMP at the concentrations so far investigated (200 ppb, 1 and 20 ppm). The normal RMP obtained are equivalent to those published by Hayes et al. (Comp. Biochem. Physiol. 26:761, 1968), the only ones available for comparison. There are no published findings of the effects of these agents on muscle fibers of this crustacean. Shealy and Sandifer (Mar. Biol. 33:7, 1975) found concentrations of 0.0005-0.05 ppm of Hg to be toxic to larval grass shrimp. 50% mortality of adult brine shrimp is caused by $HgCl_2$ concentrations ranging from 0.1 to 10 ppm depending on exposure time (Brown and Ahsanullah, Mar. Pollut. Bull. 2:182, 1971). Doyle et al. (Environ. Contamin. & Toxicol. 16:422, 1976) reported 8 to 0% survival chances of adult crayfish after 96 h. exposure to 2.5 and 5 ppm of $HgCl_2$, respectively. Ambient concentrations of mercury are usually lower than those tested here but they increase sharply around industrial pockets, bottom and sewer waters. Although no symptoms of poisoning were observed in juvenile blue crabs during a 96 h. exposure to 0.1 ppm of technical Mirex in flowing sea water, a delayed effect (irritability, paralysis, death) occurred within 18 days after being placed in Mirex-free water (Lowe et al., U.S. Dept. Inter. Circular 335, 1970). A similar delay effect 17 h. after exposure to Mirex 1 ppm for 1 h. or following 19 h. exposure to Diquat 3 and 4 ppt could not be demonstrated in our fiber preparations. (Supported by South Carolina Sea Grant R/PS-1 and Slocum-Lunz Foundation.)

620 INHIBITORY RESPONSES EVOKED BY CHOLINERGIC AGONISTS IN CRUSTACEAN STOMATOGASTRIC GANGLION NEURONS. Eve Marder and Danièle Paupardin-Tritsch*. Laboratoire de Neurobiologie, Ecole Normale Supérieure, Paris 75005 France.

In order to use pharmacological agents as tools in transmitter identification in the stomatogastric ganglion and at other Arthropod central synaptic connections, we have undertaken to characterize the pharmacological properties of the responses to ACh and other cholinergic agonists of the cells of the stomatogastric ganglion of the crab, Cancer pagurus.

In addition to the previously described depolarizing and excitatory effects most often found with iontophoretic applications of ACh, or other nicotinic and muscarinic agonists(Marder & Paupardin-Tritsch, J Physiol, 1978, in press), we now show that the muscarinic agonist acetyl-β-methyl-choline(MeCh) can elicit inhibitory responses which are due to an increase in K^+-conductance.

Cells of the stomatogastric ganglion were penetrated with double barrel microelectrodes, and agonists were applied iontophoretically from single or double barrel electrodes placed in the neuropile region of the ganglion. Responses were studied under either voltage clamp or current clamp conditions. MeCh applications at some neuropile sites produced biphasic responses at resting potential(-60mV), with an early depolarizing phase(inward current) followed by a slow hyperpolarization(outward current). The reversal potential of the inhibitory phase was -80mV, and raising the external K^+-concentration two-fold shifted the reversal potential of the inhibitory potential 17mV in the depolarizing direction. The inhibitory responses were not blocked in 20 mM $CoCl_2$ or 0 Ca^{++}, high Mg^{++}, thus showing that these responses were not synaptically mediated. Preliminary pharmacological studies have shown that high concentrations of both nicotinic and muscarinic agonists were relatively ineffective in blocking these responses, possibly because of inaccessibility, or because the receptors are insensitive to those agents thus far tried.

On occasion MeCh biphasic responses were found at neuropile sites at which ACh applications elicited purely depolarizing responses. Our current hypothesis is that ACh applications activate a ubiquitous extrajunctional, nicotinic depolarizing receptor, and thus routinely mask cholinergic inhibitory potentials. E.M. is a postdoctoral fellow of the Helen Hay Whitney Foundation.

621 SENSORY DEPRIVATION IN THE CRICKET CENTRAL NERVOUS SYSTEM: EVIDENCE FOR A CRITICAL PERIOD. S.G. Matsumoto and R.K. Murphey. Dept. of Neurobiology, Harvard Medical School, Boston, MA. 02115 and Dept. Biol. Sci., S.U.N.Y. Albany, Albany, N.Y. 12222.

The cercal sensory system of the cricket, Acheta domesticus develops extensively during the organism's postembryonic period of maturation. The majority of the adult complement of cercal-sensory neurons differentiates during this time. Sensory input is important for the development of the normal physiological characteristics of some of the neurons in this system. Chronic sensory deprivation leads to a decrease in the responsiveness of an identified interneuron, the medial giant interneuron (MGI), to acoustic stimulation (Matsumoto and Murphey, 1977, J. Physiol. 268: 533-548.).

The severity of the loss in sensitivity of the MGI depends upon the developmental stage at which deprivation is initiated and its duration. Treatment regimens of constant duration (instars) have progressively weaker effects the later they are begun. Deprivation for five instars beginning in the first, second or third instar alters the response properties of the MGI while later treatments have no effect. A recovery process is not a factor since the period of normal activity following the last deprivation treatment is longest in those cases where the MGI shows the greatest modification. No sensory neuron degeneration was detected in the earliest instars after the application of the deprivation procedure.

Treatments initiated at hatching (i.e. first instar) required a minimum of four instars to produce an effect when the animals were tested as adults. Recordings from immature specimens indicate that a partial recovery from the effects of early deprivation can occur with long post-treatment periods. Specimens deprived for the first four instars exhibit a greater degree of depression when examined in the sixth instar than in the adult (tenth instar).

We conclude that there is a well defined period during the early postembryonic development of the cercal sensory system in which it is sensitive to a reduction in neuronal activity. Manipulations of the activity levels after this period have no effect.

622 NEURONS OF THE CEREBRAL GANGLION OF APLYSIA WITH EXTENSIVE MONOSYNAPTIC EXCITATORY CONNECTIONS PROJECTING TO NEURONS IN OTHER GANGLIA. Richard E. McCaman and David G. McKenna*. Div. Neurosci., City of Hope Nat'l. Med. Ctr., Duarte, CA 91010.

Two bilaterally symmetrical clusters of neurons in the cerebral ganglion of Aplysia californica have been shown to project to follower cells in the abdominal, pedal, pleural and cerebral ganglia. The follower cell response is, in every instance, a monophasic EPSP which voltage clamp experiments demonstrate has an underlying increased conductance mainly to Na^+. The monosynaptic nature of these connections has been assessed by the persistence of the EPSPs in elevated Ca^{++}, graded reduction in elevated Mg^{++} and augmentation after intracellular injection of TEA into the presynaptic neurons. A portion of this highly divergent network has been previously described by Fredman and Jahan-Parwar, (Br. Res. 100, 209, 1975) who described connections between the neurons of the A cell clusters (presynaptic) and the B cell clusters (follower cells) within the cerebral ganglion. There are approximately 18-20 A cells in each bilaterally symmetrical cluster and a single A cell has been found to have as many as 30-50 follower cells in the various ganglia.

We have attempted to characterize the transmitter mediating these connections by combined chemical and pharmacological experimentation. Microchemical assays for various putative transmitters (5HT, ACh, DA, histamine, GABA and Oct) indicate that these substances are not present in the A neurons. The A-cell content of various amino acids (glu, asp, taur, gly) are in no way different from levels found in other pigmented Aplysia neurons.

Approximately 40 different compounds (including various biogenic amines and amino acids) were applied from microelectrodes by pressure ejection or iontophoresis to various follower cells. Only two compounds, 5HT and glu, were observed to produce a depolarization involving an increased conductance mainly to Na^+. 5HT does not appear to be the transmitter since a) bath perfusion of bufotenin (10^{-4}M) completely blocks the 5HT evoked response but has no effect on the EPSP recorded from the follower cells and b) as mentioned previously the A cells (presynaptic) do not contain measurable 5HT. Glutamate does not appear to be the transmitter since a) bath perfusion of glutamate (10^{-5}M) desensitizes and completely blocks the glutamate-evoked response while even at 10^{-3}M it has no effect on the EPSP; and b) bath perfusion of quisqualic acid (10^{-4}M) completely blocks the glutamate-evoked response but has no effect on the EPSP recorded from the follower cells. Thus, the transmitter utilized to mediate this extensive array of connections is unknown but there remains the possibility that it may be structurally related to glutamate. (Supported by N.S.F., BNS 76-06053 and U.S.P.H.S., NS 09339).

623 FEEDING AND REJECTION IN PLEUROBRANCHAEA: COMPARISON OF TWO BEHAVIORS USING SOME OF THE SAME MUSCULATURE. Andrew D. McClellan*. (SPON: R. Plonsey). Dept. Biomed. Eng. and Dept. Anat., Case Western Reserve University, Cleveland, Ohio 44106.

The organization in the nervous system of behaviors which use some of the same muscular and neural elements has been a long standing problem in neurobiology. Some muscles of the buccal mass of Pleurobranchaea are used in two similar behaviors, feeding and rejection (regurgitation). A typical feeding response involves proboscis extension and is accompanied by rhythmic jaw opening and radula movement, which brings food into the buccal cavity. A stereotypic rejection sequence, which may last 20-60 minutes, is comprised of periods of active rejection during which material is expelled from the buccal cavity. Rejection also involves proboscis extension as well as rhythmic jaw opening and radula movement; however, the net result is obviously different from feeding. The range of frequencies of radula movement during feeding overlaps with the range seen during rejection. During the rejection sequence and for several hours afterwards the feeding response is suppressed; this may represent modification of motivational state.

Appropriate muscles and nerves were recorded from during feeding and rejection to compare the motor programs. A substantial part of the motor programs for feeding and rejection are similar, as might be predicted from the resemblance of the two behaviors. The relationship between the phase of a major radula protractor muscle and cycle period (measured from a retractor muscle) is similar during feeding and rejection, suggesting that a common pattern generator is operating during both behaviors. Sharing of part of the motor program may be a mechanism for conservation of neural and muscular elements. Several of the components present during the feeding motor program are either altered or absent during rejection. The functional differences between two similar behaviors may represent an early step in the evolutionary divergence of behaviors in the nervous system. The two behaviors are presently being compared neurophysiologically to determine their organization in the central nervous system.

624 METABOLISM OF TYRAMINE IN THE CENTRAL NERVOUS SYSTEM OF THE MOTH *MANDUCA SEXTA*. Marcia M. Moore*, Gerald D. Maxwell, and John G. Hildebrand. Dept. Neurobiol., Harvard Med. Sch., Boston, MA 02115

Tyramine, a prominent candidate for a role as a neurotransmitter or neuromodulator, is synthesized from tyrosine in the CNS of the moth *Manduca sexta* (Maxwell and Tait, Soc. Neurosci. Abstr. 3:409, 1977). We have now studied the metabolism of [^{3}H]tyramine in *Manduca* central nervous tissue *in vitro*. Structures were removed from pharate adult *Manduca* and incubated for 6 hr in 50 µl of modified Grace's insect tissue culture medium containing 94 µM [^{3}H]tyramine. After incubation metabolites were extracted from the tissues and separated by high-voltage electrophoresis at pH 1.9.

Three major metabolites of [^{3}H]tyramine were detected. One has been identified as N-acetyltyramine on the basis of the following evidence: (1) the compound co-migrates with authentic N-acetyltyramine when chromatographed on paper in 4 different solvent systems and when electrophoresed at pH 1.9, 6.4, and 9.3; (2) the compound is hydrolyzed to tyramine under the conditions of pH and temperature that convert standard N-acetyltyramine to tyramine; and (3) both the compound and standard N-acetyltyramine are converted to tyramine by an N-acyl amino acid hydrolase.

The second metabolite has several chemical properties compatible with its identification as tyramine-O-sulfate. Incubation of tissue with both [^{3}H]tyramine and $^{35}SO_4$ resulted in incorporation of tyramine and SO_4 into the metabolite in nearly equimolar amounts. This metabolite has no net charge at pH 1.9. When exposed to 1 N HCl at 100° for 1 hr, it was hydrolyzed to tyramine. This behavior is consistent with that reported for sulfated metabolites of monoamines from the lobster (Kennedy, J. Neurochem., 30:315, 1978).

The third metabolite is positively charged at pH 1.9 and exhibits electrophoretic and hydrolytic behavior consistent with the hypothesis that it is an N-aminoacyl derivative of tyramine, reminiscent of the β-alanyloctopamine found in lobsters (Kennedy, Soc. Neurosci. Abstr. 3:252, 1977).

N-acetyltyramine is produced in substantial amounts by nervous tissue, tracheae, and connective tissue, but not by muscle. Production of the other two metabolites is greater in nervous tissue than in tracheae, connective tissue, or muscle.

These findings support the view that acetylation, sulfation, and other modifications possibly including N-aminoacylation may be important processes of monoamine metabolism in Arthropods.

This research was supported by a Radcliffe DuPont Fellowship to MMM, an NIH Postdoctoral Fellowship to GDM, and NSF Grant BNS 77-13281 to JGH.

625 POSTEMBRYONIC DEVELOPMENT OF AN IDENTIFIED INTERNEURON IN THE CRICKET ACHETA DOMESTICUS. R.K. Murphey. Dept. Biol., SUNY, Albany, NY 12222.

A number of recent experiments focus attention on the postembryonic development of the medial giant interneuron (MGI) of the cricket. Two types of experiment suggest that normal synaptic inputs to the MGI are susceptible to modification during development. In one experiment removal of some inputs to the MGI resulted in enhancement of the remaining inputs. In a second experiment activity in the afferents which excite the MGI was lowered (sensory deprivation) during development, and this resulted in a decrease in the sensitivity of the MGI to standard stimuli. Both experiments suggest questions which can be answered only by recording from the MGI in very young specimens.

The techniques previously reported (e.g. Murphey 73) for recording from adults have been adapted, virtually unchanged, to immature specimens. Recordings from the MGI have been obtained in specimens as young as the fourth (of 10 instars). The MGI was injected with cobalt to confirm its identity. Morphologically the neuron is very similar to the adult MGI. As in the adult, the MGI was directionally sensitive, its response increased monotonically with increasing stimulus intensities, and it received its primary excitatory input from the contralateral cercus.

The recordings were unusual in one respect, all electrical activity appeared to be electrotonically closer to the somatic recording site. Passively invading action potentials had faster rise times in the immature specimen than in the adult. Synaptic potentials also exhibited faster rise times. In some preparations, the unitary potentials giving rise to the compound postsynaptic potential (psp) which occurs upon acoustic stimulation could be distinguished. Finally, unlike adults, hyperpolarization greatly augmented the psp produced by standard stimuli and blocked action potentials in MGI, while depolarization reduced the amplitude of the psp and increased the number of action potentials in response to a standard stimulus. These results suggest that the soma recording site is a better "window" into neuron function in the immature specimen than it is in the adult.

These results provide the techniques and the baseline data upon which studies of the effects of sensory deprivation on the developing MGI will be based.

Supported by NSF research grant BNS-7523454.

626 NEURAL REGENERATION IN THE SNAIL, HELISOMA TRIVOLVIS. A. Don Murphy and S. B. Kater. Dept. of Zool., University of Iowa, Iowa City, Iowa 52242.

The advantageous characteristics afforded by gastropod molluscan nervous systems for neurophysiological studies are well documented. However, only recently have such molluscan preparations begun to be exploited for neurodevelopmental studies. The snail, Helisoma trivolvis, offers the opportunity to study neural regeneration of identified molluscan neurons with defined synaptic connections and behavioral roles. We have examined neural regeneration of the paired salivary effector neurons (4R and 4L) which are located in the buccal ganglia. These neurons send axons out the esophageal nerve trunks and innervate the salivary glands. The use of the salivary neuroeffector complex combined with the development of an in vivo organ culture technique has facilitated these studies. The salivary glands of Helisoma display excitatory post-synaptic potentials or action potentials in response to action potentials produced in neuron 4 (J. Exp. Biol. 72, 77-90 and 91-106, 1978). Thus they provide a readily available electrophysiological assay for peripheral neural regeneration and functional reinnervation of target cells. The culture technique involves explanting the paired buccal ganglia, the muscular buccal mass, and the salivary glands of one snail and implanting this neuroeffector complex in the heamocoel of a host snail. The esophageal nerve trunks containing the axons of a pair of identified salivary effector neurons located in the buccal ganglia were crushed, thus severing connections between the ganglia and the salivary glands. Within as little as five days salivary neuroeffector neurons functionally reinnervated the glands such that action potentials in neuron 4 again evoke excitatory postsynaptic potentials usually suprathreshold for action potentials in salivary gland cells. The morphology of regenerate neurons was visualized following intracellular injection of the intensely flourescent stain Lucifer Yellow CH. This neural regeneration was manifested by the growth of extensive sprouts from the proximal axon stump to the salivary glands.

627 PARALLEL PROCESSING IN THE CRAYFISH OCCULOMOTOR SYSTEM: DATA AND A HYPOTHESIS. H.B. Nudelman and R.M. Glantz. Univ. of Tex. at San Antonio and Rice Univ., Biol. Dept.,Houston,Texas 77001.

The representation of information in nervous systems by parallel ensembles of neurons may be broken into two classes; one in which the input neurons receive the same information (e.g., spindle afferents from one muscle) and one in which the input neurons receive different information (e.g., compound eye). Here we are interested in the second class. The study of this problem requires that we must simultaneously record from many neurons at once since there may be information useful to the animal, in the timing between action potentials on different channels. This information cannot be obtained from sequential single unit recordings. Furthermore, it would be useful if we had identified units to work with so that hypothesis could be made and tested. The crayfish occulomotor system's response to light position satisfies both of these criteria.

Previous studies by the authors (Fed.Proc:Vol. 36,7-1977 and J. Neurophysiol. Vol. 39,6,1976) indicate that under high physiologic intensity broad field illumination pairs of sustaining units (SU) could be made to fire in near synchrony,i.e., their cross correlations showed peaks around zero. This cross correlation decreased as the intensity was decreased and disappeared at low intensity.

In order to establish the physiological significance of these cross correlations between SU's, behavioral measurements were made on crayfish under the lighting conditions that were known to produce them. As had been observed in other crustaceans, the crayfish oriented their eyestalks with respect to the position of the light source. This response was to the position of the light and not tracking of the light source, since the light was presented at random positions and moved in the dark between these positions. The eyestalk position response lost its statistical significance at reduced light intensity levels were the SU's lost their cross correlation.

While recording from a pair of SU's from an eye fixed to the carapace it was found that the cross correlation between the two units varied as a function of the position of the light source.

It is hypothesized that for different light positions different groups of SU's will show significant cross correlation around zero and it is in this fashion that the light position is represented by the ensemble of SU's. This scheme of encoding positions may be simply decoded. If the sustaining units project to the appropriate motor neurons decoding will take place by spatial summation of the convergent input.

Data to support this hypothesis will be presented.

628 SPECTRAL SENSITIVITY OF OPTOKINETIC TRACKING IN THE CRAYFISH, PROCAMBARUS. Richard F. Olivo and William M. Petkun*. Dept. Biol. Sci., Smith College, Northampton, MA 01063.

The function of the blue-sensitive receptors in the crayfish eye remains elusive; so does the answer to the question of whether crustacean motion-detection systems are color blind, as insect systems are. We partially answer the first question by showing here that the blue receptors contribute to the optokinetic tracking system.

Restrained crayfish (Procambarus clarkii) were suspended at the center of a sinusoidally-oscillating (9.9 cyc/min, 41° excursion) drum consisting of alternating opaque and translucent (20°) stripes. We previously showed that the amplitude of sinusoidal tracking depends on the luminance of the stripes (Neurosci. Abstr. 3:581, 1977). In the present experiments, monochromatic light at intervals from 420 nm to 680 nm illuminated the drum evenly from outside; at each wavelength, neutral density filters were placed in the light path to vary the stripe radiance (range: 2 - 100 nW/cm^2), and the corresponding amplitude of optokinetic tracking was measured. The illuminating light was monitored continuously with a calibrated radiometer.

For each experiment, the stripe radiance required to elicit a criterion response was determined for each wavelength, and a log relative quantum sensitivity spectrum was calculated. Spectra from 14 experiments on 6 animals were averaged to obtain the mean spectral sensitivity; the average spectrum matches published spectra of the dark-adapted ERG.

Since the blue receptors' contribution to the ERG spectrum is not detectable without selective adaptation to red light, we repeated our experiments with blue or red adapting lights flooding the inside of the drum. The normalized blue-adapted spectrum is the same as the non-adapted spectrum; both represent essentially the response of the yellow receptors alone. The red-adapted spectrum has a second peak in the blue, and thus shows that the blue receptors do contribute to the optokinetic system.

629 CRAYFISH GIANT FIBERS ARE COMMAND AND DECISION NEURONS. Gene C. Olson* and Franklin B. Krasne. Dept. of Psychology, UCLA, Los Angeles, California 90024

Recently, it has been argued that in order for a neuron to be considered a command neuron, its firing should be both necessary and sufficient for producing behavior. It has also been pointed out that a neuron that is considered a command neuron by virtue of these criteria could be either the initial issuer of the order (i.e., a decision neuron) or merely the conveyer of an order issued elsewhere. (See Kupfermann, I. and Weiss, K.R., The Command Neuron Concept, The Behav. and Br. Sci., in press 1978.)

The crayfish lateral giant fibers (LGs) are often considered to be among the best established examples of both command and decision neurons. LG firing is perfectly correlated with the occurrence of short latency tail-flip escapes to mechanical stimulation of the abdomen, and directly applied shocks which fire the LGs produce tail-flips. It is widely believed that the LGs are necessary for this tail-flip behavior, but the available evidence does not exclude the possibility that LG firing merely serves to increase the rate of intersegmental propagation of excitation to motor neurons and that should the LG firing be prevented, tail-flips, though imperfect, would still occur, -- i.e., the LGs might not be necessary. Nor does available evidence exclude the possibility that, though the LGs receive numerous excitatory synapses directly from mechanoreceptors and first-order sensory interneurons, a substantial additional input from a specific pre-LG decision neuron is necessary to carry the membrane potential over firing threshold -- i.e., the LGs might not be decision neurons.

Therefore: (1) We have studied the effects on tail-flip behavior of hyperpolarizing both LGs so that they cannot fire. We find that a shock to primary afferents that causes fast flexor contractions when the LGs are permitted to fire does not do so when hyperpolarization prevents LG firing. (2) We have examined afferent fiber shock-evoked EPSPs in the hyperpolarized LGs just above and below the stimulus level that causes firing of the unpolarized LG. This should uncover possible decision neuron inputs whose rising portions merge smoothly with rising spikes. We find no sign of any special boost of excitation to the LGs (from a possible decision neuron) as the stimulus strength crosses threshold. We conclude that the LGs do appear to be both command and decision neurons. (Supported by USPHS Grant NS08108.)

630 A COMPARATIVE STUDY ON THE INFLUX OF RADIOACTIVE TRYPTAMINE AND 5-HYDROXYTRYPTAMINE BY SNAIL (HELIX POMATIA) NERVOUS TISSUE. Neville N. Osborne* and Volker Neuhoff* (SPON: L.T. Graham) Forschungsstelle Neurochemie, Max-Planck-Institut für experimentelle Medizin, 3400 Göttingen, Germany.

Isolated snail ganglia possess the ability to concentrate tryptamine from an external medium by a process which is saturable at very high concentrations of amine in the medium and temperature sensitive, thus able to produce a net uptake of tryptamine. Kinetic analysis of the influx of tryptamine shows that the amine is taken up by a single transport system with K_m value of 1.4×10^{-4}M. The influx of tryptamine into snail ganglia is thus fundamentally different from that of its hydroxylated analogue 5-HT (5-hydroxytryptamine), where the accumulation shows rapid saturation kinetics, is sodium dependent, slightly inhibited by ouabain and also temperature sensitive. Kinetics of 5-HT uptake show the influx to be divided into a high affinity mechanism with a K_{mH} value of 8.5×10^{-8}M (sodium sensitive component) and a low affinity mechanism with a K_{mL} value of 1.8×10^{-4}M (sodium insensitive component). The influx of tryptamine is thus, in principle, similar in character to the low affinity uptake mechanism for 5-HT, i.e. sodium insensitive with relatively high K_m value. Further evidence that the tryptamine influx mechanism is similar in character to a low affinity uptake system for 5-HT is shown by the fact that the tryptamine influx and low affinity 5-HT uptake are not influenced by a number of pharmacological agents, analogues of tryptamine and ATP. The high affinity uptake mechanism for 5-HT in contrast is very sensitive to pharmacological agents (e.g.: chlorimipramine, imipramine), analogues (e.g.: tryptamine) and a variety of other substances.

631 OCTOPAMINE MODULATES SENSITIVITY OF IDENTIFIED INSECT INTERNEURONS. Michael O'Shea* and R. K. Murphey (SPON: B. C. Abbott) Dept. Biol. Sci. USC, Los Angeles, CA 90007 & SUNY, Albany, N.Y. 12222.

The terminal ganglion of the cricket, Acheta domesticus, contains the somata and dendrites of giant auditory interneurons with axons ascending in the ventral nerve cord. These neurons receive excitatory input monosynaptically from sensory neurons which innervate sound sensitive hairs on the antennae-like anal cerci. Electronmicrographs of one of the giant interneurons, the Medial Giant Interneuron (MGI), reveal a close association between the MGI dendrite and another neuron containing large neurosecretory-type vesicles. These vesicles are similar to those of dorsal aminergic neurons in the locust, a related insect.

Neutral Red dye, which stains monoamine containing neurons, revealed about 40 large neuronal cell bodies on the dorsal midline of the terminal ganglion. These putative aminergic neurons are similar to dorsal neurons in the locust, some of which are known to be octopaminergic. For example, they have overshooting soma action potentials and project axons bilaterally to peripheral nerves. In the locust, one of these efferent aminergic neurons functions peripherally as a modulator of neuromuscular transmission; central nervous functions have not yet been attributed to them. Some of the dorsal neurons in the cricket do not project peripherally but ramify extensively in the neuropile of the terminal ganglion. Central functions of the dorsal neurons in relation to the MGI are now being sought.

We have not yet found a dorsal neuron which affects the sensitivity of the MGI but to date less than 10% of the neurons have been tested. Octopamine, however, has a specific sensitizing effect. Local perfusion of octopamine (10^{-5}—10^{-4}M) produces an increase of 10 to 20% in the response of the MGI to sound. The following amines are without effect at 10^{-4}M; tyramine, noradrenaline, dopamine and 5HT. Only synephrine is an effective agonist of octopamine. The sensitizing effect is blocked by the α-adrenergic blocking agent, phentolamine. These results are consistent with the pharmacology of the peripheral effects mediated by an octopaminergic neuron in the locust and suggests that an octopaminergic neuron, possibly among the dorsal group, causes sensitization of the cricket MGI in the terminal ganglion.

632 IS ADAPTATION DEPENDENT ON Ca^{++}? L. Donald Partridge. Dept. of Physiology, Univ. of New Mexico, Albuquerque, N.M., 87131.

Spike frequency adaptation is a process basic to the encoding mechanisms of neurons. In Archidoris neurons, adaptation has been shown to result from the gradual increase of a slowly activating potassium conductance during a train of spikes (Partridge & Stevens, J. Physiol. 256:315). Similar slow potassium currents have been found to be activated by Ca^{++} ions in numerous other molluscan neurons (Meech & Standen, J. Physiol. 249:211). The potassium conductance responsible for adaptation in Helix pomatia has been indirectly attributed to such a Ca^{++} activating mechanism (Colding-Jorgensen, Acta. Physiol. Scan. 101:382). The experiments reported here were designed to test for such a role of Ca^{++}.

Ganglion cells from Helix aspersa were studied. In an attempt to block inward Ca^{++} currents, experiments were done using the following bathing solutions: 7mM Co^{++} and 0 Ca^{++}; 2 mM Cd^{++} and 7 mM Ca^{++}; 1mM EGTA limiting free Ca^{++} to 10^{-9} M. In each case either the progressive diminution of spike amplitude and increase in spike width or the decrease in amplitude of peak inward current was used as a test for effective blockage of inward Ca^{++} current. Although there was considerable variability amongst cells, spike frequency adaptation was generally found to persist in the absence of inward Ca^{++} currents.

It is concluded that there exists a Ca^{++} independent process that is capable of producing spike frequency adaptation in these neurons. This is consistent with the original model proposed by Partridge & Stevens of a voltage dependent activation producing a gradual summing potassium conductance during a train of spikes.

633 A CENTRAL MOTOR PROGRAM FOR UROPOD BEATING IN THE ANOMURAN CRAB, EMERITA ANALOGA. Dorothy H. Paul. Dept. of Zoology, Oregon State University, Corvallis, OR 97331.

Two rhythmic motor patterns in the same motoneurons underly beating of the pair of swimming appendages (uropods) in the sand crab, Emerita analoga. In motor pattern no.2, associated with treading water, generation of bursts in the power-stroke motoneuron (PS) is dependent on proprioceptive feedback from return strokes (1). The previous attribution of motor pattern no.1, associated with swimming, to a central pattern generator is now supported by the recording of rhythmic activity in the appropriate motor nerves (central motor program) in excised portions of the ventral nerve cord including from 4 to 7 of the most posterior ganglia. The temporal organization of this central program shares 2 salient features with both the behavior (2) and motor pattern no.1 (1;2): the positive correlations of PS latency and period of return-stroke motoneuron bursts (RS) have similar slopes (Fig.1; 1;2) and PS durations are nearly invariant (Fig.2;2). The central motor program appears to be organized around a PS burst generator, since PS bursting may occur without RS bursts. Two differences of the central program compared to the behavior and motor pattern no.1, the brief and labile RS bursts and the longer periods, suggest an important role of sensory afferents and/or anterior neural centers in prolonging RS bursts and in maintaining normal frequencies of uropod beating.

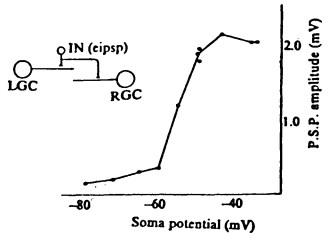
Variation in PS latency (L-$\bar{L}$), Fig.1, and variation in PS duration (PS-$\bar{PS}$), Fig.2, correlated with variation in period (P-$\bar{P}$). $\bar{L}$ = 4.17+1.04 s.; $\bar{PS}$ = 0.41+0.04 s.; $\bar{P}$ = 4.87+1.03 s.; N = 28.

634 CONTROL OF TRANSMITTER RELEASE BY SOMA POTENTIALS IN THE APLYSIA CNS. B. Peretz° and T. Shimahara*. Labo. N. B. C. of CNRS 91190 Gif s/ Yvette, France. °Dept. of Physiology, U. of Ky., Lexington, Kentucky 40506.

In an Aplysia monosynaptic pathway, imposed hyperpolarization of the pre-cell soma decreased the size of the PSP amplitude and depolarization increased it (Shimahara & Peretz, 1978). In the isolated pleural ganglion, the post-cell, left giant cell (LGC) and the interneuron (IN), which evoked EIPSPs in LGC, were each impaled with two microelectrodes. When the IN soma potential was displaced from -30mv to -110mv, and the LGC soma at its resting level of -55mv, the relationship between IN soma potential and PSP amplitude was described by an S-shaped curve (see fig.). In the linear region of the curve, -45 to -60mv, the "control constant" is 0.2mv (PSP)/mv (soma potential). At IN of -45mv (resting), PSP amplitude was close to maximum. Polarization for less than 50ms, sufficient time to alter IN spikes, had no effect on PSP size; synaptic delay of 7 ms was unchanged with imposed soma polarization; these results exclude the possibility that altered spikes are sufficient to explain the effect. With spike blockade by 94μM of TTX in the bath, soma depolarization at about +5mv initiated release and was sustained for at least 2 sec; electrotonic coupling between IN and LGC was excluded with TTX. We conclude that soma polarization controls release at the terminals. Control probably is by electrotonic spread to the terminals and involves Ca: Increased Ca++, 33mM, partially protected release from hyperpolarization and enhanced the effect of depolarization; decreased Ca++, 3.3mM, had the reverse effect. Post-tetanic potentiation, characteristic of this synapse, was enhanced by soma depolarization and suppressed by hyperpolarization. One electrical function then of large molluskan somata, those electrically close to their terminals, is to modulate transmitter release by changes in membrane potential even though a spike successfully initiates the release. (Macy Found., INSERM, NIMH).



635 EFFERENT INFLUENCE OF THE CEREBRAL GANGLION ON PHASE SETTING OF THE CIRCADIAN OSCILLATOR IN THE APLYSIA EYE. Robert G. Prichard* & Marvin E. Lickey. Dept. of Psy., U of OR, Eugene, OR 97403.

The eye of Aplysia is a self contained circadian oscillator. Circadian rhythms change their phase in response to light pulses applied at different phases of their oscillation (PRC). Most circadian rhythms are also reset by an LL→DD transition produced by transfering the organism from continuous light (LL) to continuous darkness (DD). An LL→DD transition acts as a "dusk signal" and sets the phase of most oscillators to subjective dusk (ct. 12) if at least 12 h of LL preceed the transition. Aplysia eyes were exposed to an LL→DD transition after increasing durations of LL (500 lux) to determine 1) if they too could be set to ct. 12 by a transition and 2) if the other oscillators and photoreceptors Aplysia are known to possess contribute to the resetting of the ocular oscillator. Animals were exposed to at least 5 cycles of LD 12:12 before receiving from 1 to 69 h of continuous light. Just before the end of LL the eyes and the cerebral ganglion were dissected and placed in vitro for recording. One eye was isolated by cutting the optic nerve; the other was left attached to the cerebral ganglion. The preparation was then placed in DD and the phase of both eye rhythms determined. For durations between 1 and 12 h, the transition had little effect on either isolated or attached eyes. For durations between 24 and 69 h, the transitions set both isolated and attached eyes to ct. 12 ± 3h; the phase to which the eyes were set oscillated ± 3 around ct. 12 once for each additional 21 h of LL. This shows that continuous light did not stop the oscillator. For durations between 12 and 24 h, attached and isolated eyes responded differently to the LL→DD transition. This caused a phase difference to develop between the attached and detached eyes. For example, following 21 h of LL the phase difference was around 12 h. This demonstrates an important contribution by the cerebral ganglion to the phase setting of the eye. The time course of the contribution has been examined following 21 h of LL by cutting the attached eye's optic nerve at hourly intervals from 1 to 10 h after the transition. Initial results indicate that the first 5h of neural communication produces only a minor phase difference between the attached and isolated eyes. Ten hours of communication produces the full 12 h phase difference. Therefore the major influence of the cerebral ganglion on the eye occurs between the fifth and the tenth hour after the LL→DD transition. Since the first 5 h of communication has little effect, cerebral photoreceptors are unlikely to be the direct source of the efferent influence. Experiments are being performed to determine if a cerebral oscillator may be involved. Supported by NS 12374

636 GRADED SYNAPTIC TRANSMISSION BETWEEN SPIKING NEURONS DURING THE GENERATION OF A CENTRAL MOTOR PATTERN. Jonathan A. Raper* (SPON: J. Lamborghini). Dept. of Neuroscience. UCSD, La Jolla, CA 92093.

Graded synaptic transmission between spiking neurons can be shown to exist during spontaneous cyclic activity in the pyloric subsystem of the spiny lobster stomatogastric ganglion. Localized TTX perfusion across the posterior margin of the ganglion suppresses pyloric spiking but preserves slow wave activity and central activating connections. Graded inhibitory synaptic actions can be observed from neurons which normally fire action potentials (control fig. 1a, localized toxin blocks LP in 1b).

Bath application of TTX sufficient to block spikes also halts spontaneous cycling. Bath applied TTX plus 1 mM Dopamine induces patterned cyclic activity without action potentials, but in other respects similar to normal behavior (control fig. 1c, DA + TTX 1d).† Induction involves the activation of endogenous bursting properties in the AB, and possibly plateau potentials in the LP. Graded transmission is responsible for the proper phasing of units. Its presence can be inferred by the reversal of postsynaptic waveforms with injected current and postsynaptic disinhibition with presynaptic hyperpolarization.

These results suggest that graded synaptic transmission could play an important role in the physiological functioning of a central pattern generator composed of spiking neurons.

637 SENSORY MODULATION OF RHYTHMIC FEEDING IN LIMAX MAXIMUS. Stephen C. Reingold & Alan Gelperin. Department of Biology, Princeton University, Princeton, NJ 08540.

We are using feeding behavior of the terrestrial mollusk Limax maximus to study modulation of a rhythmic behavior by sensory input.

Feeding is largely accomplished by rhythmic protraction and retraction of a rasping radula and supportive odontophore, each cycle of which results in ingestion of small amounts of food. The central neurons responsible for generation of the feeding motor program incorporate a pattern generator within the buccal and cerebral ganglia.

In intact, behaving animals, radula-odontophore movements during feeding on an artificial diet (carrot, $CaCO_3$, vitamins in an agar matrix) can be recorded with a movement transducer. A feeding bout from a 2-weeks starved animal consists of as many as 1000 bites over 20 minutes, with a characteristic warm-up period (5-30 cycles) during which instantaneous bite frequency increases slightly. A plateau phase of near constant bite frequency follows. Termination of feeding can be abrupt or can show a slight decrease in bite frequency.

Parameters of feeding behavior such as meal duration, amount of food eaten, and bite frequency can be measured as a function of characteristics of the food (type and concentration of food substance; hardness of agar matrix). When hard foods (15% agar) and soft foods (3% agar) were presented alternately to animals, bite frequencies were consistently lower for hard foods than for soft foods. Changes in bite frequency as a function of food hardness imply afferent influences on the output frequency of the CNS pattern generator for feeding.

In highly dissected preparations consisting of lips, brain, and buccal complex (musculature, medial tooth, radula and odontophore) feeding motor program and appropriate buccal complex movements can be triggered by food extracts delivered to the lips. Extracellular electrodes record sensory input from the buccal complex and motor output underlying feeding movements. Artificial loads added to buccal complex structures in such preparations mimic the effects of food hardness in intact animals. In many cases, changes in load on the medial tooth and on the radula result in changes in frequency of feeding motor output which are similar to changes seen in intact animals presented with foods of different hardness.

638 SCORPION LEG MOTOR SYSTEM: MICROSCOPIC ANATOMY AND ELECTROPHYSIOLOGY. Thomas M. Root and Robert F. Bowerman. Dept. of Zoology, Univ. Wyoming, Laramie, WY 82071.

Seven different muscles in the walking leg of the scorpion (Paruroctonus mesaensis) were studied with light microscopy, electron microscopy and intracellular recording. This represents the broadest such study of an arachnid neuromuscular system to date. These muscles control the three most active leg joints (T-F,F-P & P-T) during walking (Root & Bowerman 1978, Bowerman & Root 1978). Compared to crustacean and insect muscles, scorpion leg muscle fibers are strikingly uniform in sarcomere length both within and between muscles, and are relatively short (2-4 microns). The fibers are small (15-30 microns diameter) and are closely packed within the muscle. The fibers consist of a central region of nuclear material and mitochondria surrounded by a radially arranged pattern of contractile elements. The radiating myofibrils bifurcate near the fiber surface and may constitute up to 80% of the fiber cross-sectional area. The sarcoplasmic reticulum forms alternating dyads with the T tubules as has been previously described for Limulus, spider walking leg muscles, and the scorpion claw closer muscle. Data were collected from each of the seven muscles on fiber numbers, fiber cross-sectional area, thin-thick filament ratios, banding patterns and synaptic ultrastructure. Intracellular recording together with tension measurements have elucidated neuromuscular characteristics for each muscle, and innervation patterns for the entire leg. Values were obtained for resting potential, input resistance, number of motor axons per muscle fiber and per muscle. Features such as facilitation and fatigue are also described.

639 MOLT-RELATED "NEUROSECRETORY" CELLS IN THE ABDOMINAL NERVE CORD OF THE CRAYFISH, PROCAMBARUS CLARKII. Richard L. Roth* (SPON: Jeffrey J. Wine). Dept. Biol. Sci., Stanford Univ., Stanford, CA 94305.

Near the rostral margin of each thoracic and abdominal ganglion of the crayfish, Procambarus clarkii, there are two pairs (one on either side of the midline) of apparent neurosecretory cells. In the 6th abdominal ganglion there are an additional 16 such cells along the caudal margin. As a class, these cells are unique among neuronal somata of the ventral nerve cord in that their cytoplasm contains two systematically and inversely fluctuating populations of granules. The granules of one of these populations are about 0.5um in diameter, are fuchsinophilic by Gomori's aldehyde fuchsin method, and those in each cell are distributed into about 80 compact clusters of several hundred granules. The granules of the other population are about 0.25um in diameter, are intensely argyrophilic by the Nauta method and are uniformly dispersed except where they are displaced by clusters of fuchsinophilic granules.

The fuchsinophilic granules are discharged (apparently directly from the cell body rather than via an axonal channel to a neurohemal organ) near the time of ecdysis. There is some diminution in granular content in the day or two preceding the molt, and depletion is nearly total by 12 hours after ecdysis. Reaccumulation of fuchsinophilic granules is apparent by the 3rd post-molt day and appears to progress at a uniform rate for 4-6 weeks.

The argyrophilic granules are maximally demonstrable 1 day after ecdysis and appear to decline in number as fuchsinophilic granules accumulate. Whether the argyrophilic granules represent a separate secretory product or a precursor or part of the synthetic machinery involved in the formation of the fuchsinophilic granules is not yet known.

There is indirect evidence from coablt backfills that these apparent neurosecretory cells may also serve as ascending interneurons. Efforts to confirm this suggestion by intracellular recording with marker-filled microelectrodes are now in progress.

It is also of some interest that a brief transition from aggressive to escape behavior occurs in conjunction with the discharge of the fuchsinophilic product. Whether the behavioral shift is causally related to the neurosecretory activity is under investigation.

Supported by NIH Grant NS 02944 to D. Kennedy.

640 FIRING PATTERNS OF APLYSIA WHITE CELLS: EFFECTS OF TEMPERATURE AND MENTHOL. Ronald L. Seaman, Dept. of Physiology, Univ. of Texas Health Science Center, Dallas, Texas 75235.

Intracellular recording was used to monitor the firing rates of the neurosecretory white cells (R3-R14) in the abdominal ganglion of Aplysia californica. The rate of spontaneous firing was measured for constant temperatures between 0 and 28 °C. After a temperature change, the firing rate was allowed to stabilize before a measurement was made. Some firing patterns did not fully equilibrate after 20 minutes at a constant temperature, especially at lower temperatures. Such long equilibration periods may account for some of the differences in firing rates reported for the white cells. The response of most white cells (67%) contained a maximum rate of 0.024 to 0.263 per second between 15 and 21 °C. The others (33%) responded with faster firing rates as temperature was increased, reaching a rate of 0.6 to 0.8 per second at 22 °C. Menthol (0.1 and 1 mM) in the bathing medium affected the peaked response by increasing the magnitude of the peak, by shifting the peak to a higher temperature, or both. The peak was increased by as much as 2.5 times. Menthol (0.1 mM) did not significantly change the second type of response.

A regular rate was the most commonly observed firing pattern; however, in some cells there were instances of grouped activity resembling that exhibited by the ganglion's bursting pacemakers. The white-cell bursting patterns were much slower. They consisted of groups, or bursts, with 2 to 100 action potentials and of duration as long as 250 seconds. The interburst intervals ranged from 30 to 450 seconds. Bursting patterns were seen in the 18 to 27 °C range for both types of temperature responses. The bursting was distinct from firing patterns which developed as the result of temperatures above 30 °C. These abnormal patterns were repetitive but the firing was irregular and often contained attenuated action potentials. Bursting was seen in the presence of menthol (0.1 and 1.0 mM) in the same temperature range in the cells bursting without menthol.

In addition to bursting activity, the menthol-induced changes in the peaked responses strengthen the case for those white cells being models for "cold" thermoreceptors. The white cells showing the menthol-insensitive monotonic response may be models for "warm" thermoreceptors. The similarity between the firing patterns of white cells and bursting pacemakers seems to indicate that there is little difference in electrical properties between them other than the dynamics of slow potentials. The firing patterns of both groups of neurons depend on temperature, suggesting temperature-sensitive rate processes. The term "beating pacemaker" may be appropriate for the white cells only under certain conditions.

641 INKING IN APLYSIA: CENTRAL LOCUS OF SELECTIVE SENSITIVITY TO LONG DURATION STIMULI. E. Shapiro,* J. Koester, and J. Byrne, Dept. Physiol., Columbia Univ., New York, N.Y., and Dept. Physiol. Univ. of Pittsburgh, Pa.

Aplysia californica release ink in response to strong noxious stimuli. Ink release has been shown to have a high threshold and a steep input-output relationship when measured as a function of stimulus amplitude (Carew and Kandel, 1977). We have found that ink release also exhibits a steep input-output relation when measured as a function of stimulus duration.

Three types of behavioral experiment demonstrated that ink release is selectively sensitive to long-lasting noxious stimuli (electrical shocks). In two experiments stimulus amplitude was kept constant and we measured either amount of ink released as a function of stimulus duration or percentage of animals that released ink at given stimulus durations. In the third experiment we determined a strength-duration curve for the threshold for a "full" ink response (50% of releasable ink). In all three experiments, which covered a stimulus duration range of up to five sec, a sharp, steplike increase in stimulus effectiveness occurred for stimuli greater than about two sec.

To determine the cellular mechanisms that underlie this low-pass property of inking behavior, we recorded from and voltage-clamped the ink motor neurons (L14 cells). These are three nearly identical abdominal ganglion cells previously described by Carew and Kandel (1977). The release of ink in response to a constant frequency spike train of up to five sec duration in cell L14A was found to be a linear function of train duration with a 0-intercept of the Y-axis. Thus peripheral facilitation cannot account for the behavioral results. A five sec electrical stimulus to the head or to the connectives that carry sensory input to the ganglion produce a spike pattern in the L14 cells consisting of a brief 1-2 sec pause followed by an accelerating burst of spikes. The initial pause has previously been shown to be attributable to a rapidly activating outward current (Byrne, et al., 1976, Neurosci. Abstr.) We have now found that the late accleration in L14 spike activity in response to a five sec noxious stimulus is due to an increase in synpatic effectiveness: a slow, decreased-conductance EPSP that is recruited with some delay accounts for the late increase in firing rate. The presence of this EPSP was demonstrated by voltage-clamp examination of L14 synaptic currents. An increase in L14 input resistance and a positive shift in PSP reversal potential was correlated with L14 burst behavior.

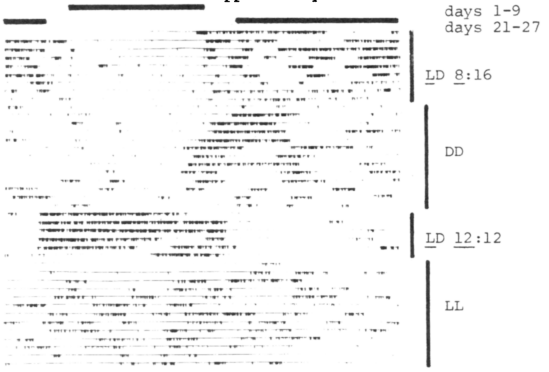
In the companion abstract Byrne describes in greater detail the ionic mechanisms responsible for the anti-accommodation firing pattern of the L14 cells.

642 PLANARIA CAN BE ENTRAINED TO LIGHT CYCLES AND EXPRESS A FREERUNING RHYTHM OF LOCOMOTOR ACTIVITY IN CONSTANT DARKNESS. John T.F. Smith, C.M. Loer*, and J.L. Larimer. Department of Zoology, University of Texas, Austin, TX 78712.

It is known that Planaria express daily cycles of feeding by making more cannibalistic attacks at night than in the day (Best, 1960). They have a daily cycle of sensitivity to electrical shock (Becker-Carus, 1970). Lunar cycles of orientation in magnetic fields have also been demonstrated (Brown, 1962). We found that Planaria entrain to light cycles and can express a freerunning circadian rhythm of locomotor behavior.

Dugesia were collected locally. Locomotor activity of single animals was monitored in small rectangular glass chambers (55mm x 15mm x 5mm) fabricated from micro slides. Activity was detected as the animal moved through an infrared beam and recorded on an event recorder. The detector could be useful for other small animals.

Shown here is the 41 day actograph of a single Planarian given different light regimen. The first 9 days were light cycles of 6 hrs light (1 lx), indicated by the bar above the record, and 18 hrs of darkness, LD 8:16. Activity was limited to the dark period. The next 12 days constant darkness, DD, prevailed and the animal appeared by inspection to freerun with a period of 23.6 hrs. The following 6 days were LD 12:12. The animal was again active during the dark. When placed in constant light, LL, activity occured in bursts of about 1 hr seperated by 2 hr "rest" periods. This behavior persisted throughout the day with no circadian component. No tidal or lunar rhythms in the behavior of Planaria were evident. Supported by NIH NS 05423.



643 SECRETORY SOURCES OF EGG-LAYING INDUCTION ALSO INFLUENCE THE ISOLATED APLYSIA HEART. T. Smock‡ S. Arch‡ and P. Lloyd* (SPON: D. Rhodes). Biological Laboratories, Reed College, Portland, OR 97202, and Zoology Department, University of Washington, Seattle, WA 98195.

Recently there has been interest in endogenous peptides that excite the heart of certain gastropods. Experiments by P. Lloyd (pers. comm.) on the Helix aspersa heart in vitro reveal that one of the peptides has a molecular weight of ca. 6000 and an alkaline isoelectric point. The biochemical similarity of the molecule to egg-laying hormone (ELH) of a related mollusc, Aplysia californica, suggested the hypothesis that the cardio-accelerating substance was a homologue of ELH. To evaluate this hypothesis, a preparation consisting only of the ventricle, auricle and cristae aorta was isolated from a freshly killed Aplysia and perfused with filtered sea water. The ventricle was cannulated through a slit approx. 5mm from the junction with the auricle. Cotton thread secured a small amount of heart muscle to the cannula. A tight ligature was necessary as the heart would not beat without positive internal fluid pressure. A hook through the cristae aorta was connected to a force transducer. Moderate tension between the hook and the cannula induced the heart to beat regularly after 1-2 hours of perfusion. As expected, 5-HT (10^{-9}M) and acetylcholine (10^{-8}M) had excitatory and inhibitory effects, respectively, when applied to the inside of the ventricle through the cannula. A survey of Aplysia tissue homogenates revealed two major loci of cardio-accelerating activity: the neuroendocrine bag cells of the parieto-visceral ganglion and the "atrial" gland of the large hermaphroditic duct. These two organs are also the sources of egg-laying factors in Aplysia. Gel filtration chromatography of extracts of each tissue revealed that the cardio-excitatory activity co-elutes with egg-laying activity at about 6000 daltons. In both cases the activity was sensitive to digestion with bacterial protease. Though the heart was much more sensitive than egg-laying as a bioassay, the relative amounts of cardio-accelerating activity in the two tissues paralleled the amounts of egg-laying activity as determined by serial dilution. Further, we found that electrical stimulation could increase release of the active substance from the atrial gland. Since the heart responds to samples that contain only 1/20 the material needed to induce egg-laying, it seems likely that it will prove to be a useful preparation for rapid and accurate bioassay. Since bag cell secretion also affects electrical activity of identified neurons that alter heart rate (Mayeri et al., J. Neurophysiol., in press) it seems that the neurodocrine effector may intervene at several levels of organization in the physiology of the animal.

644 SYNAPTIC PHYSIOLOGY AND PHARMACOLOGY OF A WHITE, PUTATIVE COMMAND INTERNEURON (C2) IN TRITONIA DIOMEDEA. Robert Snow. Dept. of Zoology, Univ. of Wash., Seattle, WA 98195.

A pair of visually identifiable neurons (C2) in the cerebral ganglia of Tritonia diomedea are thought to be command cells for escape swimming. Their activity is apparently required for the initiation of each swim cycle (Getting, J. Comp. Physiol. 121: 325, 1977: Taghert and Willows, J. Comp. Physiol. 123: 253, 1978). Antidromic stimulation of all of the brain roots suggests that C2 is an interneuron having no peripherally directed processes. C2 make contralateral synaptic connections with all cells sampled (N>60) in the pedal and pleural ganglia. Evidence that these connections are monosynaptic includes 1) they are not blocked by high Ca^{++} and Mg^{++} ASW, and 2) presynaptic polarization affects the efficacy of all psp componants (Shimahara and Tauc, J. Physiol. 247: 299, 1975).

Four different psps have been identified, and all four have been recorded together in some of the post synaptic neurons. These psps are 1) a fast (40 msec to peak), Cl^- dependent ipsp that is blocked by 10^{-4} M curare (dTC) and reverses at -56 mV, 2) a slow (100 msec to peak), rapidly facilitating, Na^+ dependent epsp that is not blocked by dTC, 3) a slow (2.5 sec to peak), K^+ dependent ipsp that is blocked by intracellular tetraethylammonium (TEA) ions and by cooling to 1° C. This psp is the most common potential seen, and 4) a very slow (15 sec to peak) epsp that is reduced as the post synaptic neuron is hyperpolarized, disappearing at -80mV. This psp is also blocked by cooling to 1° C. The first three of these potentials are due to conductance increases since they are accompanied by a marked drop in the input impedence as measured in the soma. No change in the input impedence is detectable in the soma during the fourth psp.

Positive evidence for the transmitter of C2 is still lacking. However, bath application of up to 10^{-3} M putative transmitter candidates to desensitize the receptors suggests that the transmitter is not likely to be any of the compounds for which receptors have been identified in gastropods (Carpenter et.al., J. Neurobiol. 8: 119, 1977). The transmitter candidates tested were 5-hydroxytryptamine, acetylcholine, dopamine, γ-aminobutyric acid, phenylethanolamine, octopamine, histamine, aspartic acid and glutamic acid. Also, except for the ionophore blockers dTC and TEA, no pharmacological agents have been effective on any of these psps. Pharmacological agents tested were hexamethonium, methysergide, bicuculline, phentolamine, cimetidine and fluphenazine. This evidence suggests a novel transmitter or pharmacology. (Supported by NSF grant BNS75 13597 A02.)

645 THE PEPTIDERGIC BAG CELL NEURONS OF APLYSIA: MORPHOLOGICAL AND ELECTROPHYSIOLOGICAL STUDIES OF DISSOCIATED CELLS IN TISSUE CULTURE. F. Strumwasser, L. K. Kaczmarek and D. Viele*. Division of Biology, California Institute of Technology, Pasadena, CA 91125.

The bag cell (BC) neurons exhibit interesting discharge properties in the intact BC system such as prolonged afterdischarge and postactivity refractoriness. In order to further dissect these interesting electrophysiological properties we have explored the possibility of producing primary cell cultures of BC neurons. The BC neurons also synthesize a polypeptide, egg-laying hormone, in the intact cluster. Cell cultures have the potential for eventually producing a cell line of invertebrate peptidergic neurons since Coggeshall (J. Neurophysiol. 30:1263, 1967) presented evidence that their numbers approximately triple between juvenile (5 g, body weight) and adults (200 g).

We have used a variety of individual enzymes and combinations for dissociation of cells (collagenase, elastase, neutral protease, pronase, trypsin). Our best results were obtained incubating abdominal ganglia in neutral protease (1.25% w/v solution in filtered seawater [FSW]) for 6 hours at 22°C. After removal of the BC clusters from the abdominal ganglion, the connective tissue capsule is removed and the bag cells are disaggregated using a Siliclad-coated pasteur pipet. Typical yields, with neutral protease, of single BCs (from 2 BC clusters) vary between 250 and 500 cells. We estimate about a 30-50% recovery during dissociation of the cluster. We also obtain glial and other unidentified cells.

Many of the BCs and other cells attach to the plastic surface of the dish (Falcon, 35 mm) and develop neurites, within 24 hr, in Eagle's minimum essential medium made up in FSW. This medium has been shown to support normal resting, action and synaptic potentials in the intact abdominal ganglion (Strumwasser and Bahr, Fed. Proc. 25: 512, 1966). It is interesting that some BCs exhibit as many as 6 processes emanating from their cell body indicating that a heteropolar neuronal condition can be expressed, at least in tissue culture, and is not unique to vertebrate neurons.

Intracellular recordings from BC neurons without neurites in primary culture have allowed us to conclude that the soma itself is capable of supporting a regenerative action potential (AP). The soma also supports repetitive firing, with applied transmembrane current. In our best experiments overshoot-to-undershoot values of APs are 80 mV and firing frequencies, to applied currents, are as high as 8 spikes/sec (14°C). The specific membrane resistance and specific capacitance of ∿60 µm diameter BCs (without neurites) are approximately 30,000 $\Omega.cm^2$ and 0.5 $\mu F/cm^2$. The surface receptors of BC neurons are being explored with iontophoretic applications of various transmitter candidates. We find that many BCs respond to serotonin (creatinine sulfate) with depolarization and in those BCs with APs serotonin may cause firing.

646 SITES OF ACTION OF THE POLYPEPTIDE EGG-LAYING HORMONE (ELH) IN THE HEAD GANGLIA OF APLYSIA CALIFORNICA. Duncan K. Stuart and Felix Strumwasser (SPON: C. A. G. Wiersma). Division of Biology, California Institute of Technology, Pasadena, CA 91125.

ELH is a polypeptide of about 6,000 m.w. synthesized in the bag cell neurons of the abdominal ganglion of Aplysia. When injected into an animal, ELH induces egg-laying along with characteristic behaviors, such as a nodding and weaving motion of the head as the eggs are attached to the substratum. It is not known whether these behaviors are mediated by a direct effect of ELH on the nervous system, by a secondary factor(s), and/or by a reflex response to the eggs' extrusion.

We have shown that a suppression of feeding occurs during egg-laying, as previously shown in Pleurobranchaea by Davis et al. At 20°C, starved Aplysia (n=7) injected with bag cell extract stopped eating a 1 gm piece of red algae at 17+4 min post-injection and their eggs first appeared at 29+4 min. Six of seven controls, injected with head ganglia extract, ate all their algae.

We have also studied the effect of ELH in vitro on the isolated buccal ganglia, which control the feeding movements, and on the combined head ganglia (buccal, cerebral, pleural, and pedal). ELH applied to the paired buccal ganglia activates a pair of neurons into a tonic pacing mode (∿1 spike/sec). These neurons each have an ipsilateral axon in buccal nerve 3. At 20°C, this effect is apparent between 5 and 10 min after addition of ELH to the chamber. By 15 to 25 min their rate of firing, as recorded from each buccal nerve 3, reaches a maximum. The correlation between this 15-25 min period and the time at which Aplysia, injected with ELH, stop feeding suggests that this pair of neurons may be exciting buccal muscles which retract the feeding apparatus or inhibiting others which protract it.

ELH also increases the rate of firing of a second pair of buccal neurons (∿10 spikes/min before to ∿30 spikes/min after), each with an ipsilateral axon in the cerebro-buccal connective.

When applied to the head ganglia, ELH causes large bursts of neuronal activity in the pedal ganglia nerves to the foot, and increased activity in the nerve to the penis. These pedal nerve effects may relate to changes in locomotion or the head weaving movements that occur during egg-laying.

These above neuronal effects were produced either by ELH released from activated bag cells in disconnected abdominal ganglia, then fractionated by gel filtration, or by ELH partially purified (in collaboration with Arlene Y. Chiu and Eri Heller) using ammonium sulfate precipitation, an anion exchange column, and gel filtration. The results suggest that at least some of the characteristic behavior during egg-laying is mediated by a direct, hormonal effect of ELH upon the nervous system.

647 PLASTICITY OF FEEDING IN THE OPISTHOBRANCH MOLLUSC NAVANAX INERMIS. A.J. Susswein* and M.V.L. Bennett (SPON: I. Kupfermann). Division of Cellular Neurobiology, Department of Neuroscience, Albert Einstein College of Medicine, Bronx, N.Y.10461

Several forms of plasticity of feeding behavior were investigated in Navanax. Navanax is a carnivore which ingests prey with suction caused by rapid pharyngeal expansion. Swallowing movements then move prey into the esophagus. Feeding is little affected by handling or posture, and is more resistant to noxious stimuli than in some other gastropods. By contrast, ingestion is readily affected by recent feeding history: 1)Arousal. Feeding latency is decreased following exposure to food. 2)Habituation. Repeatedly eliciting feeding responses and then rapidly withdrawing the prey causes a gradual increase in response latency dependent upon the rate of prey presentation. The latency increase is not due to motor fatigue, as shown by dishabituation with an alternate prey species. 3)Satiation. Continued feeding causes increased latency and eventual cessation of feeding after a mean weight gain of 42.5% of initial animal weight (N= 12). Effects of satiation remain after the gut has emptied, suggesting that gut distension does not alone account for satiation.

When presented with food too large to swallow whole, Navanax either ceases to respond after a few presentations, or maintains suction on the partially swallowed prey for several days while digesting the more deeply engulfed portion. Switching between rejection and maintained suction is due to activation of mechanoreceptors in the posterior pharynx, as shown by similar switching produced with non-prey, neutral objects. This behavior persists in animals in which the buccal ganglia are surgically isolated from the rest of the C.N.S. Since the neurophysiology of the buccal ganglia has been extensively studied, the behavioral switching in the isolated buccal ganglia is an attractive preparation for neurophysiological study.

648 PRESYNAPTIC ACTION OF GLUTAMATE AT A CRAYFISH NEUROMUSCULAR JUNCTION. M. THIEFFRY* AND J. BRUNER* (SPON: H. KORN). Laboratoire de Neurobiologie cellulaire du C.N.R.S., 91190 - Gif-sYvette and Laboratoire de Neurobiologie, Université de Picardie, 80039 - Amiens, France.

It is largely admitted that glutamate depolarizes crustacean muscle fibers by acting on muscle membrane receptors. However, in recent work we could demonstrate that "acute denervation" induced by isotonic calcium[1] strongly depressed the glutamate response of fast abdominal flexors of crayfish Procambarus clarkii. This observation which is in favour of a presynaptic action of glutamate, previously suggested by other authors[2] was further supported by a direct demonstration of the sensitivity of terminals to glutamate.

To this end, small axonal branches were impaled close to the point where they penetrate between muscle fibers. Another intracellular electrode was inserted into a muscle fiber at about 500 µm from the site of intra-axonal recordings.

Bath application of glutamate (0.1mM) depolarized both the muscle fiber and the axon by about 20 mV. Glutamate ionophoretically applied on to the axon far enough from the muscle still induced the response in the axon thus implying the existence of glutamate receptors on the axonal membrane.

The presence of such receptors in the vicinity of nerve terminals was further demonstrated by ionophoretic injection of glutamate on the sensitive spots of the muscle membrane. In those conditions depolarizing responses were simultaneously recorded in the muscle fiber and in the axon. Both responses disappeared when the glutamate electrode was moved from the sensitive spot.

The above observations, together with the fact that other procedures can lead to a blockade of the glutamate response with unmodified sensitivity of the post-synaptic membrane to the natural transmitter, suggest that the glutamate response of the muscle fiber could be mediated partially, by a presynaptic mechanism (supported in part by an I.N.S.E.R.M. grant n° 387670).

649 THE NATURE OF MULTIPLE α-BUNGAROTOXIN BINDING COMPONENTS IN THE BRAIN OF LIMULUS POLYPHEMUS. W. Eric Thomas* and James G. Townsel (Sponsor: John S. Thomas) Departments of Biochemistry and Physiology, Meharry Medical College, Nashville, Tennessee 37208

The binding of ^{125}I-αbungarotoxin to membrane fragments prepared from Limulus brain tissue has been reported (Thomas, et al., 1978, Arch. Biochem. Biophys. 187:53). The kinetics of toxin binding indicate multiple binding sites. However, the nicotinic cholinergic ligands d-tubocurarine and nicotine greatly inhibited toxin binding at a concentration of 10^{-5}M. Sucrose gradient sedimentation of solubilized toxin binding activity revealed the presence of three toxin binding components. The presence of multiple toxin binding components raises doubts as to the specificity of α-bungarotoxin binding in this preparation. Therefore, the nature of the three toxin binding components from Limulus brain tissue has been investigated by sucrose gradient sedimentation.

The three toxin binding components have sedimentation coefficients of 9.0S, 15.4S and 17.4S. All three components were degraded by chymotrypsin. The total toxin binding activity of the solubilized extract was inhibited 72.1%, 46.8%, 8.5% and 0% by 10^{-5}M d-tubocurarine, nicotine, scopolamine and pilocarpine, respectively. Phenylmethylsulfonylfloride and ethylenediaminetetracetate diminish the amount of the 9.0S component with a corresponding increase in the 15.4S and 17.4S components. Isolation of the 9.0S component, followed by addition to brain extract, resulted in the formation of the 15.4S and 17.4S components. Addition of isolated fractions of either the 15.4S or 17.4S components to brain extract led to the production of the 9.0S component. These findings suggest that the 15.4S and 17.4S components are separate proteins and that the 9.0S component is a subunit common to both and is the site of α-bungarotoxin binding. Thus, the binding of α-bungarotoxin in Limulus appears to be specific.

650 THE RESPONSES OF CERCAL RECEPTORS AND IDENTIFIED INTERNEURONS IN THE CRICKET (ACHETA DOMESTICUS) TO AIR STREAMS. Martha Tobias* (SPON: H.V.B. Hirsch) SUNY at Albany, Albany, N.Y. 12222

In this study, the cricket cercal to giant interneuron pathway in response to air stream stimulation was examined. The physiology of cercal displacement receptors (filiform hairs), as well as the directional sensitivity of the medial and lateral giant interneurons was characterized.

Intracellular recordings from filiform hair afferents revealed that the sensory neurons are excited when deflected in one direction, and inhibited when deflected in the opposite direction. Each filiform hair is associated with a single sensory neuron. There are two morphological classes of filiform hairs, with planes of movement oriented transversely (T-hairs) or longitudinally (L-hairs), with respect to the long axis of the cercus. I have divided each class of filiform hairs into two physiological types. T-hair afferents are composed of two populations, with preferred directions toward, or away from, the midline. Similarly, L-hair afferents are composed of two populations, with preferred directions toward, or away from, the body.

The directional sensitivity of the giant interneurons in response to air stream stimulation reflects differences in the strengths of excitation from the four receptor types described. Each member of the bilateral pair of giant interneurons elicits peak responses when air streams are directed ipsilateral to the giant interneuron's ascending axon. Furthermore, they are most responsive to ipsilateral T-hair sensory neurons excited by movement towards the midline, and ipsilateral L-hair sensory neurons excited by movement toward the body.

The directional responses of the giant interneurons to air stream stimuli were distinct from those previously obtained in response to acoustic stimuli. Directional responses of the giant interneurons to acoustic stimuli, resulted in a weak excitation when stimulating T-hairs. In contrast, the magnitude of response to air stream stimulation of either T-hairs or L-hairs is the same, suggesting an equal strength of excitation from both classes onto the giant interneurons.

The unidirectionality of the sensory neurons, as well as the circuitry from filiform receptors onto the giant interneurons, described in this study, are distinguishable only when a unidirectional stimulus, such as air streams, is employed. Supported by NSF research grant BNS 752345 A01 to R.K. Murphey.

651 PHARMACOLOGY OF PRESYNAPTIC FACILITATION OF THE GILL-WITHDRAWAL REFLEX IN APLYSIA. Thomas K. Tomosky-Sykes. Div. Neurobiol. & Behav., Dept. Physiology, P&S, Columbia Univ., New York, N.Y.10032

Various lines of evidence suggest that 5-HT may be the neurotransmitter mediating facilitation of the gill-withdrawal reflex in Aplysia. For example, of the three compounds (5-HT, octopamine, and dopamine - Cedar & Schwartz, J.Gen.Physiol. 60:570, 1972) known to increase ganglion levels of cAMP (which is also implicated in mediating facilitation) only 5-HT caused facilitation of the monosynaptic EPSP from gill and siphon sensory neurons to the motor neurons (Brunelli et al., Science, 194:1178, 1976). Both 5-HT and connective stimulation broaden the action potential in the sensory neuron by increasing Ca^{++} influx - a mechanism believed to underlie facilitation (Klein & Kandel, Abstract, Soc. for Neurosci., 1978).

I have tested the selectivity of the sensory neuron action potential broadening effect to determine other possible candidates for the facilitating neurotransmitter. Twenty-four putative transmitters have been examined, including the common monoamines, amino acids and derivatives, carbachol, adenosine, and ATP. The drugs were bath applied to a final concentration of 1 x 10^{-4}M in artificial sea water containing 10 mM tris buffer (pH 7.6) and 100 mM TEA (tetraethylammonium chloride). TEA was used to eliminate delayed rectification and make the effect of an increased Ca^{++} influx easy to measure.

The results indicate that only 5-HT and 6-HT cause significant increases in spike width. For example, 5-HT prolonged the sensory neuron action potential from a half-width of 15-30 msec to one of 125-300 msec. 6-HT was somewhat less effective, prolonging the action potential to 90-95 msec. In contrast, all other drugs produced either no increase or only inconsistent small increases (generally less than 50%) in spike width.

These data indicate that of the drugs examined, 5-HT is the most likely candidate for the facilitating transmitter. However, since more exotic amines or peptides were not examined, direct biochemical evidence is still needed to support this hypothesis.

An additional finding is that dopamine decreases the sensory neuron spike width. This suggests that this neurotransmitter may perhaps be involved in presynaptic inhibition at this synapse. Advokat et al. (Abstract, Soc. for Neurosci., 1976) have recently found that arousal by food produces attenuation of siphon withdrawal by an as yet unknown mechanism. It is attractive to think that this attenuation may be mediated by presynaptic inhibition of the sensory neurons, perhaps by dopamine.

652 SPONTANEOUSLY ACTIVE MOLLUSCAN NEURONS: SPIKE INITIATION ZONE LIES IN AXON. Steven N. Treistman. Department of Biology, Bryn Mawr College, Bryn Mawr, PA 19010.

Spontaneously active molluscan neurons have been thought to differ from other molluscan neurons, in that their pacemaker and spike initiation zones lie in the cell body membrane, rather than in an axonal site. The major lines of evidence for this conclusion were drawn from studies in which the cell bodies of spontaneously active cells were isolated by either ligation or enzymatic dissociation from their axons, and still exhibited patterned spike outputs.

By recording simultaneously from cell body and axon of intact pacemaker neurons R15, and left upper quadrant cells of Aplysia, I have found that the spike is initiated in the axon of these cells. This conclusion is based upon both the sequence and the rate of rise of the spikes in the two regions. Thus, in the intact cell, spike initiation occurs in the axon, and pacemaker neurons do not appear to differ from other cells in this respect. (This work was supported by NSF grant BMS 77-01548).

653 IDENTIFICATION OF MOTOR NEURONS MEDIATING OPALINE SECRETION IN APLYSIA CALIFORNICA. Susan Tritt* and John H. Byrne (SPON: G. Fromm) Dept. of Physiology, School of Medicine, University of Pittsburgh, Pittsburgh, Pa., 15261.

In response to noxious stimuli Aplysia californica characteristically releases two substances, ink and opaline, which are believed to act as defensive mechanisms against potential predators (Eales, 1921). Whereas there is now a fairly good understanding of the neural control of inking behavior (Carew and Kandel, 1977) little is known regarding the control of opaline secretion. Using a combined morphological and electrophysiological approach we have now identified cells which make a large contribution to the motor component of this behavior.

Electrical stimulation of tegumentary nerve 7 which innervates the region of the opaline gland (Eales, 1921) produced massive contractions of the opaline gland. Cobalt back-filling of the proximal end of this nerve resulted in the staining of a large number of cell bodies in the right pedal ganglion and three approximately 150 u diameter cell bodies in the right pleural ganglion. Intracellular recordings from the region of the stained cell bodies, revealed cells which could be antidromically activated by electrical stimulation of tegumentary nerve 7. Intracellular stimulation of the pedal ganglion cells primarily resulted in movements of the body wall near the gland, while stimulation of cells in the pleural ganglion produced marked contraction of the opaline gland itself. Like the motor neurons in the abdominal ganglion which mediate inking behavior, the pleural ganglion cells have relatively high resting potentials and are normally silent with occassional background subthreshold EPSPs. Another similarity between the ink motor neurons and those mediating opaline secretion is that the opaline motor neurons are electrically coupled with a coupling ratio of about 0.3. A train of electrical stimuli to the right pleural-abdominal connective produces large summating EPSPs in the opaline gland motor neurons which cause the cells to fire and lead to contraction of the opaline gland. Hyperpolarizing a single motor neuron can block spike activity produced by connective stimulation and reduce the gland contractions by up to 90%. Similarly firing individual neurons with intracellular current pulses to mimic firing rates produced by connective stimulation results in comparable glandular contractions, indicating that these identified neurons make a large contribution to the motor component of this behavior. The identification of cells mediating opaline secretion makes it possible to compare the neural circuits and biophysical properties of neurons mediating two similar behavioral responses to adversive stimuli. Supported by NIH grants NS13511 and NS00200.

654 SYNAPTIC INTERACTIONS BETWEEN MOTORNEURONS OF ASCARIS. J.P. Walrond*, J.E. Donmoyer*, P.A. Desnoyers*, and A.O.W. Stretton. Dept. of Zool., Univ. Wisconsin, Madison, WI 53706

Our investigation of the nervous system of the nematode Ascaris lumbricoides has employed a combination of anatomical and physiological techniques. The shapes of neurons which comprise the ventral and dorsal nerve cords have been completely reconstructed from serial 10µm sections in the light microscope. Criteria for identifying synapses in the light microscope have been developed and confirmed by examining selected sections containing putative synapses in the electron microscope. The neurons are divided into seven classes, based solely upon shape (Stretton et al., 1978 P.N.A.S.). Synapses between each of the 7 neuronal types and muscle have been identified. In the dorsal and ventral nerve cords, neurons communicate with one another through en passant synapses. In the dorsal cord, the excitatory motorneurons (DE1, DE2, and DE3) synapse directly onto the ventral inhibitory motorneurons (VI) while in the ventral cord the presumed ventral excitatory motorneurons (V-1 and V-2) synapse onto the dorsal inhibitors (DI). In the ventral nerve cord six neurons extend the entire length of the animal. They do not contact muscle, but synapse onto the excitatory motorneurons.

The synapses between the dorsal excitors and the ventral inhibitory dendrite have been investigated electrophysiologically. Activation of the dorsal excitor produces a depolarization in the dorsal musculature followed by a hyperpolarization in the ventral musculature. Stimulating various combinations of dorsal excitors and ventral inhibitors has produced a map of the synaptic interactions between dorsal excitors and ventral inhibitors.

By stimulating a single intact neuron and recording intracellularly from muscle cells along the length of the dorsal cord, the conduction velocities of each of the dorsal cord excitors has been found to be 25 cm/sec. The muscles send arms to the nerve cord where they have electrical synapses with one another in a region called a "syncytium". This arrangement permits the conduction of an action potential through the syncytium. Recordings taken posterior to neurons whose processes extend anteriorly in the dorsal cord, demonstrate a conduction velocity of 12 cm/sec in the muscles. Since a wave of propagation moves along the body of an intact animal at about 1 cm/sec, we can rule out the simple model in which the velocity of propagation of an action potential along either an excitatory motorneuron or the syncytium corresponds to the velocity of propagation of a body wave. 655 CONFLICT AND RESPONSE SELECTION IN THE LOCOMOTOR SYSTEM OF APLYSIA. E.T. Walters,* T.J. Carew, and E.R. Kandel. Div. Neurobiol. & Behav., Depts. of Physiol. and Psychiat., P & S, Col. Univ., New York, N.Y. 10032

Locomotion in Aplysia californica is a complex centrally commanded motor sequence (Hening et al., 1977) which is modulated by a variety of internal and external stimuli (Kupfermann, 1968; Advokat et al., 1977; Weiss et al., 1977). We here explore the long-term consequences of noxious stimuli (which either facilitate or depress this motor program) on response selection in a subsequent "conflict" situation.

Aplysia respond to noxious stimulation with one of two defensive programs: a strong generalized withdrawal ("freezing"), or escape walking ("fleeing"). In order to obtain reliable stimulus control of walking we first examined the effect of the site of noxious stimulation on the immediate selection of a defensive program. In all experiments, walking was measured using a blind procedure. We found that animals receiving tail shock (N=16) rapidly began escape walking (median latency=21 sec), whereas animals receiving head shock (N=15) froze for several minutes, turned and only began walking after a significant delay (median latency=380 sec, $p < .001$). The head-group also walked more slowly than the tail-group ($p < .01$). Similar results have previously been described by Wachtel and Impelman (1973) who found that walking elicited by salt to a parapodium can be terminated by a noxious stimulus to the head region.

We next examined how previous experience with either head or tail shock affected the animal's long-term response selection in a "conflict" situation 24 hours later. The "conflict" stimulus was a compound stimulus consisting of a sequence of shocks applied alternately to the head and tail for 20 seconds. In response to the "conflict" stimulus control animals with no previous shock (N=16) began walking with a median latency of 140 sec. By contrast, animals which previously received tail shock walked significantly sooner (median latency=79 sec, $p < .05$) and those that received head shock walked significantly later (median latency=435 sec, $p < .002$) than controls. The groups also differed significantly in the amount of walking they exhibited ($p < .01$ and $p < .002$ respectively).

These results indicate that an identical "conflict" stimulus can produce opposite effects on escape walking depending upon the animal's past experience. Unlike sensitization of simple defensive responses such as gill and siphon withdrawal in Aplysia, which depend only upon the intensity and quality of the sensitizing stimulus, sensitization of escape walking, a more complex defensive behavior, can be specific to the history of previous stimulation to a particular site.

656 INTERNEURONS MEDIATING SPATIAL POSITION IN A COCKROACH. W. William Walthall and H. Bernard Hartman. Dept. of Biol. Sci., Texas Tech University, Lubbock, TX 79409.

The equilibrium receptor system for the cockroach Arenivaga consists of four interneurons, each excited by primary sensory neurons from one of four rows of tricholiths. Tricholiths are sensilla suspended from the ventrobasal region of the cerci, specifically adapted to signal information regarding the insect's spatial orientation.

Interneurons mediating spatial position are inactive when the insect is in the primary orientation. Displacements from that position evoke responses from one or two of the interneurons. These interneurons fire tonically to maintained displacements of the insect at other than primary orientation. In each instance, the frequency of firing and the rate of adaptation is proportional to the angular displacement. Physiologic analysis of their responses indicates that each interneuron independently responds to rotation in a different ca. 110° quadrant. Discharge from two interneurons occurs in regions where adjacent quadrants overlap, these being roll left and right, and pitch forward and backward. However, resolution of angular position to rotations within a quadrant is not possible due to the restricted area of overlap of the receptive fields, and the symmetry of the response patterns of each of the four interneurons.

Arenivaga is a burrowing insect unable to utilize orientation cues such as vision, differential limb loading and proprioception. The insect is nocturnal and "swims" through fine quasi-fluid soil which collapses about it and does not provide a firm foothold. The discrete equilibrium receptor system of the cerci is a particularly desirable adaptation. The employment of giant fibers to mediate this modality suggests that this information is of considerable importance in modulating locomotory behavior. Our physiologic results add support to the suggestion by Fraser (Nature 268: 523, 1977) that the cerci of cockroaches are equilibrium in function.

657 A HISTAMINERGIC SYNAPTIC POTENTIAL PRODUCED BY A VOLTAGE-DEPENDENT APPARENT DECREASE OF CONDUCTANCE IN THE METACEREBRAL CELL OF APLYSIA. K.R. Weiss, E. Shapiro*, J. Koester and I. Kupfermann. Div. Neurobiol. & Behav., Coll. P & S, Columbia Univ., N.Y., N.Y. 10032

The output of the metacerebral cell(MCC) to buccal muscle and central neurons has been extensively studied. We now report that the MCC receives an excitatory synaptic input from the multiaction, histaminergic neuron C2 (Weinreich et al., 1975; Weinreich, 1977; McCaman and McKenna, 1978). This input has a number of unusual characteristics. A brief train of spikes in C2 produced a smooth excitatory synaptic potential that could persist for up to 60 sec. On occasion, the EPSP was preceded by a brief hyperpolarization, but the present analysis is exclusively on the later EPSP. Our data suggest that the EPSP is chemically mediated and is monosynaptic. It was enhanced by solutions with high Ca++ and was depressed by high Mg++. It persisted in a solution of high divalent cations (Mg++ and Ca++) which raises the threshold of possible interneurons between C2 and the MCC. It could be enhanced by injection of TEA into C2 and by depolarization of C2. Finally, even in high Mg++, histamine produced a slow EPSP in the MCC. Hyperpolarization of the MCC decreased the size of the EPSP, and voltage clamp studies of the EPSP elicited by C2 and by bath application of histamine revealed that the EPSP is associated with an apparent decrease of membrane conductance. Furthermore, unlike conventional synaptic potentials, the conductance change is highly voltage dependent. At approximately -90 mV, the synaptic current and apparent conductance decrease is no longer present. Further hyperpolarization, however, does not invert the current. Steady-state I-V plots under voltage clamp conditions suggested that the MCC normally possesses a region of negative-slope conductance that is mediated by calcium, as evidenced by the fact that it is blocked by cobalt or calcium-free solution. The negative-slope is enhanced in the presence of histamine. We are currently studying the ionic basis of the synaptic current.

Our evidence indicates a number of similarities between the synaptic potential comprising an input to the MCC and the synaptic potentials resulting from the activity of the MCC itself. In both cases a biogenic amine is involved and the action is of a modulatory type involving long duration of action and voltage-sensitive ionic conductances. Previous data suggested that the modulatory synaptic actions of the MCC are specifically related to its role in modulation of biting responses during food arousal. The present evidence suggests that the synaptic actions of neuron C2 are appropriate for it to be part of the neural circuit that modulates feeding.

658 GIANT FIBER ASSOCIATED WITH MUSHROOM-BODY NEUROPILES IN AN INSECT BRAIN: A POSSIBLE ONE-CELL FEEDBACK LOOP. Mitchell J. Weiss. Department of Biology, Livingston College, Rutgers University, New Brunswick, NJ 08903.

The corpora pedunculata or "mushroom bodies" of insects are paired brain centers of elaborate structure, whose primary role may be the higher-level processing of complex antennal sensory information (J. Morph. 142:21, 1974). In the "short-horned" or acridid grasshoppers (order Orthoptera), these centers are well developed and include the usual major neuropilar subdivisions: a calyx region mounted upon a descending, stalk-like pedunculus, which bifurcates at its lower end into a medial beta lobe and a reascending alpha lobe. In a light microscopic study of reduced silver preparations from the acridid grasshopper Melanoplus femurrubrum, I have discovered a single giant neuron on each side of the brain which interconnects different subdivisions of the ipsilateral mushroom body.

The unipolar soma of each giant neuron is located laterally in the protocerebrum, near the base of the optic lobe. After traversing the cortical layer of neuronal somata, the neurite enters the protocerebral neuropile and extends to a point close to the lateral surface of the ipsilateral pedunculus. Here the fiber expands in a T-shaped fashion into a giant process, which extends both anteriorly and posteriorly from this point. The posterior extension ascends the surface of the pedunculus, meanwhile emitting branches into it. At the top of the pedunculus the fiber ramifies widely into the "primary calyx" of the calyx region. The anterior extension of the giant process passes anteriorly and begins to bifurcate repeatedly in the general protocerebral neuropile. These branches enter the alpha lobe, in which they ramify. Adjacent to the pedunculus the giant process is flattened, with a typical width of 20-32u; the thickness varies in approximately inverse proportion from ca. 4.4u to as much as 10-15u. Although at least one minor branch of the neuron does not enter the mushroom body, the giant process connecting calyx (and pedunculus) with the alpha lobe clearly seems to represent the main conduction pathway within the neuronal tree. Similar giant neurons have been found in Schistocerca and other genera and apparently typify the entire family.

Conduction within a mushroom body is believed to extend from the calyx region (which receives the inputs) down the pedunculus and along the alpha and beta lobes (whose connections are believed to be efferent). The giant neuron may bring information from the alpha lobe back into the calyx region and thus form a striking one-cell feedback loop for the mushroom body.

659 EXCITATION OF CYCLICALLY PATTERNED FEEDING MOTOR OUTPUT BY CONSTANT CURRENT INTRACELLULAR STIMULATION. A. O. D. Willows. Friday Harbor Laboratories, Univ. of Wash., Friday Harbor, WA 98250.

The roles of various re-identifiable neurons in the brain and buccal ganglia of the mollusk Tritonia diomedea in the control of feeding behavior were determined using intact or isolated buccal mass, buccal ganglia and brain preparations. In addition to motor neurons driving various aspects of movements of the jaws, radula and odontophore, a group of interneurons were found which exert powerful, direct control over the co-ordinated output of the entire system. Brief (less than 2 s.) stimulation of particular individuals within this group of interneurons released single, co-ordinated cycles of impulse bursts in motor neurons lasting 10-20 s. These single cycles ressembled closely the cycles of impulse bursts seen in these same neurons during feeding movements. Similarly brief stimulation of other neurons in this group using differing current strengths elicited shorter or longer series of feeding motor output cycles depending upon current strength. A third class of these interneurons acted to drive feeding motor output so long as the constant current stimulus was maintained. In this last mentioned case, the duration of the cyclic output was strictly dependent upon the duration of the interneuronal stimulation whilst the frequency of the bursts in the motor output was nearly independent of the stimulus strength over a wide range. During spontaneously occurring feeding movements, the cyclic motor output (and the behavior) could be blocked, or reset by the application of hyperpolarizing currents to these interneurons.

It was found that these interneurons were electrically coupled to certain of the motor neurons, and in a few cases, connected by chemically mediated synaptic contacts as well.

It was observed also that sinusoidally varying subthreshold depolarizing currents in certain of the interneurons were capable of eliciting spikes in other neurons of the motor system. Thus spikes in the interneurons may not be essential to driving the motor output. The implication is that these interneurons are somehow closely associated with the motor pattern generator for feeding. They do not however exert exclusive control over that generator since other experiments indicate that feeding motor output can be elicited via routes independent of these interneurons.

660 EFFERENT INHIBITION OF THE LOCUST MOVEMENT DETECTOR SYSTEM DURING OPTOMOTOR NYSTAGMUS. Malcolm D. Zaretsky* (SPON: C.H.Fraser Rowell). Dept. Zoology, Univ. of California, Berkeley, CA 94720.

In the movement detection system of the locust, the lobula giant movement detector neuron (LGMD) and its post-synaptic cell, the descending contralateral movement detector neuron (DCMD), respond best to stimuli of small area in their 180 degree visual field. Rapid turning of the head with respect to the thorax by the locust is invariably associated with strong inhibition of the locust movement detector system. Chronic simultaneous single unit recordings from the DCMD and dorsal neck muscles of a tethered but otherwise freely moving locust demonstrate that this inhibition is of efferent origin. Inhibition occurs regardless of whether head movements are of optomotor or spontaneous origin.

Proprioceptive information is not required for inhibition of the DCMD response during head movement. Head turning movements are invariably preceded and accompanied by a burst of spikes from muscle 51 on the side ipsilateral to the direction of head turning. Inhibition of the DCMD persists during each burst of muscle spikes and 200-300 msec beyond regardless of whether the head is allowed to move or is prevented from moving by fixing it to the thorax. Head movements do not occur when the muscle firing rate is low, and the response of the DCMD is not inhibited when the muscle fires at a low rate, suggesting that a command for head movement is responsible for efferent inhibition of the DCMD.

The efferent inhibition of the movement detector system is distinct from two inhibitory mechanisms of visual origin which allow for discrimination of small field stimuli: (1) Feed-forward inhibition to the LGMD posterior to the site of convergence of the afferent pathway, produced by large field stimuli and (2) lateral inhibition presynaptic to the dendritic arborization of the LGMD which suppresses large field stimuli and reduces habituation at the excitatory afferent-LGMD synapses (O'Shea and Rowell, NATURE 254:53, 1975; Rowell, O'Shea and Williams, J. EXP. BIOL. 68:157, 1977).

It is biologically necessary for an animal to avoid confusion between changes in visual contrast generated by its own eye movements and those generated by moving objects. These results suggest that efferent inhibition serves this function in the locust movement detector system.

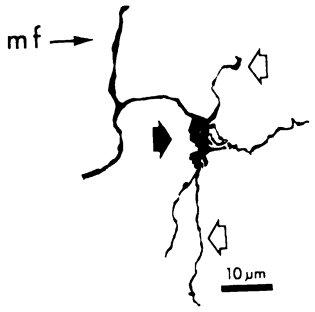
661 CALCIUM SENSITIVITY OF THE ULTRA-SLOW POTASSIUM CURRENT UNDERLYING ADAPTATION IN APLYSIA NEURONS. K. L. Zbicz* and W. A. Wilson. Dept. Pharmacol., Duke Univ. Med. Ctr., Durham, N. C. 27710 and Epilepsy Ctr., V. A. Hospital, Durham, N. C. 27705.

Certain neurons of Aplysia californica, notably R2 of the abdominal ganglion and the giant cell of the left pleural ganglion, adapt to prolonged electrical stimulation. The decrease in firing rate with time is mediated by a slowly developing potassium current which is activated when the cells are depolarized beyond approximately -50 mV. The rate of development of this current and rate of adaptation are enhanced by low concentrations of barbiturate (Cote, Zbicz, and Wilson, Nature, in press). We now report that this potassium current is calcium dependent. Exposure of these cells to low calcium or calcium free solutions reduces or abolishes the slow potassium current. In calcium free solutions, the normal tendency of the cells to adapt to electrical stimulation is lost and the cells respond to stimulation with rapid rates of firing which are occasionally interrupted by periods of prolonged depolarization. Elevation of extracellular calcium enhances the development of the slow potassium current and decreases the excitability of the cells. The metabolic inhibitor 2,4-dinitrophenol enhances the development of the slow potassium current and the tendency of the cells to adapt in a manner similar to that seen with barbiturate.

LIMBIC SYSTEM

662 SYNAPTIC EXTENSIONS FROM THE MOSSY FIBERS IN THE HILUS OF THE FASCIA DENTATA. D.G. Amaral and M.A. Connelly. Dept. Anat. and Neurobiol., Washington Univ. Sch. Med., St. Louis, MO 63110.

In an earlier Golgi study which dealt primarily with the cell types in the hilar region of the rat hippocampus, occasional filamentous extensions were observed extending from the *en passant* swellings on the axons of the dentate granule cells, usually referred to as mossy fibers. These extensions, ranged in length from about 1 µm to 30 µm, were often branched, and appeared to contact the processes of various cell types in the hilar region. As shown in the drawing below, mossy fibers (mf) give rise to *en passant* swellings (filled arrow), sometimes by way of a short collateral branch. These swellings, in turn, give rise to several filamentous or clavate extensions (open arrows). In the 28-day-old rat, there are between 4 and 9 such extensions from most mossy fiber swellings, and the total length of the extensions from any one swelling is of the order of 75 µm. Serial electron micrographs through both normal and Golgi-impregnated mossy fibers has confirmed that these extensions are, indeed, presynaptic processes; each contains one or more vesicle-rich foci along its length and associated with these are asymmetric membrane specializations where the extensions are in synaptic contact with dendrites and dendritic spines of as yet unknown origin. A quantitative analysis of these extensions in Golgi material from rats of different ages indicates that their length is greatest in young animals and declines through the first post-natal month. For example, although there is no difference in the mean *number* of extensions in 14- and 28-day-old animals, the combined length of the extensions per mossy fiber swelling is some three times greater in the 14-day-old brains.



663 CONVERGENCE OF INPUTS FROM LIMBIC AND MIDBRAIN AREAS UPON HYPOTHALAMIC NEURONS. S. Anschel, M. Alexander and A. A. Perachio Yerkes Reg. Primate Res. Ctr., Emory Univ., Atlanta, GA 30322

There is substantial neuroanatomical evidence for overlapping projections from the preoptic-anterior hypothalamic area (POA-AHA), lateral septal area (LS), amygdala, and midbrain to the mediobasal hypothalamus (MBH). Electrophysiological studies of MBH and preoptic neurons have demonstrated both converging afferent and diverging efferent connections with extra-hypothalamic areas (Renaud, L.P., J. Physiol. 264(1977), 541-564; Dreifuss, J.J. and Murphy, J.T., Brain Res. 8(1968), 167-176). The purpose of the present study was to determine the type and origin of converging projections that produce short latency, excitatory responses in single neurons in preoptic area, MBH, dorsal and posterior hypothalamus, and to identify antidromically the projection path of their axons.

A transpharyngeal approach to the basal hypothalamus was used in urethane-anesthetized male rats. Bipolar stimulating electrodes were placed on the surface of the median eminence and in limbic and midbrain sites. Approximately 700 hypothalamic neurons were tested. Of 380 cells which were responsive to single pulse (1 Hz) electrical stimulation, 99 were demonstrated to have multiple inputs. The projections of 20 of these neurons were determined by antidromic activation. Histological localization has been completed for 83 of these multiple-input neurons.

POA-AHA and cortical amygdala (ACO) convergence was observed primarily in MBH (n = 21). Of these neurons, three were antidromically identified to project to the midbrain. Converging inputs from LS and amygdala were detected in 26 preoptic and hypothalamic neurons. Eighty-one percent of these neurons were found in the MBH or preoptic area; five were antidromically activated by stimulation of POA (n = 2), midbrain (n = 2) and median eminence. In addition, two neurons, one each in the posterior hypothalamus and premammillary region, were orthodromically activated by stimulation of LS and ACO and antidromically driven by stimulation of POA. Half of the neurons that responded to stimulation of afferents from the midbrain (n = 20) converged with inputs from the amygdala or POA.

These findings demonstrate a major concurrence of afferents to the MBH from POA, LS, amygdala and midbrain. Furthermore, a number of neurons receiving these diverse inputs were found to project to extra-hypothalamic sites. These types of neurons might subserve integrative roles related to the multiple physiological and behavioral functions that have been attributed to the MBH.

664 HETEROSYNAPTIC MODIFICATION OF NEURONAL TRANSMISSION IN THE DENTATE GYRUS OF THE RAT. S.Y. Assaf*, and J.J. Miller, Dept. Physiology, University of British Columbia, Vancouver, B.C., Canada, V6T 1W5

Paired-pulse stimulation of the perforant path (PP) results in a short term potentiation of the extracellularly recorded population EPSP and population spike in the dentate gyrus. However, relatively little is known concerning the effects which extrinsic afferents to the dentate exert on these PP evoked population responses. The present investigation examined the excitability changes in these responses following conditioning pulses applied to the commissural-dentate projection. Laminar profiles of the characteristic field potentials and unit activity elicited by single pulse stimulation (1-7v) of the PP and commissural pathway (contralateral CA_3) were recorded from the dentate in urethane anaesthetized rats. The population spike evoked by the PP test stimulus was markedly enhanced (150-500%) when preceded by a conditioning stimulus to the commissural input, however the amplitude of the population EPSP was not significantly altered. The time course of the potentiation (20-300 msec) coincided with the period of inhibition of spontaneously discharging granule cells elicited by commissural stimulation. These effects were abolished by acute and chronic transection of the contralateral commissural pathway. On the basis of these data it may be suggested that potentiation of the population spike by a heterosynaptic input occurs in the absence of changes in synaptic current and that inhibitory mechanisms may underly this potentiation.

665 NEUROGENESIS AND MORPHOGENESIS IN THE RAT SEPTAL REGION. Shirley A. Bayer. Dept. Biol. Sci., Purdue Univ., W. Lafayette, IN 47907.

Neurogenesis in the rat septal region was examined autoradiographically on postnatal day 60 after exposure to 3H-thymidine on two consecutive days during both the embryonic (E13+14, E14+15,.. E21+22) and neonatal (The day of birth and postnatal day 1, P2+3, P3+4) periods. The percentage of labelled cells and the proportion of cells added during each day of formation were determined at several anatomical levels within each septal region nucleus. There were significantly different waves of neurogenesis within and between nuclei. The neurons of the midline nuclear group (diagonal band, medial, and triangular septal nuclei) formed between E13-17, the lateral septal nucleus between E15-19, the bed nuclei of the stria terminalis and anterior commissure between E14-18, the nucleus accumbens between E17-P2. All nuclei and nuclear groups showed characteristic gradients of formation. The earliest forming neurons of both the midline nuclear group and the bed nucleus of the stria terminalis were in the vicinity of the decussation of the anterior commissure; younger neurons were located both rostrally and caudally. The lateral septal nucleus formed along a strong mediolateral gradient, and the nucleus accumbens formed along a ventrodorsal gradient.

Morphogenesis of the septal region was examined in normal rat embryos from E10-22. The septal region was postulated to form from two separate anlage located in the telencephalon by E13 and E14. The anterior ventromedial telencephalic wall presumably forms the midline nuclear group and the lateral septal nucleus. A posterior ventrolateral telencephalic ridge presumably forms the bed nuclei of the stria terminalis and anterior commissure. On E15, the early differentiating cells in these anlage fuse in the same region where the anterior commissure will ducussate on E17. Later, cells accumulate rostrally, caudally, and laterally to the early fused area. In the anterior portion of the developing midline nuclear group, a prominent subependymal zone appears on E16 and E17, presumably to form the nucleus accumbens. A quantitative analysis was made of the developing septal region using matched sections from both normal and X-irradiated brains surviving 6 h. after a single exposure to 200 R. The radiosensitivity of the neuroepithelium decreased significantly after E19; the subependymal zone was highly radiosensitive throughout; the differentiating cell zone was radioresistant throughout. The significance of the morphogenetic findings is discussed in the light of the autoradiographic results. (Supported by NSF Grant #BNS 77-12622)

666 EFFECTS OF SEPTAL LESIONS ON THE RENAL SODIUM GRADIENT. Wail A. Bengelloun, Khadija Baddouri[x], and Mohamed El Hilali[x]. Dept. de Biol., Fac. des Sciences, Univ. Mohammed V, Rabat, Morocco.

Hyperdipsia subsequent to septal lesions was first described by Harvey and Hunt (1) in 1965. Several reports had suggested that serum sodium (Na) concentrations remained unaltered following septal lesions in rats (2,3). In the present study we attempted to establish whether this was also the case for renal and urinary Na concentrations. In particular, we hoped to determine the effects of septal lesions on the normal Na concentration gradient in the kidney. Our interest was justified by the reports that septal stimulation increases ADH levels in the blood (4), whereas ADH replacement eliminates septal lesion-induced polydipsia and polyuria (5). This latter finding suggests a lesion-induced decrease in ADH secretion (see also 6). Such an ADH deficit would be expected to diminish the renal cortico-medullary Na concentration gradient (7).

Water intake of septal and sham-operated rats was monitored starting at 1 wk prior to surgery and continued for 2 wks post-surgery. At 1 wk post-surgery rats were placed in metabolism cages to facilitate urine output measurement and collection. 1 wk later, rats were sacrificed by cervical fracture and kidneys removed for sectioning (7) into cortex, external medulla, and combined internal medulla and papilla. Na concentrations in urine and in renal samples were analyzed by flame photometry.

In accordance with previous studies, septal lesions resulted in pronounced hyperdipsia and polyuria. Urinary Na concentrations were however unaffected by septal lesions, irrespective of whether the urine was collected in metabolism cages or directly taken from the bladder at sacrifice. Similarly, Na concentrations in the renal cortex and external medulla of septal rats did not differ from operated control levels. In the combined renal internal medulla and papilla sample, however, septal rats exhibited a significant decrease in Na concentration relative to controls.

While this relative flattening of the renal Na concentration gradient is concordant with the ADH hypothesis, our data does not preclude other factors (see 7) being responsible for the observed effects. Our results therefore strongly suggest that a more complete examination of renal function in the septal rat is imperative to understanding the role of the septum in water intake.

667 RECIPROCAL ANATOMICAL CONNECTIONS BETWEEN HIPPOCAMPUS AND SUBICULUM IN THE RABBIT. Theodore W. Berger, Gerald W. Swanson*, Gary S. Lynch and Richard F. Thompson. Dept. of Psychobiology, Univ. of Calif., Irvine, CA 92717.

Horseradish peroxidase injections were made into the dorsal hippocampus of rabbit. Using the benzidine dihydrochloride method of development, orthograde and retrograde products were examined in the subicular cortex. A previously undescribed projection to hippocampus was seen to have its origin in dorsal prosubiculum and subiculum. Injections restricted to rostral levels of the dorsal hippocampus resulted in retrograde-filled cells first appearing in prosubiculum, several mm's posterior to the injection site. In more caudal sections, the retrograde field enlarges, extending medially and ventrally to include subiculum and limited areas of dorsal presubiculum. HRP-positive neurons were always seen contained within a well-circumscribed region of subicular cortex and were present following injections involving either hippocampal CA1 or CA3 cell fields.

Distribution of orthograde product first appeared at more caudal levels than retrograde-filled cells, and was regionally distinct from the retrograde field at rostral levels of the subicular complex. In anterior sections, labelled hippocampal terminals occupied the ventral-most part of the dorsal subiculum, near the ventricular surface. In more posterior regions, the density of orthograde product increased, as did the area over which terminals were distributed. Only in these caudal sections was considerable overlap seen between orthograde and retrograde fields, with labelled hippocampal terminals extending to subiculum and a significant portion of presubiculum. No orthograde product was ever seen in prosubicular or parasubicular areas. Finally, certain evidence indicated that cytoarchitectonic differences may exist with regard to hippocampal-subiculum projections. In total, the results strongly suggest a reciprocal, feedback anatomical relationship between hippocampus and subicular cortex.

668 EFFERENT CONNECTIONS OF THE POSTEROMEDIAL HYPOTHALAMIC NUCLEAR REGION OF THE PIGEON, COLUMBA livia. Mitchell L. Berk* (SPON: R. Adair). Dept. of Anatomy, The George Washington Univ., Washington, D.C. 20037.

The efferent projections of the rostral part of the posteromedial hypothalamic nuclear (PMH) region were determined by use of the autoradiographic technique. Iontophoretic injections of tritiated leucine were placed in PMH and the adjacent hypothalamic area of seven pigeons. Many heavily labeled fibers from PMH passed rostrally in the anterior hypothalamic area and entered the lateral preoptic area. Both the paraventricular nucleus, which lies ventral to the anterior commissure, and the medial preoptic nucleus received a moderate density of label. A few fibers passed dorsally into the lateral septal area, while grains were not found over the medial septal region. The density of grains, which occurred in the periventricular and dorsal portions of nucleus dorsomedialis anterior thalami, progressively decreased in nucleus dorsomedialis posterior thalami. Very few grains were seen in the stria medullaris and the lateral habenular nucleus. Fibers from the region dorsolateral to nucleus periventricularis magnocellularis were seen streaming dorsolateral to the occipitomesencephalic tract and entering nucleus dorsolateralis anterior thalami, pars magnocellularis (DLAmc). A few fibers passed laterally on the dorsal border of the ventrolateral thalamic nucleus and reached DLAmc ventrally.

A prominently labeled pathway coursed dorsolaterally from PMH towards, but not entering into, nucleus ovoidalis. At levels posterior to nucleus ovoidalis, these heavily labeled fibers projected laterally and densely innervated the substantia grisea et fibrosa periventricularis and nucleus intercollicularis of the midbrain. Label was also found in the central gray of the midbrain, extending posteriorly to the level of the Edinger-Westphal nucleus. Grains, concentrated medial to the lateral mammillary nucleus, continued posteriorly into the ventral tegmental area, lateral to the oculomotor nerve. Significantly, no grains appeared in the median eminence or in nucleus taeniae--archistriatum posterior and mediale, which are considered comparable to the mammalian amygdala, based on their projections to the medial hypothalamus (Zeier and Karten, 1971).

669 EFFECTS OF ELECTRICAL STIMULATION OF THE AMYGDALA UPON THE EXTENT OF THE TRIGEMINAL SENSORY FIELD PRESENT DURING ATTACK BEHAVIOR IN THE CAT. C.H. Block*, A. Siegel, and H. Edinger. Departments of Neurosciences and Physiology, College of Medicine and Dentistry of New Jersey-New Jersey Medical School, Newark, New Jersey 07103.

It has been clearly demonstrated that trigeminal somatosensory input from the region of the lipline constitutes an important element for the occurence of the quiet biting attack response in the cat (MacDonnell and Flynn, 1966). It has also been shown that the amygdala exerts a powerful modulatory role upon this form of aggression (Egger and Flynn, 1963). The present study was undertaken to determine whether amygdaloid control of attack behavior is manifested through its regulation of the sensory fields supplied by the trigeminal nerve or upon motor components associated with this response.

Electrodes for stimulation and recording were implanted bilaterally into the amygdala and hypothalamus under aseptic conditions in cats. Postoperatively, stage I of the experimental procedure consisted of identifying sites in the amygdala which significantly modulated ($p<0.05$) hypothalamically-elicited quiet biting attack. In stage II of the experiment, the lateral extent of the lipline that, when probed, could elicit the jaw opening component of the attack response was determined for a given intensity of hypothalamic stimulation. Subsequently, the effect of dual stimulation of the amygdala and hypothalamus upon the "effective" extent of the lipline was determined.

The results indicate that sites in the amygdlala which significantly inhibited quiet attack also significantly reduced ($p<0.01$) the lateral extent of the lipline from which jaw opening could be generated. Other observations suggest that the amygdala does not significantly modulate motor components of the attack response. For example, latencies to initial movement during the attack sequence following either single stimulation of the hypothalamus or dual stimulation of the amygdala and hypothalamus were not significantly different ($p>0.1$). Further, latencies to jaw opening following midline probing of the lip were not significantly different when compared under conditions of single and dual stimulation ($p>0.1$).

It thus appears that amygdaloid modulation of the attack response is achieved, in part at least, through its effects upon the sensory component of this behavior.

670 HIPPOCAMPAL INFLUENCE ON AFFECTIVE COMPONENTS OF FEMININE SEXUAL AND AGGRESSIVE BEHAVIOR IN THE RAT: DORSAL-VENTPAL DISTINCTIONS. William R. Cameron, Fred H. Gage, III, Cheryl L. Boedeker* and John C. Hitt. Chemistry of Behavior Program, Dept. of Psychology, Texas Christian University, Fort Worth, Texas 76129.

Recent research has revealed that limbic structures (i.e., septal area & hippocampus) exert modulatory influence on feminine sexual behavior. In addition neuroanatomical, neurochemical, electrophysiological, and behavioral studies all indicate that the hippocampus may be both, functionally and structurally organized along a dorsal-ventral axis.

On the basis of this information, we assessed the influence of the hippocampus on feminine sexual and aggressive behaviors focusing on dorsal-ventral distinctions in mediation of these behaviors. Bilateral radio-frequency lesions were made in either the anterodorsal (DHL) or posteroventral (VHL) aspects of the hippocampal formation of ovariectomized rats. Sham-lesioned and unoperated rats served as controls. In the first phase of the study, subjects were tested with varying dosages of estrogen alone and then retested with a combination of estrogen and progesterone 6 hrs. later. The second phase consisted of testing the subjects under varying dosages of progesterone with estrogen held constant. Measures of lordosis, rejection, soliciting and aggression were taken.

Lesions of the anterodorsal and posteroventral hippocampus had differential effects on feminine sexual behavior. DHL animals displayed a lower probability and intensity of lordotic behavior than controls on both pre-and post-progesterone tests. Soliciting was also decreased in post-progesterone tests. The DHL animals also displayed little active rejection of the male and little fighting behavior. Conversely, the VHL animals demonstrated heightened probability and intensity of lordosis in both pre-and post-progesterone tests, although the most dramatic effects were in the post-progesterone tests. Soliciting was also somewhat decreased. Additionally, the VHL animals showed increases in active rejection of the male and increases in fighting behavior. Moreover, the VHL animals were reactive to touch by both the male rats and the experimenter.

The results suggest that the dorsal and ventral hippocampus have differential input into the diencephalic structures mediating feminine sexual and aggressive behavior. This input may best be characterized as mediating an affective component of female sexual and aggressive behavior.

671 OESTROGENIC INFLUENCES ON THE ELECTRICAL ACTIVITY OF THE OLFACTORY PATHWAY. L. Cartas-Heredia*, R. Guevara-Aguilar and H.U. Aguilar-Baturoni. Departamento de Fisiologia, Facultad de Medicina, U.N.A.M., Mexico.

The influence of the oestrogenic hormones over the spontaneous and induced activity of the olfactory pathway was studied in normal female cats. Electrodes were placed chronically or acutely in the olfactory bulb (OB), olfactory tubercle (OT) and in the prepyriform cortex(PPC). Oestrogenic hormones were applied locally in the posterior hypothalamic region. Recordings were made during the two different phases of the oestral cycle. In addition, another group of castrated animals was studied. The oestral phase was induced in these cats by the subcutaneous administration of 17-ß-oestradiol. Results indicate that the pattern of the electroencephalographic spontaneous activity as well as the response induced by hypothalamic stimulation changed. The number of the "bursts" for each 10 sec of trace, was higher in oestrus than in anoestrus for all the structures studied. The duration of each burst also changed, being shorter in oestrus than in anoestrus cats. The threshold for significant bursting in the olfactory structures following hypothalamic stimulation was lower in oestrus than in anoestrus. The evoked potentials recorded in the same 3 olfactory structures by hypothalamic stimulation exhibited changes in correlation with the hormonal administration. In all the structures studied the amplitude of the different components of the evoked potentials increased immediately after the hormones were administered. However the most dramatic increase was observed in the olfactory tubercle. In order to further investigate these changes in acute preparations, a study evaluating the excitability changes was conducted. Applied pulse pairs, with different interpulse intervals between 200 to 1000 m sec were delivered in the hypothalamus before and after 200 γ of the hormone were administered into the posterior hypothalamus. Results illustrated that a significant increase in the amplitude of evoked potentials occurred following the smaller interpulse intervals in the OB. In the OT, the administration of the hormone resulted in a decrease in the amplitude of the potentials for all interpulse intervals studied. A relatively smaller decrease in evoked potential amplitude was observed for longer interpulse intervals in the PPC.

672 NON-PYRAMIDAL LAYER PROJECTION NEURONS OF HIPPOCAMPUS. Robert B. Chronister. Dept. Anat. Sch. Med., Univ. S. Ala., Mobile, Ala. 36688

With the advent of the axoplasmic transport methods, the understanding of hippocampal hodology has changed considerably. Emphasis has shifted from the CA fields to subiculum. Throughout this research appears to be the assumption that only cells within the stratum pyramidale project out of hippocampus. This view has been buttressed by the recent observations (Ribak et al, 1978) that GAD positive neurons exist in stratum oriens and radiatum of hippocampus. No comment has been made concerning the total distribution and number of these GAD positive neurons.

In order to ascertain the distribution of projection neurons in hippocampus, discrete injections (0.02-0.05µℓ) of horseradish peroxidase were made in the various regions of the septal complex in adult Sprague-Dawley derived rats. After a 36 hour survival time, the animals were prefused with dilute Karnovsky's fixative in phosphate buffer (pH 7.4). They were sectioned at 80µ and reacted with DAB. Examination of these sections revealed numerous HRP positive neurons in stratum oriens and the alveus. An occasional positive neuron was also found in stratum radiatum. Characteristically, the highest density of positive neurons were found in the regions of stratum oriens and the alveus of the fundus of the hippocampal fissure.

Examination of standard Nissl and Heidenhain sections of adult rat revealed that there are more neurons in stratum oriens and the alveus of CA2-CA3 than in the adjacent CA1 (especially CA1c). This distribution was even more pronounced in stratum radiatum. The neurons also characteristically were found in small cluster or islands of cells. The results of these studies indicate that neurons other than those in stratum pyramidale project outside the hippocampus. The HRP technique does not allow statements to be made of the the terminations of these efferents but the involved neurons clearly cannot be considered interneurons or short-axoned cells. Supported in part by an Intramural Research Grant from the College of Medicine.

673 THE ROLE OF ENTORHINAL CORTEX DURING CLASSICAL CONDITIONING: EVIDENCE FOR ENTORHINAL-DENTATE FACILITATION. Gregory A. Clark*, Theodore W. Berger, and Richard F. Thompson. Dept. Psychobio., UCI, Irvine, CA 92717.

Previous investigations[1,2] have demonstrated an early, rapid and substantial increase in hippocampal neuronal activity induced by a behavioral learning paradigm. While certain anatomical and electrophysiological evidence suggested the entorhinal-dentate synapse as a potential site of facilitation, the possibility remained that such increases in hippocampal neural activation merely reflected corresponding changes in preceding structures. In the present study, electrophysiological analysis of entorhinal cortex was coupled with simultaneous recordings from hippocampus during learning to discriminate between these two hypotheses.

Microelectrodes were implanted in the CA1 or dentate granule cell layers of the hippocampus and in layers II or III of entorhinal cortex of New Zealand white rabbits. Entorhinal and hippocampal activity were recorded subsequently during a classical conditioning paradigm in which a tone CS was associated with a corneal air puff UCS to evoke nictitating membrane extension.Unit activity and behavior were analyzed for 250 msec prior to CS onset (Pre-CS background period), 250 msec between CS and UCS onset (CS period), and for 250 msec following UCS onset (UCS period).

Results showed that, while entorhinal and hippocampal activity were similar within trial periods, recordings from hippocampus and entorhinal cortex proved markedly different across trials (that is, over the course of learning). Within trials, neuronal records from both structures exhibited a heightened neural discharge (compared to spontaneous rates) during the UCS period early in training--prior to behavioral conditioning. Unit discharges in both areas shifted into the CS period as behavioral conditioning developed. Across trials, however, entorhinal discharges remained constant or increased slightly, yet rapid and substantial increases occured in the magnitude of the hippocampal discharge. Such hippocampal neuronal increases cannot be accounted for solely on the basis of activity either in entorhinal cortex or, as previously reported[3], in medial septum (the other major afferent to the hippocampus). Thus, these findings suggest facilitation across the entorhinal-dentate synapse and indicate the initial locus of these learning dependent neural changes to be the hippocampus per se.

674 FINK-HEIMER STAINING FOLLOWING KAINIC ACID LESIONS: A NEW MODIFICATION OF AN ESTABLISHED TRACING METHOD. Timothy J. Collier,* Russell E. Ruth and Aryeh Routtenberg (SPON: R. Santos-Anderson). Cresap Neuroscience Laboratory, Northwestern University, Evanston, ILL 60201.

In tracing fiber systems emanating from a given anatomical locus, traditional electrolytic and chemical lesion techniques coupled with the Fink-Heimer silver staining method possess the drawback of damaging fibers traversing the area of the lesions, thus producing a degeneration pattern which combines fibers of passage and the degenerating system of interest. This problem can be circumvented through the use of autoradiographic tracing, using labelled amino acids and providing information about terminal fields and cells of origin. These methods do not, however, allow detailed tracing of the trajectory of fiber systems, nor do they provide data on the caliber and detailed pattern of terminal innervation of the fibers comprising the system of interest.

We propose that the use of kainic acid lesions in combination with Fink-Heimer silver staining of degenerating axons and terminals provides a method which is potentially as selective as autoradiographic tracing and horseradish peroxidase techniques, while, in addition, allowing detailed study of the course of the degenerating fiber system. Since local injections of kainic acid destroy nerve cell bodies but leave axons of passage intact, the Fink-Heimer method can be used to reveal unambiguously the course, trajectory, caliber and terminal field of the fiber system under consideration.

We have previously described the distribution of islands of dopamine fibers and terminals in the ventral lateral entorhinal cortex, and the apparent association of this dopamine innervation with cell clusters found at anterior levels of this cortical area (Collier and Routtenberg, Brain Research, 128, 1977, 354-360). Kainic acid lesions of these cell clusters, followed by Fink-Heimer silver staining, provides a technique for revealing the trajectory of this pathway along its course through the hippocampal formation as well as the details of the system's terminal ramifications. In addition, Vibratome® sections, prepared for detection of catecholamines, enable evaluation of the extent to which presynaptic dopamine islands remain undamaged following cell destruction by kainate. 675 AUTORADIOGRAPHIC INVESTIGATION OF THE CENTRAL PROJECTIONS OF THE OLFACTORY TRACTS IN MACROPODUS OPERCULARIS (L.) (OSTEICHTHYES: BELONTIDAE). Roger E. Davis, Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109.

The distribution of the lateral and medial olfactory tracts was investigated using radioautography. Twentysix adult male Macropodus were administered 0.2 to 0.5 μCi of L [^{3}H-2,3] proline on a dry 60 to 80 μm diameter bead of Dowex resin which was implanted unilaterally in the olfactory bulb. As a control for diffusion of labeled amino acid from the bulb to the telencephalon, which could result in direct uptake into telencephalic neurons, in 2 additional males the bead was implanted in the rostral pole of the area dorsalis telencephali, or pallium. Following a 5 hr or 10 day survival period, the male was sacrificed, and the brain was embedded in paraffin. Horizontal or transverse, sections 10 μm thick were mounted on glass slides, coated with NTB-2 emulsion and kept in the dark at 5°C for 8 or 21 days. The slides were developed, fixed, and the sections stained with cresyl violet acetate. The sections were examined with dark and bright field microscopy to locate labeled axons and terminals. Reduced silver grains were distributed ipsi- and contralaterally in the medial and ventrolateral subpallium and in nucleus taenia and area Dp in the basolateral and posterior pallium. Extensive portions of the dorsal, central and posterior pallium contained no label or only scattered label suggesting that these areas do not receive primary olfactory input. The median forebrain bundle from the posterior telencephalon to the posterior medial thalamus was lightly labeled. A large labeled tract was seen in the ventrolateral subpallium projecting extensively to the neuropil adjacent to the nucleus lateral tuberis, nucleus of the posterior recess, and ventromedial to the nucleus of the lateral recess. Implantation in the rostral-pallium resulted in intense labeling in the area of the bead, the medial and lateral subpallium, and the projections to the posterior thalamus and hypothalamus. However, nucleus taenia and area Dp were only slightly labeled.

676 CHOLINERGIC MECHANISMS AND POST-TETANIC POTENTIATION. J.F. DeFrance, J.C. Stanley, J.E. Marchand, P. Divakaran and Y. Clement-Cormier. Department of Neurobiology and Anatomy and the Department of Pharmacology, The University of Texas Medical School at Houston, P.O. Box 20708, Houston, Texas 77025.

Acutely prepared rabbits were used to study, electrophysiologically and biochemically, the contribution of cholinergic mechanisms to post-tetanic potentiation in hippocampal field CA1.

Rabbits were acutely prepared under urethane or urethane-chloralose anesthesia. The dorsal aspects of the hippocampal formation and septal region were exposed by removing the cortex and corpus callosum. This allowed for precise positioning of the stimulating and recording electrodes.

Monosynaptic responses were recorded in hippocampal field CA1 with microelectrodes following activation of: (1) the septal-hippocampal pathway which takes its origin primarily from the medial septal region (MSR) (i.e., the medial septal nucleus (MSN) and the nucleus of the diagonal band of Broca (nDBB)), and (2) from the contralateral hippocampal field CA3 (CCA3). Stimulation of MSR and CCA3 was done with microelectrodes (1-50 megohms).

To study the influence of various drugs on the normal and potentiated responses, multibarrel electrodes were used. This array included a recording barrel and a current-summing barrel in addition to the drug containing barrels. The compounds studied were: acetylcholine (ACh: 0.1-0.5M, pH 6.7), guanosine 3', 5' monophosphate (cGMP, 0.1-0.5M, pH 6.0), atropine sulfate (Atp 0.1M, pH 6.2), physostigmine (Phys: 0.5M, pH 6.5), isobutyl methyl xanthine (MIX: 0.1M, pH 6.5), K^+Cl^- (1.0M, pH 6.8). Theophylline was administered peripherally (2.0-6.0 mg/kg). ACh, physostigmine, and cGMP each had an excitatory effect upon pyramidal cell responses when applied in stratum radiatum. The time-course studies showed that these effects outlasted the duration of the injection current for many minutes.

Phosphodiesterase inhibitors (e.g., isobutyl methyl xanthine) prolonged the time course of recovery with test responses which were post-tetanically potentiated. K^+, on the other hand, selectively enhanced tetanic potentiation.

It was suggested, with respect to the potentiation phenomena, that K^+ acted primarily presynaptically to facilitate transmitter release, whereas cGMP acted primarily postsynaptically for the enhancement of pyramidal cell excitability.

The electrophysiology findings were supported by biochemical analysis for cyclic GMP and cyclic AMP levels. Hippocampal tissue showed over a twofold increase in cyclic GMP levels following trains of stimuli which maximally produce post-tetanic potentiation. Cyclic AMP levels were only slightly depressed. Supported by NSF #GB35532 and NIH #1F32 NS05874-01.

677 EFFECTS OF A PAINFUL FOOTSHOCK ON THE PSYCHOPHYSICS OF SELF-STIMULATION BEHAVIOR. Philippe De Witte* and Michel Meulders. Lab. Neurophysiol., Université de Louvain, UCL 5449, 54, av. Hippocrate, B-1200 Bruxelles, Belgium.

In a study on the psychophysics of self-stimulation a rewarding hypothalamic stimulation served as a conditioned stimulus (C.S.) in an avoidance paradigm in the rat. Generalization tests were conducted by modifying the electrical parameters of the C.S. forming a set of substitute stimuli (S.E.). Results show that a Stevensian power function relates the reinforcing sensation, measured by the generalization tests, to the intensity of the rewarding stumulation (calculated by the bar-pressing rate for all the S.S.).

The effects of a concomitant painful footshock upon the reinforcing sensation as estimated by the power function were then studied. Data show that the greater the intensity of the footshock, the greater the length of each self-stimulation volley behavior, showing that animals attempt to compensate aversive properties of the footshock by procuring more intracranial reward. Further studies showing that injection of naloxone (5×10^{-4} mg) increases significantly the time elapsed to self-stimulate, suggesting the release of an intracerebral morphine-like substance during compensatory behavior when concomitant painful footshock is added during self-stimulation behavior.

678 BEHAVIORAL EFFECTS OF SYSTEMIC L-DOPA AND DIRECT APPLICATION OF DOPAMINE TO MESOLIMBIC FOREBRAIN IN NONHUMAN PRIMATES. Russell E. Dill, Daniel L. Jones,* J. Christian Gillin, and Greer Murphy.* Dept. Anat., Baylor Coll. Dent., Dallas, Tx. 75246 and NIMH, Bethesda, Md. 20014.

Six adult rhesus and four adult squirrel monkeys were given L-DOPA, 100 and 50 mg/kg i.p. respectively in combination with 20 mg/kg carbidopa and 5 mg/kg ascorbic acid. All animals were then observed in their home cage or a plastic observation cage. Both primates showed an initial period of depressed activity having mean durations of 24 and 23 min followed by increased locomotion, hypervigilance and in the case of the squirrel monkeys, protracted rubbing of the face alternating with "searching" activity. Both species developed a compulsive gnawing syndrome. The duration of these activities was 4 to 5 hours.

The nucleus accumbens (NA) was cannulated bilaterally in the 4 squirrel monkeys and 1 rhesus monkey. All animals were pretreated 18 hr prior to intracranial (i.c.) injection with the monoamine oxidase inhibitor tranylcypromine 1 mg/kg i.p. The NA of squirrel monkeys was injected bilaterally with 100 µg dopamine (DA) and observed as before. These animals showed an initial period of depressed activity lasting 79 min followed by increased locomotor activity characterized by "searching" activity, grooming and rapid stereotyped submissive or juvenile posturing. No gnawing and less face rubbing was seen as compared with systemic L-DOPA. The i.c. injection of 300 µg DA in each NA of the rhesus monkey produced a depressed period followed by intense stereotyped pacing. No other unusual behavior was seen.

Haloperidol, 0.1 mg/kg i.p. markedly delayed the onset of locomotor stimulation and prevented the appearance of all stereotypic and gnawing activity induced by either systemic L-DOPA or i.c. DA.

The i.c. injection of 100 µg L-norepinephrine into each NA of the squirrel monkeys produced a period of depressed activity lasting about 2 hr followed by minimal locomotor activity consisting of retropulsion in a sitting position. All animals displayed a marked loss of extensor muscle strength and tone in the lower extremity. The latter effect lasted between 6 and 12 hr. The i.c. injection of saline in all animals produced no unusual behavior.

These results confirm the locomotor stimulating and stereotypy-inducing properties of systemic L-DOPA in primates and suggest that some of the activities could be related to increased dopaminergic activity in the mesolimbic nucleus accumbens.

679 ELECTROPHYSIOLOGICAL EVIDENCE FOR THE PERFORANT-CA1 PATHWAY IN THE HIPPOCAMPAL SLICE. Herbert J. Doller* and Forrest F. Weight (SPON: A. P. Oliver). Laboratory of Neuropharmacology, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032.

A hippocampal pathway originating in the entorhinal cortex, traversing as part of the perforant pathway and terminating on the apical dendrites of the CA1 pyramidal cells has been described anatomically (Acta Anat 35:202, 1958; Brain 88:963, 1965). However, electrophysiological identification remains inconclusive (Exp. Neurol. 35:541, 1972; The Hippocampus, Isaacson and Pribrum (eds.), p. 161, 1975). We investigated this perforant pathway using electrophysiological techniques in the hippocampal slice (Epilepsia 18:543, 1977). Stimulation of the perforant pathway resulted an evoked potential with a latency of approximately 10 msec in the CA1 cell layer. This response was inhibited by media containing 0.1 mM Ca and 5 mM Mg suggesting synaptic mediation. Two types of experiments suggest this CA1 response was not the result of activation via the mossy fiber and Schaeffer collateral pathways. First, the sum of the latencies of the perforant pathway to the granule cells, the mossy fiber pathway, and the Schaeffer collateral pathway was approximately twice the latency of the perforant stimulation directly to the CA1 cells. In a second series of experiments, the mossy fiber pathway was transected. Despite this, evoked potentials were recorded in CA1 following perforant stimulation. Another possible interpretation of the data is that Schaeffer collaterals are being antidromically stimulated. To test for this possibility, 1 mm sections were cut out of the CA1 region of the slice between the stimulating and recording electrodes. The section was from the alveus to, but not including, the perforant pathway. This includes the stratum lacunosum which contains Schaeffer collaterals. With this lesion, evoked responses were still recorded in CA1 with perforant stimulation. These results provide electrophysiological evidence for a synaptic input to CA1 cells from the perforant pathway.

680 GENETIC AND NEUROCHEMICAL ASPECTS OF THE ACQUISITION OF AVOIDANCE BEHAVIOR FOLLOWING SEPTAL LESIONS IN THE MOUSE. Richard J. Fanelli*, Peter J. Donovick and Richard G. Burright*. Dept. of Psychology, SUNY-Binghamton, Binghamton, NY 13901.

One of the well defined behavioral alterations that occurs in animals with septal lesions is enhanced acquisition of a two-way active avoidance task. Previous work from our laboratory showed that many of the effects of septal lesions can be altered by manipulations of environment, experience and genotype. Recently, we reported that enhanced acquisition of the two-way active avoidance task associated with septal lesions is dependent on the strain of mouse tested. The present investigation examined the levels of brain catecholamines and their relation to the genotype dependent behavior following septal damage in mice.

Mice of the C57BL/6J and RF/J strains were assigned to either receive control operations or bilateral electrolytic lesions of the septal area. Following a ten day recovery period, animals were tested on a two-way active avoidance task in standard shuttle boxes. After the behavioral testing, the mice were sacrificed. For most of the mice, brains were removed, weighed and frozen, and a fluorometric analysis of catecholamine levels was done later. Remaining mice were perfused and examined for the extent of the lesion.

The mice of the C57 strain, which normally perform poorly in the two-way active avoidance task, showed an enhanced acquisition following septal lesions. The RF mice, which normally acquire the task rapidly, did not show the reported septal enhancement. The forebrain, hindbrain and total brain weights of the two strains were very similar across surgical conditions, but brains of lesioned mice tended to be somewhat lighter then the controls of both strains. There was a slight decrease in norepinephrine levels in the forebrain of the lesioned animals of both strains, however, there was no major lesion effect upon catecholamine levels, nor a lesion-by-strain interaction. Neither norepinephrine nor dopamine transmitter levels predicted the behavior of these two strains of mice or the septal effects.

From this data, it seems that the strain differences in the behavioral response to septal damage can not be explained exclusively on the basis of differences in catecholamine levels. The fact that differences do exist may implicate differential fine effects of the lesion, and their interaction with existing genotypic and experiential factors.

681 EFFECTS OF STIMULATION OF SUBSTANTIA INNOMINATA AND OTHER CORTICAL AND SUBCORTICAL SITES ON THE ELECTROPHYSIOLOGY OF AMYGDALOID NEURONS. Philip A. Femano*, Henry M. Edinger, Allan Siegel, and Stanley Z. Kramer*. Departments of Physiology and Neurosciences, College of Medicine and Dentistry of New Jersey - New Jersey Medical School, Newark, NJ 07103, and Department of Biology, Seton Hall University, So. Orange, NJ 07079.

The effects of electrical stimulation of neocortical and subcortical structures on the electrophysiology of amygdaloid neurons were examined in the ketamine anesthetized cat. Glass microelectrodes (3M NaCl, 8-10 MΩ) were used to record extracellular unit responses within the amygdala. Square wave stimulus pulses (25-1000 µA) were delivered through stainless steel electrodes located in the lateral olfactory tract, sylvian cortex, substantia innominata, and ventromedial hypothalamus.

All sites produced both excitatory and inhibitory influences on amygdaloid neurons. Of the sites tested, the substantia innominata and sylvian cortex exhibited the most powerful excitatory inputs upon amygdaloid neurons. Onset latencies were in the range of 5-30ms. Stimulation of the lateral olfactory tract and ventromedial hypothalamus elicited both a short latency excitatory response of approximately 20-50ms, plus a second population of longer latency excitatory responses. Orthodromic activation of single units could occasionally be elicited by more than one stimulus site. The preliminary evidence also suggests the presence of more complex convergent interactions of cortical and subcortical afferents on amygdalar neurons.

682 HIPPOCAMPAL FIELD POTENTIALS AND SINGLE UNIT ACTIVITY EVOKED BY STIMULATION OF MEDIAL SEPTAL NUCLEUS, ENTORHINAL CORTEX AND VENTRAL HIPPOCAMPAL COMMISSURE IN FREELY-MOVING RATS. S. E. Fox and J. B. Ranck, Jr., Dept. of Physiology, Downstate Medical Center, State University of New York, Brooklyn, NY 11203.

Using aseptic stereotaxic surgery, rats were prepared with three independently moveable microelectrodes for chronic recording in the hippocampal region, and three stimulating electrodes in medial septal nucleus (MSN), entorhinal cortex (EC) and ventral hippocampal commissure (VHC) as reported previously (Fox and Ranck, Neuroscience Abstracts 3: 198, 1977). Electrodes for recording neocortical EEG and neck-muscle EMG were also implanted to facilitate behavioral monitoring. Prior to surgery, rats were trained to walk continuously on a motor-driven treadmill. They were also taught to drink continuously, immediately on presentation of water, by allowing them access to the water spout only a few minutes at a time, several times a day. They were housed in the treadmill for several days, so that after recovery, recordings could by obtained during both slow wave and paradoxical sleep.

Several days after surgery, field potentials and unit activity evoked by stimulation of MSN, EC and VHC were recorded from the hippocampal region during walking, drinking, slow wave sleep and paradoxical sleep, taking care to keep behaviors constant during each bout. These behaviors represent two theta-mode behaviors and two non-theta behaviors, one each during sleep and wakefulness. Field potentials evoked at fixed time of day were stable over many days once electrodes were in place. Three categories of results were obtained. 1) Field potentials in response to MSN stimulation did not correspond to their description in the literature. Strength/duration curves indicated that the chronaxie of the elements stimulated in MSN to produce the field potential in hippocampus was about 1 msec. This suggests that unmyelinated axons, dendrites, somas or some combination were being stimulated. 2) Dual pulse facilitation was observed in the VHC to CA1 afferent system, and its characteristics were similar to the facilitation in the EC to fascia dentata system. 3) Behavioral dependence of amplitude of components of field potentials from EC stimulation, reported by Winson and Abzug (Science 196: 1223, 1977) was confirmed, and extended to include other afferent systems and unit activity.

683 THE INTERCALATED NUCLEI OF THE AMYGDALA: A GOLGI STUDY IN THE RAT. JoAnn E. Franck, Dept. Psych., Univ. Rochester, Rochester, NY 14627.

In Nissl stained material the intercalated masses (MI) are clusters of medium-sized (15-20μ) cells in the external capsule and longitudinal association bundle (LAB), fiber tracts surrounding the lateral and basolateral amygdala. One large island appearing beneath the anterior commissure's lateral wing, is displaced ventromedially by the basolateral nucleus. Caudally, it lies in the fibers of the stria terminalis. The strategic location of the MI within the major fiber bundles of the amygdala prompted this analysis.

The appearance of the MI in Nissl material belies their heterogeneity and the formidable extent of their processes. Intercalated cells within the external capsule and LAB have several sinuous primary and secondary dendrites oriented parallel to the entering and exiting axons in frontal sections. The cells of the MI in the stria terminalis are identical except the dendritic axis is perpendicular to the strial axons. The dendritic spines are often so dense they obscure the dendritic shaft. Individual spines are extremely ornate; as many as four separate peduncles and twigs arise from a single stalk. Somatic spines are also observed. The axons give off several collaterals which ramify near the parent cell. The main axon continues dorsally or ventrally in the passing fiber bundle. Along their course the collaterals have numerous varicosities and twigs suggesting presynaptic specializations. A second type of MI cell associated with passing fibers also is observed medial to the ventral tip of the basolateral nucleus. Two or three dendrites emerge from the soma and are oriented parallel to the LAB. The most striking feature is the length of the primarily unbranched dendrites; some are often over 600μ long. Thus, these cells, which are more than 1mm long from tip to tip, form a formidable dorsal-ventral band between the basolateral and lateral nuclei and more medial areas. The spines of these cells, while fewer in number, are ornate and unusually long (10μ).

Many cells in the single large MI are not in the way of passing axons and are stellate in appearance. Dendritic spines are numerous but much shorter and simpler. The axons of these cells also emit several local collaterals. A single branch goes dorsally towards either the central amygdala or LAB.

Nothing is known of the function of the MI, however, many are located so that fibers exiting and entering the amygdala pass through them. In turn, the MI cells give off numerous short axon collaterals which may modulate function in neighboring amygdaloid nuclei. In addition, it is possible that some of these cells may project to extra-amygdaloid structures via the LAB.

(Supported by NIMH grant R03 MH 28678.)

684 ATTENUATION OF SEPTAL HYPERREACTIVITY BY INTRACRANIAL INJECTION OF MORPHINE INTO THE PERIAQUEDUCTAL GRAY (PAG) Fred H. Gage, III James J. Valdes*, and Roy G. Thompson, Dept. of Psychology, Chemistry of Behavior Program, Texas Christian University, Fort Worth, Texas 76129.

Lesions to the septal nuclei of rats initiate a transient hyperreactivity to somatosensory stimuli which lasts approximately two weeks. This increase in responsiveness has been previously described as an increase in aggression, irritability, emotionality, or rage; the common element of the syndrome reflecting an increase in affective responding to stimuli. We have previously demonstrated the possible involvement of both norepinephrine and serotonin in modulating this hyperreactivity. Opioid narcotics have similarly been suggested to modulate the affective component of pain via interactions with the biogenic amines, particularly serotonin. The purpose of this study was to determine whether an opioid narcotic (morphine) could selectively attenuate the increase in affective responding following septal lesions. Rats with sham or septal lesions received 1ul injections of either saline or morphine (5ug/ul or 15ug/ul) into the rostral PAG, an area involved in analgesia and through which aminergic projections to the limbic forebrain pass, within one day following the lesion when the hyperreactivity was maximal. The animals were behaviorally tested for reactivity at 10 and 60 minutes after injection, and at 2, 4, 8, 16, and 30 days following surgery. Magnitude of response to electric foot shock was quantitatively assessed using a calibrated force transducer and polygraph recorder. A standard rating scale of septal hyperreactivity was employed along with additional measures of motor and sensory abilities. Immediately and for 24 hours following injection, morphine completely eliminated the increased affective responding induced by the septal lesion on all measures, without debilitating motor or sensory components. The selective attenuation of affective responding was immediately reversed by a 1ul injection of naloxone (40ug/ul) given 10 minutes after the morphine injection. These results demonstrate a selective, naloxone reversible, morphine attenuation of septal lesion-induced hyperreactivity. The effect appears specific to the affective component of the septal syndrome as neither motor nor sensory abilities were impaired, and suggests the involvement of brain mechanisms of pain perception in the syndrome.

685 AMYGDALOID LESIONS DISRUPT INCENTIVE-MOTIVATION IN THE RAT. Michael G. Gaston* (SPON: K. M. Gregory). California State Univ., Los Angeles, CA 90032

A series of three experiments provided data consistent with the view that the amygdala is involved with mechanisms of incentive-motivation. Rats with electrolytic lesions aimed at the basolateral amygdala were less responsive than Controls under conditions that afforded reward, but more responsive when reward was not obtainable. The performance of lesioned animals was also relatively unaffected by differences or shifts in amount of reward. In Experiment I, subjects were trained on a go-no-go successive discrimination problem. They found food at the end of a black (white) straight-alley and no food in a white (black) alley. Amygdalectomized rats ran significantly slower than Controls in the positive alley, but significantly faster in the negative alley. These subjects were subsequently tested in a T-maze, one arm of which was black and the other white. Lesioned rats entered the positive arm significantly less often than Controls, suggesting that amygdaloid lesions disrupt the extent to which a stimulus paired with primary reward acquires secondary reinforcing and/or incentive-motivational properties. In Experiment II, subjects found a large quantity of food at the end of a black or white alley and a small amount of food in the other alley. Control rats ran much faster in the high reward alley than in the low. For amygdala lesioned animals, however, there was little difference between the speeds with which they ran to get large and small amounts of food. Anticipatory attempts to push through a top-hinged startbox door were automatically recorded. Lesioned rats showed less overall anticipatory responding than Controls. Further, amygdaloid animals, unlike Controls, made almost as many anticipatory responses before entering the low reward alley as before entering the high reward alley. In Experiment III, separate groups of subjects ran a gray straight-alley for either a large or a small amount of food reward. Subsequently, half the high (low) reward rats were shifted to low (high) and half the animals continued to run for the same reward quantity. Differences in running speed as a function of reward amount were significantly less for lesioned subjects than for Controls. Lesioned rats shifted down in reward amount showed less of a negative contrast effect, and those shifted up displayed less of a positive contrast effect, than did Controls. Taken together, the findings reported here suggest that amygdaloid lesions produce deficits in the development of appropriate excitatory or inhibitory motivational tendencies in situations involving changes in the parameters of reward.

686 CORTICAL PROJECTIONS OF THE THALAMIC MEDIODORSAL NUCLEUS IN THE OPOSSUM. Gregory T. Golden, Jan C. Jackson* and Robert M. Benjamin. Dept. of Neurophysiology, University of Wisconsin Medical School, Madison, Wisconsin 53706.

The cortical projection field of the thalamic mediodorsal nucleus (MD) in the opossum was mapped with retrograde horseradish peroxidase and anterograde tritiated proline techniques. The results of several large proline injections placed in MD indicate that MD projection cortex extends to all four surfaces of the frontal lobe. The labeled area begins at the frontal pole and includes most of the medial wall rostral to the tip of the fissura intercalata. It widens on the dorsal surface to reach a posterior limit at the caudal limb of the orbital fissure. On the lateral and ventral cortical surfaces the area widens again to produce a 'tail' which extends along the rhinal sulcus for a short distance behind the orbital fissure and ends ventral to taste cortex as defined electrophysiologically.

Cortical HRP injections corroborated the major findings obtained with proline and added detail concerning the topography of the MD projection. In general, lateral portions of the MD project to the dorsal cortical surface and within this field anterior lateral MD projects to anterior dorsal cortex while posterior lateral MD projects to posterior dorsal cortex. Medial portions of MD project to medial and lateral walls of cortex: anterior medial MD to the medial wall and posterior medial MD to the lateral wall.

The location and the topographic arrangement of projections from medial MD are similar to those previously described for the rabbit. However, the position of the lateral MD projection field is strikingly different in the two species.

687 DESTRUCTION OF GRANULE CELLS IN THE DENTATE GYRUS AND CEREBELLAR CORTEX OF ADULT RATS FOLLOWING INJECTIONS OF COLCHICINE. Richard Goldschmidt* and Oswald Steward (SPON: S.S.Winans). Depts of Neurosurgery, Anatomy and Physiology, University of Virginia School of Medicine, Charlottesville, VA 22901.

In experiments attempting to use colchicine to block axonal transport in the dentate gyrus (DG), a seemingly selective cytotoxicity of colchicine for DG granule cells was observed. Forty-eight hours after injections of 25 or 2.5µg of colchicine in 0.5µl of distilled water, affected granule cells were shrunken and of irregular shape and small densely stained particles of cell debris were present in the granular layer. Massive invasion of the affected area by microglial cells was also observed. A variety of longer survival times were investigated, and by 50 days after the injection only glial cells remained in the injected area of the DG. Pyramidal cells in the hilus of the DG were also destroyed, but other nearby pyramidal cells seemed unaffected. Fink-Heimer staining of cases 3 and 4 days after injection revealed degeneration in the mossy fiber and commissural systems within the hippocampus.

Injections of 25µg of colchicine into the vermis of the cerebellar cortex were made to investigate the generality of this colchicine effect on granule cells. Gross behavioral abnormality appeared within hours after the injections. Forth-eight hours after injection microglial invasion and cell debris in the granular layer of the vermis was apparent around the injection site. Purkinje cells nearby appeared paler staining and misaligned while the cytoarchitecture of more lateral regions of cerebellar cortex appeared normal.

Since control injections of colcemid or saline do not produce this effect, the cytotoxic action of colchicine on granule cells seems to be unrelated to its effects on microtubules. A toxic effect on membrane nucleoside transport mechanisms might explain this cytotoxic action. Why this effect is relatively specific for granule cells remains uncertain.

(Supported by NIH Grant #5 RO1 NS12333 to O.S.)

688 SUPPRESSION OF EMOTIONAL BEHAVIOR IN CATS BY STIMULATION OF VENTRAL TEGMENTAL AREA AND NUCLEUS ACCUMBENS. Jeffrey M. Goldstein* and Jerome Siegel, Institute for Neuroscience and Behavior and School of Life and Health Sciences, University of Delaware, Newark, DE 19711.

Previous studies have shown that the mesolimbic dopamine system may subserve a functional role in emotional behavior. The present study investigated the effects of concomittant electrical stimulation of the ventral tegmental area (VTA) or nucleus accumbens (NA) on lateral hypothalamic-induced attack behavior in cats. Low frequency (6pps) stimulation of VTA or NA suppressed hypothalamically-induced attack without affecting the autonomic or non-directed somatic components of the attack reaction. High frequency (60pps) stimulation either failed to suppress attack (VTA) or produced less suppression of attack compared to low frequency stimulation (NA). To rule out the possibility that low frequency stimulation per se would disrupt ongoing behavior, natural (light flashes) and artificial (lateral geniculate) stimulation were tested against hypothalamically-induced attack. Both forms of sensory stimulation failed to alter the attack reaction. The results of this study suggest that a function of the mesolimbic dopamine system is to inhibit emotional behavior.

689 LESION OF HIPPOCAMPAL CA3 PYRAMIDAL CELLS WITH KAINIC ACID IMPAIRS SPATIAL MEMORY IN RATS. Gail E. Handelmann*, Joseph T. Coyle, and David S. Olton. (SPON: B.L. Bird) Dept. Psychol., and Dept. Pharmacol., Sch. Med., The Johns Hopkins Univ., Baltimore, Md. 21218.

Numerous studies have suggested that the subfields of the hippocampus mediate different behaviors. Due to the complex anatomy of the structure, however, destruction of a single subfield without interrupting efferent or afferent fibers of other areas has been difficult. In the present experiment, selective destruction of subfield CA3 was produced by chemical means, making it possible to study the behavioral function of this subfield alone.

Bilateral injections of kainic acid, each containing 160 nanograms, were made directly into the CA3 subfield, causing pyramidal cell death without damage to fibers of passage. Three groups of rats were tested. The first received an injection in only the dorsal hippocampus, the second in only the ventral hippocampus, and the third received injections in both sites. The injections of kainic acid were found to produce damage only at the sites of injection. Therefore, the rats who received injections in only the dorsal or ventral hippocampus had damage in only these areas, but the group that received both injections showed damage to the entire extent of CA3.

All rats were tested for acquisition of a spatial memory task, the eight-arm radial maze. Controls performed identically to normals. Rats with total CA3 damage were impaired on the task and tended to perseverate their choice of arms. Rats with only partial damage acquired the task faster than the impaired group but slower than controls. Rats were also observed for emotional reactivity to aversive stimulation. All lesioned animals were hyperreactive compared to controls, and rats with damage to either the dorsal or ventral CA3 alone displayed the greatest reactivity.

These data demonstrate that selective damage to a group of anatomically similar cells within the hippocampus, the CA3 pyramidal cells, produces identifiable changes in spatial and emotional behavior. The findings on spatial memory are consistent with data from total hippocampus ablations, but those on emotionality are not.

690 DEMONSTRATION OF THE HABENULO-INTERPEDUNCULAR FIBER SYSTEM BY [^{14}C]-2-DEOXY-GLUCOSE. Miles Herkenham. Laboratory of Neurophysiology, NIMH, Bethesda, MD 20014.

The habenular complex is composed of two anatomically distinct parts, the medial and lateral nuclei, differing in morphology and input-output connections. As an extension of an ongoing study of their anatomical differences, an attempt was made to use a functional marker to select out one of the habenular mechanisms. The medial habenula is the source of all habenulo-interpeduncular tract fibers that terminate in the interpeduncular nucleus. It issues thin, myelinated axons that comprise the central core of the fasciculus retroflexus. The 2-deoxy-D-[^{14}C]-glucose method for determining regional brain glucose consumption was used to examine this neural system. The autoradiographic maps of glucose consumption in awake rats show that 1) the medial habenula consumes slightly less glucose than does the lateral habenula, 2) the habenulo-interpeduncular tract cannot be distinguished from surrounding neuropil, and 3) the interpeduncular nucleus consumes more glucose than does the adjacent tegmentum. However, when rats are anaesthetized with chloral hydrate, a very different pattern emerges: glucose consumption is generally reduced throughout the brain, but the medial habenula, the habenulo-interpeduncular tract and the interpeduncular nucleus all consume much more glucose than the surrounding tissue and appear by contrast as very dark spots on the autoradiograms. The result is not specific to chloral hydrate since the pathway can also be visualized with pentobarbital or ether anaesthesia. Since anaesthesia (barbiturate) is known to reduce brain glucose consumption, part of the effect must have been due to a drop in glucose consumption in the surrounding tissue. Quantitative methods will be needed to determine whether there may have been an actual increase in glucose utilization within the habenulo-interpeduncular system.

This demonstrates that anaesthesia can selectively spare metabolism in an anatomically defined neuronal fiber system including the regions containing the cells of origin, the *myelinated fiber tract* and the terminal field. The actual subcellular compartments responsible for the altered glucose consumption in each component of the pathway cannot be determined at the present time. The high amount of glucose consumption in the habenulo-interpeduncular tract is quite puzzling since 1) white matter generally has less glucose consumption than does gray matter and 2) anaesthesia generally reduces consumption in both gray and white matter. The greater glucose utilization by this tract than by the surrounding gray matter under conditions of anaesthesia suggests that the habenulo-interpeduncular tract has unique metabolic and functional properties.

691 SLEEP EEG RECORDING FROM THE CAT AMYGDALA. J. Eric Holmes and Judith F. Stern.* Dept. of Neurology, USC School of Medicine, Los Angeles, CA 90033.

Chronically implanted electrodes were used to monitor sleep, arousal, and paradoxical sleep in unrestrained cats. A 30-40 cycle per second (Hz) sinusoidal burst of waves characterizes the EEG from the cat amygdala during arousal. During slow wave sleep this activity disappears from the records. During paradoxical sleep there is a slower, approximately 20 Hz sinusoidal wave form occurring periodically in the amygdala. Paradoxical sleep was identified by recordings of cortical EEG, geniculate spikes, hippocampal theta rhythms or eye movements. The slower, paradoxical sleep bursts of the amygdala are not obviously correlated with respiration. Preliminary results from chronically implanted microelectrodes indicate a decrease in firing of amygdala neurons during paradoxical sleep.

692 SUBCORTICAL PROJECTIONS TO THE ORBITAL REGION OF THE FRONTAL LOBE. S. Jacobson, N. Butters*, and H. Kowalski*. Depts. Anat. and Neurosurg., Tufts Univ. Sch. Med., Boston, MA 02111, and Dept. Psychol., BU Sch. Med., Boston, MA 02118.

In a previous study (Jacobson, Butters, and Tovsky; Brain Res., 1978) on subcortical relationships of the cortex forming the wall of the principal sulcus, we have demonstrated projections from thalamus and hypothalamus to the convexity of the frontal lobe. In this study we have investigated the subcortical projections into the orbitofrontal cortex of the monkey to determine if they are similar to those into the convexity.

Five young adult male Macaca nemestrina monkeys were used for this study. The orbital surface was divided into 5 behaviorally important zones: gyrus rectus, posterior orbital, anterior orbital, lateral orbital, and central orbital. One animal was used for each division. The zone under investigation was injected with a "cocktail" of horseradish peroxidase (HRP: Boehringer Mannheim, Grad I) and tritiated amino acids. The animals were perfused 2-4 days postoperative, frozen sections were reacted with diaminobenzidine (DAB) to demonstrate the presence of HRP positive cells.

The thalamic afferents to the orbital region were primarily from the medial dorsal nucleus. Many cells were also seen in the anterior medial, ventral anterior, and medial pulvinar nuclei. Some cells were also seen in the intralaminar and posterior group. A few cells were also seen in the lateral hypothalamic area, lateral mamillary nucleus and dorsomedial nucleus. The observations from this study will be discussed in relationship to the behavioral studies on these same regions.

693 SELECTIVE HIPPOCAMPAL LESIONS AND SPATIAL DISCRIMINATION IN THE RAT. Leonard E. Jarrard. Dept. Psychol., Washington & Lee Univ., Lexington, VA 24450.

Recent research demonstrating different behavioral effects resulting from selective damage to either hippocampal cell fields or hippocampal projections, together with studies implicating the hippocampus in spatial memory, prompted the present investigation of the effects of selective hippocampal lesions on spatial discrimination in the rat. The apparatus consisted of an 8-arm radial maze. The animals were trained preoperatively to choose 4 of the 8 arms for food (Problem A) and then underwent reversal training where the opposite 4 arms were baited (Problem B). The rats were then divided into two control groups (operated and unoperated) and 3 groups that received bilateral lesions to either the fimbria, posterior CA1 cell field and alveus, or hippocampus (including damage to all cell fields, dentate gyrus, and fimbria). Following recovery the animals were retrained to approach the last 4 arms that had been learned (Problem B).

Analysis of the data indicated that animals with extensive damage to hippocampus and those with fimbrial lesions were impaired in postoperative testing; performance of animals with CA1-alveus lesions and those in the operated and unoperated control groups was similar. Further analysis of the error data revealed that the performance impairment in complete hippocampals, and to a less extent in fimbrials, was due to the animals reentering correct (baited) arms that had already been visited on that trial rather than entering incorrect (unbaited) arms. These results indicate that the difficulty encountered in performing the complex spatial task was not in remembering which of the arms were correct from trial to trial (reference memory) but rather in remembering which of the correct arms had been visited during a trial (working memory).

694 ATTENUATION OF LATERAL HYPOTHALAMIC SELF-STIMULATION BY MICROINJECTION OF LIORESAL INTO THE VENTRAL ANTERIOR NUCLEUS OF THE THALAMUS. James A. Johnsen and Ernest W. Kent, Dept. Psch., UICC, Chicago, IL 60680

Male Sprague-Dawley rats were implanted with 70μ twisted wire stainless steel monopolar electrodes directed at the far lateral aspect of the lateral hypothalamus (Pellegrino and Cushman coordinates: AP +5.4, H -2.1, L 1.8). In addition, 27 guage injection cannulae were directed bilaterally at the ventroanterior nucleus of the thalamus (VAT).

The rats were trained to press for constant current, square wave form trains of current (train duration, 250 msec; frequency, 100 pulses/sec; pulse width, 30 msec) at intensities sufficiently strong to maintain stable rates (usually 60 to 80μA). Rats pressed at rates averaging 200 presses per minute. 126 minute trials consisted of an initial 20 minutes to establish daily baseline rates, followed by intracranial injection of the drug and replacement of the animal in the stimulation chamber. Doses of Lioresal as low as 90 nanograms (in .5μl saline) were seen to attenuate self-stimulation rates. Effects were usually seen within 10-20 minutes following the injection. 90 ng injections were followed by a gradual decay to a much reduced rate, or zero. In some cases this was followed by full or partial resumption. Injections of 180 ng, however, were less likely to be followed by a return to the lever. During the period when the effect was seen, the animals appeared neither hypoactive nor sedated. Priming at this time elicited sniffing and exploratory behavior, often inducing a return to the lever. However, as soon as priming ceased, the animals no longer attended to the lever.

As Lioresal is reported to be a GABA agonist and substance P antagonist, the possible role of these substances in the thalamic control of self-stimulation requires further examination. It is noteworthy that the VAT receives projections from the substantia nigra and striatum. These areas support self-stimulation and are reported to contain GABA and substance P cell bodies.

695 EFFERENTS OF THE "VOMERONASAL AMYGDALA" TO PROJECTION FIELDS OF THE ACCESSORY OLFACTORY BULB. Golda A. Kevetter and Sarah S. Winans. Neuroscience Prog. and Dept. Anatomy; Univ. of Michigan; Ann Arbor, MI. 48109. USA

The projections of the "vomeronasal amygdala", i.e., those nuclei which receive direct projections from the accessory olfactory bulb, were traced autoradiographically. Tritiated proline (1 - 5 μCi in 20 - 250 nl) was stereotaxically injected via a 1 or 5 μl Hamilton syringe into the amygdala of 25 male hamsters. After survival times ranging from 6 hours to 6 days (average survival time was 27 hours), animals were perfused through the left ventricle with isotonic saline followed by phosphate-buffered 10% formalin, 20 micron frozen sections were mounted on slides and coated with Kodak NTB2 emulsion and exposed for 2 - 6 weeks in the dark. Slides were developed with Kodak D - 19 developer, counterstained with cresyl violet and observed under darkfield light microscopy.

Efferents of the "vomeronasal amygdala" include projections to other primary projection fields of the accessory olfactory bulb (AOB). Specifically, the posteromedial cortical nucleus, C3, projects to the ipsilateral Nucleus of the Accessory Olfactory Tract (NAOT), ipsilateral AOB, ipsilateral medial nucleus (M), ipsilateral and contralateral Bed Nucleus of the Stria Terminalis (BNST), and the contralateral C3. Efferents of the medial nucleus terminate in the ipsilateral NAOT, ipsilateral C3, and the ipsilateral and contralateral BNST. The projections of C3 and M terminate in different layers of these structures than the efferents of AOB.

Additionally, M projects to the anterior hypothalamic-medial preoptic area, ventromedial nucleus of the hypothalamus, premammillary nucleus, and the subiculum.

696 **AFFERENTS TO AREA 8 AND OTHER PREFRONTAL AREAS IN THE MONKEY AND BABOON: AN HRP STUDY.** **George R. Leichnetz and Juan A. Astruc, Department of Anatomy, Medical College of Virginia, Health Sciences Division, Virginia Commonwealth University, Richmond, Virginia 23298.**

The large expanse of granular cortex rostral to the agranular motor areas of the frontal lobe distinguishes primates from other mammals. The prefrontal cortex has been shown to be involved in many seemingly divergent functions: learning and memory, attention-focusing mechanisms, eye movement, sensory convergence, and limbic mechanisms. Its cytoarchitecture is also varied in several respects. On this basis, Walker subdivided the prefrontal cortex into a number of sectors. Our previous work has focused on prefrontal efferent systems in primates, and this report represents preliminary findings in our study of its afferents in the general context of our efforts to better understand prefrontal function through a more complete definition of its connectivity.

Large horseradish peroxidase injections (3-5ul, 50% sol. in sterile saline, Sigma Type VI) or solid HRP pellets were introduced into arcuate cortex (Area 8), dorsal convexity or medial prefrontal cortex in three macaque monkeys, two cebus monkeys and three baboons. After survival periods of 1-6 days, the animals were perfused transcardially with normal saline followed by a mixed aldehyde fixative (1%Paraformaldehyde, 1.25% Glutaraldehyde) in a 0.1M phosphate buffer. The brains were removed, blocked, and immersed in a 10% sucrose/buffer solution overnight in the refrigerator prior to cutting. The brains were sectioned on a freezing microtome at 40 micra, and were reacted according to the Mesulam (1976) blue-reaction protocol.

Area 8 (arcuate, "frontal eye field") placements resulted in labelled cells in Lamina III of the ipsilateral inferior parietal cortex (Area PG of Von Bonin and Bailey) and caudal cingulate cortex, and Area PE, nucleus basalis in the basal forebrain, and the thalamic intralaminar complex (paracentral and central lateral nuclei). The mediodorsal nucleus of the thalamus contained a few back-filled cells. The intralaminar complex was characterized by both retrogradely and orthogradely-transported HRP.

Dorsal convexity and medial prefrontal placements resulted in labelled cells in MDpc, ventral cingulate cortex (Areas 24 and 25) basal forebrain, lateral hypothalamus, ventral tegmental area, dorsal raphe and superior central nuclei of the midbrain.

The differences in these afferent projections to the prefrontal cortex may account in part for its many divergent functional roles which will be discussed.

697 LONG-TERM LIMBIC STIMULATION WITHOUT KINDLING OF SEIZURES. Henry Lesse and Jeremiah Collins. Department of Psychiatry and Brain Research Institute, School of Medicine, University of California, Los Angeles, Calif. 90024.

Cats were trained to use electrical stimulation of limbic sites (amygdala, hippocampus, septal region) as a discriminative stimulus for a food-reinforced bar-pressing response. Current required to elicit focal afterdischarges (AD) was determined initially for each site and intensities 80% below this level were then employed in training sessions. Behavioral and electrophysiological responses of subjects stimulated repeatedly in a series of conditioning experiments extending over 1 to 4 years were analyzed for evidence of kindling.

Neither generalized convulsions nor behavioral automatisms characteristic of limbic seizures were observed in any subject even following thousands of focal stimulations. There was no decrement in discriminative performance associated with the repeated brain stimulations and subjects continued to respond to limbic excitation with appropriate bar pressing and milk drinking. Concomitant electrophysiological recordings disclosed no abnormalities (i.e., epileptoid afteridscharges, interictal spikes). Detection thresholds (the minimal current required to elicit the conditioned response) remained stable over extended periods. When initial AD thresholds were retested following long series of training stimulations, there were no progressive declines in threshold and neither increases in AD duration, nor propagation of the localized AD to other brain sites. Behavioral reactions to these induced ADs remained limited to automatisms and did not progress to generalized convulsions despite numerous intervening conditioning stimulations.

These results indicate that limbic sites can be excited repeatedly at intensities that elicit conditioned behavioral responses without engendering kindling effects or inducing progressive changes in the excitability of the stimulated structure. Although kindling procedures that result in repeated induction of seizure afterdischarges and other abnormalities provide a useful model for studying epileptogenesis, caution is indicated in generalizing conclusions based on kindling phenomena to other brain stimulation situations.

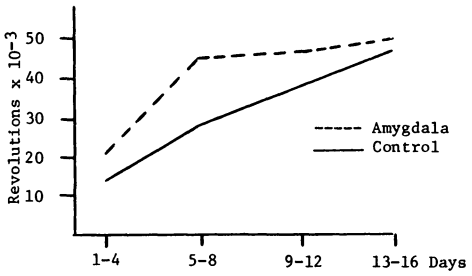
698 EVOKED POTENTIALS IN HIPPOCAMPAL CA1 IN ANESTHETIZED AND WAKING RATS. L. Stan Leung. Dept. Physiol.-Anat., UC Berkeley, CA 94720.

Three inputs -- the posterior alveus (PA), the anterior alveus (AA) and the Schaffer collaterals (Sch) -- were studied in rats anesthetized with sodium pentobarbital, using near-threshold electrical stimuli. Averaged evoked potentials (AEPs) were mapped in order to calculate the current source-links over a coronal plane. By correlating AEPs with unitary post-stimulus time histograms, a field generated by excitatory postsynaptic potentials (EPSPs) in pyramidal and interneurons and another generated by inhibitory postsynaptic potentials (IPSPs) in pyramidal cells could be inferred for each stimuli. The sink for the EPSP field components evoked by the alvear stimuli (AA,PA) was at stratum oriens and that evoked by Sch at stratum radiatum. The source of the IPSP component included strata pyramidale and radiatum. The sinks of the EPSP fields and the source of the IPSP field were the active synaptic sites for the respective events. By recording simultaneously from a 64-electrode array, anterior stimuli evoked a broad surface distribution of AEP which suggested significant spatial divergence of the orthodromic inputs in contrast to the sharp projection of the caudally directed efferent fibers in PA.

In implanted, awake animals, AEPs showed signifcant changes. For AA and PA stimulations, the late component inferred as the IPSP field became smaller while the early EPSP field was enhanced. For Sch stimulations, the AEPs showed multiple peaks and valleys or oscillations (at 20 to 50 Hz) when the rat was moving. These oscillations were likely manifested by the recurrent-inhibitory or negative-feedback interactions between pyramidal cells and interneurons either in CA1 or in CA3. The significance of these results will be discussed. (Supported by MH 06686).

699 AMYGDALOID MODULATION OF WHEEL RUNNING ACQUISITION. Irwin N. Lourie*, Michael M. Krieger* (SPON: N. S. Thampi). Research Laboratory, Norristown State Hospital, Norristown, PA 19401

Using females from an inbred strain of Sprague Dawley derived rats selectively bred for high activity wheel levels for 18 generations, the following paradigm was carried out. Subjects starting at 68 days of age were allowed to acquire a wheel running pattern through free access to an activity wheel over a period of 20 days. Bilateral lesions to both basolateral and corticomedial structures were produced by radiofrequency technique in 4 subjects (A). An equal number of sham operated controls (C) were prepared. After a period of 16 days to allow for recovery and partial extinction of the activity pattern, reacquisition of wheel running was measured over a period of 16 days. In addition to measurement of circadian patterns, hourly activity determinations were taken. The results of the acquisition are shown in the accompanying graph. (A) shows a 57% increase in initial activity (days 1-4). The acquisition rate for both (A) and (C) are the same for the first 8 days, both showing a doubling of activity. From day 9 to 16 a compensatory mechanism becomes evident and the activity levels are essentially the same in the last block (13-16). The averaged hourly data taken during the last block also indicate a tendency to rhythmic lability of response in (A) with peak activity occurring at hours 2, 5 and 9, (C) showing one major peak at 2 hrs with a gradual decline. The observed disinhibitory effect in (A) does not appear to be related to a concommitant deprivation state due to food or water uptake. The results suggest that the amygdala, receiving input from all sensory modalities, functions as a scanning and gating organ which determines 'physiological readiness' in behavioral states.



700 LIMBIC INPUT INTO THE VENTROMEDIAL NUCLEUS OF THE RABBIT. J.E. Marchand, J.F. DeFrance, and J.C. Stanley. Department of Neurobiology and Anatomy, The University of Texas Medical School at Houston, P.O. Box 20708, Houston, Texas 77025.

Field and extracellular potentials were recorded in the Ventromedial Nucleus of the Hypothalamus (VMH) to stimulation in the fimbria and stria terminalis at the level of the dorsal hippocampus. Recording and stimulating electrodes were glass micropipettes filled with 2M NaCl and fast green for later localization of tip position (Thomas and Wilson, 1965). Animals were anesthetized with urethane (1g/kg, i.p.). In order to better visualize recording and stimulating electrode placements, the overlying cortex was removed by aspiration and the exposed structures were covered with warm mineral oil. Recording positions were localized to the VMH using field responses to stria terminalis stimulation (Renaud, 1976), and later verified by histology.

The field response to lateral fimbria stimulation was dominated by a positivity with a peak latency of approximately 15 msec. Responses to stria terminalis were of two types: a negativity with peak latency of 8 msec, and a positivity with peak latency of 25 msec. Histology of stimulating locations indicated that the 8 msec negativity occurred when the electrode tip (25-50μm) was in the ventral component of the stria terminalis, and that the 25 msec positivity occurred when the electrode tip was in the dorsal component of the stria. This corresponds well with the anatomical studies of de Olmos (1972). All three responses were sharply localized to the VMH and in depth profiles, their appearance and disappearance were parallel to each other.

Paired stimulus testing was used to evaluate the functional characteristics of these pathways, in particular with regard to inhibition. Most notable was a long-term suppression of the negativity to stria stimulation with interstimulus intervals of up to 3 seconds.

Anatomical studies indicate that the fibers of the lateral fimbria originate in the ventral subiculum of the hippocampal formation, and as they curve ventral and caudal, they make up the medial cortico-hypothalamic tract (Raisman, 1966). The stria terminalis consists of fibers arising largely from the amygdala. This study, then, indicates a strong and apparently complete overlap of amygdala and subicular inputs to the VMH. Such overlap suggests strong functional interaction of these two limbic centers in control of the VMH.

701 AFFERENTS TO THE INTERPEDUNCULAR NUCLEUS OF THE RAT. R. Marchand, J. N. Riley, and R. Y. Moore. Dept. of Neuroscience School of Medicine, Univ. Calif., San Diego, LaJolla, CA 92093.

The interpeduncular nucleus (IPN) receives its major input from the habenular nuclei. Recent studies indicate that fibers of other afferents may undergo sprouting in the IPN, following lesioning of the habenular nuclei. It seemed worthwhile, therefore, to further characterize the afferent connections of the IPN in order to determine candidate structures for this observed morphological and biochemical plasticity.

Horseradish peroxidase (HRP) was deposited in the IPN of adult female Sprague-Dawley rats by microelectrophoresis. Following intracardiac perfusion, frozen sections were prepared and processed for a blue reaction product. To date, brains from 20 animals have been examined.

Reaction product was observed in neurons of the medial habenular nuclei, raphe nuclei (nucleus central superior and nucleus dorsalis), dorsal and probably ventral tegmental nuclei, parabigeminal nucleus and the locus coeruleus. In addition, neurons of the trigeminal principal sensory nucleus were labeled following injections of caudal IPN, probably reflecting uptake into fibers of passage. While our analysis of caudal brainstem structures is incomplete, there appear to be no major afferents to IPN from this region.

Afferents from the habenular nuclei appear to arise exclusively from the medial cell group. Following injections restricted to the IPN, only cells in the medial nucleus were labeled. The number of labeled cells in the lateral habenular nuclei appears directly related to the degree of spread of HRP into the ventral tegmental area. The projection of the medial habenular nuclei appears to be bilateral, with a tendency for the ipsilateral side to predominate.

The input from the raphe nuclei appears to be topographically organized. Deposits of HRP restricted to ventral IPN only occasionally labeled cells in the nucleus central superior. Cells in raphe dorsalis are labeled only after injections of the entire or lateral portions of the IPN.

Dorsal tegmental nucleus labeling is restricted to its medial and dorsal portions; few labeled cells appear in the central portion. Labeled cells were observed lateral to the dorsal tegmental nucleus. The ventral tegmental nucleus is filled with a dense fiber plexus making interpretation of labeled cells difficult.

Based on the number of cells demonstrating HRP reaction product, the major afferents to the IPN appear to be the medial habenular nucleus and restricted portions of the dorsal tegmental nucleus.

702 DISSOCIATIONS BETWEEN HYPOTHALAMIC KNIFE CUTS AFFECTING SEXUAL BEHAVIOR, PUP RETRIEVAL, AND OBJECT RETRIEVAL IN FEMALE HAMSTERS. David M. Marquest, Charles W. Malsbury§, and Joanne T. Daood*§. †Dept. Psychol., U. of Pittsburgh, and §Depts. Psychiatry and Psychol., Western Psychiat. Inst. and Clinic, U. of Pittsburgh Sch. Med., Pittsburgh, PA 15260

This study explores the roles of the lateral connections of the medial hypothalamus in hamster pup retrieval, pup cannibalism, nest building, sexual behavior, and object retrieval. Sagittal knife cuts lateral to the medial preoptic-anterior hypothalamic area disrupt pup retrieval and nest building but not sexual behavior in female rats (Numan, JCPP, 1974, 87:746). Sagittal knife cuts lateral to this area do not disrupt female mating behavior (lordosis) in the hamster, either, but more posterior cuts do (Malsbury and Daood, sub. for pub.). In the present study, female hamsters were pretested for their response to pups as virgins, then received sagittal cuts either lateral to the anterior hypothalamic area (anterior cuts) or lateral to the medial anterior hypothalamic-ventromedial nucleus (posterior cuts). Postoperatively females were tested a) as virgins, for changes in pup retrieval and cannibalism, b) for mating behavior, c) for maternal care and cannibalism of their own pups, and d) for object retrieval.

On first encountering hamster pups, virgin female hamsters typically either retrieve pups to their nest or cannibalize them. When mated, nearly all female hamsters cannibalize part of their litters, yet retrieve all pups in retrieval tests. Anterior cuts converted retrieving virgins to cannibalistic ones and reduced nest building. Almost all females with anterior cuts cannibalized their entire litters within a few days of parturition. Half of these females, however, did retrieve all pups in retrieval tests during the first three days post partum, and most of them retrieved pieces of wood and food. In contrast, posterior cuts reduced pup retrieval and cannibalism in virgins, and disrupted object retrieval. Posterior cuts did not reduce postpartum pup retrieval, but did reduce postpartum cannibalism. Anterior cuts did not affect lordosis; posterior cuts greatly reduced lordosis without eliminating ovulation. Anterior cuts are interpreted as having a somewhat selective effect of increasing cannibalism, and posterior cuts as having a more general disruptive effect on behavior.

703 INCREASED ACOUSTIC STARTLE FOLLOWING DORSAL RAPHE OR FORNIX LESIONS. C. M. Miezejeski, L. W. Hamilton, and C. R. Timmons. N.Y.S. Inst. Bas. Res. Ment. Retardation, 1050 Forest Hill Rd., Staten Island, N.Y. 10314 and Rutgers University, New Brunswick, N.J.

Contrary to most other reports, Miezejeski (EPA, 1977) demonstrated that dorsal raphe lesions produce a form of hyperreactivity that is distinguishable from that produced by median raphe lesions. While the latter appear to cause indiscriminate hyperreactivity, the dorsal lesion produces heightened reactivity to distinctive forms of stimulation. Using a form of stimulation that offers a very high signal/noise ratio, i.e. a startle eliciting auditory stimulus, the first experiment examined the effect of a dorsal raphe lesion on the acoustic startle response.

A special apparatus that could record the rapid ballistic movement of the rat's muscular response to the stimulus was developed. The startle-eliciting stimulus was the click of a heavy duty 24VDC solenoid at 50 cm from the test cage. The startle apparatus was interfaced with a Nova-2 computer equipped with an A-D converter. After a 50 msec post-stimulus delay, the computer cumulated the voltage output of the apparatus during the next successive 450msec. Adult male Sprague-Dawley rats, 8 with dorsal raphe lesions and 8 operated controls, were each tested during one 90 min session in the startle apparatus. A session consisted of 15 min of adaptation during which the computer sampled baseline body movement once every 30 sec and 75 min during which the startle-eliciting stimulus was presented every 30 sec (150 trials). Rats with dorsal raphe lesions showed greater startle amplitudes than did the controls ($< .05$).

Recent findings indicate that surgical disruption of either the forebrain septo-hippocampal pathway of the fornix or the midbrain dorsal raphe produces similar increases in behavioral reactivity (Capobianco & Hamilton, Physiol. Behav. 17:65, 1976; Miezejeski, EPA, 1977; Miezejeski, Life Sci. 20:2087, 1977; Ross, Grossman, & Grossman, J. comp. physiol. Psychol 89:5, 1975). Consequently, in a second experiment identical to the first, 10 rats with fornix lesions and 10 operated controls were each examined once in the startle apparatus. Again, the lesioned rats showed greater startle amplitudes ($< .001$).

These results, combined with the above mentioned previous reports of similar changes after either dorsal raphe or fornix lesions, can be contrasted with other findings obtained following either median raphe or hippocampal lesions (Jacobs, Trimbach, Eubanks, & Trulson, Brain Res. 94:253, 1975). Such comparisons suggest that there may exist two functionally different ascending midbrain raphe inhibitory circuits: 1)a direct monosynaptic median raphe-hippocampal pathway and 2)an indirect polysynaptic dorsal raphe-septo-hippocampal pathway.

704 FIMBRIA-FORNIX LESIONS EFFECT THE RESPONSE OF HIPPOCAMPAL UNITS TO SPATIAL CUES IN THE RAT. Virginia M. Miller* and Phillip J. Best. Dept. Psychol., Univ. of Va., Charlottesville, Va. 22901.

Hippocampal unit activity (HUA) is correlated with an animal's location in space while performing spatial discrimination tasks. Intact animals trained to sample each arm of an 8 arm radial maze for food rely on distal spatial cues in making arm selections. Fimbria-fornix (FF) lesions substantially debilitate performance on this task. Furthermore, following axial rotation of the maze, intact animals do not avoid the physical arm from which food has previously been removed, but rather avoid the directional orientation that the arm had occupied.

The present study considers two problems: does the spatial correlate of HUA persist after axial rotation of a radial maze, and how do FF lesions effect the spatial behavior of hippocampal units?

All 15 units recorded in intact rats showed spatial correlates. Typically, the unit showed substantial increase in activity on one of the arms. After 90° rotation of the maze, 13 of the 15 ($p<.004$) maintained increased activity in the original directional orientation. Nine of the 13 units studied in FF rats showed spatial correlates similar to those seen in intact rats. However, only 2 of these 9 ($p>.98$) maintained increased activity in respect to the original directional orientation after rotation of the maze.

Of the units which did not show maintained directional orientation, the activity of 3 units (1 intact, 2 FF) followed the physical arm. The activity of the remaining 6 (1 intact, 5 FF) showed no relationship to the physical arm or the original directional orientation.

The directional orientation of HUA is maintained following axial rotation of the maze. Since 9 of 13 units in FF lesioned animals showed spatial responses prior to maze rotation, the deficit in performance of FF lesioned rats must be due in part to disturbance of hippocampal efferents. However, since most of the units (7 of 9) did not show the maintained spatial response seen in intact animals following maze rotation, afferent information entering the hippocampus by way of the FF must also play a role. (Supported by Sloan Foundation Fellowship to VMM and NIMH Grant #16578 to PJB).

705 CROSS CORRELATION ANALYSIS OF 40 Hz ACTIVITY IN THE SIGMOID GYRUS, NUCLEUS ACCUMBENS AND AMYGDALA. R. John Morgan, Colorado State Univ., Ft. Collins, CO 80523; Calvin C. Turbes, Gerald T. Schneider* and J. Marc Simard*. Dept. Anat., Sch. Med., Creighton University, Omaha, NE 68178

Cross correlation analysis is carried out on electrical activity in the sigmoid gyrus, nucleus accumbens and amygdala. The studies are on eight cats with chronic electrode implants. Recordings are made using radiotelemetry and hardwire procedures.

Correlation analysis shows the direction of signal flow (40 Hz) between the sigmoid gyrus and nucleus accumbens and amygdala. With correlation analysis feedback pathways as from sigmoid gyrus to the amygdala or amygdala to nucleus accumbens and vice versa can be investigated. This aspect of the analysis is important and interesting since it is possible to study functional oscillating or reverberating circuits in relation to hormonal and/or behavioral influences.

Time delay, or, tau (τ), values indicate direction of electrophysiologic transmission of information from one recording site to another. Tau values for amygdala to sigmoid gyrus ranges from 20.13 to 22.43 milliseconds. Neurotransmission between sigmoid gyrus to amygdala shows one pathway ranging from 612 μs to 7.21 ms. There is another pathway with (τ) value of 24.31 ms to 26.70 ms; another animal showed a sigmoid gyrus to amygdala transmission of 6.82 ms with an average of 1000 samples.

In three animals amygdala to sigmoid gyrus transmission ranged between 10.35 ms to 14.51 ms. Another slower transmission pathway was apparent in these data at 38.21 ms to 42.43 ms. Transmission from amygdala to nucleus accumbens ranged between 12.06 ms to 13.40 ms in two animals. Accumbens to amygdala transmission ranged between 4.80 ms to 5.32 ms. In this data there was a second path with values that ranged between 10.34 ms to 11.78 ms.

706 PROJECTIONS TO MESENCEPHALIC CENTRAL GREY RELATED TO ESTROGENIC CONTROL OF REPRODUCTIVE BEHAVIORS. J. I. Morrell, L. M. Greenberger*, D. W. Pfaff. The Rockefeller Univ., New York, NY 10021.

Many specific cell groups in the forebrain contain cells which concentrate sex steroids; the neuroanatomical connections of these cell groups are of particular interest with regard to mediation of reproductive behavior and neuroendocrine events (Krieger et al., 1977, Brain-Endocrine Interaction III, Scott et al., eds., Karger). Several such cell groups in the hypothalamus have been shown to have connections with the central grey, which itself has been implicated by neurophysiological data in the control of sex behavior and pain mechanisms. To study its afferent connections, horseradish peroxidase (HRP) was applied in and around the central grey of 41 rats. The animals were allowed to survive 2 days, and after appropriate preparation, the sections were reacted in a DAB (diaminobenzidine) procedure. The brains from 14 animals were fully analyzed for cells with regular brown granules in the somatic cytoplasm and processes (defined as an HRP labeled cell). The ventromedial nucleus (VMN) of the hypothalamus contained the largest number of HRP labeled cells, mostly in the rostral half of the nucleus, and scattered in the ventrolateral portion, ipsilateral to application site. A smaller number of HRP labeled cells were seen contralateral to the application site. Zona incerta also contained many labeled cells. In addition, labeled cells were seen, mostly ipsilateral, in the anterior and the lateral hypothalamic areas, periventricular area, arcuate nucleus and paraventricular nucleus. A small number of labeled cells were found in the lumbar and sacral spinal cord contralateral and mostly in laminae III-V. Control applications of HRP just outside the central grey resulted in very few labeled cells in the hypothalamus. Injections into the mesencephalic ventricle produced no HRP labeled cells or fibers. These results are consistent with previous reports on the efferent projections of hypothalamic cell groups, specifically the VMN (Krieger et al., 1978, J.C.N. in press). The connections are a route by which hypothalamic cell groups which contain sex steroid concentrating cells could effect activity in behaviorally-relevant brainstem circuits.

707 CYTOPATHOLOGICAL CHANGES IN HIPPOCAMPUS AFTER INTRAVENTRICULAR INJECTION OF KAINIC ACID. J. Victor Nadler, Bruce W. Perry*, Christine Gentry* and Carl W. Cotman. Dept. Psychobiol., Univ. Calif., Irvine, CA 92717.

Kainic acid preferentially destroys hippocampal pyramidal cells when the drug is injected intraventricularly. We have characterized the hippocampal cytopathology by light and electron microscopy. In these studies 2.5 nmol of kainic acid was injected into each lateral ventricle over a period of 30 min. Pathological changes in area CA3, the most sensitive hippocampal region, could be detected by electron microscopy as soon as 1 h after kainic acid administration, a time when convulsive symptoms were already prominent. The earliest changes included astrocytic hypertrophy, irregularities in the shape of pyramidal cell nuclei and some increase in the number of lipofuscin granules within the pyramidal cell cytoplasm. There followed dilation of cisternae of the endoplasmic reticulum, disaggregation of polyribosomes, dissolution of chromatin and dendritic swelling. Within 4 h the pyramidal cells atrophied, assumed an irregular shape and became electron dense. Similar changes could be recognized at 4-h survival in light microscopic preparations stained with cresyl violet. Breakdown of cytoplasmic organelles and glial phagocytosis were well advanced 24 h after treatment. Some neurons in area CA3 appeared completely unaffected, but it is not clear what proportion of these were pyramidal cells and what proportion interneurons.

When the CA3 pyramidal cells had degenerated, mossy fiber boutons were less frequently encountered. Very few of them appeared to degenerate, however. Mossy fiber boutons present 6-8 wk after treatment were nearly always found to be making synapses on the remaining neuronal population. These afferents therefore did not seem to have been directly or permanently injured by the drug treatment.

Bilateral kainic acid administration considerably reduced the synaptic density of the molecular layer of the fascia dentata and of stratum radiatum of area CA1. The synaptic loss in the dentate molecular layer was attributable in part to degeneration of associational and commissural boutons within its inner third and in part to a decrease in the incidence of small dendritic spines throughout the layer. In stratum radiatum of area CA1 up to 90% of the presynaptic elements were found to be degenerating 1-7 d after treatment, due to destruction of Schaffer collateral and commissural afferents. Both denervated zones were largely reinnervated by 6-8 wk after treatment. (Supported by NSF grant BNS 76-09973 and NIH grant NS 08597).

708 IMMUNOHISTOCHEMICAL LOCALIZATION OF N-ACETYLSEROTONIN IN RAT HIPPOCAMPUS. Aldis V. Porietis, Gregory M. Brown and Lee J.Grota Dept. Neurosciences, McMaster University, Hamilton, Ontario, Canada, L8S 4J9.

In order to investigate the function of indolealkylamines, in particular N-Acetylserotonin(NAS), in brain, we have developed several antibodies to these compounds. Antiserum against both NAS and melatonin was produced in rabbits using NAS coupled to bovine serum albumin(BSA) via the Mannich reaction, (Br.Res.81, 233,1974). Antibody to melatonin only was produced using the antigen melatonin-BSA, coupled by the Mannich reaction (Can.J. Bioch.52,196,1974). Antiserum to NAS was produced using, as an antigen, NAS coupled to BSA via a paracarboxybenzyl bridge attached at the indole nitrogen (unpubl.). The first two antibodies have been used in the past studies to differentiate, histologically, between NAS and melatonin (Br.Res.118,417,1976). We decided to use this technique as well as the more recent, specific anti-NAS antibody to extend an earlier observation which suggested the presence of N-Acetylindolealkylamines (NAI's) in the hippocampus.

All three antibodies were used in parallel preparations in a double-antibody fluorescence technique. Controls consisted of saturating the primary antibody with the appropriate amine,either NAS or melatonin, in a small volume of ethanol. The non-absorbed sera contained an identical concentration of ethanol. Results using the anti-NAI antibody confirmed the presence of either or both NAS and Melatonin in the hippocampus of rats. This staining was localized to the polymorphic cell layer of the dentate gyrus, and Layer III of the hippocampus proper. An identical distribution of staining was seen with the antibody directed against NAS. The antibody directed against melatonin, however, did not stain the hippocampus in any detectable fashion, leading to the conclusions that the staining seen in the hippocampus is largely, if now exclusively, NAS. Present data suggest that the visualized NAS is located in smaller structures, perhaps nerve fibres, rather than in cell bodies of the hippocampal formation. Studies are presently under way to improve the resolution of the technique to the point where the precise localization within cells is possible.

It is concluded that NAS is specifically localized in the hippocampus of the rat. Further physiological and anatomical studies will be necessary to determine the possible function of this amine as a neurotransmitter or neuromodulator in this area of brain.

709 NEOCORTICAL AND HIPPOCAMPAL ELECTRICAL ACTIVITY IN THE DOPAMINE DEPLETED RAT: RELATIONS TO BEHAVIOR AND EFFECTS OF ATROPINE. T.E. Robinson*, I.Q. Whishaw* and T. Schallert* (SPON.: C.H. Vanderwolf). Dept. of Psychology, Univ. of Lethbridge, Lethbridge, Alberta Canada.

Previous studies have shown that dopamine(DA)-depleted rats are impaired in initiating movements such as rearing and walking ('voluntary' or Type I movements), movements which are accompanied by neocortical low voltage fast activity (LVF) and hippocampal rhythmical slow activity (RSA; theta; see Vanderwolf, JCPP 38: 300, 1975). This study examined the possibility that DA is also involved in producing these slow wave (EEG) waveforms. EEG records were obtained from unrestrained rats which were depleted of 97-100% of brain DA by the use of multiple intraventricular injections of 6-hydroxydopamine (6-OHDA), following pretreatment with pargyline. Neocortex: For the first 1-5 days following 6-OHDA large amplitude slow waves were common in the neocortical record during behavioral immobility. The presence of these immobility-related slow waves decreased from 91% of the sample time on day 1 post-op to 3% on day 5 and 0.1% on day 10. Although the 6-OHDA treated rats were severely akinetic, whenever they did move spontaneously, or were induced to struggle, LVF appeared (even on day 1). Hippocampus: On days 1 through 30 post-op RSA with normal amplitude and frequency accompanied any spontaneous Type I movements, and induced struggling. After day 5 post-op low frequency RSA was occasionally observed during immobility, in 6-OHDA treated rats only. Atropine: After treatment with atropine sulfate (50mg/kg, i.p.) both RSA and LVF continued to accompany any Type I movements, as in controls. On days 15 and 30 post-op atropine caused 6-OHDA rats to walk vigorously with short abbreviated steps, and RSA and LVF accompanied this behavior. Behavior: Video-recordings (24 hr) of behavior revealed that 6-OHDA rats did not initiate movements such as walking or rearing, did initiate grooming as often as controls, and continuously made postural shifts reminiscent of the akathisia of some Parkinson patients.

In conclusion, DA is probably not critically important for the production of RSA or LVF. However, DA may be indirectly involved in controlling the probability of occurence of LVF and RSA by controlling the probability of occurence of behaviors such as walking and rearing (Type I behaviors). In addition, comparison of the effects of 6-OHDA treatment and hypothalamic lesions on neocortical and hippocampal electrical activity suggests that the effects of hypothalamic lesions on the EEG are not due only to DA depletion.

710 FURTHER OBSERVATIONS ON GRANULE CELL DETERIORATION AFTER ANODAL DIRECT CURRENT LESIONS. Russell E. Ruth, Scott Cain,* Anthony DiGianfilippo* and Aryeh Routtenberg. Cresap Neuroscience Laboratory, Northwestern University, Evanston, ILL 60201.

We recently described extensive granule cell deterioration (GCD) following small, electrophysiologically-guided anodal direct current (a-DC; 60 μA) lesions of rat dentate gyrus (Ruth and Routtenberg, Brain Research, in press). It was found that (i) a-DC lesions caused the spread of GCD far beyond the confines of the primary lesion (defined as central cavity plus surrounding acellular region); (ii) GCD appeared as a beam of degenerated cells oriented roughly in the lamellar plane of Blackstad et al. (J. comp. Neur., 103, 1970, 433-450); (iii) this reaction was detectable light-microscopically between 1½ - 3 hrs post-lesion; (iv) neither radio-frequency (heat) nor microknife lesions provoked GCD outside the lesion boundary.

Several additional observations have been made. 5 μA a-DC is near threshold for provoking GCD. At 7 μA (applied for 2 min) extensive GCD can be observed. The severity of GCD appears greater in younger animals (25 days old). Spontaneous discharge rate of granule cells recorded approximately 1 mm from the lesion site shows a rapid decrease following small a-DC lesions.

Of particular interest is the failure of cathodal direct current lesions to provoke GCD even though the primary lesion is at least as large as in the case of anodal lesions. This observation, coupled with the failure of radio-frequency or microknife lesions in producing GCD, emphasizes that a lesion per se is not sufficient to produce GCD. The specificity of response of granule cells to a-DC may be indicative of an endogenous sensitivity to DC gradients, which are known to exist in dentate gyrus (Gloor et al., Electroenceph. Clin. Neurophysiol., 15, 1963, 353-378). (Supported by MH 25281 and NSF 19388 to A. R.)

711 ELECTROPHYSIOLOGICAL ACTION OF KAINIC ACID ON HIPPOCAMPAL SLICES. John Ryan* and Carl W. Cotman. Dept. Psychobiology, Univ. Calif., Irvine, CA 92717.

Intraventricular kainic acid (KA) destroys rat hippocampal pyramidal cells with great potency. CA3 pyramidal cells are most sensitive to KA, followed by CA1 pyramidal cells, and dentate granule cells are virtually resistant to the drug. Since it is believed that the neurotoxic action of KA is linked to its neuroexcitatory properties, we have investigated its electrophysiological actions on hippocampal neurons in a slice preparation. KA (47 μM) similarly altered the response of CA3 pyramidal cells to mossy fiber stimulation, CA1 pyramidal cells to Schaffer-commissural stimulation and dentate granule cells to perforant path stimulation. First, a population spike appeared on the extracellularly recorded EPSP, then the amplitude of the population spike increased and its latency decreased, and finally the population spike broadened and subsided as all postsynaptic response was lost. This sequence occurred rapidly in area CA3 and relatively slowly in the dentate gyrus. The loss of the orthodromic response recorded in area CA3 is coincident with loss of the antidromic response to the same region. Prolonged washing with drug-free solution often restored the evoked response to perforant path stimulation, but only seldom to Schaffer-commissural stimulation and never to mossy fiber stimulation.

All hippocampal neuronal types responded to KA (47 nM-47 μM) with a large burst of firing, usually followed by an abrupt decline in spontaneous activity while still in KA. CA3 pyramidal cells were most sensitive and dentate gyrus granule cells least sensitive to KA. Bursting cells responded similarly to non-bursting cells of the same region. In contrast to the sensitivity of extracellular EPSPs and single unit activity to KA, the fiber potential of the mossy fibers was unaffected.

In the absence of Ca^{2+} only a slight increase in spontaneous unit firing preceded the cessation of activity in pyramidal cells. The offset of activity was typically more gradual than in Ca^{2+} media; it partially returned in some cases when KA was removed. No spontaneous activity of granule cells was observed. KA also reversibly abolished activation of all cells by antidromic stimulation in Ca^{2+} free media and, for CA3, in normal media. Thus Ca^{2+} deficient medium essentially dissociated the excitatory effect of KA on hippocampal neurons from the ultimate depression. These findings suggest that the excitatory action of KA depends on a Ca^{2+}-dependent process, but its depressant effect does not. (Supported by NIMH grant MH19691).

712 THE DISTRIBUTION OF CELLULAR DEGENERATION FOLLOWING SYSTEMIC OR INTRACEREBRAL INJECTION OF KAINIC ACID. J.E. Schwob*, T. Fuller*, and J.L. Price, (SPON: W.T. Thach, Jr.). Depts. Anat. & Neurobiol., and Psychiat., Wash. Univ. Sch. Med., St. Louis, MO 63110

The intracerebral or systemic injection of kainic acid (KA) or other analogues of glutamate causes neuronal cell death; this toxicity has been suggested to be related to the direct excitatory action of glutamate and its analogues (Olney et al., '74). We have surveyed the effects of systemic or intracerebral injections of KA on the forebrain of rats using frozen sections stained with the Nissl method or the cupric-silver method of De Olmos to reveal areas of cellular damage and agyrophilia.

Systemic administration of KA has effects on widespread regions on the forebrain although the extent of the lesion can vary even among animals that received the same dosage of KA. Agyrophilic neurons and/or cellular debris and gliosis are seen especially in parts of the hippocampal formation, septum, olfactory cortex, amygdaloid complex, mediodorsal and medioventral nuclei of the thalamus and several related neocortical areas, as well as in other parts of the neocortex, thalamus and hypothalamus. More severe lesions have an increased degree of degeneration within the listed areas as well as damage that extends to other areas of neocortex and thalamus.

Direct intracerebral injections will destroy neurons near the injection in virtually all forebrain regions and may also cause cell damage at more distant sites. These patterns of cellular degeneration vary with the injection site, and may be different from those seen with systemic injections. For example, field CA3 of the hippocampus is more sensitive than field CA1 to systemic or direct intracerebral injections near the dorsal hippocampus. However, intracerebral injections of KA into the posterior piriform cortex (PC)/entorhinal area (EA) affect CA1 more severely than CA3. Damage to CA1 is correlated with degeneration of the cells in layer III of the EA and in the ventral subiculum. Also, injections that cause cellular degeneration in some parts of neocortex can induce cell death in the corresponding thalamic nuclei (e.g. the taste cortex and VM, pars basalis of the thalamus may be affected concurrently although they are relatively undamaged following systemic injections which destroy adjacent neocortical areas). Furthermore, injections in the rostral PC cause cellular damage extending to the posterior limit of PC ipsilateral and, in some cases, contralateral to the injection. These results are difficult to explain on the basis of diffusion and/or differential sensitivity and suggest that the pattern of damage may be related to axonal connections between the affected areas. (Supported by NIH grants NS09518, GM07200, ES07066)

713 REGIONAL ORGANIZATION OF INPUT AND OUTPUT PATHWAYS OF THE NUCLEUS ACCUMBENS SEPTI. R.W. Sikes, J.F. DeFrance, R.B. Chronister, J.E. Marchand, and J.C. Stanley. Department of Neurobiology and Anatomy, The University of Texas Medical School at Houston, P.O. Box 20708, Houston, Texas 77025, and the Department of Anatomy, University of South Alabama, Mobile, Alabama 36688.

Combined electrophysiological and horseradish peroxidase (HRP) techniques were used to explore regional differences within the nucleus accumbens septi (nAcS), with respect to efferent and afferent pathways. Glass micropipettes, filled with fast green (Thomas and Wilson, 1965), were used both for stimulation and recording in acutely prepared rabbits. Field and unitary potentials were recorded in the nucleus accumbens septi following stimulation of the following regions or structures: fimbria (IFIM), stria terminalis (ST), lateral septal nucleus (LSN), lateral preoptic area (lPOA), and mesencephalic cell group A10. HRP injections were made in the nAcS and in A10.

The results can be summarized as follows: IFIM, ST, and LSN input terminate, for the most part, in the nucleus accumbens septi, proper of Koikegami et al (1967). The IFIM and ST are restricted to the more caudal aspects of the nucleus. The lPOA input is heaviest in the portion of the accumbens nucleus below the proper nucleus accumbens septi; i.e., nucleus accumbens pars medialis. The major efferent projection of the nucleus accumbens appears to arise from pars medialis.

714 POTENTIATION CHARACTERISTICS OF HIPPOCAMPAL RESPONSES IN THE ACUTE RABBIT. J. C. Stanley, J. F. DeFrance, and J. E. Marchand. Dept. Neurobiol. and Anat., Univ. of Texas, Houston, TX 77025.

A variety of studies have shown that the hippocampus (HC) displays considerable plasticity of response. Stimulation of HC afferents using low frequency pulse trains causes marked potentiation of responses during and after the stimulus train. Facilitation during the train, called tetanic potentiation (TP), can reach several hundred percent of pre-tetanic levels. The potentiation can outlast the stimulus train for seconds or hours; this effect is post-tetanic potentiation (PTP). Potentiation has been investigated using a number of HC afferent systems, both in vivo and in vitro. Afferents from the septum have not been well studied, however. We deal here with the potentiation characteristics of septo-hippocampal and HC commissural afferents to field CA1 of the acutely prepared rabbit.

Adult, male, New Zealand rabbits were anesthetized with urethane. Following craniotomy, the cortex overlying the septum and HC was removed by suction and the exposed tissue was covered with warm paraffin oil. Micropipettes filled with 2M NaCl (1-10 MOhm) were used for both stimulating and recording. Recording was carried out in the stratum radiatum layer of field CA1 of the dorsal HC, where both septal and commissural afferents terminate. Stimulation of contralateral CA3 (cCA3) and of a fiber bundle arising from the ipsilateral medial septal region (MSR) gave rise to slow negativities, indicative of population EPSPs, and spikes, indicative of the simultaneous discharge of pyramidal cells. Brief trains (8 or 16 stimuli) of low frequency (1 to 20 Hz) were used. To study TP, the responses were averaged. In the study of PTP, individual responses elicited following the tetanus train were recorded for study.

Slow-wave responses to both cCA3 and MSR stimulation showed TP that commenced at 2Hz and reached a plateau at 8-12Hz. Both slow-wave responses displayed PTP which decreased rapidly in the first two seconds following the tetanus and decayed more slowly thereafter; baselines were generally reached after 8-10 seconds. The population spike exhibited TP in the range of 2-6Hz, but was suppressed at higher frequencies. The spike also showed PTP lasting several seconds. cCA3 test responses were enhanced 10-20% following a tetanus train applied to the MSR. Our results show that responses in the acute rabbit to both MSR and cCA3 stimulation display TP in the range of frequencies of the rabbit theta rhythm. Both responses displayed PTP lasting several seconds. Facilitation of the MSR response led to a small but consistent increase in the cCA3 response, in a process of heterosynaptic facilitation.

715 ORGANIZATION AND EFFERENT PROJECTIONS OF THE INTERPEDUNCULAR COMPLEX IN THE CAT. W.D. Stofer* and S.B. Edwards. Dept. Anat., Sch. Med., Univ. of Va., Charlottesville, Va. 22901

The cytoarchitecture and efferent projections of the interpeduncular complex (IPC) were studied using Nissl-stained normal material and autoradiographic and horseradish peroxidase (HRP) tracing techniques.

Observations of normal material show that the IPC can be divided into rostral, central, and caudal thirds. Within each third are two or three cytologically distinct subgroups. A total of eight paired and unpaired subgroups are identifiable.

The autoradiographic tracing method revealed that IPC efferents are organized into two main fiber bundles. One main bundle ascends and then splits in the rostral midbrain into two divisions. One division follows the fasciculus retroflexus and terminates largely in the dorsomedial nucleus of the thalamus and not, as previously thought, in the lateral habenula. The other division follows the medial forebrain bundle to the diagonal band of Broca with en passage terminations in the lateral hypothalamus. Other fibers in the medial forebrain bundle turn dorsally and terminate in a triangular-shaped region of the thalamus situated ventrolateral to the central medial nucleus. Still other fibers leave the medial forebrain bundle and pass into medial and lateral septal nuclei and region CA3 of the ventral hippocampus. The other main efferent bundle from the IPC descends to the nucleus centralis superior, ventral central grey matter, dorsal and ventral tegmental nuclei of Gudden, and nucleus raphe dorsalis. Autoradiographic and HRP methods were used to determine whether these various efferent connections arise from specific IPC subgroups. Tritiated leucine injections restricted to the central third of the IPC produce labeling mainly of descending fibers. Single HRP injections in the lateral hypothalamus, septum, or raphe dorsalis consistently produce reaction product filled neurons restricted to some, but not all, of the subgroups of the IPC. Thus, at least some of the subgroups of the IPC maintain selective projections within the total pattern of IPC efferent projections.

These results reveal IPC efferent projections that are new or different from previous reports. New projections are those to the thalamus, hippocampus, and raphe dorsalis. The results further indicate that a high degree of specificity exists within the efferent connections of the different subgroups of the IPC.

716 VALIUM: A SUPPRESSOR OF HIPPOCAMPAL PYRAMIDAL CELL EXCITABILITY. K. Taber, J.F. DeFrance, J.C. Stanley, J.E. Marchand, P. Divakaran and Y. Clement-Cormier. Department of Neurobiology and Anatomy and the Department of Pharmacology, The University of Texas Medical School at Houston, P.O. Box 20708, Houston, Texas 77025.

Diazepam (Valium) was studied electrophysiologically and biochemically in the hippocampus of acutely prepared rabbits. For the electrophysiological analysis microstimulation electrodes (1-2 megohms) were placed in the medial septal region (MSR) and in the contralateral hippocampal field CA3. Microelectrodes were used to record monosynaptic field responses in hippocampal field CA1. Power and paired-stimulus testing, along with trains of tetanically potentiating stimuli, were used to characterize field responses and to assess the drug effect. The results were: (1) Iontophoretically applied diazepam increased the threshold for the appearance of the population spike to single stimuli. The corresponding population EPSPs were unaffected, except at high dosages given either i.v. or i.p. Also, there was a reliable increase in the amplitude of the population spike at supramaximal stimulus intensities. (2) Diazepam attenuated test response facilitation in paired-stimulus testing paradigms. (3) Diazepam attenuated the post-tetanic potentiation seen following the presentation of high-frequency trains. (4) Diazepam prevented the normal increase in cyclic GMP levels following tetanic stimulation.

The data indicate that diazepam decreases hippocampal pyramidal cells excitability, and may do so by suppressing cyclic GMP mechanisms.

717 AFFERENTS TO THE MACAQUE AMYGDALA BY WAY OF THE ANTERIOR COMMISSURE. Blair H. Turner. Howard University, Washington, D.C. 20059.

A study was made to determine if the primate amygdala receives afferents from the contralateral telencephalon by way of the anterior commissure. In the control monkey, an aspiration lesion was made in that part of the body of the corpus callosum through which the anterior commissure can be approached. In the two experimental animals, the same part of the corpus callosum was cut, and the anterior commissure visualized and sectioned. Following a survival period of six days, the animals were perfused and their brains prepared with the Fink-Heimer technique. No evidence of terminal degeneration was found in the amygdala of the control brain. In the experimental brains, degeneration was observed in layers I and III of the temporal prepiriform cortex, and in layers I and III of the medial amygdaloid nucleus. Of the deep amygdaloid nuclei, only the lateral nucleus received contralateral afferents via the anterior commissure. Moderately dense degeneration was seen in this nucleus in its entire anterior-posterior and dorso-ventral extent. In the medio-lateral direction, degeneration was heavier in the lateral two-thirds than in the medial third of the lateral nucleus.

Besides containing fibers en route to the amygdala, the anterior commissure is known to include axons connected with temporal neocortex. In a previous study, unilateral lesions had been made in all of the cytoarchitectural divisions of temporal neocortex, and these brains revealed no evidence of projections to the contralateral amygdala. Based on these results, it may be hypothesized that the cells of origin of the projections reported here following section of the anterior commissure are located in the contralateral amygdala.

718 CORTICAL PROJECTIONS TO THE LATERAL ENTORHINAL AREA IN THE RHESUS MONKEY. Gary W. Van Hoesen, Douglas L. Rosene and Marek-Marsel Mesulam. Depts. Anat. and Neurol., Univ. Iowa, Iowa City, IA 52242, and Harvard Neurol. Unit, Beth Israel Hosp., Boston, MA 02215.

Previous silver impregnation studies in the monkey have demonstrated that the hippocampal formation is linked to cortical association areas via the entorhinal cortex. More recently, autoradiographic studies have demonstrated reciprocal connections between the subicular area of the hippocampal formation and several cortical areas of the temporal lobe. Although these studies establish a strong hippocampal-cortical relationship in the primate, much more remains to be learned about this linkage. In this study cortical projections to the entorhinal cortex were investigated in the rhesus monkey using the autoradiographic method. All major architectonic subdivisions of the temporal lobe were sampled with the exception of the primary auditory cortices.

Four areas have been identified which send direct, powerful projections to the entorhinal area. Individually, these correspond to Brodmann's area 35 and Bonin and Bailey's areas TF, TG and TH. Projections from areas TG and TH are directed primarily toward the lateral entorhinal area and a sizable zone previously called the intermediate entorhinal area. Projections from area 35 are distributed widely within the entorhinal area, but are especially heavy in the lateral and intermediate entorhinal areas. These projections as well as those from areas TG and TH terminate primarily in layers I-III. Projections from area TF are directed primarily toward the medial and intermediate entorhinal areas where evidence of termination is observed over layers I-II. In addition to these projections, areas TF, TG, TH and also area TE send projections to area 35 (perirhinal cortex) immediately lateral to the rhinal sulcus, and to the prorhinal cortex immediately medial to the rhinal sulcus.

These results demonstrate that the lateral and intermediate portions of the entorhinal area in the rhesus monkey receive several direct and powerful cortical projections. It would seem of considerable interest that in the human brain entorhinal areas greatly resembling these in terms of architecture are massive, and account for a majority of the cortex forming the hippocampal gyrus. Moreover, the temporal areas which project to the lateral and intermediate entorhinal areas have themselves been implicated in memory-related processes in both non-human primates and humans.

719 HISTOCHEMICAL DISTRIBUTION OF ACETYLCHOLINESTERASE IN THE HIPPOCAMPAL REGION OF THE RHESUS MONKEY (Macaca mulatta). Vijaya K. Vijayan* (SPON: Richard C. Carlsen). Department of Human Anatomy, University of California, Davis, California, 95616.

The localization of cholinergic neurotransmitter enzyme acetylcholinesterase (AChE, EC 3.1.1.7) in the hippocampus (H) and the dentate gyrus (DG) of the adult rhesus monkey was examined using a histochemical procedure. The supragranular zone of the molecular layer of DG exhibited the most intense AChE staining in the form of a band of reaction product occupying the lower one-third of that layer. Moderate enzyme reaction was present in the hilus of DG, in the neuropil as well as intracellularly in a small percentage of the polymorphic neurons located there. The AChE activity in the H appeared to be relatively greater in subdivisions CA3 and CA4 than in CA2 and CA1. The alveus and the fimbria exhibited a small percentage of stained fibers intermixed with a major number of unstained ones. The stratum oriens and the stratum radiatum demonstrated moderately AChE-reactive neuropil with occasional spindle shaped, AChE-positive neurons in the former zone. The mossy fiber zone was devoid of AChE staining with the exception of few enzyme-reactive processes running across it.

The distribution of AChE in the H and DG of the adult monkey was compared to that in neonatal animals and also to the previously described pattern of enzyme localization in the hippocampal region of the mouse (Vijayan, Anat. Rec. 187: 738, 1977).

720 DIFFERENTIAL EFFECTS OF LIMBIC SYSTEM LESIONS ON LONG-TERM AND SHORT-TERM SPATIAL MEMORY IN THE RAT. John A. Walker* (Spon: W. S. Stark) Department of Psychology, Johns Hopkins Univ., Baltimore, MD 21218

The limbic system in rats has recently been proposed to have a critical role in all types of spatial processing. However, damage to the limbic system, particularly hippocampus and its connection often results in no deficit in relatively simple tasks, but severe deficits in more complicated tasks requiring flexibility of memory. The present experiment was conducted to determine if the memory requirements of spatial tasks influences the retention of those tasks following limbic system damage.

Two tasks were developed, requiring either memory for only one goal within a test (a long-term memory task) or memory for each of two goals within a test (a short-term memory task). Each rat was assigned to one of the two tasks. Both tasks were conducted on an elevated spatial maze. In both tasks, rats were presented with a choice between two goals. In the long-term memory task, only one goal was rewarded, the same goal on each test, so that the rat was required to remember which goal was the rewarded goal. In the short-term memory task, both goals were rewarded, but only on the first choice of each goal, so that within a test the rat was required to remember which of the two goals had already been chosen in order to choose the other goal (rewarded alternation). Care was taken to prevent simple position habits from providing a solution to the tasks. Rats in both groups were tested preoperatively. Rats were then given either bilateral fornix lesions, disconnecting the hippocampal connections to subcortical structures, or sham operations. Testing was resumed after a week of recovery.

After surgery, sham operated rats in both groups continued to choose as accurately as in the preoperative period. In contrast, rats with fornix lesions in both groups showed a deficit in performance immediately after surgery. For rats with fornix lesions in the long-term memory task, performance improved over postoperative sessions with a time course similar to that of preoperative acquisition. For rats with fornix lesions in the short-term memory task, performance did not recover even when tested for 250 postoperative sessions, remaining at levels expected by chance.

The recovery of accurate performance by the rats in the long-term memory condition suggests that the fornix lesions abolished the memory of the preoperatively learned task, but did not prevent relearning the task postoperatively. The lack of recovery of accurate performance by rats in the short-term memory condition suggests that the fornix lesions permanantly abolished the ability to form short-term memories. These data indicate that performance in spatial tasks following limbic system damage is a function of the memory requirements of the task.

721 FUNCTIONAL ANATOMICAL MAPPING OF THE BASAL FOREBRAIN IN THE RAT AND CAT: A (^{14}C)-2-DEOXYGLUCOSE STUDY. R. Watson,* R. Troiano,* A. Siegel, R. Basri, R. D'Ascoli, C. Block* and J. Kerr.* (SPON: J. McArdle). Departments of Neurosciences and Physiology, New Jersey Medical School, Newark, New Jersey 07103.

When a specific brain region is electrically stimulated in order to evoke a specific behavior in an awake animal, it is difficult to determine the sum total of the functional subsystems which are activated or inhibited during the time period relative to that stimulation. We have utilized the technique of (^{14}C)-2-deoxyglucose radioautography to analyze the pattern of brain activity in the rat and cat following electrical stimulation of sites in the basal forebrain and limbic system. Most of the preliminary experiments have been performed in rats lightly anesthetized with ketamine and xylazine.

The results obtained to date indicate that the pattern of distribution of brain activity corresponds closely to the known anatomical pathways related to the stimulated sites. Specifically, orthodromic activation of efferent connections appear to predominate over other possibilities such as antidromic activation or recurrent inhibition. Multisynaptic activity has been difficult to identify under these experimental conditions.

When the lateral hypothalamus was stimulated a wide extent of the ipsilateral septal area, lateral habenular nucleus, ventral and central tegmental regions, and central gray were diffusely activated. Similarly, stimulation of the region of the mamillary bodies, dorsal hypothalamus, ventromedial nucleus, preoptic region and substantia innominata resulted in the activation of the known anatomical target neurons associated with these respective structures. Current experiments are attempting to compare the patterns of brain activity in unanesthetized, awake animals manifesting stimulus-bound behaviors with those obtained in the anesthetized preparations.

722 ULTRASTRUCTURAL EVIDENCE FOR CHANGES IN THE X-IRRADIATED RAT HIPPOCAMPUS. Walter I. Weiss*, Robert B. Wallace (SPON: N. Kirkland) Dept. of Psych., Univ. of Hartford, CT 06117.

Previous studies (Wallace, Kaplan & Werboff, 1976, Exp. Brain Res.; Neuroscience Abstracts, 1977) have reported the behavioral effects of focal hippocampal X-irradiation on neonatal rats. These studies included morphological evidence by light microscopy of dentate granule cell layer population depletions of about 80%. The following study was carried out to assess ultrastructural changes as a result of the X-irradiation.

Timed pregnant Long-Evans female rats were obtained from the Blue Spruce Breeding Farms. Ten pups served as experimental animals, and were exposed to 200 rads per day on days two and three, then 150 rads per day on alternate days 5 through 15 post partum. An additional 10 pups served as controls. All animals were weaned at 30 days and caged separately, with food and water available ad libitum.

At 90 days of age, 8 animals from each group were perfused according to the method of Cole, Matter & Karnovsky (J. Mol. & Exp. Path., 1971). Brains were removed and the dentate gyrus and area CA3 dissected bilaterally. Blocks were post-fixed in 1% Osmium Textroxide, stained en block in uranyl acetate, and embedded in Epon-Araldite. Toluidine blue lu sections were examined to facilitate orientation and localization. Gold sections were mounted on copper grids, stained with lead citrate, and examined on a Zeiss EM9S-2. The remaining 2 animals in each group were perfused, via the aorta, with 10% buffered formalin, post-fixed in Bouin's solution, and cleared for three weeks with daily changes of buffered formalin. They were then blocked, embedded in Paraplast + cut at 6u and stained H & E.

Light studies of the experimental animals showed 80% reduction in dentate granule cells. The EM studies revealed granule cell nuclear shrinkage, as well as other ultrastructural changes. Axo-somatic synapses on area CA3 were also significantly reduced. The significance of these results will be discussed.

723 THE ORGANIZATION OF THE FIMBRIA, DORSAL FORNIX AND VENTRAL HIPPOCAMPAL COMMISSURE IN THE RAT. J.M. Wyss. Dept. of Anat., Washington U. Sch. Med., St. Louis, MO 63110.

The morphological organization of the fimbria, dorsal fornix and ventral hippocampal commissure has been studied in a large number of rats, each of which was injected with a small amount of a ^{3}H-labeled amino acid in one or another cytoarchitectonic field of either Ammon's horn (fields CA_1-CA_4) or the subicular complex (subiculum, presubiculum and parasubiculum). Efferent fibers from the septal parts of the subiculum and field CA_1 project through the dorsal fornix; all the remaining rostrally directed efferents from the hippocampal formation are distributed by way of the fimbria, and the fibers arising within each cytoarchitectonic field are confined, for the most part, to a discrete portion of the fimbria. Thus axons arising within the hilus of the dentate gyrus (fields CA_4 and CA_{3c}) are distributed, in an ordered manner, along the ventral (or pial) surface of the fimbria; fibers from the rest of fields CA_3, CA_2 and CA_1 occupy its mid-portion, and fibers from the subicular complex are located along the ependymal (or dorsal) surface. Similarly, fibers from the temporal part of the hippocampal formation are located near the tip of the fimbria (close to the stria terminalis) whereas those from septal levels are located close to the stratum oriens beneath field CA_3. Septo-hippocampal fibers are confined to the tip of the fimbria. Commissural fibers from the temporal parts of fields CA_3 and CA_4 cross the midline in the rostral part of the ventral hippocampal commissure, while those from septal levels cross in the most caudal part of the commissure. Near its rostral pole the fimbria contains about 900,000 fibers. Of these 700,000 (76%) are myelinated with internal diameters ranging from 0.2-2.7 µm (mean 0.76 µm), and the remainder are unmyelinated with diameters between 0.1 and 0.6 µm (mean 0.25 µm).

724 AUTORADIOGRAPHIC MAPPING OF BRAIN REGIONS ACTIVATED DURING SELF-STIMULATION USING ^{14}C-2-DEOXY-D-GLUCOSE. John S. Yeomans*, Charles R. Gallistel and Martin Reivich (SPON: Harvey Grill). U. Pennsylvania, Phila., PA 19174.

Seven self-stimulating rats were injected via intracardiac catheters with ^{14}C-2-deoxy-D-glucose, a glucose analog taken up by active neurons. The rats were awake and freely behaving, delivering current through electrode tips placed in the lateral hypothalamus, substantia nigra or diagonal band of Broca. In all cases intense unilateral uptake of the isotope was found around the electrode tip, as compared to a contralateral control electrode, even when bar pressing was irregular. The uptake around the tip spread roughly 1 mm per 500 µA of current using 0.1 msec duration cathodal pulses, but the shape of the region of uptake was sometimes irregular.

For all rewarding placements increased uptake was found throughout the medial forebrain bundle (MFB) from medial septum to ventral tegmental area and substantia nigra, zona compacta. The intensity of of MFB uptake correlated poorly with the absolute current intensity, but correlated well with how far the stimulating current exceeded the threshold current for bar pressing. At currents considerably above threshold, unilateral uptake was also found in midbrain reticular formation and central gray, and in the medial frontal cortex immediately anterior to the septum.

In only one rat was unilateral activity clearly found in locus coeruleus, and unilateral uptake was not apparent in striatum. Uptake in these catecholaminergic areas, then, was not found to correlate well with reward.

MEMBRANE BIOPHYSICS

725 A MECHANISM FOR CUMULATIVE INACTIVATION OF OUTWARD CURRENT IN MOLLUSCAN SOMATA. R. W. Aldrich Jr., S. H. Thompson*, P. A. Getting. Department of Biological Sciences, Stanford University, Stanford, CA 94305.

During prolonged or repetitive low frequency voltage-clamp steps, the outward current recorded from molluscan somata shows marked inactivation. A prominent feature of this inactivation is that the peak outward current during successive voltage clamp pulses at low frequency (e.g. 1 Hz) is less than the minimum current at the end of the preceding pulse. We have termed this phenomenon cumulative inactivation. To account for the apparent increase in inactivation during the inter-pulse interval, Eckert and Lux (Science, 197, 472-475, 1977) postulated that cumulative inactivation in Helix neurons results from an intracellular accumulation of calcium ions.

In voltage clamp studies of dorid somata, we have found that cumulative inactivation can be attributed to the delayed, voltage-dependent component of outward current termed K-current and that inactivation is independent of calcium influx. The kinetics of cumulative inactivation are voltage and time dependent. At 10°C, the time course of inactivation can be approximated by the sum of two exponentials having time constants of about 0.5 sec. and 3.5 sec. The time constant for recovery from inactivation is very much slower, about 30 seconds.

The mechanism of cumulative inactivation has two contributing factors. The first is the large difference between the onset and recovery time courses of inactivation. Slow recovery means that most of the channels inactivated by one pulse are not available for activation by the next pulse. The second contributing factor is competition between the activation and inactivation rate constants. This means that, at a given voltage, the number of open channels can never equal the total number of available channels. Provided that the amount of recovery during the interval is less than the rapid inactivation occurring at the onset of the second pulse, the peak current on one pulse will be less than the minimum current of the preceding pulse. Inactivation will, therefore accumulate until it saturates.

726 ACTIONS OF MANGANESE AT THE MEMBRANES OF MYOEPITHELIAL CELLS. Margaret Anderson. Dept. of Biol. Sci., Smith College, Northampton, MA 01063.

Current pulses (30 - 200 ms duration and 0.7 - 6.0 x 10^{-6}A) applied directly to the myoepithelial cells of the proventriculus of the marine polychaete worm Syllis spongiphila elicited overshooting, regenerative responses which were associated with contractions. Responses elicited in control artificial sea water (ASW) were 72 - 118 mV in amplitude and 60 - 680 ms in duration. Several results suggest that the regenerative responses result from an influx of calcium ions. The responses were abolished in calcium-free ASW (Ca^{++} replaced by equimolar Mg^{++}) and in calcium-free ASW containing 1 mM EGTA. They were maintained in solutions containing $\leq 10^{-5}$ M TTX. Their amplitudes remained at control levels in solutions in which 80, 90 or 95% of the sodium was replaced by sucrose. Mn^{++} can replace Ca^{++} in the generation of the regenerative spike. The amplitudes of responses elicited in calcium-free ASW containing Mn^{++} increased as the $[Mn]_o$ (these responses were not associated with contractions). The mean slope for a 10-fold change in $[Mn]_o$ in calcium-free ASW was 22 mV (15 preparations): amplitudes (in mV) in 5 mM Mn, 93 ± 3 (S.E., n = 13); in 10 mM Mn, 98 ± 2 (S.E., n = 27); in 25 mM Mn, 107 ± 2 (S.E., n = 11); in 50 mM Mn, 115 ± 2 (S.E., n = 19). These data indicate a dependence of the regenerative responses on Mn^{++}. The increase in amplitudes with increasing $[Mn]_o$ was less in calcium-containing ASW than in calcium-free ASW. The mean slope for a 10-fold change in $[Mn]_o$ in ASW containing 10 mM Ca^{++} was 5 mV (6 preparations): amplitudes (in mV) in 5 mM Mn, 105 ± 3 (S.E., n = 5); in 10 mM Mn, 107 ± 3 (S.E., n = 10); in 25 mM Mn, 107 ± 4 (S.E., n = 6); in 50 mM Mn, 111 ± 4 (S.E., n = 5). These data indicate a competition between Ca^{++} and Mn^{++}, and they suggest that Mn^{++} ions permeate calcium channels of the myoepithelial cell membrane. Although variable, durations of responses in manganese-containing solutions were consistently longer than those in control ASW, often exceeding 10 s. However, at any given $[Mn]_o$, the durations of responses elicited in the presence of Ca^{++} were consistently shorter than those in the absence of Ca^{++}. In addition to permeating calcium channels, Mn^{++} ions may also affect the general condition of leakiness of the myoepithelial cell membrane. Strength-duration curves indicate that at any given duration of applied current pulse, the intensity required to elicit a threshold response decreased as the $[Mn]_o$ increased. Further, current-voltage relationships of electrotonic responses elicited in solutions of different manganese concentrations indicate that, for a given intensity current pulse, the amplitude of the responses increased as the $[Mn]_o$. 727 BLOCKAGE OF Na^+-Ca^{++} EXCHANGE SLOWS OUTWARD TAIL CURRENTS. M. E. Barish. Hopkins Marine Station, Stanford Univ., Pacific Grove, CA 93950.

The potassium conductance of molluscan neurons is partially dependent on intracellular free Ca^{++} ions for its activation (Meech & Standen, 1975, J. Physiol. 249: 211-239). According to this hypothesis, the kinetics of Ca^{++}-dependent K^+ current should depend on the rate of removal of free Ca^{++} ions from the vicinity of the membrane. After a transient load, Gorman & Thomas (1978, J. Physiol. 275: 357-376) showed that a slow component of K^+ tail current followed a time course similar to changes in arsenazo absorption. This suggests that the decay of outward current reflects a decline in free Ca^{++} concentration. Treatments that will change the time course of free Ca^{++} decline should therefore result in parallel changes in the relaxation of outward current. One important component of Ca^{++} removal from cytoplasm in squid axon is the Na^+-Ca^{++} exchange pump (Baker, 1972, Prog. Biophys. Mol. Biol. 24: 177-223). This process can be substantially slowed by removal of extracellular Na^+.

Microsurgically isolated dorid central ganglion somata were studied with two microelectrode voltage clamp. Tail currents were measured between 0.5 and 7 seconds following repolarization to a holding voltage of -40mV from a step to 0mV. Substitution of Tris for Na^+ in artificial sea water (ASW) significantly slowed the relaxation of tail current. During this time period, as a first approximation, the time course of the decay of tail current can be decomposed into two summed exponentials with time constants (TCs) in normal ASW of 0.74 and 4.18 seconds. In Tris (0 Na) ASW, the faster component remained essentially unchanged (TC: 0.72 sec.) while the slower time constant was increased (TC: 5.71 sec.).

The inhibition of Na^+-Ca^{++} exchange should increase the concentration of free Ca^{++} at the membrane. These experiments suggest the time course of decay of the Ca^{++}-dependent K^+ current is dependent on the rate of cellular Ca^{++} removal, binding and sequestration. Further, they point towards an important contribution of the Na^+-Ca^{++} exchange pump in the removal of free Ca^{++} following Ca^{++} influx.

728 CALCIUM BINDING TO INTACT AND SUBCELLULAR FRACTIONS OF CRAB NERVE. Jesse Baumgold* and Susumu Terakawa* (SPON: Robert H. Wurtz), Lab of Neurobiology, NIMH, Bethesda, Maryland 20014

The mechanism of action of calcium in nerve conduction is still quite controversial. In an attempt at elucidating this mechanism, we have studied the binding of calcium-45 both to intact crab nerves and to subcellular fractions of crab nerves. The subcellular fractionation procedure used was essentially that of Balerma et al. (FEBS Lett. 21: 335, 1975), yielding a membrane fraction with very little mitochondrial contamination. Calcium-45 binding to this fraction was studied by incubating the membranes for 9 min in 10 mM Tris buffer (pH 7.4) containing either 170 mM NaCl or 170 mM KCl, and the appropriate amount of calcium-45. The mixture was then filtered through a Millipore filter and, after washing the filter, the radioactivity was measured in a scintillation counter. By plotting the data according to the Scatchard formulation, two components of binding were detected. In the NaCl containing buffer, one component had a dissociation constant of about 2 x 10^{-5} M with a binding capacity of about 4 nmoles of calcium per mg protein, and the other component had a dissociation constant of about 2 x 10^{-4} M with a binding capacity of about 45 nmole of calcium per mg protein. By replacing the NaCl in the incubation buffer with KCl, the binding capacity of the higher affinity site was doubled. The binding under study is not an energy dependent process since the addition of ATP to the incubation medium did not enhance the calcium binding. Since neither tetrodotoxin, veratridine nor diphenylhydantoin had any effect on the calcium binding, the calcium binding characteristics reported in this work represent the binding to the membrane as a whole rather than to the excitable sites.

The binding of calcium-45 to intact desheathed crab nerve was studied as follows. After being labeled in calcium-45 containing sea water, the nerve was inserted into a chamber made by drilling a hole through a cylindrical piece of plexiglass. By passing artificial sea water through this chamber and collecting it as it dripped out, the level of calcium-45 desorbed from the nerve could be studied. After a prolonged washing period, the nerve could be electrically stimulated through two pairs of electrodes in the chamber, resulting in an increase in the level of calcium-45 desorbed from the nerve. Electrical stimulation has previously been shown to increase the rate of desorption of calcium-45 from muscle and ganglion cells. This finding suggests that calcium ions bound to the excitable sites are immobile in the resting state of the membrane and that they become more mobile during excitation.

729 SYNAPTIC VESICLE REUTILIZATION AT ACTIVE SITES: THEORETICAL CONSIDERATIONS. Alan F. Boyne and Michael Mento* Dept. Pharm., Northwestern Medical School, Chicago, Ill. 60611.

Divalent cations facilitate the fusion (adhesion) of synaptic vesicles to the nerve terminal membrane. Neurosecretion apparently requires a subsequent fission or tearing open of the fused region. One hypothesis for the fission event is that the local surface tension rises in the fusion site and exceeds allowable levels so that a tear forms. Such a local rise in surface tension would be transient because lateral diffusion of lipid molecules from adjacent regions would relieve the tension. This simple model has two obvious implications which seem to correlate with the experimental facts of neurotransmission:

(1) The rate of rise of tension in the fused region must exceed the compensating lateral diffusion of lipid into the area, otherwise the tension cannot reach threshold and fission cannot occur. This suggestion is consistent with the phenomenal speed of the Ca-triggered physiological fusion + fission events (200 microsec; Llinas et al., PNAS 73 2918 (1976)). On the other hand, published micrographs of Ca-induced vesicle fusions to the nerve terminal membranes in aldehyde treated tissues (Boyne et al., J Cell Biol. 63 780 (1974)) may represent fusions forming too slowly to fission.

(2) A fission opening may be reversible if lateral lipid diffusion can occur before the vesicle flattens into the membrane plane.

It has previously been noted that the removal of free Ca from the active site region would tend to retard or reverse flattening (Hall and Simon B & B Acta 436 613 (1976) and Boyne, Life Sci. 22 (1978)). A second retarding influence can now be suggested. Electron microscopy of the apparent active sites in fast-frozen, freeze substituted Torpedine ray electric organ shows that clusters of synaptic vesicles are aligned against the terminal membrane. While this clustering probably serves to provide a pool of releasable quanta, a second likely consequence is that the entry of Ca will fuse vesicles both to the terminal membrane and to each other. Such additional adherences may retard the flattening of those vesicles opening to the synaptic cleft. As indicated above, lateral lipid diffusion may then reseal the fission site and permit local vesicle reutilization. In this tissue there is strong evidence that during 0.1 Hz stimulation, there is no vesicle loss but rather that vesicles are immediately reutilized (e.g. to release newly synthesized acetylcholine) (Zimmerman and Denston, Neurosci. 2 695 (1977)).

We are considering possible mechanisms for an increase in surface tension at the fusion site and hope to be able to relate the kinetics of fusion and fission to the rate of lateral lipid diffusion.

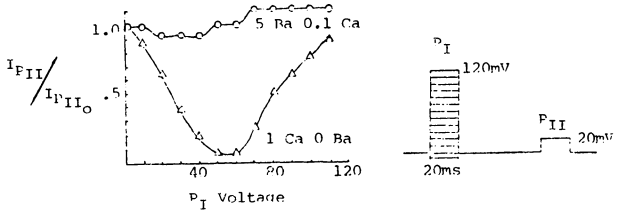
730 CA-DEPENDENT INACTIVATION OF CALCIUM CONDUCTANCE IN PARAMECIUM. Paul Brehm* and Roger Eckert (SPON: Douglas Junge). Biology Dept. UCLA, Los Angeles, CA 90024.

Inactivation of early inward calcium current (I_{Ca}) was examined in voltage-clamped P. caudatum. In 1.0 mM Ca, depolarizations of 5 to 25 mV from rest (which averaged -25 mV) activated an early inward current which reached maximum within 3 ms and showed nearly complete inactivation within another 5 ms. There was no sign of late voltage-activated outward current over this potential range.

The inactivation seen during one pulse (PI) persists so that there is suppression of inward current recorded during a subsequent pulse (PII) presented after a 60 ms interval (See Fig.). The inactivation of the Ca channel was shown to depend on the entry of Ca as follows. PI amplitudes progressing from 0 to 60 mV resulted in more complete inactivation of I_{Ca} during PII. Further increase of PI amplitude toward the calculated E_{Ca} (ca. +150 mV) resulted in a return of the early I_{Ca} during PII to 90% of its control value. The outward current during PII was independent of PI amplitude indicating no substantial persistent-Ca activated I_K. Substitution of Ca by Ba decreased inactivation of the early inward current. In 0.1 mM Ca, 5 mM Ba there was essentially no PII inactivation (See Fig.). Injection of EGTA slows inactivation of I_{Ca} and also increases peak I_{Ca}.

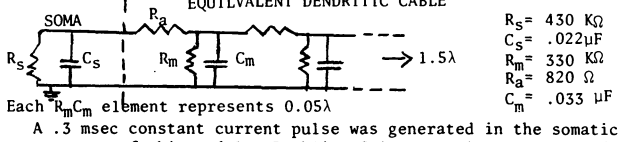
During a 100 ms, 20 mV depolarization the inward current shows substantial time-dependent inactivation in a 5 Ba, 0.1 Ca solution. This inactivation may result from either Ba influx, Ca influx, or direct voltage effects on the channel. A 120 mV, 100 ms pre-pulse was followed without interval by a 20 mV depolarization. The inward current with and without the 100 ms prepulse was nearly identical indicating no significant voltage-dependent inactivation.

These results indicate that inactivation of the Ca channel in Paramecium depends on entry of Ca ions. Interference with Ca entry by competition from Ba or by voltages approaching E_{Ca} eliminates or diminishes the inactivation. In contrast, there appears to be little or no H-H voltage-dependent inactivation of the Ca channel with depolarization. Supported by NSF BNS 77-19161.



731 MODELLING THE EFFECTS OF TONIC CONDUCTANCE CHANGES ON EPSP'S AND SHORT INTRASOMATIC CONSTANT CURRENT PULSES - WAYS TO ESTIMATE THE LOCATION AND EXTENT OF NEURONAL CONDUCTANCE CHANGES DUE TO LONG-LASTING POSTSYNAPTIC POTENTIALS OR DRUGS. Peter L. Carlen and W.A. Corrigall, Neurobiology Lab, Addiction Research Foundation, Toronto, Canada, and University of Toronto.

Tonic conductance (G) changes which result from temporally summated or long-lasting PSP's, or from drugs, play an important role in central neuronal integration. Using the short intrasomatic constant current pulse technique developed by Redman and colleagues (Jack & Redman, J. Physiol. 1971, 215, 321-352) it is possible to calculate neuronal membrane parameters including τ_m (neuron time constant), τ_1 (first peeled exponential), L (electrotonic length of neuron) and $\rho\left(\frac{G\ dendrites}{G\ soma}\right)$. This technique also permits estimation of the location and extent of a tonic G change in a neuron under certain circumstances. A simple analogue soma-dendritic compartmental neuronal model modified from Walmsley, B. (Ph.D. thesis, 1975, Dept. Electrical Engineering, Monash University, Australia) with a time constant of 12 msec, and an electrotonic length of 1.5 λ (time constant) was used.



A .3 msec constant current pulse was generated in the somatic compartment of this model. Doubling G in a proximal as opposed to a more peripheral compartment of the dendritic cable caused a more rapid voltage decay of the short pulse with an earlier onset of decay. The final τ_m as estimated from the semilogarithmic decay of the intrasomatic short pulse differed little with relatively small peripheral or proximal G increase, whereas the τ_1 was smaller with more proximal G increase. The opposite effect occurred with decreased compartmental G. Electrotonic EPSPs generated in the dendritic tree and measured in the soma were diminished more by a somatic G increase as opposed to the same G increase in the compartment wherein the EPSP was generated, except for the most distally generated EPSPs. Equal but opposite effects were noted for compartmental G decreases. Using this simple analogue neuronal model facilitates interpretation of physiological and pharmacological conductance changes measured from intracellular neuronal recordings.

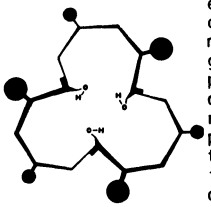
732 THE TRIPLE HELIX: A POSSIBLE STRUCTURE FOR EXCITABLE MEMBRANE CHANNELS. H. Robert Guy* (Spon: D.O. Carpenter). Armed Forces Radiobiology Research Institute, Bethesda, MD 20014.

Although excitable membrane channels differ in ion selectivities and gating mechanisms, some drugs (e.g. local anesthetics, barbiturates, and strychnine) apparently block a large number of these channels. This suggests that the structure of the ion conducting portion of these channels is similar. I have explored the possibility that this structure is a beta helix. β helices are perhaps the simplest family of peptide structures which form ion permeable channels in membranes. Of many β helices that I have analyzed, a triple stranded left handed beta helix with slightly more than 15 residues per turn ($^3L_{\beta^{15}}$ helix) is most consistent with electrophysiological and pharmacological data obtained from 5 biological channels (the Na^+ and K^+ channels underlying the action potential, the fast i.p.s.p. Cl^- and e.p.s.p. Na^+ channels of Aplysia neurons, and the end plate channels of frog skeletal muscle). The polypeptide (Ser-Gly-Apl-Gly-Apl)$_n$, where Apl is a residue with an apolar side chain, should form a $^3L_{\beta^{15}}$ channel (see figure) which has a high conductance, is relatively nonselective, and is blocked by drugs which block all five of the biological channels. Differences between the ion selectivities of the biological channels may be due to a more ion selective segment of a $^3L_{\beta^{15}}$ helix which is in series with this nonselective segment. Sequences which form selectivity filters for the respective channels consistent with experimental data are: (Ser-Ala-Pro-Ala-Pro) for end plate, (Asp-Ala-Pro-Ala-Pro) for a.p. Na^+, (Arg-Ala-Pro-Ala-Pro) for i.p.s.p. Cl^-, and (Gln-Ala-Pro-Gly-Apl) for a.p. K^+. Some drugs which affect only one channel type can bind at the selectivity filter; these include tetrodotoxin and saxitoxin for the a.p. Na^+ channel, tetraethylammonium and its derivatives for the a.p. K^+ channel, and pentylenetetrazol, penicillin G, bicuculline and picrotoxin for the i.p.s.p. channel. The nonselective conformation should be able to undergo a conformational change to a closed state. Large molecules which enter the open channel should inhibit this conformational change. A number of molecules, e.g. batrachotoxin, aconitine, grayanotoxin, veratridine, and DTT, may prolong the open conformation of a.p. Na^+ channels by only partially blocking the nonselective segment of the channel while preventing its closing. This theory can be tested by synthesizing the polypeptides, incorporating them into membranes, and comparing the pharmacology and ion selectivities of the synthetic channels with those of biological channels.



733 VOLTAGE CONTROLLED GAP JUNCTIONS BETWEEN EMBRYONIC CELLS: A VOLTAGE CLAMP STUDY. A.L.Harris*, D.C.Spray, M.V.L.Bennett, & R.B. Hanna*, Dept. Neurosci., Einstein Coll. Med., Bronx, N.Y. and Ctr. Intrastructural Studies, SUNY, Syracuse, N.Y.

Current clamp studies reveal voltage dependence of electrical coupling between blastomeres of early axolotl (Ambystoma mexicanum). To study the junctional conductance under voltage-clamp, each blastomere of a coupled pair was clamped near the resting potential with a two microelectrode circuit. Voltage in either cell was stepped to various potentials and current flowing across the junction was measured as current provided by the clamp on the other cell. This new method allowed us to directly measure junctional current and to study its voltage dependence and kinetics. Consistent with current clamp data, junctional conductance is highly dependent, decreasing as a function of the voltage difference between the cells. Typically, junctional conductance (1-4 μmho) drops to less than 10% of its resting level with a 20mV step, but a small voltage insensitive conductance persists, even at much greater polarizations. Voltage steps of either polarity in either cell produce similar conductance changes with respect to voltage sensitivity and kinetics. Large polarizations of both cells simultaneously have little or no effect on junctional resistance. The decrease in junctional current is stable and does not reverse over the longest voltage steps given (50 sec). The time course of the conductance decrease can be fit with a single exponential and is voltage dependent. The relaxation of the junction to the conducting state when the cells are returned to zero potential difference can be fit with a single exponential with a time constant of 350 ms and is slightly voltage-dependent. Junctional conductance shows only partial transient recovery when transjunctional voltage is stepped between voltages of opposite sign, each of which is sufficient to cause low conductance. We believe that the conductance elements which underlie this phenomenon are the gap junction particles which we have visualized in freeze-fracture electron micrographs. Unlike iontophores of nerve and muscle, they have conductance symmetry around zero potential and first order kinetics. The precise nature of the control of their conductance is unclear, but it is likely to be more complex than that of channels which are sensitive to voltage differences across only one membrane.

734 ACTION OF 4-AMINOPYRIDINE ON VOLTAGE-AND CALCIUM-DEPENDENT POTASSIUM CURRENTS OF MOLLUSCAN PACEMAKER NEURONS. Anton Hermann* and A.L.F. Gorman, Dept. of Physiology, Boston U. Sch. of Med., Boston, MA 02118.

Neuronal soma membranes exhibit both, a voltage-dependent potassium-current, $I_{K(V)}$ and a calcium-dependent potassium-current, $I_{K(Ca)}$. These current components in Aplysia pacemaker neurons were separated as reported previously (Hermann and Gorman, J. Biophys. 21, 178a, 1978) and the external and internal effects of 4-Amino-pyridine (4-AP) investigated. External application of 4-AP reduced $I_{K(V)}$ (activated by voltage steps of 200 msec duration in zero Ca^{2+} solution) in a dosage dependent manner. The blockage was voltage dependent. No blockage of $I_{K(Ca)}$ (activated by intracellular iontophoretic injection of Ca^{2+}), however was observed; rather with higher concentrations of 4-AP this current component was increased. These results are consistent with the observation of the effect of 4-AP on the total outward current obtained with step depolarizations in artificial seawater (ASW). 4-AP reduced the N-shaped I-V-relation in the voltage range between +80 and +120 mV where $I_{K(V)}$ is predominant, while the outward current was increased in the voltage range between -20 and +80 mV where $I_{K(Ca)}$ is predominant. Maximal blocking effects were observed after about 5 minutes; recovery from blockage had a similar time course. The effect of internal 4-AP was qualitatively similar to external 4-AP. The results suggest that with external or internal application the drug acts at the same site near the internal surface of the membrane. 4-AP appears to constitute a useful means to separate pharmacologically voltage- and calcium dependent potassium currents.

735 NOREPINEPHRINE ANTAGONIZES CALCIUM-DEPENDENT POTENTIALS IN RAT SYMPATHETIC NEURONS. John P. Horn and Donald A. McAfee, Dept. of Physiol. & Biophys., U. of Miami Schl. of Med., Miami, FL 33152, and Div. of Neurosciences, City of Hope Natl. Med. Ctr., Duarte, CA 91010.

Depolarization of the rat sympathetic postganglionic neuron results in a hyperpolarizing afterpotential (HAP). Yarowsky and McAfee (Neurosci. Abstr. 3:25, 1977) have demonstrated that the HAP is caused in part by an increased gK^+ triggered by Ca^{++} influx during the depolarization. We now report that norepinephrine inhibits this process.

Superior cervical sympathetic ganglia were isolated from mature rats and superfused with oxygenated Locke's solution (24° C) for up to 12 hrs. Drugs and ionic changes in the extracellular fluid were introduced via modified superfusates. A single-barreled microelectrode was used for both transmembrane current passage and voltage recording from impaled postganglionic neurons.

Norepinephrine (NE) reduced the amplitude and duration of the HAP in a dose-dependent manner (EC_{50} = 1-2 μM) with little or no effect on resting membrane potential. This reversible effect of NE was quite reproducible, occurred within 2 min., and did not desensitize during a 15-min. exposure. The response to NE appeared to be mediated by an α-receptor. Dopamine and isoproterenol antagonized the HAP but were less potent and less efficacious than NE. Phentolamine (5 μM), an α-adrenergic antagonist, reduced the potency of NE about twofold. While NE did not affect the resting input resistance, the transient conductance increase during the inhibited HAP was reduced. This observation suggests that the decrease of the HAP in NE occurred by some mechanism which reduced gK^+ rather than by a mechanism which increased conductances to other ions.

The mechanism of NE action appears to be related to Ca^{++}-dependent processes. The magnitude of the HAP is substantially reduced in low (0.1 mM) extracellular Ca^{++}. NE had no effect on the remaining Ca^{++}-independent portion of the HAP. A Ca^{++} action potential followed by a HAP can be evoked in postganglionic neurons treated with tetrodotoxin (1 μM) and tetraethylammonium (5 mM) to block gNa^+ and gK^+. NE reversibly inhibited this Ca^{++} action potential and the subsequent HAP in a dose-dependent manner (EC_{50} = 1-2 μM). We conclude that NE inhibits Ca^{++} influx during depolarization and thus the Ca^{++}-dependent portion of the HAP.

736 INTRACELLULAR RECORDING FROM THE BRAINS OF CONSCIOUS BEHAVING CATS ACHIEVED BY A NEW METHOD OF FLOATING THE PIPETTE TIP. Gregory L. King* and James E. Skinner. Dept. Physiol. and Sect. Neurophys., Dept. Neurol., Baylor College of Medicine, Houston, Texas 77030, U.S.A.

A difficulty inherent in recording transmembrane potentials from the higher vertebrate brain is the prevention of movement of the neurons to be recorded relative to the penetrating pipette tip. These movements are generally thought to be caused by cardiovascular pulsations and respiratory cycles and can be minimized in anesthetized animals by placing pressor foots on or in the tissue and draining the cerebrospinal fluid that couples the thoracic pressures to the cranial cavity. However, spontaneous or evoked limb movements produce small shock waves that travel through the gelatinous brain tissue and also cause micromovements of the cells relative to the rigid penetrating micropipette tip. This latter difficulty makes transmembrane recording from the conscious animal brain practically impossible since such recordings are infrequently achieved and can be maintained, at most, for only 5-10 min. To deal with these problems we have minimized the cardiovascular- and respiratory-induced movements by a closed-cranium method utilizing agar and solved the limb movement problem by "floating" the micropipette tip in the brain so that it moves with the tissue, thus eliminating the problem of the relative motion.

We have successfully and frequently recorded intracellular potentials from moving animals with the times of holding the cell ranging from 20 to 55 min. We employ filled micropipette tips that are electrically coupled to the amplified by a 25-micron diameter wire and mechanically coupled to the hydraulic drive unit by -2°C ice. The temperature of the ice is maintained by a circulating alcohol coolant and direct current heater. A slight increase in the heater current causes a rapid melting of the ice, thus allowing the small, almost massless micropipette tip to float freely in the brain. We believe that this method provides a breakthrough in intracellular recording from the conscious vertebrate brain and will enable us to investigate the membrane properties of neurons during higher cerebral processes.

737 DIFFERENTIAL PROLONGATION OF ACTION POTENTIAL DURATION BY SPARTEINE AND ITS POSSIBLE RELATION TO Ca-DEPENDENT MEMBRANE RESPONSES IN FOUR IDENTIFIED LEECH NEURONS. Anna L. Kleinhaus. Dept. Neurol. Yale Med. Sch., New Haven, CT. 06510.

Previous work from this laboratory showed that tetraethylammonium chloride (TEA) prolonged the action potentials of Retzius and N, P and T sensory leech neurons probably by blocking a K current which normally repolarizes them. As a consequence, a late divalent cation conductance was unmasked which dominated membrane behavior during excitation. The order of responsiveness of the neurons to TEA was R>N>P>T which paralleled their ability to sustain active membrane responses in Na-free solutions. These observations led us to postulate that the differential responses of the cells could be explained by variations among them in the number of Ca conductance channels available to affect membrane behavior when outward K currents were blocked (J. Physiol. 246: 351, 1975; J. Physiol. 270: 181, 1977).

The present work was undertaken to test this hypothesis with Sparteine (SPT) which is known to block K currents in other excitable membranes (Ohta and Narahashi, J. Pharm. exp. Therap.,1973; Schauf, et al, J. Pharm. exp. Therap., 1976).

SPT, 0.1-1.0 mM, applied extracellularly in the bath produced a dose-dependent, reversible prolongation of the action potential of Retzius and N, P and T sensory leech neurons. After application of 0.5 mM SPT, the average value for the increase above control of action potential duration was 2700% for R cells, 245% for N cells, 200% for P cells and 130% for T cells. The prolongation of the R and N cell's action potentials by SPT was seen in normal Ringer containing 2.0 mM Ca or when 2.0 mM Sr replaced Ca, but was partially reversed by Mn. These findings suggest that a large portion of the prolongation was due to current going through the divalent cation channel known to dominate R and N cell electrical behavior when the K current,which normally counteracts it, is blocked. Further confirmation of this interpretation was obtained by experiments in Na-free solutions in which R and N cells were capable of sustaining active membrane responses induced by SPT. The responses to stimulation of the neurons in Na-free, SPT solutions were dependent on extracellular Ca. Sr was capable of substituting for Ca as a current carrier, while Mn, known to block divalent cation responses in leech R and N cells, abolished them. Intracellular injection of SPT by pressure had essentially no effect in R, P and T cells, in contrast to intracellular TEA injection. However, preliminary results with pH changes indicate that SPT is more active at pH 8.0 than at pH 7.4 which might in part explain its low intracellular potency.

Pharmacological block of K current may provide a useful method for the study of Ca channels in individual neurons and further our understanding of their responses to drugs.

738 THE ACTION OF ANTHOPLEURIN A ON CRAYFISH AXON. Phillip A. Low*, Chau H. Wu and Toshio Narahashi. Dept. Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611.

The effects of anthopleurin A (AP-A) isolated from Anthopleura xanthogrammica on resting and action potentials and membrane currents were studied on crayfish giant axons using the intracellular microelectrode and voltage clamp techniques. At low concentrations of AP-A (10^{-8}M) the resting potential underwent cycles of spontaneous depolarization followed by repolarization, producing an undulating pattern. Repetitive firing occurred both spontaneously and in response to a single stimulus. The rate of rise, amplitude and initial falling phase of the action potential were unaffected but the later falling phase was replaced by a long plateau. At higher concentrations of AP-A (10^{-7} - 10^{-6}M), depolarizations of 10-40mV were seen, which were not followed by repolarizations. Both the depolarization and undulating pattern were antagonized by each of the following modified van Harreveld (VH) solutions: 1) VH + 300nM TTX; 2) VH + 10-20mM procaine; and 3) VH containing 1mM sodium. This indicated that the ionic channel responsible for these perturbations was that of sodium.

In contrast to the effects of neurotoxin II of Anemonia sulcata (ATX II), prior treatment with TTX or procaine did not affect subsequent interaction of AP-A with its receptor. As the TTX effect was reversed on washing, the action potential returned and had a marked plateau typical of AP-A effect. Identical findings were made with the procaine protocol.

Membrane currents were measured on the axons in which potassium channels were blocked with 2mM 4-aminopyridine. Sodium activation appeared normal but inactivation was markedly slowed in the presence of 10^{-7}M AP-A. The peak current was slightly reduced after AP-A application and the reversal potential was unaffected. However, steady-state currents reflecting mainly altered sodium channels were greatly increased following AP-A treatment.

A potent and specific action of this toxin on sodium inactivation by external application provides another useful tool in the pharmacologic dissection of ionic channels. The close structural similarity between ATX II and AP-A and their identical actions on membrane currents and action potentials are contrasted by their quite different interactions with TTX. This difference, when explored, may provide insights into the physical and molecular relationship of TTX receptor and the sodium channel. Supported by NIH grant 14144.

739 INTRACELLULAR pH REGULATION IN CRAYFISH SLOW MUSCLE FIBERS: EFFECTS OF CHANGES IN INTERNAL pH ON CALCIUM ELECTROGENESIS. W. Moody, Jr. Dept. Physiology, UCLA, Los Angeles, CA 90024.

I previously reported that crayfish slow flexor muscle fibers, which normally generate only small graded responses when depolarized with constant current pulses, become capable of generating all-or-none Ca^{++} action potentials after prolonged anoxia or treatment with uncouplers of oxidative phosphorylation (J. Comp. Physiol., in press). The possibility that changes in intracellular pH might in part mediate the effects of alterations in cell energy metabolism on membrane calcium electrogenesis has been investigated. Internal pH was measured using recessed-tip pH microelectrodes (Thomas, J. Physiol. 1974. 238:159). Lowering the external pH from 7.4 to 5.6 had little effect on internal pH or fiber electrical properties. Exposure to 100% CO_2-10mM HCO_3 at pH 5.6 caused a drop in internal pH from the normal 6.9-7.3 to between 6.15 and 6.4. During CO_2 exposure, the small graded electrical responses of the fibers were converted into overshooting action potentials. Effects of CO_2 on internal pH and electrical properties were readily reversible upon perfusion with CO_2-free pH 5.6 Ringer's. Linearization of steady-state constant-current I-V plots obtained in Ca^{++}-free, Mn^{++} Ringer's upon CO_2 exposure suggests that the decrease in internal pH blocks delayed rectification. This suggests that internal H^+ may block a voltage-dependent potassium current which normally shunts the inward Ca^{++} current and limits the size of the depolarizing response in these fibers. Effects of internal pH on the inward current were not studied. Another, preferable, means of producing internal acidification while the fiber is exposed to the normal external solution is by removal of external NH_4Cl after brief exposure. The internal pH of the slow flexor fibers increased 0.5-0.8 units upon exposure to 30-50mM NH_4Cl at pH 7.4. Removal of NH_4^+ after 15-35min exposure caused a prolonged drop in internal pH below the pre-NH_4^+ value by 0.5-1.0 units. Preliminary results indicate that as this NH^+ rebound acidification develops, a gradual potentiation of Ca^{++} responses occurs, with all-or-none spikes appearing at internal pH values below about 6.3. Evidence relating the electrophysiological changes during NH_4^+ rebound to the internal pH changes, as well as the significance of these results to calcium electrogenesis in other cells, will be discussed. Supported by USPHS 09012 to S. Hagiwara and a Helen Hay Whitney Foundation postdoctoral fellowship to the author.

740 TETRA-ALKYL AMMONIUM IONS AS PROBES OF BRAIN CELL MICROENVIRONMENT. J.M. Phillips* and C. Nicholson. Dept. Physiol. & Biophys., N.Y. Univ. Med. Ctr., 550 First Ave., New York NY 10016

In order to better define the physical properties of the extracellular space of the brain, and provide a reference for the movement of endogenous cations within the brain cell microenvironment, the migration of tetra-alkyl ammonium ions (TAA) was examined in the rat cerebellar cortex. Tetra-alkyl ammonium ions were chosen as probes because their spherical symmetry and single charge facilitates theoretical analysis, and allows direct comparison with K^+.

Halide salts of tetramethylammonium, tetraethylammonium and tetrapropylammonium ions at 1 mM/L concentration in Ringer solution were superfused over the cerebellar cortex for 1-3 hr. Locally evoked field potentials remained unchanged during the TAA superfusion, thus showing that neuronal function was unaffected by the concentration of TAA used. Concentration profiles of the TAA ions were measured to a depth of 500 µm using ion-selective micropipettes containing Corning 477317 ion exchanger. Although this exchanger is nominally a K^+-sensor, its primary sensitivity is to quaternary ammonium ions (selectivity 250:1 for TAA^+: K^+).

$[TAA^+]_0$ as a function of depth was highly consistent with Fickian diffusion in a semi-infinite, homogeneous medium. In some cases, however, the profile was more consistent with diffusion through a 2-component, semi-infinite composite medium, indicating the presence of a superficial barrier. Values of the apparent diffusion coefficient, D*, were computed. For TAA ions, D* decreased monotonically with increasing ionic radius, and was about 20-25 times smaller than their theoretical diffusion coefficients in water. In contrast, D* for K^+ in the cerebellar cortex was only 8-10 times less than that in water.

When current is passed normal to the brain surface, $[K^+]_0$ decreased for current into the brain, or increases for current out of the brain, due to K^+ penetration of brain cell membranes (Gardner-Medwin and Nicholson, J. Physiol. 275: 66-67P, 1978). In contrast, all $[TAA^+]_0$ behaved in the opposite fashion. Interpreted on the basis of electrodiffusion theory, these results, together with the lack of influence on evoked potentials, confirm that the TAA ions remain in the extracellular space.

TAA ions thus serve as microenvironment probes, confined to the extracellular space and contrast with the behavior of K^+, whose movement through the brain is not so restricted, apparently. (Supported by Public Health Service, Grant NS-13742).

741 VOLTAGE-SENSITIVE Ca-CHANNELS AND Ba ION IN PARAMECIUM TETRAURELIA. Youko Satow. Lab. Molecular Biology, Univ. of Wisconsin, Madison, WI 53706.

Transient inward current (I_{in}) in Paramecium tetraurelia recorded upon a step depolarization with a voltage clamp is normally carried by Ca^{++} through a Ca-channel. The maximal inward current (I_{max}) is smaller when the membrane is held at a depolarized or a hyperpolarized level. In order to maximize the resolution of the Ca-channel activity, the membrane is held at or near the resting potentials registered in various test solutions.

Maximal inward current (6.8±0.7 nA) of paramecia bathed in a Ca-solution (1.5 mM Ca, 1 mM citric acid, 1.3 mM Tris, pH 7.2; $[Ca^{++}]_o$ 0.91 mM) is reduced by the addition of Ba (up to 2 mM) (2.7±0.9 nA in 1.5 mM Ca-2 mM Ba and 2.8±0.8 nA in 1.5 mM Ca - 4 mM Ba). The remaining I_{in} appears to be insensitive to further addition of Ba in terms of I_{max}. The 1.5 mM Ca-solution (or over 1.5 mM Ca) gives the highest I_{max} in Paramecium. The I_{max} is smaller in a Ca-solution with 0.75 mM Ca ($[Ca^{++}]_o$ 0.38 mM). The addition of Ba to this 0.75 mM Ca-solution reduces the I_{max}. It is not possible to study the membrane of paramecium in Ca-free solutions, since it disintegrates in such solutions.

The addition of Ba shifts the V-I_{peak} curve in the direction of more sensitive to voltage. The processes of activation and inactivation of the Ca-channels are slowed down in the presence of Ba. Ca competes with Ba in terms of their effects in sensitivity and the time courses of activation and inactivation. Addition of Ca shifts the V-I_{peak} curve in the direction of less sensitivity and speeds up activation and inactivation. Peak times (T_{max}) of the inward current are 2.1±0.3, 4.1±0.3, 3.9±0.7 and 2.4±0.1 msec in 1.5 mM Ca, 1.5 mM Ca - 4 mM Ba, 0.75 Ca - 2 mM Ba and 3.5 mM Ca - 2 mM Ba solutions, respectively.

Ionophoretically injected Ba^{++} reduces the I_{max}. On the other hand, such internally applied Ba^{++} has no effect on the voltage sensitivity and the time courses of activation and inactivation.

These results show that Ba inhibits rather than enhances the maximal inward transient in Paramecium. External but not internal Ba^{++} changes the behavior of Ca-channels or its surrounding leading to a change in their voltage sensitivity and the time course of their activation and inactivation.

742 EFFECTS OF EXTERNAL CALCIUM AND CALCIUM BLOCKING AGENTS ON THE PHOTORESPONSE IN LIMULUS VENTRAL PHOTORECEPTORS. Jeffrey A. Schmidt* and Alan Fein* (SPON: Ernest M. Wright). Marine Biological Laboratory, Woods Hole, MA 02543.

The effects of Ca-blocking agents and changes in extracellular calcium, $[Ca]_o$, on the light-evoked discrete wave responses (bumps) were measured. Ca-blocking agents $CdCl_2$ (2 mM), or D-600 (10^{-4}M) in the presence of 10 mM Ca did not significantly alter bump depolarization amplitude or response latency, while reduction in $[Ca]_o$ reversibly increased both parameters. A slowing of the bump repolarization occurred with these blocking agents but not with reduced $[Ca]_o$. The hyperpolarization which follows the depolarizing transient becomes larger under steady depolarization. The amplitude of the hyperpolarization was correlated with amplitude of the depolarizing transient on top of steady depolarization of +10mV, and was eliminated when the membrane was hyperpolarized. The hyperpolarization was smaller in low $[Ca]_o$ when normalized to the depolarization amplitude, and was eliminated by the Ca-blocking agents and by the K-blocking agent quinidine (10^{-4}M).

The magnitude of outward tail currents measured under voltage clamp following depolarization depend on duration and magnitude of the depolarization. The outward currents appeared maximal at depolarizing pulse durations approximating bump durations. D-600 and quinidine reversibly suppress the tail currents as well as the outward current during the depolarization. Reversal of the tail current occurred at a potential negative relative to resting potential.

Thus, elimination of the hyperpolarization by Ca-blocking agents and reversal of the outward current at a potential somewhat negative to the resting potential suggests that the hyperpolarization results from a Ca-dependent rise in K conductance that may serve to actively repolarize the photoresponse in the unclamped receptor.

Superfusion of IBMX (5mM), a phosphodiesterase inhibitor, qualitatively mimicked the effect of these two blocking agents on both tail currents and outward current during depolarization. Thus, cyclic nucleotide metabolism may play a role in generation of the Ca-dependent outward current.

Waveshapes of light-evoked bumps and photoresponses elicited by dim flashes could be mimicked by intracellular current injection. The hyperpolarizing phase of these responses was reversibly reduced in low Ca and eliminated by the Ca-blocking agents. A late outward current was absent following the light-evoked inward current at all steady clamped voltages. These results indicate that the Ca entry that activates a late K conductance requires depolarization and is not produced in direct response to light.

(Partially supported by a Grass Fellowship given to J.A.S.)

743 A PERSISTENT INWARD CURRENT PROBABLY CARRIED BY CA^{++} IS ACTIVATED OVER A LARGE RANGE OF MEMBRANE POTENTIALS IN CAT SPINAL MOTONEURONS. Peter C. Schwindt* and Wayne E. Crill. VA Hosp. and Depts. Physiol. Biophys. and Med., Univ. Wash., Seattle, WA 98118.

Voltage clamp analysis has revealed that motoneurons may exhibit two regions of negative resistance in their steady current-voltage relations. A previously described negative resistance occuring ca. 10-30 mV above rest is caused by a persistent inward current component. The time course and voltage dependence of this current component, as well as its resistance to intracellular injection of the lidocaine derivative QX314 and its occurrance in some cells with inactivated sodium suggest this inward current component is carried by ions other than Na^+. A second region of negative resistance, seen ca. 100-150 mV above rest, also results from activation of a persistent inward current component which achieves relative dominance over the outward K^+ currents at these potentials. Furthermore, the behavior of tail currents upon repolarization from intermediate potentials in normal cells and in those in which the K^+ current is partially blocked by agents such as tetraethylammonium (TEA), suggests that a persistent inward current component also underlies the more dominant K^+ currents over this range of membrane potentials. The behavior is qualitatively similar to that of certain mollusk neurons. It is concluded that depolarization over the range 10-150 mV above rest activates one or more components of persistent inward current probably carried by Ca^{++} in addition to the transient Na^+ and steady K^+ currents.

(Supported by V.A. research grant MRIS 1610.)

744 BLOCKAGE OF PEAK AND STEADY STATE SODIUM CURRENTS IN SQUID AXON BY TETRAETHYLAMMONIUM IONS. Jonathan J. Shoukimas* and Robert J. French* (SPON: D. C. Eaton). Lab. of Biophysics, IRP, NINCDS, NIH, Marine Biological Laboratory, Woods Hole, MA 02543.

In squid axons perfused with K-free NaF solutions, the sodium conductance does not inactivate completely (Chandler & Meves, 1970. J. Physiol. 211: 623). We have performed experiments on axons perfused with high Cs, low K solutions, without the use of any proteolytic enzymes, and on intact axons with and without 4-aminopyridine to reduce K conductance. For the intact axons, sodium currents were determined as the difference between records taken in the absence and presence of tetrodotoxin (TTX). In no case was sodium inactivation complete. Rather, the current approached a non-zero steady state plateau at long times. Thus, incomplete inactivation appears to be a general property of the squid axon sodium conductance. Measured in perfused axons, the ratio of the amplitude of the plateau current to the amplitude of the peak current rose from <0.1 for E_m (inside minus outside) = -40 mV to 0.2-0.25 at E_m = +80 mV.

We have studied the effect of tetraethylammonium (TEA) ions on both peak and plateau sodium currents. Although TEA is widely used to block potassium channels and facilitate the study of other conductances in excitable cells, there are contradictory reports of its effect on sodium channels. Armstrong and Binstock (1965. J. Gen. Physiol. 48: 859) noted about 50% reduction of sodium currents in TEA-injected axons, whereas Rojas and Rudy (1976. J. Physiol. 262: 501) state that TEA has no effect on sodium conductance unless inactivation has been removed by prior perfusion with pronase. In our experiments, axons with normal sodium inactivation showed decreased sodium currents with TEA present internally. About 40 mM TEA produced a 50% reduction in the currents when there was 50 mM internal Na. The TEA reduced both TTX-sensitive peak and steady state currents by approximately equal proportions. Both inward and outward currents were blocked by TEA, but the block was somewhat greater at more positive potentials. We also observed an increase in time to peak of sodium currents in axons perfused with TEA.

745 DOES CALCIUM INFLUX FACILITATE DURING REPETITIVE VOLTAGE-CLAMP DEPOLARIZATIONS OF MOLLUSCAN NEURAL SOMATA? Stephen J. Smith* and Robert S. Zucker. Dept. Physiol.-Anat., Univ. Calif., Berkeley, CA 94720.

It has been suggested that membrane calcium channels undergo facilitation during repetitive membrane depolarizations. This has been inferred from 1) studies using potassium-sensitive microelectrodes to resolve voltage-clamp currents into potassium and calcium components, and 2) studies using the calcium-sensitive photoprotein aequorin as an indicator of calcium influx.

We have studied this facilitation using voltage-clamp and aequorin methods in identified neurons in Aplysia abdominal ganglia. In TEA-substituted zero-sodium medium, we record a sustained inward calcium current which does not facilitate to successive depolarizing pulses. In normal sea water, we record a rapidly decaying inward tail current following depolarizing pulses. This inward tail current may be isolated by the use of a postpulse to the potassium equilibrium potential. The inward tail vanishes in cobalt-substituted zero-calcium sea water. These calcium inward tail currents do not facilitate.

In normal sea water, successive depolarizations elicit increasing aequorin emissions and are accompanied by a cumulatively inactivating outward potassium current. Due to the series resistance, this leads to increasing membrane depolarizations in a train of identical command pulses. Elimination of this artefact by electronic series resistance compensation or by the use of TEA to block outward currents removes the portion of the aequorin emission facilitation due to the series resistance artefact.

The remainder of the facilitation of aequorin emissions may be due to the power law and calcium detection threshold properties of the calcium-aequorin reaction. This possibility is now under study. 746 VOLTAGE CONTROLLED RESISTANCE AND PERMEABILITY OF GAP JUNCTIONS BETWEEN EMBRYONIC CELLS. D.C.Spray, A.L.Harris*, M.V.L.Bennett, & P.G.Model, Dept. Neurosci., A.Einstein Coll. Med., Bronx, N.Y.

Blastomeres (32-cell stage to morula) of the axolotl Ambystoma mexicanum are electrotonically coupled and are joined by gap junctions. Each blastomere of a coupled pair was doubly impaled for current delivery and potential measurement; junctional and cell resistances were calculated by the π-T transformation. Moderate polarization of either cell in either direction resulted in increased input resistance of both injected and recipient cells and a decrease in coupling coefficient from 0.8 or more to 0.1 or less. The increase in input resistance developed in a sigmoid manner; its onset was more rapid with larger pulses and it completely reversed in less than a second after the pulse was terminated. The non-junctional membrane rectifies only slightly over the same voltage range, and junctional resistance increases as a function of transjunctional voltage over 10-20mV in either direction. The changes are insensitive to absolute membrane potential over the range of ±30mV. The increase in junctional resistance is sufficiently sensitive to voltage for there to be negative slope regions in both quadrants of the I-V relation for currents applied in either cell. As a consequence regenerative increases in input resistance can be produced by brief pulses superimposed on longer ones of the same polarity. The increase in junctional resistance is accompanied by a decrease in permeability to moderately sized molecules. Long hyperpolarizing current pulses through an electrode containing Lucifer Yellow CH (MW 443) simultaneously held pairs of cells uncoupled and injected dye into one cell. After 5 min of iontophoresis with short and weak pulses that did not uncouple, dye passage between cells was always observed. Even when dye was injected for 20 min with pulses that uncoupled the cells, there was little transjunctional dye passage. After either iontophoresis ended or the second cell was similarly hyperpolarized, the cells recoupled, and dye soon crossed to the second cell. Thus, for the embryonic gap junctions both resistance and permeability to information carrying molecules may be controllable by voltage, and changes in resting potential in different regions of an embryo could rapidly interrupt communication to allow independent development.

747 REPETITIVE MINIATURE RESPONSES EVOKED BY CHEMICAL STIMULATION OF SQUID GIANT AXONS. I. Tasaki, Lab of Neurobiology, NIMH, Bethesda, Maryland 20014.

Periodic electric signals of 1 to 30 μV (peak-to-peak) across the squid axon membrane were recorded by using an intracellular electrode connected to a real-time spectrum analyzer (purchased from Nicolet Scientific Cor.). Various chemical stimulants, including scorpion venoms, 4-dimethylaminopyridine, low calcium, etc. were employed to evoke these "periodic miniature responses". The frequency spectra of these responses were always broad, extending usually from 100 to 200 Hz at room temperature (19°C). The frequency of response maximum (usually about 150 Hz) was decreased by lowering of the temperature, as well as by intracellular injection of tetraethylammonium (TEA). Tetrodotoxin (TTX) was found to suppress the miniature responses completely.

The spectra of the miniature responses evoked by scorpion venoms were found to be very irregular. There is little doubt that this irregularity is caused by the difference in the frequency of periodic responses at different membrane sites. As the effect of the chemical stimulant advanced, there was a gradual enhancement of the response amplitude, indicating that the number of membrane sites involved in production of miniature responses was increased. When the response amplitude exceeded about 100 μV, there was a strong tendency toward synchronization of periodic responses, resulting in a decrease in the band-width of the spectrum. Eventually, the axon was thrown into a state of repetitive firing of full-sized action potentials. With a given chemical stimulant, the frequency of repetitively fired full-sized action potentialswas found to be very close to the peak frequency of the miniature responses.

The resting membrane potential was measured during the course of the development of miniature responses. With scorpion venoms, 4-dimethylaminopyridine, low calcium, etc., the production of miniature responses was not preceded by a fall in the membrane potential. This finding strongly suggests that these responses are not produced by potential-dependent changes in the membrane conductance. The origin of these responses is discussed. A portion of the results reported here has been published in Japan. J. Physiol. 28: 89, 1978.

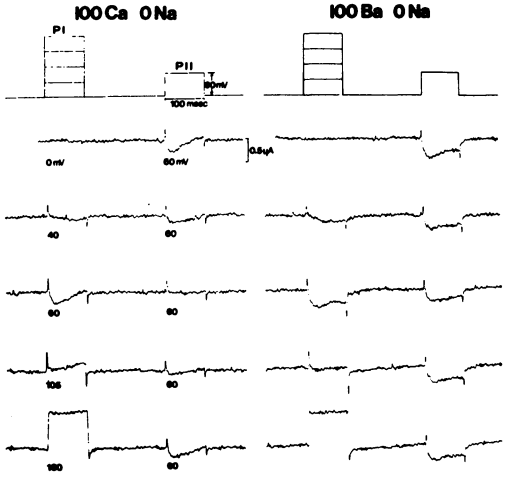
748 A CAUTION REGARDING THE USE OF TEA AND COBALT TO SEPARATE VOLTAGE-DEPENDENT AND CA-DEPENDENT OUTWARD CURRENTS. S. H. Thompson*, R. W. Aldrich Jr., P. A. Getting. Department of Biological Sciences, Stanford University, Stanford, CA 94305.

Cobalt and TEA have been used to separate the delayed outward currents in molluscan neurons into two components; one, called K-current, which is voltage dependent, and another, called C-current, which is Ca^{++} dependent. The use of these two blocking agents results in a variety of current patterns in different cells. Using voltage clamp of dorid somata we found that this variability results from 1) incomplete block of either component by these agents, and 2) differences in the ratio of C-current to K-current (I_c/I_k) in different identified cells. Analysis of tail currents, which allows temporal separation of the components independent of the pharmacological techniques, indicate that 100 mM TEA blocks 90% of K-current and 10% of C-current. Ca-free Co (10mM) saline blocks 84% of C-current with minimal effect on K-current.

Due to incomplete block, the applicability of these agents for the study of current components depends on the C-current to K-current ratio. If I_c/I_k is small, then Ca-free-Co saline will have little effect on the outward current pattern. Under these conditions the properties of K-current can be studied because contamination from residual C-current will be very small. Isolated in this way, K-current shows time and voltage dependent inactivation. When I_c/I_k is large, TEA can be used to isolate C-current since residual K-current is comparatively small. C-current activates more slowly and does not inactivate during depolarization. If, however, I_c/I_k is small, TEA cannot be used to isolate C-current since the resulting current pattern will be strongly contaminated by K-current. At intermediate values of the I_c/I_k ratio, outward currents do not truly reflect the properties of either component.

749 CALCIUM CURRENT INACTIVATION DEPENDENT ON CALCIUM ENTRY IN APLYSIA NEURONS. Douglas Tillotson.* (SPON: Roger Eckert) Dept. Biol., UCLA, Los Angeles CA 90024

Inactivation of calcium current (I_{Ca}) is revealed when interference by other ionic currents is eliminated. I_{Ca} in Aplysia neurons was observed directly under voltage clamp by substituting the impermeant ion Cs for nearly all internal K with aid of the antibiotic nystatin. This eliminates effects due to changes in both the voltage- and calcium-activated K channels. Further, all test solutions contained no Na or K. The Figure shows representative data from a double-pulse experiment on R-15 recorded with a holding potential of -40mV in 100mM Ca bathing solution. Two 100msec pulses were separated by 200 msec. The voltage of the first pulse (PI) was varied while the voltage of the second pulse (PII) was held constant at +20mV. Inactivation of I_{Ca} of PII increases in the PI voltage range -20 to +20mV; is completely inactivated from +20 to +50mV; and returns to 80% of control (without PI) as PI voltage increases toward putative E_{Ca} (ca +140mV). When barium was substituted for bathing Ca far less inactivation was seen. These data indicate that it is the calcium entry associated with PI rather than the voltage of PI that accounts for the major portion of inactivation of I_{Ca} during PII. NIH NS8364 and S07RR07009.



750 CALCIUM ACTION POTENTIALS IN SINGLE, FRESHLY ISOLATED SMOOTH MUSCLE CELLS. John V. Walsh, Jr. and Joshua J. Singer*. Dept. Physiol., Univ. Mass. Med. Sch., Worcester, MA 01605.

The use of single, isolated cells makes it possible to study the electrical properties of smooth muscle without such complications as low resistance intercellular coupling or the presence of neural elements found in tissue. Tissue strips of the stomach muscularis of the toad Bufo marinus were digested with trypsin and collagenase to yield single, isolated smooth muscle cells which were employed for experiments on the same day as isolation to avoid long term changes which might occur in culture. Cells were impaled with one or two high resistance (100-200 MΩ) micropipettes.

When external calcium was elevated to 10mM or greater, an action potential could be elicited with a depolarizing step of current or at the offset of a large hyperpolarizing step. Spontaneous activity was not observed. At 2lmM calcium the action potential duration at half-maximum amplitude typically ranged about 20 msec with a maximum rate of rise of about 5V/sec or less and an approximately equal maximum rate of repolarization; these parameters are of the same order of magnitude as seen in a variety of smooth muscle tissue preparations. In the presence of TEA (≥ 18mM), the action potential duration was markedly prolonged with a "plateau" in the range of 100 msec preceding the phase of maximum repolarization; prolonged repetitive discharge was common. The following data indicate that calcium ions carry the inward current of these action potentials: 1) Action potentials with overshoots were readily obtained at sodium concentrations as low as 3mM. A comparison of overshoot amplitude in 12 vs. 100mM Na^+ solutions (choline substitution for Na^+ with Ca^{++} constant at 21 mM) disclosed a mean increase of only 5mv which is significantly different ($p < 0.001$) from the 54mv change to be expected of a Na^+ electrode. 2) In the presence of 18mM TEA, the mean overshoot amplitude was 17mv greater at 50mM Ca^{++} than at 15mM ($p < 0.001$, n = 10), in good agreement with the expected difference of 15mv for a calcium electrode. 3) At high concentrations of Ba^{++} or Sr^{++} (64-74mM), but low concentrations of Na^+ (12mM), Ca^{++}(0.16mM) and Mg^{++} (0.09mM), overshooting spikes could be elicited; Sr^{++} spikes displaying overshoots required TEA (18mM) to be elicited. Barium spikes were extremely prolonged with no phase of rapid repolarization.

The steady-state current-voltage relationship of the cells always showed outward going rectification. Input resistance increased as $[Ca^{++}]_o$ was raised and often exceeded 500MΩ, ranging as high as 3000MΩ; specific resistance often exceeded $30 \cdot 10^3 \Omega\text{-cm}^2$ and ranged as high as $150 \cdot 10^3 \Omega\text{-cm}^2$. Specific membrane capacity was 1.32±0.33 μF/cm² (mean±S.D.). Supported by Nat'l. Fdn. March of Dimes and by NIH HL #14523.

751 PENICILLIN BLOCKS INHIBITORY CONTROL OF DENDRITIC BURST GENERATION IN HIPPOCAMPAL NEURONS. R.K.S. Wong and D.A. Prince, Dept. Neurology, Stanford University Med. Ctr., Stanford, CA 94305.

Previous studies have shown that epileptiform field potentials occur spontaneously in CA1 and CA3 regions of hippocampal slices exposed to penicillin in vitro. Intrasomatic recordings show that neurons in these areas generate depolarization shifts (DSs) and spike bursts coincident with spontaneous or orthodromically evoked epileptiform field potentials. Data suggest that DSs are intrinsically generated in dendrites. In contrast, CA1 neurons from slices bathed in normal medium generate neither spontaneous nor orthodromically evoked bursts. In order to determine how penicillin alters the behavior of CA1 cells rendering them susceptible to burst generation, we obtained intracellular recordings from somata and dendrites of CA1 cells in hippocampal slices bathed in normal and penicillin containing media. Dendritic recording sites were confirmed by intracellular injection of horseradish peroxidase. In normal medium, orthodromic stimulation in stratum radiatum produced EPSP-IPSP sequences in dendrites. EPSPs could reach amplitudes of up to 30 millivolts. The magnitude and duration of the conductance change associated with dendritic IPSPs was comparable to that recorded in the soma suggesting that these IPSPs were generated on dendritic membrane. Short duration, intracellularly injected depolarizing current pulses regularly triggered intrinsic burst responses in the dendrites. Supramaximal orthodromic input however could only evoke single spikes postsynaptically. This could be due to the shunting effect of IPSPs during orthodromic activation. Following exposure to penicillin (2000 units/ml) orthodromic stimuli became effective in generating dendritic bursts. This change was due to a gradual attenuation of the IPSP and associated conductance change. The EPSP was not obviously increased in amplitude after penicillin however it was significantly prolonged (> 50%) due to the attenuation of the following IPSP. Penicillin produced no significant effect on passive membrane properties. Simultaneous recordings from dendrite and soma of CA3 neurons revealed that dendritically evoked bursts could trigger bursts in the soma and thus affect the output of the soma. We conclude that penicillin in this system leads to generation of spike bursts by interfering with the inhibitory mechanism on dendrites which normally serves to block the occurrence of dendritic burst generation during orthodromic activation of these neurons. (Supported by NIH Grant NS06477).

752 TEMPERATURE ACCLIMATION ALTERS MEMBRANE PROPERTIES OF IDENTIFIED NEURON IN THE LAND SNAIL, HELIX. Dejan Zecevic* and Herbert Levitan. Dept. Zool., Univ. Maryland, College Park, MD. 20742

The physiological and biochemical properties of neurons are in general very sensitive to temperature change. Even though Helix neurons are affected in this way the snails exhibit a similar behavioral repertoire at 5° and 20°C when acclimated to these environmental temperature extremes. In order to explore the neuronal correlates for thermal acclimation we examined the effects of temperature acclimation on several properties of a neuron from H. aspersa. The large, easily identifiable bursting neuron in the isolated right parietal ganglion of snails acclimated for at least two weeks at either 5° or 20°C was penetrated with two independent microelectrodes filled with 3M KCl. Membrane potential (RMP) was monitored with one electrode and current passed through the other allowed determination of effective membrane resistance (R_m). A third electrode filled with 3M NaCl was used to inject Na^+ ions to test the activity of the electrogenic pump. Cooling neurons from warm (20°C) acclimated snails (active or dormant) to 5°C generally caused 1) cessation of spontaneous activity, 2) decrease in excitability, 3) increase in R_m, 4) prolongation and slight increase in amplitude of individual action potentials, 5) 70% decrease in calculated electrogenic pump current, 6) decrease in absolute passive Na-permeability, 7) change in cation permselectivity such that P_{Na}/P_K decreased 75%, but P_{Cs}/P_K and P_{Rb}/P_K both increased about 20%, and 8) no change in RMP. Some but not all of these characteristics changed further with acclimation to 5°C. For example, neurons from animals acclimated to 5°C were quite excitable and spontaneously active when tested at 5°C, their permselectivity properties more closely resembled those of warm acclimated neurons at 20°C than at 5°C, and the passive Na-permeability of the cell membrane increased. Acclimation appeared to have little effect however, on the RMP, R_m, action potential duration, or activity of the electrogenic Na-K pump. These membrane characteristics were very similar at a given temperature (5 to 20°C), independent of the animal's thermal history. Warming to 20°C a neuron from an animal acclimated to 5°C caused a greatly increased frequency of spontaneous activity, and the permselectivity changed such that P_{Na}/P_K was 90% greater, and P_{Cs}/P_K and P_{Rb}/P_K 50% and 15% less than in cells acclimated to 20°C. In sum, the thermal acclimation of snails is reflected at the level of a single neuron by changes in specific physiological properties, and these in turn are the result of changes in membrane biophysical properties such as permselectivity to different ions.

MEMBRANE STRUCTURE AND FUNCTION

753 ASSOCIATION OF TWO RAPIDLY-LABELED MEMBRANE GLYCOPROTEINS WITH SPECIFIC SUBCELLULAR ORGANELLES IN R2, THE GIANT NEURON OF *APLYSIA*. Richard T. Ambron, Ariel A. Sherbany*, and James H. Schwartz. Depts. of Anatomy and Physiol., Div. of Neurobiol. and Behav., Columbia Coll. Phys. & Surg., New York, N.Y. 10032.

Giant neurons are ideal for studying the synthesis of membrane glycoproteins and their subsequent assembly into specific organelles. Injection of ^{3}H-L-fucose or ^{3}H-N-acetylgalactosamine directly into the cell body of R2 rapidly labels a small number of membrane glycoproteins. Analyses of electron-microscope radioautographs indicate that these ^{3}H-glycoproteins are first synthesized on membranes of the reticula and Golgi and later become associated with other somatic organelles. Can individual glycoprotein components be assigned to specific organelles? We have begun to answer this question by isolating the external membrane and vesicles from R2's cell body after removing it from the abdominal ganglion. The labeled external membrane was separated from the cytoplasm and nucleus by manual dissection. Gel electrophoresis in SDS shows the external membrane to be greatly enriched in a glycoprotein with M.W. 120,000. A component of similar mobility was labeled when the isolated cell body was treated with galactose oxidase and $NaB^{3}H_{4}$. Treatment of R2 *in situ* with 0.01% trypsin 24 h after injection releases ^{3}H-glycopeptides into the bath, indicating that glycosyl moieties extend outward from R2's surface. R2's resting potential was normal throughout this mild digestion.

A different labeled somatic glycoprotein appears to be associated with vesicles. It was previously shown that only glycoprotein-I (apparent M.W. = 180,000) continues to be glycosylated in the presence of anisomycin, an inhibitor of protein synthesis. Thus, in cells injected under these conditions almost all of the incorporated radioactivity is present in this glycoprotein. Analyses of radioautographs showed a marked increase in the proportion of silver grains over vesicles in cells exposed to the inhibitor compared with untreated cells. To demonstrate the association of this component with vesicles, the cytoplasm from an injected R2 treated with anisomycin was fractionated by differential centrifugation, glass bead column filtration, and discontinuous sucrose-Ficoll gradient centrifugation. ^{3}H-glycoprotein-I and marker vesicles containing ^{3}H-serotonin co-purified and were found in a vesicle fraction characterized by electron microscopy. When cytoplasm from untreated cells was fractionated in this way, ^{3}H-glycoprotein-I was slightly enriched in the vesicle fraction. Thus it is likely that this glycoprotein is a constituent of vesicles, but it probably is not the only glycoprotein component. Further fractionation is necessary to determine whether specific types of vesicles contain unique glycoproteins.

754 FILIPIN TREATMENT GIVES EVIDENCE FOR CHOLESTEROL IN PARTICLE-FREE PATCHES OF MOUSE ROD OUTER SEGMENTS. Lary Andrews* and Adolph I. Cohen. Dept. Ophth., Sch. Med., Washington U., St. Louis, Mo. 63110

Particle-free patches have been reported in freeze-fracture replicas of mouse and bovine ROS plasma membrane (Jan and Revel, J. Cell Biol. 62: 257-273, 1974; Krebs and Kühn, Exp. Eye Res. 25: 511-526, 1977) and have been seen by us in mouse, rat, and goldfish acclimated to about 20° C. Persistance of these patches in mouse ROS incubated at temperatures from 5 to 80 °C raised doubts that they were due to phase separation in membrane phospholipids. Patches were seen in unfixed, uncryoprotected retinas as well. Filipin has been found to produce characteristic membrane lesions observable by freeze-fracture (Tillack and Kinsky, BBA 323: 43-54, 1973; Verkleij et al., BBA 291: 577-581, 1973) as a result of interaction with sterols present in exposed membranes (Kinsky, Ann. Rev. Physiol. 10: 119-142, 1970). Hubbel's observation that incorporation of cholesterol into artificial membranes containing rhodopsin produces particle-free patches not present before its addition (Accounts Chem. Res. 8: 85-91, 1975) suggested to us that the particle-free patches found in mouse ROS plasma membrane could be due to cholesterol. Treatment of mouse retinas with filipin was used here to explore this possibility. In mouse ROS plasma membrane, filipin-induced pits were found in particle-free patches but not in particulate regions. Particle-free patches are also observed in the basal discs of mouse, rat, goldfish, and frog ROS. In mice, filipin-induced pits were found confined to these patches also. Mature discs have no patches or pits. The plasma membrane of the sclerad portion of the inner segment is densely covered with pits, involving areas containing many particles. These observations suggest that cholesterol in mouse ROS is largely confined to particle-free patches in the plasma membrane, and that a relatively large concentration of cholesterol is found in the nearby inner segment plasma membrane.

755 NEUTRAL AMINO ACID TRANSPORT INTO ISOLATED BRAIN CAPILLARIES: EVIDENCE FOR POLARITY OF THE BLOOD-BRAIN BARRIER. A. Lorris Betz* and Gary W. Goldstein. Depts. of Neurology and Pediatrics, Univ. of California, San Francisco, CA 94143.

Transport of neutral amino acids into cells occurs by at least two distinct systems, a Na^{+}-dependent A-system and a Na^{+}-independent L-system. The neutral amino acid analogue α-(methyl-amino)isobutyric acid (αMeAIB), serves as a specific substrate for the A-system, while L-leucine is a good substrate for the L-system (Fed. Proc. 32: 19, 1973). In this investigation, we studied the transport of ^{14}C-αMeAIB and ^{14}C-L-leucine into capillary endothelial cells isolated from rat brain.

Capillaries were prepared from a rat brain homogenate by albumin flotation and glass bead filtration as previously described (J. Neurochem. 25: 715, 1975). Suspensions of capillary segments were incubated at 37° for various periods of time in the presence of labelled amino acid and the reaction was terminated by filtration through glass fiber filters.

Uptake of αMeAIB by brain capillaries required the presence of Na^{+} and occurred against a concentration gradient. However, when the transcellular Na^{+} gradient was eliminated by preincubation with ouabain, uptake of αMeAIB was equilibrative rather than concentrative. In contrast, L-leucine uptake was unaffected by the presence or absence of Na^{+}. There was minimal accumulation of L-leucine against a concentration gradient and this could be eliminated by preincubation with ouabain. The uptake of these two amino acids was differentially inhibited by a number of other neutral amino acids. The pattern of this inhibition was similar to that observed for the A- and L-systems in other cells.

These results indicate that both an A-system and an L-system for neutral amino acid transport are present in brain capillaries. Since numerous in vivo studies demonstrate that the A-system carrier is not present on the luminal (blood side) of the brain capillary, we conclude that this transport system is located on the antiluminal (brain side). Thus, brain capillary endothelial cells demonstrate a functional polarity for neutral amino acid transport.

756 EXPERIMENTAL BASIS FOR AN AUTORADIOGRAPHIC TECHNIQUE TO MEASURE THE PERMEABILITY OF NORMAL AND ABNORMAL BRAIN CAPILLARIES. Ronald G. Blasberg*, Clifford S. Patlak* and Joseph D. Fenstermacher. NCI, NIMH, NIH, Bethesda, Maryland 20014.

An autoradiographic technique has been developed to measure the blood to brain transfer of a small neutral amino acid, α-aminoisobutyric acid (AIB) (Neurol. 28:363,1978). The technique is based on very slow transport of AIB across normal brain capillaries coupled with rapid transport into brain cells. A three compartment model (blood, brain extracellular fluid (ECF), and brain cells) separated by two unit membranes (capillary and cell wall) was constructed. The rate constants for AIB flux across both the capillary and the cell wall have been determined by independent studies. The capillary rate constant for blood to brain ECF transport (K_1) was determined from experiments during which the plasma concentration of AIB was maintained constant and during which the plasma level was falling. The values for K_1 obtained for rat cerebrum and rhesus monkey caudate nucleus and corpus callosum were 1.8×10^{-3}, 3.4×10^{-4}, and 2.6×10^{-4} min^{-1}, respectively. The capillary rate constant for AIB transport in the opposite direction (K_o) - brain ECF to blood - was estimated from ventricutocisternal perfusion (VC-P) studies with serial periventricular tissue sampling in the rhesus monkey. K_o was found to be less than 1×10^{-3} min^{-1}. The brain cell rate constants for AIB influx and efflux were determined from the time course of brain tissue (cell) uptake. Previous in vitro studies with slices of mouse cerebrum (Blasberg and Lajtha, Biochem. Biophys. 112: 361, 1965) and recent VC-P studies in rhesus monkey were analyzed. The rate constants for AIB flux into the cells (K_1') of mouse cerebrum and monkey caudate nucleus and corpus callosum were calculated to be 1.9×10^{-1}, 8.4×10^{-2}, and 3.4×10^{-2} min^{-1}, respectively. The cell efflux rate constants (K_o') for AIB transport out of the cells of the above tissues were calculated to be 4.3×10^{-3}, 1.0×10^{-2}, and 1.4×10^{-2} min^{-1}, respectively.

On the basis of the above brain model and the experimentally determined rate constants, it is possible to measure directly up to a 100-fold increase in the permeability of brain capillaries to AIB from the autoradiograph. It is possible to localize that increase in capillary permeability to a brain region as small as 100 to 200 microns in diameter. ^{14}C-AIB autoradiographs demonstrating brain capillary disruption caused by a freeze lesion will be presented.

757 CHARACTERIZATION OF TRITIUM LABELED BATRACHOTOXIN BENZOATE BINDING TO MURINE CORTEX. George B. Brown and Stuart Tieszen*, The Neurosciences Program, University of Alabama in Birmingham, Birmingham, Al. 35294.

The specific binding of batrachotoxinin A-20α-para ^{3}H-benzoate (^{3}H-BTX-B) - specific activity 18C per mmole - to mouse cortex has been characterized with respect to the apparent dissociation constant, maximum number of binding sites, and the interaction with other batrachotoxin analogs. Using crude mouse cortex homogenates, specific binding was measured with a pellet assay as the difference in ^{3}H-BTX-B binding in the presence and absence of a 100-fold excess of unlabeled BTX-B. The results of these studies indicate that BTX-B binds to a single class of high affinity sites in mouse cortex with an apparent dissociation constant $K_d = 2 \times 10^{-8}$M. This binding is slowly reversible. The maximum number of specific binding sites is determined to be 15 pmole per gram of tissue (wet weight). Specific binding is completely inhibited by excess batrachotoxin, whereas initial experiments indicated that batrachotoxinin-A, an inactive congener of batrachotoxin, has no effect. Application of a similar pellet binding assay to red blood cell ghosts, selected as a membrane preparation lacking voltage sensitive sodium channels, showed no specific binding of ^{3}H-BTX-B.

758 AMINOPHOSPHOLIPID ASYMMETRY IN MURINE SYNAPTOSOMAL PLASMA MEMBRANE FRACTIONS. R.N. Fontaine*, R.A. Harris, and F. Schroeder* (Spon. D.G. Sherman). Dept. of Pharmacology, U. of Missouri Med. School, Columbia, MO 65212.

Vertical phospholipid asymmetry has been reported in many cellular membranes but not in the central nervous system (CNS). It is known that serum lipid components can alter membrane phospholipid composition by simple exchange processes. However, serum lipoproteins are not known to cross the blood brain barrier. Therefore, the possibility that aminophospholipid asymmetry of cell surface membranes within the CNS may be different from that of cellular membranes from outside the CNS was investigated. Synaptosomes were isolated from whole mouse brains and covalently labelled with the amino-reactive reagent, trinitrobenzenesulfonate (TNBS), under nonpenetrating conditions. The synaptosomes were then lysed. Two synaptosomal plasma membrane fractions (SPM-1 & SPM-2; fractions A and B of Gurd et al., J. Neurochem. 22:281, 1974) and two intrasynaptosomal mitochondria fractions (MITO-1 & MITO-2; Lai et al., J. Neurochem. 28:625, 1977) were isolated. The latter were used to monitor TNBS penetration into the synaptosomes. The results indicated that TNBS labelled 9.9±2.1% and 14.5±0.4% (n=6) of SPM-1 and SPM-2 phosphatidylethanolamine (PE) and 21.6±1.9% and 19.9±3.5% (n=6) of phosphatidylserine (PS) respectively. Mitochondrial fractions 1 and 2 had only 7.6% and 5.7% (n=6) of their PE labelled.. If purified synaptosomal mitochondria are labelled with TNBS under similar conditions, over 70% of the PE reacted with TNBS. These data indicate that little TNBS penetrated into the intact synaptosomes. The fatty acyl composition of labelled PE (derived from the outer monolayer of SPM-1 & SPM-2) was significantly higher in saturated fatty acids than the unlabelled PE (derived from the innter monolayer of SPM-1 and SPM-2). In conclusion, synaptosomal plasma membranes have an asymmetric distribution of both aminophospholipids and of PE acyl chains. A similar lipid assymetry has been reported for plasma membranes of murine fibroblast (LM) cells cultured in a defined medium (Fontaine and Schroeder, Fed. Proc.,in press, 1978).

759 EVIDENCE FOR COUPLING AND VARIATION IN COUPLING BETWEEN MOUSE SALIVARY GLAND ACINAR CELLS. N. Galvin* and S. B. Kater (SPON: R. Waziri). University of Iowa, Iowa City, Iowa 52242.

Coupling between cells of the mouse submaxillary gland was demonstrated by three experimental techniques. Intracellular injection of D.C. current pulses showed that electrical current could be passed from one cell to neighboring cells. The transmission of small molecules between cells was demonstrated by intracellular injection of the dye Lucifer Yellow CH, which spread from the interior of one cell to other cells within the same acinus and, occasionally, to cells of adjacent acini. Electron microscopical examination of freeze-fracture replicas of acinar cell membranes indicated the presence of gap junctions, which are the probable intercellular pathway for exchange of small ions and molecules. Utilizing these techniques, genetic variability in junctional communication between salivary acinar cells is being examined in different inbred strains of mice.

760 EFFECT OF ACETAZOLAMIDE ON THE CONCENTRATION OF ^{14}C-UREA AND ^{14}C-THIOUREA IN THE EPITHELIUM OF THE CHOROID PLEXUS. Conrad E. Johanson* (SPON: S.A. Turkanis) Dept. Pharmacology, Univ. of Utah Coll. of Med., Salt Lake City, Utah 84132

To ascertain the effect of the bulk flow of cerebrospinal fluid (CSF) on the distribution of non-electrolytes in the epithelium of the in vivo choroid plexus, the short-term uptake of radioisotopic urea and thiourea by the lateral ventricular choroid plexus (LVP) was analyzed in rats treated with acetazolamide, an inhibitor of carbonic anhydrase, which decreases CSF flow.

Sprague-Dawley rats (175-300 g) were iniected i.p. with either acetazolamide (20 mg/kg) or saline vehicle together with either ^{14}C-urea or ^{14}C-thiourea. Each animal was sacrificed one hour after the injection of drug and radioisotope; plasma, CSF, LVP, cerebral cortex, skeletal muscle and submaxillary gland (SSG) were all assayed for radioactivity. The effect of drug on the extent of uptake of radioisotope, expressed as a space (%): 100x (dpm/mg tissue ÷ dpm/μl plasma H_2O), varied considerably among the various tissues. After acetazolamide treatment, the ^{14}C-urea space in the LVP increased significantly from 29% to 39%; in contrast, in SSG (another secretory tissue containing carbonic anhydrase activity) and in skeletal muscle (a tissue without carbonic anhydrase), the ^{14}C-urea space was the same (i.e., 77-78%) in control and in drug-treated animals. Moreover, the 1-hr ^{14}C-urea space in cisternal CSF (26-28%) and in cerebral cortex (22-23%) was not significantly altered by acetazolamide. The ^{14}C-thiourea spaces are being investigated.

The significant increase in radiourea concentration in the in vivo LVP after acetazolamide treatment is presumably related to the decreased turnover of CSF by the choroid plexus subsequent to inhibition of carbonic anhydrase in the latter. Thus, it is postulated that acetazolamide affects the distribution of ^{14}C-urea in the LVP indirectly by decreasing the turnover of fluid across this tissue, thereby attenuating the previously-demonstrated sieving of urea in the basolateral membrane of the choroidal epithelium.

Supported by NIH Grant NS 13988 and RCDA # NS 00302.

761 SOUND STIMULATION INCREASES POLYPHOSPHOINOSITIDE LABELING IN AN ACOUSTIC RECEPTOR. Patricia L. Kilian and Jochen Schacht. Kresge Hearing Research Institute, University of Michigan, Ann Arbor, MI 48109.

The possible involvement of polyphosphoinositides in hearing processes was investigated in the auditory organ of the noctuid moth, Agrotis ypsilon. This organ was selected because of its morphological and electrophysiological simplicity. The sensory tissue of this ear, the scoloparium, contains two auditory receptors along with supporting cells. Only two bioelectric events take place in these primary sensory cells: sound energy is transduced into generator potential which leads to spike activity.

Biochemical mechanisms responsible for membrane permeability changes with bioelectric events are unknown. A model has been proposed by which phosphorylation and dephosphorylation of polyphosphoinositides regulate membrane phenomena in auditory transduction (Kilian & Schacht, Neurosci. Abs. 3, 219, 1977).

This hypothesis was tested by studying the effects of acoustic stimulation on labeling of polyphosphoinositides in the scoloparium. In the first series of experiments, insects were stimulated with a pulsed tone (40 kHz) of supra-threshold intensity for 30 min after an injection of ^{32}P-orthophosphate. This stimulation led to a 50% increase of labeling of both phosphatidylinositol phosphate and diphosphate. This change seemed specific for the polyphosphoinositides, since labeling of nucleotide phosphate and of other phospholipids was not affected. It also seemed specific for the sensory tissue, since labeling in the nodular sclerite remained unchanged. The nodular sclerite is a tissue of the moth ear, but no active role in the hearing process has been ascribed to it. In a second series of experiments, a continuous tone of the same frequency and intensity was presented 30 sec before killing the moths. This stimulus did not alter polyphosphoinositide labeling in the ear tissues.

In the acoustic receptor of the moth, pulsed tones trigger both generator and action potential while continuous tones lead to adaptation of action potentials. This leads to the conclusion that the increased labeling of polyphosphoinositides is associated with spike activity in this tissue.

While a mechanism of auditory transduction remains to be established, this study demonstrates the feasibility of using the auditory receptor of the moth for such experiments. Insects may also provide suitable systems for combined biochemical and electrophysiological studies of the role of polyphosphoinositides in sensory processes other than hearing since these lipids were also demonstrated in the eye, antenna, and proboscis of the moth. (Supported by a grant from The Deafness Research Foundation and by NIH Program Project Grant No. 05785).

762 THE EFFECT OF LEAD ON MONOSACCHARIDE TRANSPORT IN CAPILLARIES ISOLATED FROM RAT BRAIN. A. R. Kolber*, P. Morell, and M. R. Krigman. Biological Sciences Research Center, Department of Biochemistry, and Department of Pathology, University of North Carolina, Chapel Hill, North Carolina 27514

Preparations of microvessels isolated from rat brain have been used as an in vitro model for the blood-brain barrier to sugars. Transport of 3-O-methylglucose (3OMG) by isolated capillaries exhibits the kinetics predicted from a carrier-mediated diffusion model. The affinity constant of 3OMG for the isolated capillary transport system (13.5 mM) is similar to that obtained from in vivo experiments.

Previous morphological studies (Toews et al., Brain Research, in press) have demonstrated that acute lead intoxication (daily intubation with 1,000 µg lead as lead acetate/gram body weight) of rats from 5 days after birth onward causes capillary vasculopathies including granular, edematous, vacuolated endothelium and distorted capillary anastamoses. These changes regress in animals which survive such acute lead intoxication for 20 days. The effect of this treatment on 3OMG transport in vitro was studied. Capillaries isolated from treated animals lost the facilitated component for 3OMG transport; the half time of uptake was not concentration-dependent and transport appeared to follow the kinetics of simple passive diffusion. The loss of the facilitated component for 3OMG transport was evident in animals treated with dosages as low as 100 µg lead/gram body weight per day. The loss of the facilitated component of transport could also be induced in capillaries isolated from normal rats by in vitro treatment at lead concentration greater than 5×10^{-7} M.

In another series of experiments capillaries isolated from normal animals were incubated with varying concentrations of lead-210. Radioactive lead was concentrated by isolated capillaries to 10-15 times the extracellular lead concentration. This accumulation of lead was not inhibited by equivalent concentrations of Ca^{++}. It is concluded that lead is tightly bound to brain capillaries, and that this association interferes with the carrier mechanism of monosaccharide transport.

763 CHARACTERISTICS OF THE GLUTAMATE BINDING GLYCOPROTEIN FROM BRAIN SYNAPTIC MEMBRANES. Donald R. Kuonen* and Elias K. Michaelis. Dept. of Human Development, U. of Kansas, Lawrence, KS 66045.

A small molecular weight, anionic glycoprotein from brain synaptic membranes has previously been purified and found to bind L-glytamic acid with a high affinity (K_D=0.8µM) (Michaelis, Biochem. Biophys. Res. Communic. 65, 1004, 1975). Recent studies employing sucrose density centrifugation have revealed that this glutamate binding protein (GBP) tends to form multimers with molecular weights of 24,780, 40,600, 60,400 and 103,500. The specific binding activity is increased in the 40,600 and 60,400 M.W. form of the multimer. Pretreatment of this glycoprotein with 2-mercaptoethanol (10^{-4}M) reduces the binding activity of the protein and leads to an apparent decrease of the multimeric forms of the GBP. Exposure of the GBP to p-chloromercuriphenyl sulfonate (PCMPS, 10^{-4}M) does not affect the glutamate binding activity or the appearance of the various multimeric forms of the protein. SDS electrophoresis of the purified GBP yields only one protein band of 13,000 M.W.

Amino acid analysis of this glycoprotein reveals a relative enrichment in acidic and hydrophobic amino acids. Analysis of the carbohydrate make up of the protein has shown the presence of fucose, mannose, galactose, and sialic acid which represents 20-30% of the protein M.W. This carbohydrate constitution of the protein corresponds well with its demonstrated interaction with the lectin Concanavalin A. Attempts to explore the characteristics of the binding site by means of protein modification techniques are currently under way. In addition, the activity of this protein as a site for Kainic acid binding is being explored. Kainic acid is a very potent excitatory agent presumed to interact with physiologic glutamate receptors. The purified GBP can function as a binding site for [^{3}H]-kainic acid only if the non-ionic detergent Triton X-100 is dialyzed out of the system and the GBP is allowed to interact with phospholipids (phosphatidylserine). The relevance of these results in terms of the physiologic function of the glutamate receptors will be discussed. (This research has been supported by PHS grants GM 22357 from NIGMS and AA 01911 from NIAAA).

764 ANTIGENIC COMPONENTS OF NEURAL MEMBRANES. S. P. Mahadik, A. Korenovsky*, Y. Huang*, L. Graf*, and M. M. Rapport. N. Y. State Psychiatric Inst. and Columbia Univ., Coll. Phys. & Surg., New York, N. Y. 10032.

Antisera against the synaptic membrane fraction have been shown to alter several in vivo CNS functions.[1] They induce seizure activity, block passive avoidance memory consolidation, interfere with maze performance, and induce deficits during development. Since such antisera contain antibodies directed against many synaptic antigens, it is essential to separate and identify the individual antigens in order to examine the various mechanisms underlying the different biological phenomena. Immunochemical analysis of membrane antigens presents a special problem because their solubilization requires the addition of detergents (such as Triton X-100 and Berol 043), but conditions have been found that are useful in rocket immunoelectrophoresis. The antigens in membrane extracts obtained with Berol 043 (Protein:Berol, 1:4 w/w) were more stable than those obtained with Triton X-100. Extracts both of synaptic membranes and microsomes from rat brain cortex showed at least two rockets when tested with antisera to a carefully purified synaptic membrane fraction.[2] No reactions were obtained with extracts of the total membrane fraction from liver, kidney, or spleen; or with the soluble fraction from these tissues or from brain. The antigenic components were also detected by immunodiffusion (Ouchterlony). The antigens were characterized further by separation on gradient slab gels in buffers containing SDS, followed by rocket immunoelectrophoresis. Berol extracts of a synaptic membrane fraction (fraction B) and of brain microsomes[3] contained many polypeptide bands; although most were qualitatively the same in extracts of both subcellular fractions, each contained several polypeptides that were distinctive. Only 4 polypeptide bands produced rockets with the antisera. The apparent molecular weights of these bands were 56 000, 58 000, 62 000, and 66 000. These antigens were therefore different from those described by other investigators (D-1, D-2, D-3 of Jørgensen[4]; X-1, X-2 of MacPherson and Kleine[5,6]). The quantities (rocket height) of each of these antigens in extracts of synaptic membranes differed from those in extracts of microsomes. Further characterizations will be described.

765 LECTIN PEROXIDASE LABELING OF PIGMENT EPITHELIAL AND PHOTORECEPTOR MEMBRANES IN INHERITED RETINAL DEGENERATION. Barbara J. McLaughlin and John G. Wood. Department of Anatomy, University of Tennessee Center for the Health Sciences, Memphis, Tenn. 38163

Carbohydrate-containing macromolecules are thought to be involved in intercellular recognition. One type of intercellular recognition which occurs in the retina is that between the pigment epithelium (PE) and the discarded photoreceptor outer segments (OS) during the normal ongoing process of phagocytosis and OS membrane turnover. In the Royal College of Surgeons (RCS) strain of rat, there is a presumed breakdown in this recognition step and a failure of the PE to phagocytize OS discs. Because this breakdown may be related to changes in carbohydrate-containing macromolecules on these membranes, we have studied the localization of some sugar residues on PE and OS membranes of 15 day old RCS rats and their genetic control (RCS/rdy+) by using peroxidase-conjugated lectins from wheat germ agglutinin (WGA), castor bean (CB) and Lens culinaris (LC). Aldehyde fixed retinal slices were incubated with the lectin (either WGA, specific for n-acetylglucosamine sugars and sialic acid, or CB, specific for n-acetylgalactosamine or galactose, or LC, specific for mannose), followed by buffer rinsing, diaminobenzidine treatment, osmication and processing for EM. In both control and RCS retinas, LC, WGA and CB uniformly label the OS plasma membranes of intact photoreceptor discs but internal disc membranes are never labeled. In the controls, LC, WGA and CB also label the plasma membranes of discarded OS and WGA labels some internal disc membranes as well. In contrast, WGA and CB do not label the OS debris membranes of RCS retinas, whereas LC appears to label some of the debris membranes. The lectin labeling on PE microvilli in both control and RCS retinas differs in that WGA and LC label both proximal and distal membrane surfaces of PE microvilli whereas CB labels primarily the distal regions. In control PE cells, CB and LC label phagosome membranes whereas WGA does not. The major difference between control and RCS retinas is the absence of CB and WGA labeling on membranous debris of RCS photoreceptors and the presence of LC staining on some debris membranes. These observations may reflect some basic change in the accessibility or composition of certain cell surface sugars on photoreceptor OS membranes and PE microvilli which may be related to the breakdown in phagocytosis in RCS retinas. Supported by Fight for Sight, Inc., New York City, NS-12590 and the Sloan Foundation.

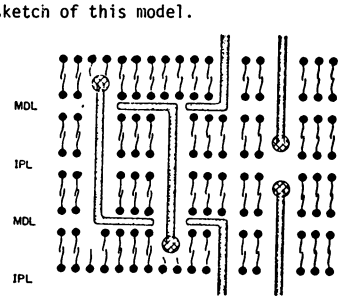
766 EFFECT OF ACETAZOLAMIDE AND FUROSEMIDE ON CSF PRODUCTION BY CAT CHOROID PLEXUS IN SITU. James M. Melby* and Donal J Reed* (SPON: J.W. Woodbury) Dept. of Pharmacology, Col. of Med., Univ. of Utah, Salt Lake City, Utah 84132

It is well known that the choroid plexus (CP) is involved in the secretion of cerebrospinal fluid (CSF). However, the magnitude of the contribution of the CP remains controversial and the mechanisms of fluid production is still obscure. In order to elucidate the role of the CP in CSF production, the present studies were conducted. The isolated CP in situ technique in the cat (Miner and Reed, J. Physiol., London 227:127-139, 1972) was used. After a control steady-state period 2-1/2 hours or more, 3-5 kg cats of either sex were given either 20 mg/kg acetazolamide or 50 mg/kg furosemide intravenously and measurements were made at 1/2 hr intervals for 2-1/2 hrs. Acetazolamide reduced flow (µl/mg CP/min) from a control value of 0.60 ± 0.05 SEM to 0.22 ± 0.09 SEM after 1/2 hr, and to 0.01 ± 0.01 SEM after 2-1/2 hr. Furosemide reduced flow from a control value of 0.52 ± 0.04 SEM to 0.31 ± 0.06 SEM after 1/2 hr and to 0.13 ± 0.06 SEM after 2-1/2 hr. After the first 30 min, the rate of reduction in CSF flow is nearly the same with both drugs, as each approached O flow. The only apparent difference in the actions of the two drugs is the magnitude of the decrease in flow during the first 30 min (the decrease produced by acetazolamide was greater than that produced by furosemide). The only statistically significant change in CSF electrolytes was a decrease in potassium, produced by both drugs. Acetazolamide lowered CSF $[K^+]$ from 3.18 ± 0.15 SEM mEq/l to 2.38 ± 0.22 SEM mEq/l ($P < 0.05$), while furosemide lowered $[K^+]$ from 3.18 ± 0.15 SEM mEq/l to 2.25 ± 0.22 SEM mEq/l ($P < 0.01$). The above results suggest that secretion by the CP can be blocked completely and that the CP is responsible for 50-60% of total CSF fluid production. (This work was supported by U.S.P.H.S. Grants NS 12869 and GM 00153).

767 A MODEL FOR THE LOCATION OF BASIC MYELIN PROTEIN (MBP) AND PROTEOLIPID (PL) ON CAMELLAR MYELIN. Rodman G. Miller The Salk Institute for Biological Studies, P.O. Box 1809, San Diego, Ca. 92114. London and coworkers have shown that the MBP can be protected from proteolytic attack by partial insertion into a lipid monolayer at the air water interface (e.g., BBA 311, 420). Plateau and coworkers (J. M. B. 75, 6976) have shown that introduction of MBP into a lipid bilayer system induces a double bilayer repeat pattern as measured by X-ray diffraction studies. The degree of hydrophobicity of the PL and freeze fracture studies of the incorporation of the PB into artificial vesicles (e.g., Vail, et al. BBA 345, 463) indicate that the PL is located in the hydrophobic matrix of the myelin membranes. Freeze fracture of myelin which has been fixed and which has been freshly frozen indicates a pleomorphism of the membrane particles, suggesting that the PL alone cannot be responsible for the particles. Freeze fracture also indicates a structural link between particles (neurokeritin formation) which must extend across both the main dense line and the interperiod line (Pinto da Silva and Miller, PNAS 72, 4046).

These lines of evidence suggest a model for the location of the two major proteins in myelin membranes in which the MBP extends through at least one membrane and interacts with the PL in anotner membrane. Arguments of economy and arguments arising from the swelling properites of meylin (e.g., Finean, and Millington, J.BC. 3, 89 and Bornstein and Raine, Lab. Invest. 35, 391) suggest that the MBP may traverse a second membrane and interact with the PL in a third.

Below is a sketch of this model.



This work was done during the tenure of an MDA Fellowship.

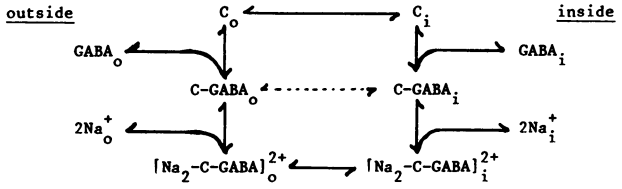
768 ANALYSIS OF CEREBELLAR NEURONAL CELL SURFACE PROTEINS DURING GROWTH AND DIFFERENTIATION IN VITRO. Lee N. Minier*, Robert S. Lasher, and Paul F. Erickson*. Anat. Dept., Univ. Colo. Med. Center, Denver, Colorado 80262.

A number of morphogenetic processes may be regulated through the interaction of specific proteins located at the cell surface. Since proper function of the central nervous system is highly dependent upon faithful recognition and matching of given sets of neuronal cells, it is important to have a knowledge of the organization of the neuronal cell surface. We have used dispersed cell cultures of 2-day old rat cerebellum as a developmental model to determine the surface composition of neuronal and non-neuronal cells. Enzymatic radioiodination coupled with discontinuous SDS-polyacrylamide gel electrophoresis methods were used to detect and resolve the cell surface protein complement. To ensure the purity of neuronal samples for analysis after labeling, small aggregates of neurons together with fasciculi were gently loosened from the surface of the culture dish with a sharpened tungsten needle, and then collected using a micropipette attached to a micromanipulator. The preliminary results may be summarized as follows: a) the classes of neuronal cell surface proteins were generally constant during development; radioautographs indicated between nine and fourteen discernible peptides falling in the range of 3.0×10^4d and 1.5×10^5d. b) considerable radioactivity traveled with the electrophoretic front, indicating labeling of low molecular weight macromolecules c) radioautographs of gels derived from cultures containing a greater relative proportion of mitotic neuroblasts and undifferentiated neurons contained 2-3 prominent bands which decreased markedly in those gels obtained from cultures having differentiating or more mature neurons. While the qualitative aspects of the surface profiles remained fairly constant during neuronal differentiation, quantitative differences occasionally appeared which may be due to variability between individual cell cultures. d) some dissimilarities existed between the labeling patterns of neuronal and nonneuronal cells.

The cell surface protein complement of nonneuronal cerebellar cells did not appear to change significantly during growth in culture. One of the major cell surface components of the non-neuronal cell population, the LETS or CSP protein, was shown by indirect immunofluorescence microscopy to appear as an increasingly complex reticular network on the surface of some nonneuronal cells. As reported previously, the LETS protein was never detected on the surfaces of neuronal cells. Research Support: NIH Training Grant GM01981 (LNM), NIH Grant NS13133 (RSL,PFE).

769 KINETICS OF CARRIER-MEDIATED γ-AMINOBUTYRIC ACID (GABA) TRANSPORT IN PINCHED-OFF PRESYNAPTIC TERMINALS (SYNAPTOSOMES). M.T. Nelson* and M.P. Blaustein, (SPON: C.M. Rovainen), Dept. Physiol. and Biophys., Washington U. Med. Sch., St. Louis, MO 63110.

GABA uptake by synaptosomes from rat brain occurs via the voltage-sensitive, carrier-mediated co-transport of two Na^+ ions with one GABA (J. Membrane Biol. 30: 153, 1976). Martin's (J. Neurochem. 21: 345, 1973) observations on high-affinity GABA uptake kinetics, which we have verified, fit the carrier model shown below. According to this model, the binding of the transported substances is ordered, and GABA binds before the Na^+ ions; only free carriers (C) and fully-loaded carriers ($[Na_2\text{-C-GABA}]^{2+}$) can cycle. The derived kinetic model has been tested by measuring GABA efflux from rat brain synaptosomes preloaded with ^{3}H-GABA; Ca-free, EGTA-containing (0.5 mM) media were employed to minimize the extrusion of GABA by exocytosis (cf. Cotman et al., J. Physiol. 245: 475, 1976). Some GABA efflux appears to be carrier-mediated since it is stimulated by external GABA in the presence of Na (Simon et al., J. Neurochem. 23: 981, 1974). We confirmed this observation, but found that ^{3}H-GABA efflux is inhibited by external GABA when Li is the predominant external cation. This implies that external GABA can bind to the carriers in the absence of external Na, thereby limiting the number of carriers available at the inside - presumably because the GABA-loaded carriers (C-GABA) cycle slowly, if at all, in the absence of external Na. We also found that depolarizing agents (veratridine or elevated external potassium concentrations) enhance ^{3}H-GABA efflux into Ca-free, EGTA-containing media; this suggests that carrier-mediated GABA efflux involves the net exit of positive charge (e.g., Na^+ moving out with the GABA, which is a zwitterion at neutral pH).



[Supported by USPHS grant NS-08442.]

770 EARLY STAGES OF EXOCYTOSIS CAPTURED BY RAPID-FREEZING. R. L. Ornberg* and T. S. Reese. LNNS, NINCDS, NIH, Bethesda, MD 20014 and Marine Biological Laboratory, Woods Hole, MA 02543.

The interactions between secretory granules and the plasmalemma which lead to exocytosis in various secretory cells have been studied in considerable detail with morphological techniques. Since the effects of chemical fixatives used in these studies to stop the secretory process undoubtedly progress from the outside in and are rather slow, there is reason to question whether current views of the earliest stages of exocytosis are representative of their actual configurations and frequencies. In order to minimize distortions, we rapidly froze the secretory blood cells (amebocytes) from the horseshoe crab, Limulus polyphemus and used freeze-fracture and freeze-substitution techniques to prepare them for electronmicroscopy. Limulus amebocytes are particularly advantageous for studying secretion in that they: 1) are essentially the only blood cell in the crab and are highly concentrated ($2x10^5$ cells/ml) making centrifugation and purification unnecessary; 2) are large (10-20 μm diameter) with many large secretory granules; 3) secrete clotting proteins very rapidly upon exposure to endotoxin; 4) can be reversibly inhibited by propanolol (1 mM). Freshly drawn amebocytes were stimulated by application to an endotoxin-soaked filter paper on a freezing stage and frozen after various times. There was a progressive loss of granules up to two minutes when all but a few amebocytes were devoid of granules. Also, there were progressively more images in thin sections of granules fused with the plasmalemma, and the freezing even preserved the concentration gradient of granule contents as it was released from the cell. Amebocytes frozen 3-15 seconds after endotoxin showed the earliest precursors of exocytosis. Unlike the smooth plasmalemma of inhibited cells, these stimulated cells have variable numbers of outward bulges and flat-bottomed inward depressions as well as small exocytotic granule openings. Comparison of freeze-fracture and thin section micrographs showed that the outward bulges are where small cisterns of endoplasmic reticulum expanded against the plasmalemma. It was at the inward depressions where secretory granules usually contacted the plasmalemma. Fractures through these regions of contact occasionally revealed single, minute (500 A) perforations where a granule membrane had fused with the plasmalemma. We could find no particle specializations or rearrangement associated with these sites, nor any changes in the contents of granules in this position. We conclude that granules are readied for exocytosis when the plasmalemma puckers in to contact them. We infer from their frequency that this contact stage is relatively long-lived but ends suddenly when a minute perforation occurs between the closely opposed membranes, and rapidly widens to release the granule contents.

771 POLYPEPTIDE COMPOSITIONS AND Ca^{2+}- AND cAMP-PROMOTED PHOSPHORYLATION OF MEMBRANE PROTEINS OF SYNAPTIC SUBFRACTIONS. Elena H. Petrali*, Brenda J. Thiessen*, Peter N. Dessens* and Prakash V. Sulakhe. Dept. Physiol., Univ. Sask., Saskatoon, Canada.

Polypeptide (PP) profiles of membrane fractions from rat cerebral cortex (CC) were analyzed by SDS (1%)-PAGE on slab gel (10%, Laemmli). Synaptosomes (SN) contained 46 PP bands; the molecular mass (M) in K daltons of major PPs was - 230, 165, 130, 107, 105, 58, 55, 54, 48, 40 and 36. Synaptic vesicles (SV) contained 30 PP bands; major PPs were similar to those of SN and in addition contained 280, 260, 250 and 200. Synaptic plasma membranes (SPM) contained 50 PP bands and major PPs were similar to those of SN. Synaptic junctions (SJ) contained about 24 PP bands and M of major PPs was 270, 130, 55, 54, 34 and 30. Post-synaptic density (PSD) contained about 4-6 PP bands and M of major PP was 58 and 55. SN, SPM and SJ isolated from 8-day old rat CC contained fewer PPs - SN contained 4 major PPs of 58, 55, 54 and 47; SPM about 30 PPs and protein profile relatively similar to adult SN; SJ, about 15 PPs and M of major PPs were 55, 32 and 30. All fractions, except PSD, from adult rat CC contained endogenous protein kinase (ePK); ePK was progressively enriched in SJ. In the absence and presence of Triton (Tx) about 14 PP bands of SN were phosphorylated (autoradiography); cAMP (μM) promoted (↑) phosphorylation (PR) of 280 (doublet), 80, 76 and 59 regions, the extent of stimulation being greater with Tx. Ca^{2+} (μM) ↑ PR of 175, 80, 76, 64, 55 and 51; SPM exhibited similar pattern of PR (± Tx). SJ showed PR of 280, 83 and 79 regions and which was ↑ with cAMP but not Ca^{2+} (± Tx). Purified myelin contained ePK that phosphorylated 18K and 16K PPs (identified as myelin basic proteins), PR of which was profoundly ↑ with Ca^{2+} (but not cAMP). SV showed PPs of multiple bands (± Tx); in the absence of Tx, cAMP ↑ PR of 250 while Ca^{2+} ↑ PP of 250, 65, 60 and 55; with Tx present similar results were obtained except that Ca^{2+} ↑ PP of 55 was considerably reduced. PSD even in the presence of exogenous PK showed little PP. Stimulatory effects of cAMP (-Tx) on PP of 83 and 79 regions could not be observed in either SPM or SJ prepared from 8-day old rat CC, although some effect was detectable with SN. Ca^{2+}, but not cAMP (-Tx), ↑ turnover of phosphate in 83, 79, 65, 60 and 55 regions of SN, SV and SPM. From these findings we suggest that Ca^{2+} acts pre-synaptically and ↑ PP of 65 and 55 regions of SV and 83 and 79 regions of SN; this may be involved in Ca^{2+}-induced release of transmitter from SV. cAMP action at the post-synaptic membrane is localized to 83 and especially 79 regions; cAMP ↑ PP of 79 occurs following synaptogenesis and may be of significance in neurotransmitter-induced changes in excitability of the post-synaptic cell.

772 CORRELATION OF INTRAMEMBRANOUS PARTICLES WITH α-BUNGAROTOXIN BINDING IN CULTURED CHICK MYOTUBES: QUANTIZATION OF PARTICLE CLUSTERS. D.W. Pumplin, Dept. Anat., Univ. Md. at Baltimore and LNNS, NINCDS, NIH and S.A. Cohen, LDN,NICHD,NIH. Bethesda, Md. 20014.

Acetylcholine receptor (AChR) distribution on chick skeletal muscle fibers developing in tissue culture was mapped using a specific ligand, α-bungarotoxin, covalently bound to the fluorescent dye, tetramethylrhodamine (TMR-α-BGT). The myotubes were subsequently freeze-fractured, and complementary replicas were obtained of cytoplasmic and external leaflets of the sarcolemma. There was excellent correlation between patches of intense fluorescence$_o$specific to TMR-α-BGT binding and clusters of large (~100 A) angularly shaped particles and the suggestion that the particles represent the ultrastructural correlate of the AChR has been previously reported (Cohen and Pumplin, Soc. for Neuroscience Abstracts, Vol. III, 1977). This correspondence was found on noninnervated muscle fibers grown in the routine manner as well as in the presence of tetrodotoxin (TTX). In the latter, the size of both the fluorescent and the particle patches was greater. These particles were distributed in about a 2:1 ratio between the cytoplasmic and external leaflets, but otherwise resembled closely particles seen at postsynaptic membranes of neuromuscular junctions. Innervated myotubes in cultures to which small fragments (explants) of spinal cord had been added were also fractured as were lengths of the neurites (previously visualized with Nomarski optics) overlying them. We have seen organizations of particles in neuronal plasmalemmas apposing the muscle which may represent precursors to active-zone specializations. When present these are found along some but not all short segments (several microns) of nerve-muscle contact which have intense fluorescence and clusters of large angular particles in the sarcolemma immediately adjacent to the nerve. Fluorescent patches and particle clusters were absent along the lengths of many neurites contacting the muscle but often were present away from sites of contact. The cluster size (number of particles/cluster) was determined for a large number of clusters on muscle fibers in each of the three categories above. The distribution of cluster sizes was not smooth, but contained peaks which were multiples of a "unit size" of 10-12 particles. Many examples of membrane depressions containing about this number of particles were also seen. Such "quantization" puts contraints on the possible mechanisms by which particle clusters are formed and degraded.

773 CROSS TALK BETWEEN BARE AND MYELINATED AXONS IN SPINAL ROOTS OF DYSTROPHIC MICE. Michael Rasminsky. Division of Neurology, Montreal General Hospital and Department of Neurology and Neurosurgery, McGill University, Montreal, Quebec, Canada.

In spinal roots of dystrophic mice some axons are bare and others are ensheathed with inappropriately thin myelin. Impulses are generated ectopically in these spinal root axons; some of the ectopic activity is due to ephaptic conduction or cross talk between adjacent single fibers (Rasminsky, Ann. Neurol. 3:351, 1978). The present experiments were designed to examine conduction in both the exciting and excited fibers in the immediate vicinity of sites of cross talk.

Spontaneous activity on lumbosacral spinal roots of 129B6F1/J dy/dy dystrophic mice was recorded differentially between pairs of Ag or Pt-Ir electrodes separated by 200-300 μm. This recording technique permits identification of the direction of propagation of each impulse as centrifugal or centripetal. The site of origin of an ectopically arising impulse can be identified as the site of change in polarity of the action potential recorded from the fiber in question. Simultaneous recordings were made from a pair of reference electrodes held immobile at a site on the root a few mm remote from an ephapse and a pair of mobile electrodes which was moved in steps of 100 μm between successive recording sites over the 4-6 mm straddling the ephapse. With this recording configuration the impulse in the excited fiber will traverse the reference electrodes after the events of interest near the ephapse have occurred. Transmission of the impulse in the excited fiber past the reference electrodes was used to initiate pre-triggered averaging of events occurring at the mobile electrodes.

In the pairs of fibers studied so far, there was a striking difference in the conduction velocity (CV) in the exciting and excited fibers. In the exciting fiber impulses were conducted past the ephapse relatively slowly (CV ≈1 m/sec) and CV was uniform for more than 1 mm on either side of the ephapse. In the excited fiber the local CV in the immediate vicinity (within 1 mm) of the ephapse was >4 m/sec for propagation of the impulse both centrifugally and centripetally. Propagation over the next 2 or 3 mm away from the ephapse usually proceeded at a non-uniform CV in both directions in the excited fiber.

These results suggest (but do not definitively prove) that the exciting impulse is conducted in a bare axon in which conduction is continuous (Rasminsky et al, Brain Res. 143:71,1978) and that the excited impulse arises in a myelinated fiber in which conduction is saltatory but relatively slow due to thin myelin. Myelinated fibers may be more susceptible to cross excitation than bare axons because the current required to stimulate a myelinated fiber to activity is theoretically much less than that required to excite a highly capacitive bare axon.

774 ATPASE ACTIVITIES IN RETINAL PIGMENT EPITHELIUM AND CHOROID. Michael V. Riley*, Barry S. Winkler, Jennifer Benner* and Ellen M. Yates*. Institute of Biological Sciences, Oakland University, Rochester, Michigan 48063.

The Mg^{2+}-, the Na^+-K^+- and the HCO_3^--dependent ATPase activities of retinal pigment epithelium-choroid tissue from grassfrog, bullfrog and rabbit have been measured. In the frogs, Mg^{2+} ATPase activity was between 1 and 2 μmols P_i liberated $hr^{-1}mg^{-1}$protein, while Na^+-K^+ ATPase and HCO_3^- ATPase were about 20% and 25% of this activity respectively. Corresponding values for the rabbit were 8.5 μmol P_i $hr^{-1}mg^{-1}$protein, 8% and 9%. Na^+-K^+ ATPase activity in each species was completely inhibited by 2 mM calcium, while HCO_3^- ATPase was unaffected by calcium or ouabain.

The pigment epithelium-choroid preparations of bullfrog and rabbit were scraped to yield suspensions of isolated epithelial cells, relatively free of other tissue components, and a residual fraction which contained some epithelial cells, choroidal elements and red blood cells. Na^+- K^+ ATPase activity was present in the epithelial cells of both species and in the choroid of only the frog. HCO_3^- ATPase and Mg^{2+} ATPase activities were roughly equally distributed in each of the bullfrog fractions, but in the rabbit were concentrated in the choroid.

The magnitude of the ion-dependent ATPase activities in the bullfrog are comparable to the magnitude of the ion fluxes measured across similar preparations in other laboratories. These results suggest that the ATPases of the pigment epithelium are capable of mediating the active transport of sodium ions, and possibly of bicarbonate ions, that is postulated to account for the observed short circuit current across this cell layer.

775 PHOTOLABELING OF SURFACE PROTEINS OF RAT BRAIN SYNAPTOSOMES. James C. Schaeffer, Michael Hurst*, Mark Ediger*, and Michael Peck*. Dept. of Chemistry, University of Missouri, Kansas City, Missouri, 64110.

A number of functionally important presynaptic receptors and transport systems are associated with synaptosomal membranes. Since at least components of these receptor and transport systems are integral proteins partially exposed to the extracellular medium, non-specific photolabeling experiments have been performed in an attempt to determine the apparent molecular weights of the surface proteins of synaptosomes and thus shed light on the size distribution of these functional presynaptic proteins.

Whole rat brain synaptosomes were prepared by the procedure of Gurd, et al. (J. Neurochem. 22:281, 1974) and photolyzed in the presence of 100μM of tritium labeled N-4-azido-2-nitrophenylglycine at 4°C for one hour. All experiments were run at pH 7.4 to insure that the photolabel was completely ionized and therefore non-penetrable by diffusion. Furthermore, low temperatures were employed to prevent label uptake by any non-specific synaptosomal transport system. After photolysis, the labeled synaptosomes were separated by centrifugation at 10,000 x g, washed twice with isotonic saline, freeze-thawed, solubilized in sodium dodecylsulfate (SDS), heated to 100°C and dialyzed. The resulting solubilized synaptosomal protein mixture was resolved into eighteen bands by SDS-gel electrophoresis. One millimeter gel slices were solubilized and counted. Radioactivity was detected in slices corresponding to molecular weights of 115kD, 91kD, 72kD, 62kD, 54kD, and 41kD. These results indicate that synaptosomal surface proteins fall within a broad molecular weight range, but do not include polypeptides whose molecular weights are less than 40kD.

776 CELL JUNCTIONS BETWEEN THE PHOTORECEPTOR CELLS OF DROSOPHILA. Rudolf H. Schinz*(SPON: J.E. Mittenthal). Purdue University, West Lafayette, IN 47907

It has been known for some time that there are desmosomes between the membranes of two neighboring dipteran photoreceptor cells. We found still another type of photoreceptor cell contact in freeze-fracture studies of the Drosophila retina. Within this cell contact, the protoplasmic membrane leaflet showed a rather loose and irregular pattern of ridges, which under high magnification displayed a particulate substructure. The exoplasmic leaflet of the adjacent cell showed furrows corresponding to the ridges. These cell contacts were found throughout the retina, but favorable preparations yielded pictures showing that the structures occur also between two neighboring photoreceptor cells. These structures satisfy the criteria for cell junctions published by Satir and Gilula (1973). Moreover, because there were no conspicuous structures at the corresponding sites in thin sections, other than a gap of about 150Å between the neighboring membranes, the observed cell junction corresponds most closely to a "continuous junction", found in various other invertebrate tissues. The physiological significance of this type of junction is still poorly understood. (Supported by NSF BNS77-18647 and NIH EY00033 granted to W.L. Pak)

777 THE USE OF ANTIBODY + COMPLEMENT TO GAIN ACCESS TO THE INTERIOR OF PRESYNAPTIC TERMINALS. Erik S. Schweitzer and Mordecai P. Blaustein, Department of Physiology and Biophysics, Washington University Medical School, St. Louis, MO 63110.

Treatment of synaptosomes with antiserum directed against synaptosomal membranes (Ab) and complement (C') results in a rapid release of intracellular potassium. This release does not occur after treatment with antiserum alone, or with normal serum + C'. Ab + C' treatment releases 40% of the total K content of intact synaptosomes, while osmotic lysis or saponin treatment (procedures that appear to disrupt completely the permeability barrier at the plasma membrane) release 50% of the total K.

The Ab + C' reaction can be carried out in separate steps. Binding, but not pore formation, occurs at 0°. When the incubation medium is warmed to 30° after a 20 minute incubation at 0°, K release is complete in less than 5 minutes. This latter step can be carried out in a medium containing sub-micromolar Ca^{2+}.

The perm-selectivity of the complement-induced pores is consistent with a pore size of 25 Å, as has been suggested by Michaels and Mayer (Biophys. J. 21: 125a, 1978). The pores are large enough to allow the rapid release of intra-terminal K and, presumably, to cause the collapse of the membrane potential; however, they are too small to permit the soluble cytoplasmic enzyme, lactate dehydrogenase, to escape. In addition, preliminary EM studies indicate that Ab + C' treatment does not lead to gross morphological disruption of the synaptosomes.

This treatment may allow the manipulation of the intra-terminal ion and metabolite composition without the loss of macromolecules or subcellular organelles, such as synaptic vesicles, microtubules, endoplasmic reticulum, and mitochondria. [Supported by USPHS grant NS-04882.]

778 GENESIS AND DEVELOPMENT OF SERTONERGIC VESICLES IN THE IDENTIFIED GIANT CEREBRAL NEURON (GCN) OF *APLYSIA*. Ludmiela J. Shkolnik* and James H. Schwartz. Dept. Physiol., Div. of Neurobiol. & Behav., Columbia Coll. of Phys. & Surg., New York, N.Y. 10032.

In order to trace the genesis of the serotonergic vesicle in the cell body and its subsequent development in axons and nerve terminals, we have injected ^{3}H-N-acetylgalactosamine directly into the cell body of GCN in the isolated *Aplysia* central nervous system. Membrane glycoproteins, labeled by incorporation of the ^{3}H-sugar precursor, are rapidly transported along the axon in the cerebrobuccal connective to the buccal ganglion where they can serve to identify terminal varicosities of the injected neuron by electron microscopic radioautography.

Labeled synaptic varicosities, examined after conventional glutaraldehyde-osmium fixation, revealed a heterogeneous population of vesicles. Two regions can be defined within varicosities by the types of vesicles they contain. One region contains an equal number of dense-cored (DCV) and empty vesicles, 80-90 nm in diameter. Filling the other region are small (50 nm) lucent vesicles, many of which cluster along active zones; occasional DCVs, some of which abut the membrane, are also present in this region. Similar serotonergic terminals have now been described in other invertebrates and in the vertebrate brain indicating that serotonergic terminals have common morphological features in phylogenetically distant animals. On the other hand, only one characteristic and different type of vesicle occurs along the entire length of GCN's axon. This is a 70-80 nm *lucent* vesicle containing a lucent 50 nm vesicle, one inside the other. Similar compound vesicles are also seen in the cell body and axon hillock, where they are occasionally attached to short tubules, 30-35 nm wide. These compound vesicles have previously been shown to be the only significantly labeled organelle in the axon of GCN after intrasomatic injection of ^{3}H-serotonin. When we treated the tissue with $KMnO_4$ or chromium salts, the lucent compound vesicles became intensely dense-cored, indicating that they contain endogenous serotonin.

We suggest that the lucent compound vesicle observed in the cell body and axon is formed by budding of smooth endoplasmic reticulum and is the precursor of the synaptic DCV, which reaches maturity only within the varicosity. By an exocytotic process, which occurs only once for each DCV, the DCV contributes its inner membranous component to the presynaptic membrane and releases both transmitter and core proteins into the synaptic cleft. Thus, although the DCV functions primarily to store transmitter, its inner membrane component is also the source of the small vesicles observed clustered along active zones, which mediate the routine and *repeated* release of neurotransmitter.

779 LOCALIZATION OF RAT BLOOD-CSF BARRIER Na-K ATPase Quentin R. Smith* and Conrad E. Johanson* (Spon:W. Stevens Dept. of Pharmacology, Univ. of Utah Col. Med., Salt Lake City, Utah 84132

Two properties of ouabain, the biphasic effect on Na-K ATPase and its low permeativity, were utilized to investigate the localization of the Na-K pump to the apical or basolateral membrane of the blood-CSF barrier. Adult rats were injected i.p. with ouabain at a dose of either 0.01 or 10 mg/kg (or vehicle) and sacrificed 1 hr later for analysis of Na and K. The extracellular fluid space and residual erythrocyte volume were measured with tritiated inulin and ^{51}Cr-tagged-RBC, respectively. With the lower dose, no effect on electrolyte concentration was detected in any fluids or tissues examined. At the 10 mg/kg dose, analysis of choroid plexus (CP) epithelial cell concentration of electrolytes by compartmentation analysis revealed that cell [K] rose by 13% to 171 mmole/kg H_2O and cell [Na] fell by 45% to 25 mmole/kg. The cerebral cortical cell [K]/[Na] increased, but not significantly. Although plasma [K] increased by 101% to 9.41 mmole/L and plasma [Na] decreased by 7% to 140 mmole/L, no significant alteration was seen in CSF electrolytes. Erythrocyte and skeletal muscle cell electrolytes changed in the directions expected for an inhibited Na-K pump.

The electrolyte data for the CP strongly suggest a stimulation of the Na-K pump in this tissue subsequent to the intraperitoneal administration of 10 mg/kg ouabain. This, along with the lack of effect of the 0.01 mg/kg dose, is consistent with an apical membrane model for the Na-K pump of the rat blood-CSF barrier. (Supported by NIH Grant Nos. NS-04553 and GM 00153)

780 CALCIUM ION-STIMULATED ENDOGENOUS PROTEIN KINASE CATALYZED PHOSPHORYLATION OF MYELIN AND ITS BASIC PROTEINS. Prakash V. Sulakhe, Elena H. Petrali* and Brenda J. Thiessen* (SPON: J.W. Phillis). Dept. Physiol., Univ. Sask., Saskatoon, Canada.

Myelin-enriched particulate fraction (R) and purified myelin (M) isolated from the white matter of rat brain were phosphorylated by the endogenous (Mg^{2+}-supported) protein kinase (ePK). With either R and M, myelin basic proteins of molecular mass 18,000 (MPII) and 16,000 (MPI) were the major substrates for phosphorylation (PP) and their PP accounted for greater than 85% of the phosphate incorporated into R or M. Low concentrations of Ca^{2+} markedly stimulated PP of R, M as well as MPI and MPII. Triton X-100 (Tx) at 0.05% increased both Ca^{2+}-independent (basal) and Ca^{2+}-stimulable PP. The maximal stimulation (3- to 5-fold) of PP by Ca^{2+} was observed at 10 μM (free) Ca^{2+} with the half-maximal at about 0.5 μM; Ca^{2+} greater than 1.0 mM caused significant inhibition of PP of R, M, MPI and MPII. cAMP (0.01-100 μM), showed no stimulation of PP in the absence of Tx; with Tx, only modest (30%) but consistent stimulation of PP of M, R, MPI and MPII was noted. Calcium increased the apparent affinity of ePK-catalyzed PP of M, R, MPI and MPII for Mg^{2+} (0.2 mM with Ca^{2+} vs. 2.0 mM without Ca^{2+}) but not for ATP; Tx increased the V_{max} without changing the apparent affinity for Mg^{2+}, ATP, or Ca^{2+}. In the presence of Ca^{2+} and Tx the apparent affinity towards cAMP of ePK-catalyzed PP was increased nearly 100-fold. Tx even at 3 μmole/mg protein failed to solubilize Ca^{2+}-dependent ePK while cAMP-dependent ePK was solubilized only poorly (up to 20%). Tx effects on basal and Ca^{2+}-dependent ePK-catalyzed PP are hence unrelated to solubilization of ePK by Tx. The PP of R, M, MPI and MPII was rapid, reaching maximum between 1-2 min at 30°C; this was true for ± Tx and/or Ca^{2+}. Inhibition of phosphatase (PPase) by NaF failed to increase the initial rate of PP under a variety of conditions. PPase was present and was capable of dephosphorylation (dPP) of MPI and MPII and appear to be stimulated by Ca^{2+} but not cAMP. Amongst the various divalent cations tested, Mg^{2+} was most effective in supporting basal ePK and Ca^{2+} was by far the most effective stimulator of Mg^{2+}-dependent basal ePK. Ca^{2+} stimulated PP of polypeptides similar to MPI and MPII was seen with the particulate and not the soluble fractions of white matter; similar PP was absent from (a) particulate and soluble fractions of the gray matter (b) axolemmal and oligodendroglial cell membrane fragments (c) synaptic plasma membranes, synaptic junctions and post-synaptic density. These results show the presence of a highly Ca^{2+}-sensitive ePK in myelin that catalyzes PP of myelin basic proteins. ePK is tightly bound to the myelin and appears buried within the membrane matrix.

781 TWO Na,K-ATPases OF BRAIN: BIOCHEMICAL, KINETIC, AND DISTRIBUTIONAL DIFFERENCES. Kathleen J. Sweadner Dept. Neurobiology, Harvard Med. Sch., Boston, Mass. 02115.

The large subunits of two different Na,K-ATPases from mammalian brain can be separated by polyacrylamide gel electrophoresis in SDS. The two bands differ by ~500 in apparent molecular weight. Both bands are phosphorylated by γ-[^{32}P]ATP in the presence of Na^+ and are dephosphorylated in the presence of K^+. The bands cannot be interconverted by incubation of crude homogenates of brain at 37°C, or by mild tryptic or chymotryptic proteolysis. The two bands differ in their sensitivity to digestion with trypsin, to crosslinking with Cu^{++}-o-phenanthroline, and in their reactivity to N-ethyl maleimide. In the rat, there are two Na,K-ATPase activities in brain with dramatically different affinities for cardiac glycosides; the high affinity species of Na,K-ATPase can be assigned to the band with the higher apparent molecular weight, and the low affinity species to the other band. The two ATPases may differ functionally, in that the activity of the high affinity species is stimulated 15-20 fold by K^+, while the low affinity species has a high basal activity in the absence of K^+, and is stimulated only 2-5 fold.

Attempts to localize each of the two species have given the following results: the low affinity, lower apparent molecular weight species is indistinguishable from the Na,K-ATPases found in kidney, cardiac muscle, skeletal muscle, and cultured sympathetic neurons. Both species are found together in white and in gray matter, in retina, and in synaptosomal plasma membrane. A heterogeneous mixture of non-neuronal cells cultured from whole brain shows only the species which is found in the peripheral tissues. The higher affinity, higher apparent molecular weight form unique to brain and retina has not yet been isolated free of the other species, but it is most likely that it is associated with some, but not all, classes of neurons. The possibility that the two ATPases modulate synaptic activity in different ways deserves further investigation.

782 PLASTICITY OF DENDRITIC SPINE SYNAPSES OF THE DENTATE GYRUS: ASSOCIATION OF SPINE APPARATUS WITH SYNAPTIC SPINULES. Sally Tarrant* and Aryeh Routtenberg (SPON: W. Bondareff). Cresap Neuroscience Laboratory, Northwestern University, Evanston, ILL 60201.

Ultrastructural analysis of serial sections reveals two distinct types of dendritic spines present in the molecular layer of the dentate gyrus of the adult rat hippocampal formation. One is small and slender, spine head circumference $< 1.5\ \mu$ in single sections, with a straight synaptic cleft, no spine apparatus and no synaptic spinules. The other is large, with an irregular shaped spine head, circumference $> 1.5\ \mu$ in single sections and is observed to contain spine apparatus and synaptic spinules. As we have recently described (Tissue and Cell, 9 (3), 1977, 461-473), the synaptic spinule is a protrusion of dendritic spine cytoplasm and membrane, which is devoid of postsynaptic density, into the presynaptic terminal region within the active zone of the synapse. Coated vesicles are observed on the extremities of the presynaptic membrane portion of the spinule; ribosomes and filamentous material are present in the spinule cytoplasm.

We have previously reported observations of an association between spine apparatus and spinule-containing synapses, i.e., all spines which terminate in spinules, contain a spine apparatus in the cytoplasm. We have now observed membranous structures which extend from spine apparatus to the postsynaptic membrane region in these synapses. It is speculated that these elements, spine apparatus and synaptic spinules, are labile membranous structures within certain dendritic spines. Preliminary evidence regarding the lability of synaptic spinules is suggested by our observations of increased number of spinules counted following knife cuts which axotomized the parent granule cells. To determine whether this increase is due to an increase in the number of spinules or to an elaboration of already existing ones will require study of serial sections.

An examination of serial sections has revealed that the presence of synaptic spinules and spine apparatus in all dendritic spines is about 10%. When only the large spines are considered, at least 40% of these dendritic spines contain synaptic spinules. If a considerable number of certain dendritic spines are in fact labile, then perhaps electrophysiological events related to potentiation (Lomo, Exp. Br. Res., 12, 1976, 36-63) or memory formation (Collier and Routtenberg, Brain Research, in press) may be related to this lability. (Supported by MH25281 and NSF 19388 to A. R.)

783 PERMEABILITY OF THE FROG PERINEURIUM UNDER CONDITIONS OF STRETCH AND HYPERTONICITY. Ananda Weerasuriya*, Robert E. Taylor and Stanley I. Rapoport. NINCDS, NIH, Bethesda, Md. 20014 and NIA, NIH, Baltimore, Md. 21224.

The permeability to ^{14}C-sucrose of the isolated perineurium of the sciatic nerve of female R. pipiens was measured at room temperature at rest length, when the perineurium was stretched and after the perineurium had been subjected to hypertonic treatment. The perineurium was removed as a cylindrical tissue from the sciatic nerve. The ends of the perineurial cylinder were mounted and sealed on cannulae. Ringer fluid was infused at a constant rate into the inlet cannula and was collected in scintillation vials from the outlet cannula. The preparation was placed in a stirred isotonic Ringer bath containing ^{14}C-sucrose. The permeability coefficient is defined as the tracer flux per sec, from bath to interior, per unit concentration gradient across the perineurium divided by the perineurial surface area. Mean permeability was calculated to be 5.6 ± 0.27 (S.E.M., n=45)$\times 10^{-7}$ cm sec^{-1}. Stretch of the perineurium by 10% from rest length reversibly increased perineurial permeability to ^{14}C-sucrose by a factor of 2. A 20% stretch increased permeability by a factor of 5, but the increase was not fully reversed when the preparation was returned to rest length. The perineurial permeability increased in a tonicity-dependent fashion in isotonic Ringer fluid after it had been immersed for 25-50 minutes in a Ringer bath made hypertonic by the addition of either NaCl or sucrose. NaCl addition produced a greater increase in permeability than did a sucrose solution of equal osmolality; the increase in both cases was irreversible. The threshold for a significant increase in the perineurial permeability was a 25 minute immersion in a Ringer bath containing an additional 1.0 M of NaCl. If the perineurial cylinder was inverted and the inverted preparation was immersed in a Ringer bath made hypertonic with NaCl, an increase in permeability was noticed, but in a Ringer bath made hypertonic with sucrose no increase in permeability was detected. The experiments quantify, for the first time, the diffusional restriction that the perineurium places on exchange between the endoneurial space and general extracellular fluid space, and indicate that stretch or hypertonicity can reduce this restriction.

784 IDENTIFICATION OF LECTIN BINDING POLYPEPTIDES IN MICROSOMAL FRACTIONS OF PIG CEREBELLAR CORTEX. John G. Wood and Francis I. Byrd. Department of Anatomy, University of Tennessee Center for the Health Sciences, Memphis, Tennessee 38163.

We have identified smooth membrane cisternae in cerebellar Purkinje cell dendrites and axons which appear to be specialized in their capacity to bind certain lectins (J. Cell Biol., 63:541-549, 1974; Brain Res., 118:15-26, 1976) and which may serve as part of a transport system in these processes. In order to identify and characterize the macromolecules on smooth membrane systems which bind different lectins, we first isolated microsomal fractions from the molecular layer (hand dissected) of pig brain cerebellar cortex, an area rich in Purkinje cell dendrites containing the cisternae. The microsomal fractions were solubilized in sodium lauryl sulfate (SDS) and dithiothreitol (DTT) and subjected to electrophoresis in a 12.5% SDS slab gel. The slab gel was cut into strips and one strip was stained for protein using Coomassie Brilliant Blue dye. The other strips were treated to remove SDS exactly as described by Fairbanks et al., (Biochem., 10:2606-17,1971) using isopropyl alcohol and acetic acid. The strips were then "stained" for lectin binding sites using Concanavalin A (Con A), wheat germ agglutinin (WGA) and castor bean (CB), three lectins which we have extensively used in cytochemical experiments. In all cases peroxidase was used to mark the sites of lectin staining of the gel pattern; Con A and peroxidase were applied sequentially (Exp. Cell Res., 64:232-236, 1971) and WGA and CB were conjugated to peroxidase before being used to stain the gel. Several Coomassie Blue positive bands were also stained by each of the lectins. The staining pattern with WGA and CB were very similar, a result in accord with our cytochemical results (J. Cell Biol., 75:117a, 1977). The staining with Con A differed, however, with several new lectin positive bands apparent, especially in the high molecular weight region of the gel. Since Con A stains the smooth membrane cisternae in Purkinje dendrites while WGA and CB do not (J. Cell Biol., 63:541-549, 1974; 75:117a, 1977), the additional Con A positive bands may represent a family of carbohydrates lining the specialized cisternae. Further study of this problem will be possible by employing a wider range of lectins in comparative cytochemical and gel labeling studies. Supported by NS-12590 and the Sloan Foundation (JGW).

785 CLOSE ASSOCIATION OF SELECTIVE ACID HYDROLASES WITH RAT CNS MYELIN. Shuichi Yamaguchi*, Eisuke Hanada*, and Kunihiko Suzuki, Departments of Neurology & Neuroscience, The R. F. Kennedy Center, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

Constituents of normal CNS myelin are known to turn over metabolically during the life of the animal. Turnover of such a highly extended plasma membrane may require an unusual metabolic machinery. Contrary to the earlier concept, an increasing number of enzymes are being found associated with purified myelin preparations. The results of the present study suggest that even some of the acid hydrolases, generally considered to be of lysosomal localization, may also be closely associated with myelin.

Myelin was isolated from adult rat brain according to Norton & Poduslo. Judged by the electron microscopic appearance and the essentially undetectable activities of UDP-glc:ceramide glucosyltransferase and the magnesium-dependent neutral sphingomyelinase, our myelin preparations were of the generally accepted purity with no more than 5% impurities. Acid hydrolase activities in purified myelin could be divided into two distinct groups. The specific activities of the first group were 3.3 ± 0.7(SEM)% of those in the starting homogenate. This group included β-hexosaminidase, β-glucosidase, acid phosphatase, and arylsulfatase B. On the other hand, the specific activities of the second group of hydrolases were 40.2 ± 2.1(SEM)% of those in whole homogenate. This group included arylsulfatase A, 4-MU β-galactosidase, galactosylceramidase, G_{M1}-ganglioside β-galactosidase, sphingomyelinase, α-fucosidase, and α-mannosidase. These activities could not be removed by washing the purified myelin with various aqueous salt solutions. The activities of the hydrolases in myelin showed pH optima similar to those in whole homogenate. When the purified myelin was arbitrarily fractionated into light, medium and heavy subfractions, the heavy myelin had the highest specific activities of the acid hydrolases. The medium myelin showed specific activities approximately half of those in the heavy myelin. The light myelin was least active with acid hydrolases. These findings suggest that a group of selective acid hydrolases may be either intrinsic to myelin or present in structures closely associated with myelin, such as axolemma, the lateral loops, or the junctional area between myelin and the oligodendroglial cell body. It is noteworthy that the hydrolases found in purified myelin have their natural substrates in myelin --- sulfatide, galactosylceramide, sphingomyelin, G_{M1}-ganglioside, and myelin glycoproteins, while no myelin constituents appear to be the natural substrates for those hydrolases that are not found in myelin. The possible degradation of myelin constituents in situ by the associated acid hydrolases is under investigation. (Supported by NS-10885, NS-03356, and HD-01799 from the U.S.P.H.S.)

786 MODIFICATION OF SH GROUPS OF THE MUSCLE MEMBRANES OF A MARINE CRUSTACEAN RESULTS IN OSCILLATORY SPIKE ACTIVITY.* C. Zuazaga de Ortiz and J. del Castillo. Lab. of Neurobiol., Med. Sci. Campus, U.P.R., San Juan, P.R. 00936.

Reagents that modify SH groups usually block excitability in a variety of excitable membranes. However, we have found that several sulfhydryl reagents induce oscillatory spike activity in the electrically inexcitable muscles of the fresh water crustaceans Xiphocaris elongatus and Atyas occidentalis (C. Zuazaga de Ortiz and J. del Castillo, to be published). The purpose of the present work is to determine if this effect is specific for fresh water crustaceans or if it is more general, and it is found also working on muscles from marine species. The ventroabdominal flexor muscle of the marine shrimp Stenopus hispidus was used for this purpose. The reagents used were N-ethylmaleimide (NEM), maleimide and 4-cyclopentene-1,3-dione (4-CPD). Exposure of Stenopus muscle to these reagents (2mM, 5-10 min) induces action potentials with low membrane accomodation. Depolarization by injected current causes repetitive spike activity. Free SH groups are required for this effect to appear. If before applying the sulfhydryl reagents, the muscle is exposed to an organic mercurial which blocks the SH groups, the effect is prevented. Furthermore, 1,3-cyclopentanedione, the saturated analog of 4-CPD, has no effect. The spikes are not affected by tetrodotoxin (50μM) but are reversibly blocked by Mn^{2+} (50mM), suggesting thay are partially due to Ca^{2+} ions. It is proposed that the induction of excitability in crustacean muscles by the above reagents depends upon the modification of the cysteinyl residues to carbonyl containing thioethers which allows the occurrence of new interactions between the proteins that control the ionic conductances of the membrane.

MEMORY AND LEARNING

787 THE BLOCKADE OF CONDITIONED REINFORCEMENT BY PIMOZIDE. Richard J. Beninger* and Anthony G. Phillips. Dept. Psychol., Univ. British Columbia, Vancouver, B.C., Canada, V6T 1W5.

Psychomotor stimulant drugs which serve as dopamine agonists have been shown to potentiate conditioned reinforcement (Hill, 1970; Robbins, 1975). However, the involvement of dopaminergic neurons in the establishment of conditioned reinforcement has not been investigated. As a direct test of this possibility, the present experiment examined the effect of the dopamine receptor blocker pimozide on the establishment of conditioned reinforcement in which a tone was paired with food reward. The experimental design consisted of five groups (N=6) of food-deprived rats each tested in three distinct phases. Phase one measured preference for each of two levers one of which produced a tone. In phase two, with the levers absent, the tone was paired with food over four sessions. Phase three again measured preference for each of the two levers. Control rats injected with saline during phase two showed a significant increase in preference for the tone lever in phase three. An additional control group which received pellets explicitly unpaired with the tone in phase two showed no change in lever preference in phase three. A third group was tested in phase two under the influence of 1.0 mg/Kg pimozide; they were observed to eat all the pellets readily during phase two but showed no change in preference for the tone lever in phase three. The similar performance of a group which was under the influence of pimozide during phases two and three ruled out the possibility of state dependent learning. A final group was injected with pimozide 60-70 mins after each session of phase two and during phase three. This group showed a shift in preference for the tone lever thus ruling out the possibility that the state dependent learning group failed to show conditioning to the tone because of a drug-induced motor impairment. These results implicate dopaminergic neurons in the learning process which underlies the establishment of conditioned reinforcement.

788 SEPARATION OF ASSOCIATIVE FROM NON-ASSOCIATIVE SHORT LATENCY CHANGES IN MEDIAL GENICULATE AND INFERIOR COLLICULUS DURING DIFFERENTIAL CONDITIONING AND REVERSAL IN RATS. Dorwin Birt, Robert Nienhuis*, and Marianne Olds*. Div. Biol., 216-76 Calif. Inst. of Tech., Pasadena, CA 91125.

Results obtained in a recent experiment in this laboratory drew attention to the possible contribution of subtle non-associative processes to changes in the early latency unit responses obtained in MGB and IC of the rat during the learning of a differential appetitive conditioning task. An important possible source of such non-associative effects was shown to arise from differences in the interval between a previous food pellet presentation and the following CS+ or CS-. To determine whether previously reported changes in MGB and IC were due to associative processes or to non-associative ones, the present experiments were carried out using a counterbalanced stimulus presentation schedule which placed the CS+ and CS- at the same average time following a previous food pellet. Criteria adopted for characterizing a change as associative required that the response to the CS+ be enhanced relative to that to the CS- throughout repeated reversal sessions.

The results obtained support previous findings of early latency associative changes in MGB, and are consistent with the idea that such changes are most likely to occur in the medial division of this nucleus. The findings in the IC thus far do not support the notion that this nucleus participates in this process. However, in view of the complex structure of the IC and the fact that not all of its subdivisions were sampled, these negative findings must be viewed with caution. The results also support the view that the anatomical distribution of neurons participating in the elaboration of associative changes may be more restricted than that of neurons participating in non-associative ones.

789 BIOCHEMICAL AND BEHAVIORAL EFFECTS OF STREPTOVITACIN A IN MICE. C.A. Boast and B.W. Agranoff. Neuroscience Laboratory Building, University of Michigan, Ann Arbor, MI 48109.

Disruption of long-term memory formation by protein synthesis inhibitors has been documented in several species. In goldfish these agents are injected into the cranial cavity, while in mice a parenteral route has been most commonly employed. Experiments to establish a neuroanatomical site of action of the inhibitors have been limited by technical factors. For example, small brain size has precluded localization studies in the goldfish. In experiments with mice (Eichenbaum et al, Brain Res. 101:171, 1976) we found memory loss following bilateral intracerebral injections of cycloheximide (CXM, 30 µg) into striatum, hippocampus (Hpc), amygdala (AM) or posterior lateral thalamus, but not in other brain regions examined. Partlow et al, (Trans. Am. Soc. Neurochem. 9:212, 1978) recently reported that injections of CXM directly into rat AM can result in amnesia. Similar injections into the internal capsule do not impair memory. In the present experiments we have employed the antibiotic streptovitacin A (SVA), a potent protein synthesis inhibitor. SVA in saline was injected into ether-anesthetized mice through 26 g cannulae during 35 sec. One µg of SVA in 0.5 µl was injected bilaterally into ventral Hpc at various times following one-trial inhibitory avoidance training. Retention was tested 24 h after training. Amnesia resulted from injections immediately after or 1 h following training, while a 6 h delay was less effective, a result consistent with the well-established time-dependence of memory susceptibility. We found that 0.1 µg of SVA in 0.05 µl injected into the ventral Hpc immediately following training was ineffective, while 1 µg of SVA in 0.05 µl resulted in amnesia. An intermediate dose and vol (0.6 µg SVA in 0.03 µl) yielded variable results. These results indicate a dose-dependent, volume-independent, amnestic effect of SVA. SVA (1.0 µg in 0.05 µl) injected bilaterally into dorsal Hpc resulted in amnesia, but was ineffective when injected into cortex overlying ventral Hpc or corpus callosum overlying dorsal Hpc. The behavioral results are compared with studies on the extent of regional inhibition of protein synthesis assessed by radioautography and scintillation counting of brain samples following unilateral intracerebral injection of SVA combined with a systemic ^{14}C-methionine pulse. 790 DECREASES IN EXCITABILITY OF CORTICAL NEURONS TO EXTRACELLULARLY DELIVERED CURRENT AFTER EYEBLINK CONDITIONING, EXTINCTION, AND PRESENTATION OF US ALONE. J. Brons* and C.D. Woody, UCLA Med. Center, Los Angeles, CA. 90024

The excitability of 304 neurons in pericruciate cortex to extracellularly delivered nA currents was studied in awake cats after conditioning (click CS-glabella tap US); during extinction (US-CS); and during presentation of US or CS alone in untrained animals. The CR and UR each consisted of a short latency concurrent eyeblink and nose twitch. Extracellular unit activity was recorded with 15-50 MΩ, 1.4M K+ citrate filled glass microelectrodes. Up to 6 nA positive current pulses (10 msec width, 10 Hz) were passed extracellularly through the recording electrode to determine the threshold level of current required to elicit spikes on 50% of the stimulus pulses. Cortical neurons were classified as ultimately projective to eye (orbicularis oculi), nose (levator oris), both eye and nose, or neither eye nor nose musculature on the basis of averaged EMG responses to the cortical stimulation used to measure cell excitability.

Neurons which individually projected their activity to eye, nose, and both eye and nose muscles concurrently required significantly more extracellular current for spike initiation in all cats given the glabella tap US (i.e. conditioning, extinction, and US only groups) as compared with the cats given the CS only, ($F(3, 13) = 6.11$, $p < .01$). Neurons that did not project to either eye or nose muscles did not show any consistent differences in excitability among the four behavioral groups.

The results indicate that a glabella tap, which elicits a reflex eyeblink mediated by brainstem pathways, also produces decreases in excitability to weak (up to 6nA) extracellularly applied currents in neurons of sensorimotor cortex. Thus, serial presentation of a US during Pavlovian conditioning or extinction can produce non-associative alterations in cortical neural excitability as well as other associative effects. Studies of the latter have been reported elsewhere (Woody and Black-Cleworth, J. Neurophysiol., 1973; Brons et al., Fed. Proc., 1978). Different cellular mechanisms appear to support alterations in excitability to weak nA extracellular current than support altered excitability to intracellularly injected current (Woody et al., J. Neurophysiol. 1976; Woody and Gruen, Soc. Neurosci. Abstr., 1977). Supp. by BNS76-06886.

791 ENHANCEMENT OF THE LOCAL INHIBITORY EFFECT OF DOPAMINE ON A MOTOR CONDITIONED RESPONSE IN CATS TREATED WITH MICROINJECTION OF 6-HYDROXYDOPAMINE IN THE CAUDATE NUCLEUS. H. Brust-Carmona and C. Reyes Vázquez*. Depto. de Fisiología, Div. de Investigación, Fac. de Medicina, UNAM. México 20, D.F., México.

Different observations have shown the involvement of catecholamines as inhibitory neurotransmitters in the caudate nucleus (CN). Dopamine (DA) microinjections enhance the suppression of a lever pressing motor conditioned response (SMCR). Therefore, we proposed that lesions of the dopaminergic terminals of CN would diminish the SMCR.

Cats were conditioned to press a lever (MCR) to obtain 0.5 ml of milk while a small light was on; no reinforcement was given when it was off, and the animals learned to suppress (SMCR) the MCR. After three training sessions, the cats, under pentobarbital anesthesia, received bilateral injections of 6-hydroxydopamine (6-OHDA) into the head of the CN, in doses of 5, 10, 20, 40, 80 and 160 μg. After two or three days the conditioning was started anew. MCR was not affected by any of the injections in any session. In contrast, the lower doses (5, 10, 20 μg) significatively increased ($P < 0.05$) SMCR while the 80 and 160 μg doses decreased it ($P < 0.05$). The 40 μg dose did not produce any differences from those injected with NaCl. To further evaluate the differences the lever pressing for all sessions of the animals in each group was pooled. The U-test comparing the totals showed that the differences are statistically significant at the level of $P < 0.05$. The results support the postulation that DA acts as inhibitory neurotransmitter, but they also led us to conclude that low doses produce sensitization by denervation as postulated by other authors. To test this possibility, another group of cats was conditioned similarly and afterwards bilateral cannulae were chronically implanted in the head of CN. After a recovery period the effect of 4 microinjections of NaCl or DA, applied one every other day, was tested and, afterwards, one 6-OHDA dose (20 μg) or NaCl (5 μl) was injected. Two days later a new series of microinjections of NaCl or DA was repeated. The cats injected with NaCl showed a slight increase of lever pressing in the suppression condition, while DA produce a decrement of the lever pressing. This depressor effect was more intense after the 6-OHDA application and was not observed after NaCl injection. It is important to mention that the lever pressing in the reward situation did not change with any of the treatments.

792 COMPARING NEURAL PLASTICITY IN THE HIPPOCAMPUS DURING CLASSICAL CONDITIONING OF THE RABBIT NICTITATING MEMBRANE RESPONSE TO LIGHT AND TONE. Steven R. Coates and Richard F. Thompson. Dept. Psychobiology, UCI, Irvine, CA 92717.

Unit activity was recorded from the CA1 area of dorsal hippocampus in New Zealand White rabbits (Oryctolagus cuniculus) during conditioning. The conditioning paradigm involved using a corneal air puff unconditioned stimulus (UCS) to classically condition nictitating membrane movement to the presentation of either a tone or a light conditioned stimulus (CS). Twelve rabbits were divided equally into 3 stimulus presentation groups. In the first group the stimulus presentations consisted of pairing the light with the air puff. In the second group, initially, the tone was paired with the air puff. Once conditioning had been established, the light was then paired with the air puff. The third group received random, unpaired presentations of either the light or air puff. For all 3 stimulus presentation groups, the CS was presented for 350 msec and the UCS was presented for 100 msec. For the paired presentations, the CS and UCS were overlapping and coterminating. Systematic increases in patterns of unit activity occurred during conditioning to both the light and tone CS. The plasticity associated with both types of CS was found to be similar in terms of pattern, magnitude and time course. When animals were shifted from one CS to the other, conditioned behavioral responding ceased and hippocampal activity was markedly reduced. Relearning, both in terms of behavioral responses and hippocampal unit activity, was slower than original learning.

These data demonstrate that the large increase in hippocampal unit activity in this learning paradigm is not dependent on the specific properties of the CS.

793 IMPAIRED MOTOR MEMORY AND INTACT MOTOR SKILLS ACQUISITION IN ANTEROGRADE AMNESIA. Neal Cohen and Larry R. Squire. Departments of Neurosciences and Psychiatry, UCSD, School of Medicine, La Jolla, CA 92093.

Studies of human amnesia have reported that acquisition of perceptual-motor skills is spared in patients who otherwise are deficient in committing new information to long-term memory. In normal subjects, kinesthetic (motor) memory seems to exhibit certain unique characteristics. These observations have sometimes been interpreted to mean that the organization of motor information and its neurological substrate are special in some way. The present study explored further the status of motor skill acquisition and motor memory in the amnesic syndrome.

Patients receiving bilateral electroconvulsive therapy (ECT) and the chronic amnesic patient N.A. were given the rotary pursuit task to test motor skill acquisition, and a lever-positioning task to test motor memory. Rotary pursuit required patients to maintain contact with a small target on a rotating disc. Lever-positioning required patients, in the absence of visual cues, to reproduce horizontal criterion movements (ranging from 28.5 to 71.5 cm) after a variable interval (0, 12, 60 sec).

In the rotary pursuit task, these patients exhibited a normal rate of acquisition over three weekly sessions. In the lever positioning task, the patients were able to reproduce criterion movements as well as control subjects in the 0-sec delay condition. However, patients were slightly impaired in the 12-sec delay condition and markedly impaired in the 60-sec delay condition.

These results clearly demonstrate that, in the amnesic syndrome, motor memory can be impaired despite a preserved capacity for motor skill acquisition. The finding that motor memory is impaired raises difficulty with the notion that motor information in general enjoys a special neurological status. Possible differences between motor skills acquisition and motor memory will be discussed.

794 ATROPINE INJECTIONS IN THE ANTERIOR AND POSTERIOR CAUDATE NUCLEUS: EFFECTS ON PASSIVE AVOIDANCE. Sara E. Cruz-Morales*, Flavio A. López-Miro* and Roberto A. Prado Alcalá. Physiol. Dept. Sch. Med. Ntnt. Univ. of México, México City, México.

Cholinergic blockade of the caudate nucleus (CN) produces significant deficits in learned behaviors. Further, differential impairments are found, in active avoidance, after dorsal or ventral blockade of the head of the CN.

The present results deal with the effects of atropine injections in different areas of the CN.

Rats were implanted with cannulae in the anterior or posterior CN, and later trained in a two - compartment box. During the first session, the latency to cross from one compartment to the second compartment, in which a footshock was delivered, was noted. Twenty-four hr later this procedure was repeated, except for the footshock (retention session). An unimplanted group of rats was also trained. Half of the implanted rats were injected through each cannula with 60 μg of atropine, and the other half with saline, 1 min after the first training session.

It was found that the saline groups and the group injected with atropine in the posterior CN had retention scores that were not statistically different from the unimplanted group. In contrast, the group injected with the anticholinergic drug in the anterior CN displayed a significative impairment in retention ability.

These results further support the hypotheses that: a) a cholinergic mechanism is involved, within the CN, in learned performance, and b) the caudate nucleus is not functionally homogeneous.

795 AMNESIA IN CHICKS AND MICE INDUCED BY 3,4 DEHYDRO-DL-PROLINE. Joel L. Davis and Arthur Cherkin. Psychobiology Research Laboratory, VA Hospital, Sepulveda, CA 91343.

Intraventricular injection of L-proline (L-PRO; 6.0 µmols/chick) or its analog baikiain (4,5 dehydro-L-pipecolic acid; 1.5 µmol/chick) induces retroactive amnesia without brain seizure or isoelectric activity. D-PRO is non-amnestic. We now report that 3,4 dehydro-DL-proline (DHP), an analog of PRO and baikiain, has amnestic properties. We injected chicks intracerebrally with 10 µl/hemisphere of 150 mM L-PRO or DHP, or 75 mM DHP, 1 min after one-trial training to suppress the peck response to a stainless steel bead. Avoidance was conditioned by coating the bead with an aversive liquid (methyl anthranilate) immediately prior to training. Retention of avoidance was tested 24 hr later using the uncoated bead; reduced avoidance scores and increased peck scores indicate impaired memory.

Compound	Dose/Chick (µmols)	N	Avoidance Score (%)	Peck Score ($\sqrt{p}$±S.D.)
DHP	1.5	57	47.3	1.29±1.54
DHP	3.0	49	12.2	2.48±1.35
L-PRO	3.0	39	51.3	0.93±1.15
L-PRO	6.0	304	34.5	1.59±1.49
D-PRO	6.0	296	56.1	0.77±1.15

The results demonstrate that DHP is an effective amnestic agent at a dose (3 µmols) below the amnestic dose of L-PRO (6 µmols); for DHP and L-PRO at 3.0 µmols, the avoidance scores ($p<0.001$; χ^2 test) and peck scores ($p<0.0001$; t-test) differ significantly. The amnestic effect of 1.5 µmols of DHP is significantly less than that of 3.0 µmols of DHP (peck score, $p<0.0001$) but not significantly greater than that of 3.0 µmols of L-PRO ($p>0.23$). Previous scores for 6.0 µmols of L- and D-PRO are tabulated for reference. No seizure spiking or isoelectric activity from chick ectostriata were found in EEG recordings under DHP or PRO conditions resembling the behavioral paradigm.

We injected DHP intracranially into mice 1 or 60 min after one-trial passive avoidance training. Mice (Swiss HLA-sw/ICR males, 50-65 days old) were injected through implanted cannulae with 5 µl/hemisphere of 150 mM DHP (1.5 µmols) or saline, then tested 24 hr later. Results indicate a significant amnestic effect for DHP compared to saline controls at the 1-min interval. Delaying the injection for 60 min abolished the amnestic effect, suggesting a retrograde effect.

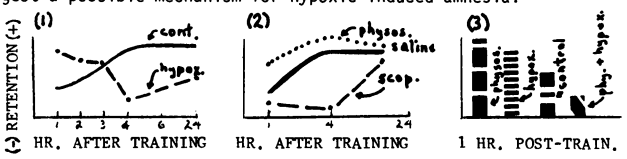
Compound	Injection Interval (min)	N	Median Latency (sec)	U	p
3,4 DHP	1	13	20.0	26.5	<0.01
Saline	1	26	158.0		
3,4 DHP	60	9	184.0	45.0	>0.05
Saline	60	10	151.0		

796 HYPOXIC-INDUCED AMNESIA IN PASSIVE AVOIDANCE LEARNING: EVIDENCE FOR A DYNAMIC CHOLINERGIC INVOLVEMENT. Reginald L. Dean* and Raymond T. Bartus, Warner-Lambert/Parke-Davis Res., Ann Arbor, MI

Memory for a brief, one-trial learning experience improves during the first few hours after training. Thus, if retention is tested too soon after training, memory is poor, but rapidly improves with time (McGaugh, Sci., 153, 1966). An amnestic treatment given soon after training also requires time before the amnesia is manifested. Thus, memory immediately after recovery from the systemic trauma shows little amnesia, but gradually worsens with time (Sara, Phys. & Behav., 13, 1974). Using a single trial, passive avoidance task, we investigated possible mechanisms for these phenomena.

The first study confirmed that mice tested within 1 hr after training showed poor retention, but improved over the next 3 hrs, reaching a peak 4 to 6 hrs after training. Exposure to hypoxia (3.5% O^2) immediately after training produced no amnesia during the first 3 hours after training. In fact, retention was paradoxically improved 1 to 2 hrs after the training/hypoxic treatment. Significant amnesia was not manifested until 4 hrs (Fig.1)

Next, we evaluated whether changes in cholinergic processes may be involved in both the gradual memory improvement and delayed amnesia. Scopolamine (1.0 m/k) given immediately after training produced temporary amnesia, mimicking the anoxic treatment 4 hrs post-training. Physostigmine (.1 m/k) given immediately after training improved retention, mimicking the paradoxical effects of the anoxic treatment 1 hr after training (Fig. 2). Finally, combined anoxia and physostigmine immediately after training (which both improved retention 1 hr after training), produced amnesia on the 1 hr retention test, implying that their combined effects, i.e.; increasing post-synaptic cholinergic levels, produced synaptic blockade (Fig. 3). These results, when considered with recent hypoxia/biochemical data (Gibson & Blass, J. Neuroch., 27, 1976; Sterling, et al., Neurobiol. of Aging, 1976), imply that a primary effect of hypoxia may involve an initial dumping of cholinergic pools (temporarily facilitating retention), followed by inadequate cholinergic synthesis (leading to amnesia within a few hours). These data therefore support the notion of an important, dynamic role of cholinergic mechanisms in new learning and suggest a possible mechanism for hypoxic-induced amnesia.



797 NOREPINEPHRINE INJECTIONS INTO AMYGDALA IMPAIR PASSIVE-AVOIDANCE LEARNING. Maureen E. Ellis and Raymond P. Kesner. Dept. Psychol., Univ. of Utah, Salt Lake City, 84112.

Water-deprived rats were trained to enter a goal box in order to lick a tube containing water. After reaching a predetermined latency criterion, rats were given a single 3 sec, 3mA footshock and then tested for retention of the footshock experience 30 min or 24 hr later. Retention was evaluated as an increase in latency to approach the lick tube relative to pretreatment latency. Immediately or 12 hr after the footshock, rats were injected bilaterally via stainless steel cannulas chronically implanted into the amygdala with norepinephrine (NE, dose range: .02ßug, .05ug, .1ug, 1ug) dissolved in 1ul special buffered saline (SBS). Rats injected with 1ug NE immediately after footshock did not show retention (amnesia) when tested 24 hr later. In contrast, rats injected immediately after footshock with doses less than 1ug NE or injected 12 hr post-footshock with 1ug NE did show retention, i.e. they showed an increase in approach latency, which was similar to unoperated and SBS controls. Additionally, rats injected with 1ug NE + 1.5ug propranolol (a B-adrenergic blocking agent) or 1.5ug propranolol alone also showed retention. To test for possible proactive and toxicity effects of 1ug NE injection immediately following a footshock, rats were given a 30 min retention test and monitored for food consumption, water intake, and body weight over the subsequent 24 hr period. Rats showed retention at the 30 min test and no changes occured in food and water consumption or body weight over the 24 hr period. These results suggest that the noradrenergic system within the amygdala and possibly interconnected neural systems is involved in storage and retrieval of aversive experiences.

798 CHANGES IN DENDRITIC SPINES OF THE DENTATE MOLECULAR LAYER DURING CONDITIONING. Eva Fifková and A. Van Harreveld. Dept. Psych., Univ. Colorado, Boulder, CO 80309 and Calif. Inst. Technol., Pasadena, CA 91125.

Following a classical conditioning paradigm we have observed an enlargement of dendritic spines at the projection site of the perforant path in the dentate molecular layer (Neurosci. Abstr. 1977). Present experiments were aimed at a comparison of the effect of conditioning and pseudoconditioning on spine dimensions in the dentate molecular layer. Forty-seven mice (18 g) had twice a day 50 pellets (45 mg) available for 2 consecutive days in experimental cages. On the third day animals were at random assigned either to the conditioning, pseudoconditioning or control procedures. In a single 2-hr session, 50 trials of tone followed by a pellet were presented during conditioning and 50 trials of a random presentation of tone and pellet were given during pseudoconditioning. Controls spent 2 hrs in the training cage with 50 pellets available. Since these control mice were on a food restricting regimen similar to the experimental ones they were referred to as "starved controls." As another control served 22 mice which had food ad libitum and which were never placed into the training cage. In conditioned mice the area of dendritic spines was significantly larger in the middle (12%; $p<0.01$) and distal third (20%; $p<0.01$) of the dentate molecular layer as compared to "starved controls." Comparing the conditioned animals with controls the difference was 10% ($p<0.02$) and 17% ($p<0.01$), respectively. In pseudoconditioned mice spines in the middle and distal third were also larger but the difference relative to either of the controls did not attain the level of significance. Both controls had spines of comparable dimensions in the middle and distal third. However, spines in the proximal third of "starved controls" were significantly smaller (6%; $p<0.05$) than of the controls. Thus, it seems that conditioning induces a significant spine enlargement in the dentate molecular layer which is restricted to the projection site of the perforant path. Supported by NIMH grant MH 27240.

	n	Dentate Molecular Layer Proximal 1/3	Medial 1/3	Distal 1/3
Conditioning	12	1.249±0.055	1.372±0.031	1.643±0.048
Pseudocondi.	23	1.233±0.033	1.348±0.061	1.456±0.033
"Starved control"	12	1.110±0.042	1.224±0.024	1.360±0.046
Control	22	1.181±0.028	1.251±0.027	1.402±0.041

799 INSTRUMENTAL RESPONDING BY SINGLE NEURONS UNDER DISCRIMINATIVE STIMULUS CONTROL IN CERVEAU ISOLE CATS. Ana L. Figueroa* and James J. Keene. Dept. Physiol., Sch. Med., Univ. Puerto Rico, San Juan, PR 00936.

A recent paper (Physiol. Psych., 5: 181, 1977) presented evidence of intracranial self-stimulation and escape in unanesthetized cerveau isolé rats, where the operant response was derived from the cortical EEG. We now report that similarly prepared unanesthetized, post-collicular, pretrigeminal cerveau isolé cats (N=7) are able to manipulate single cell activity as an instrumental response (IR) in an operant learning paradigm.

Trials consisted of (1) a discriminative stimulus (SD+)--a small light near the eye, and (2) a reinforcing stimulus (SR)--a 0.5 sec train of 40 Hz, 0.5 msec cathodal pulses delivered by an isolated constant current device to rewarding medial forebrain bundle sites, or in other runs, to aversive midbrain reticular sites. Trials were presented with a random variable ITI of 20 sec in blocks of 50. An IR was defined as an increased unit firing rate comparing pre-SD+ and SD+ periods in a given trial; thus, random responding produced IRs on 50% of the trials. A PDP 11/20 computer determined IR occurrence over real time.

For each unit recorded, habituation blocks (HAB) presenting the SD+ alone were run until performance stabilized around 50% for 3 consecutive blocks. Next, 4 or more acquisition blocks (ACQ), in which the SR was presented at the end of the SD+ if an IR was made, were run. A unit "acquired" an IR if there was (1) a sig. difference ($p < .05$) in % performance between HAB and ACQ blocks, and (2) a sig. change ($p < .05$) in % performance from random responding (50%). Increased and decreased % performances were considered approach and avoidance learning respectively.

Of 109 well-isolated units studied, 34 (31%) acquired IRs. The table below shows the mean (± SEM) changes in % performance from 50% for units showing approach, avoidance, and no learning.

	APPROACH (N=26)	AVOIDANCE (N=8)	NON-IR (N=75)
HAB & EXT blocks...	6.41 ± 1.80	-6.08 ± 4.50	1.67 ± 1.46
ACQ blocks.....	19.90 ± 2.13	-24.97 ± 4.19	1.01 ± 1.08

The interpretation that these 34 cells located in cortex, diencephalon, and basal ganglia showed instrumental responding is supported by the following: (1) The animal could limit IRs to the SD+ period. (2) IRs by a given cell could be acquired and extinguished (EXT) repeatedly. (3) Many cells also discriminated between the SD+ and a second light. (4) Comparing among the 3 groups above or between HAB & EXT blocks and ACQ blocks in each of the groups, there were not sig. differences in spontaneous firing rate or in post-SR unit responses. (5) The cerveau isolé prevents somatosensory feedback. We propose that the present method be used to map units involved in volitional or intentional control of learned behavior. (Supported by NIH Grant RR-8102.)

800 MEDIAL FOREBRAIN BUNDLE LESIONS AND PAVLOVIAN CONDITIONING OF CORNEORETINAL POTENTIAL AND HEART RATE CHANGES. James S. Francis, Dept. of Pharmacology, University of Houston, Houston, Texas; Linda L. Hernandez*, Donovan D. Clark*, & D. A. Powell, Neuroscience Laboratory, VA Hospital and University of S.C., Columbia, S.C.

Ten rabbits received bilateral radio frequency lesions in the far lateral hypothalamus interrupting the fibers of the medial forebrain bundle (MFB). A second group of eight rabbits served as operated sham controls with the electrode lowered into the hypothalamus but no current passed through its tip. Corneoretinal potential (CRP) and heart rate (HR) CRs were assessed in a simple Pavlovian conditioning experiment in which adaptation, acquisition, and extinction sessions were administered. A 1216 Hz, 80 db, 500 msec tone was the CS, and a 3 ma, 300 msec paraorbital electric shock was the US. At the end of conditioning training, (a) free field activity, (b) paraorbital shock thresholds and (c) HR URs were determined. The Ss were then sacrificed by decapitation and regional CNS concentrations of serotonin and norepinephrine determined in the hippocampus and cerebral cortex.

It was found that MFB lesions had no effect on the number of trials to reach a CRP acquisition criterion of 10 consecutive CRs or on an extinction criterion of 10 consecutive trials without the occurrence of a CR. Total number of CRP CRs also did not differ significantly for the two groups. However, the HR CR was accelerative in the lesioned group during both adaptation and acquisition, whereas it was decelerative in the sham-operated group. Since bradycardiac HR CRs are typically obtained in the normal rabbit, MFB lesions reversed the topography of this response, but had no effect upon the CRP response. Similarly, free field activity, shock thresholds and the HR UR were unaffected by MFB lesions. Hippocampal and cortical 5-HT and NE were significantly depleted by the lesions, but these monoamine levels were uncorrelated with the behavioral effects. This latter finding suggests that the reversal of the HR CR was due to disruption of descending MFB fibers to brain stem cardiac control centers rather than ascending cortical and/or hippocampal modulatory mechanisms.

801 DEVELOPMENT OF DISCRIMINATIVE UNIT ACTIVITY IN CINGULATE CORTEX AND ANTEROVENTRAL THALAMUS DURING CONDITIONING AND OVERTRAINING IN RABBITS. Michael Gabriel, Kent Foster*. and Edward Orona*. Dept. Psychol., Univ. Texas, Austin, TX 78712.

Multiple unit activity was recorded in the cingulate cortex (CC) and in the anteroventral nucleus of the thalamus (AV) during conditioning of a discriminative avoidance response (locomotion) in rabbits. A previous study had shown a greater unit response in CC to the positive conditioned stimulus (a tone paired with footshock) relative to the negative conditioned stimulus (a tone randomly interspersed with the positive stimulus, but never paired with footshock). The discriminative neuronal effect in CC developed at an early stage of conditioning, but discrimination in AV did not develop until the behavioral discrimination was well-learned. Here we extend these findings by examining new locations (30 in CC and eight in AV), by analyzing neuronal activity in relation to behaviorally defined stages of conditioning, and by testing the persistence of neuronal discrimination during overtraining in the conditioning task. The results replicated our previous findings in showing the first neuronal discrimination in CC during the session in which the rabbits first achieved significant behavioral discrimination. The first neuronal discrimination in AV occurred at a later stage of conditioning, during the session in which the strict criterion of behavioral discrimination was met. The early developing discrimination in CC was restricted to the deep layers (V-VI) of CC. Certain locations within the superficial layers (I-IV) of CC showed late developing neuronal discrimination that was coincident with the late developing discrimination in AV. This outcome suggests that the late developing discrimination in AV is fed back to the superficial layers of CC via the thalamocortical projection known to interconnect these structures. Finally the present study showed that once established the neuronal discriminations in CC and in AV persisted throughout six sessions (720 trials) of overtraining which occurred after the rabbits attained the strict criterion of behavioral discrimination. Thus thalamic discrimination does not replace cortical discrimination. Rather once acquired both effects persist in parallel for a considerable period of training.

802 OPIATE ADMINISTRATION INTO THE AMYGDALA: EFFECTS ON MEMORY PROCESSES. Michela Gallagher and Bruce S. Kapp, Dept. Psychol., Univ. of Vermont, Burlington, VT 05401.

The function of opioid peptides in brain regions not generally associated with pain processing remains largely undetermined. For example, opiate administration into the amygdala complex, an area possessing high concentrations of opiate receptors and opioid peptides, does not reliably alter pain sensitivity. This finding is in basic agreement with other research indicating that amygdala lesions do not alter pain sensitivity. However, opioid peptides within this region may participate in other functions for which the amygdala has been implicated. Since numerous studies have reported that manipulating amygdala activity alters memory processes, particularly for aversive experiences, this experiment examined the effects of post-training administration of opiate agents into the amygdala of rats on retention of passive avoidance conditioning.

Male Sprague-Dawley rats were surgically prepared with cannulae positioned at the dorsal surface of the amygdala complex. Intracerebral injections were administered bilaterally in a 0.5 µl volume of a Krebs Ringer phosphate solution. The opiate agents used were the agonist levorphanol, its inactive enantiomer dextrorphan, and the antagonist naloxone. Administration of levorphanol immediately after training produced dose-dependent decreases in retention measured 24 hrs. later compared to vehicle injected and unoperated control groups. The effects obtained with levorphanol were observed to be stereospecific and time-dependent; neither dextrorphan nor delayed administration of levorphanol for six hours after training exerted a significant effect on retention. Administration of the antagonist naloxone into the amygdala immediately after training significantly increased retention. This effect was likewise dose-dependent and time-dependent. In addition, combined naloxone and levorphanol administration into the amygdala immediately after training blocked the retention deficit produced by opiate agonist administration. Finally, injections of opiate agents comparable to those which significantly altered retention when injected into the amygdala did not significantly alter retention when administered into the basal ganglia 1.0 mm dorsal to the amygdala complex. These data suggest a role for amygdala opioid peptides in time-dependent memory processes.

803 INTEROCULAR TRANSFER OF PATTERN DISCRIMINATION LEARNING AS A FUNCTION OF AGE IN THE DEVELOPING CHICK. Karen E. Gaston* (SPON: R. W. Sperry). Division of Biology, California Institute of Technology, Pasadena, CA 91125.

Complete optic decussation in birds restricts direct visual input from each eye to the contralateral hemisphere, making interocular transfer of visual learning dependent on interhemispheric connections. An intact supraoptic decussation (DSO) is apparently necessary for transfer of pattern discrimination learning in adult birds. The extent of interocular transfer of this type of learning in chicks might be expected to vary directly with age and the functional maturity of the participating interhemispheric connections. The present experiment is the first stage of a developmental study designed to establish the degree of interocular transfer of pattern discrimination learning in newly-hatched chicks and to determine whether the extent of transfer varies with age, possibly as a result of progressive myelination of a forebrain fiber system such as the DSO.

In the first phase of the investigation, 24 3-6 day-old domestic chicks were trained monocularly to perform a simultaneous two-choice visual pattern discrimination (+,Δ) for heat reward and then were tested for interocular transfer of the discrimination learning. After each animal was shaped to peck in an operant chamber, one of its eyes was covered with an occluder and the discrimination was trained to a criterion of 36/40 correct responses. The discrimination was readily learned, with nearly all animals reaching criterion in less than 300 trials. Immediately following the acquisition session the chicks were retrained to criterion on the discrimination problem with either the same eye (monocular retention, n=12) or the other eye (interocular transfer, n=12). The chicks retested with the trained eye demonstrated excellent retention of the discrimination task. In marked contrast, animals tested for interocular transfer showed no significant savings. Initial performance (errors in the first 40 trials) and total trials and errors to criterion with the second eye were not appreciably different from those of the earlier acquisition session with the first eye. These results indicate that, under the present experimental conditions, pattern discrimination learning fails to transfer from the trained to the untrained eye in very young chicks, in contrast to the findings in adult birds and to the good transfer reported for one-trial passive avoidance and for an object discrimination in newly-hatched chicks. Progressively older chicks are presently being tested on the pattern discrimination in order to determine whether there is a positive correlation between behavioral transfer and the maturation of interhemispheric connections.

804 EEG DEPRESSION IS NOT ESSENTIAL FOR L-PROLINE INDUCED RETROGRADE AMNESIA. L. K. Gerbrandt* and J. L. Davis. Dept. Psychol., CSUN, Northridge, CA 91324 and Psychobiology Research Laboratory, VA Hospital, Sepulveda, CA 91343.

Previous experiments (Gerbrandt et al., 1977) have shown EEG and multiple unit depression within 20 sec (rapid onset and lasting 20 sec) under amnestic levels of L-proline (L-PRO). Since activity like spreading depression (S.D.) has been shown to cause amnesia (Buresova and Bures, 1969), the question is raised whether amnesia produced by L-PRO includes a S.D. induced component. The objective of these experiments is to compare electrophysiological and amnestic effects of KCl and L-PRO at doses of KCl sufficient to produce EEG depression similar to those observed after L-PRO injections. Chicks (N=6), 44±12 hrs old, were implanted with bilateral electrodes in the ectostriata. The following day, after 15-min adaptation and baseline period, chicks were trained with methyl anthranilate (MeA) to mimic interactions of training and injection in the behavioral paradigm and then injected intracerebrally with 10 µl/hemisphere of 300 mM L-PRO (N=6), or 250 mM KCl (N=6). EEG was recorded for 11 min after injection. The 250 mM concentration of KCl was chosen because preliminary experiments indicated it would yield a reliable EEG depression comparable to that by 300 mM L-PRO. None of the injections produced isoelectricity or seizure spiking. Comparable durations and amounts of depression were found for KCl and L-PRO.

To test whether 250 mM KCl induces a S.D. related amnesia, we injected chicks intracerebrally with 10 µl/hemisphere of 300 mM L-PRO (N=90), 300 mM D-PRO (N=85), or 250 mM KCl (N=87) 1 min after a 10 sec one-trial training of the chicks to suppress their "innate" peck response to a small, shiny bead. Peck suppression, with avoidance of the normally attractive bead, was conditioned by coating the bead with an aversant (MeA). Retention of the avoidance response was measured 24 hr later using the dry, uncoated bead; increasing pecking indicated impaired memory retention. Results confirmed the amnestic effects of L-PRO relative to D-PRO ($p<.0001$), and to KCl ($p<.005$). KCl did not differ significantly in its amnestic effects from D-PRO ($p>.10$).

These results indicate L-PRO-induced amnesia cannot be duplicated by another agent which produces a comparable EEG depression. Therefore, these data support the Van Harreveld - Fifkova theory that L-PRO-induced amnesia is dependent upon blocking the effects of glutamate release and is not merely the result of EEG depression independent of a glutamate mechanism.

805 RIGHT HEMISPHERE SUPERIORITY IN THE PERCEPTION OF FACIAL EMOTION. Edward C. Hansch*, Francis J. Pirozzolo, Jackson Beatty*. Department of Psychology, University of California, Los Angeles, California 90024.

A special role for the right hemisphere in the processing of affective stimuli has been suggested recently in the ability to respond to emotionally-laden questions (Schwartz, 1975) and in the perception of nonverbal human emotional voices (Carmen & Nachison, 1973). This work corresponds with clinical neurological evidence for a diminished capacity to respond to emotionally-charged stimuli in patients with right hemisphere brain damage (Wechsler, 1972). While facial recognition has been reliably demonstrated as a right hemisphere specialized skill (Pirozzolo & Rayner, 1977), the laterality of facial emotion perception has not been studied.

The present experiment examined hemispheric differences in the perception of both emotional and non-emotional stimuli, utilizing a forced-choice reaction time procedure. Four types of trials were employed: facial emotion, emotional word, facial recognition, and neutral word recognition. Word and facial stimuli occurred interspersed so that laterality effects could not be attributed to an "attentional bias".

Subjects were required to decide whether an orally-presented cue matched a fifty msec exposure of a lateralized stimulus. Left visual field presentation of facial emotion trials yielded significantly shorter latencies than did those for the right visual field. Latencies for response to word stimuli were shorter in the right visual field than in the left.

These results strongly support the notion of right hemisphere specialization for the perception of facial emotion, and cast doubt on the alternative hypothesis that a constant attentional bias to a given visual field mediates laterality effects. This evidence would also seem to support the clinical observations that patients with right hemisphere disease have difficulty discriminating and comprehending affectively-charged stimuli (Heilman, Scholes & Watson, 1975; Tucker, Watson & Heilman, 1977).

806 NEURAL ACTIVITY RECORDED IN THE ABDUCENS AND OCULOMOTOR NUCLEI DURING NICTITATING MEMBRANE CONDITIONING IN THE RABBIT. T.A. Harrison*, C.F. Cegavske (Dept. Psychology, SUNY, Binghamton, NY 13901) and R.F. Thompson (Dept. Psychobiology, UCI, Irvine, CA 92717).

This experiment was designed to characterize the neural activity in the motor output systems controlling movement of the rabbit nictitating membrane (NM) during acquisition and extinction of the classically conditioned NM response to tone CS and airpuff UCS. Multiple unit activity (MUA) was recorded in each animal during conditioning from electrodes chronically implanted in 1) the ipsilateral abducens (VI) nucleus, and 2) the dorsocaudal portion of either the ipsilateral or the contralateral oculomotor (III) nucleus. These areas have been determined to control NM extension (indirectly, via activation of the retractor bulbi muscle of the orbit), and, potentially, NM retraction (via a slip of the levator palpebrae superioris muscle attached to the NM), respectively (Cegavske, Thompson, Patterson & Gormezano, JCPP, 1976, 90, 411-423; Harrison, Torigoe & Cegavske, in preparation).

The conditioning procedure consisted of 13 blocks of trials (one block contained one CS-alone trial followed by 8 CS-UCS paired trials) per day for two days or until the rabbit reached criterion of 100% responding in one block of trials. Extinction consisted of 104 CS-alone presentations per day for two days. Data were recorded on audio tape for later analysis by computer. Histograms of the number of cells firing per 3 msec time bin were constructed for each trial for comparison with NM magnitude and latency data.

The patterns of increases and decreases of MUA in the oculomotor and abducens nuclei in relation to the NM response were examined. Comparisons of the abducens MUA and the NM response confirmed previous work (Cegavske, Patterson & Thompson, submitted). Abducens MUA was highly correlated in time and magnitude with the NM response over the course of extension and retraction of the NM. Increases in MUA consistently began before the onset of NM extension, and decreased prior to full retraction of the NM. Increases in oculomotor MUA began after abducens MUA had already increased. The relationship between the NM response onset and oculomotor activity depended upon the topography of the response. The temporal relationships of the behavioral response and the MUA recorded from both areas were maintained over the course of acquisition and exinction, whether the response was a UCR or a CR. It is concluded that changes in patterns of MUA recorded in these motor nuclei during conditioning reflect performance of the NM response, and not other aspects of conditioning.

807 FOUR MEMORY CHANNELS FOR SHUTTLE-BOX LEARNING IN THE RAT. Ivan Izquierdo, Deusa A. Vendite*, and Elaine Elisabetsky*. Dept. Biochem., Inst. Biosciences, UFRGS, 90000-Porto Alegre, Brazil.

Rats were trained to make shuttle responses to a 5-sec buzzer using 1.5 mA footshocks as a reinforcement in two different modes: a) classical conditioning (DP), in which the two stimuli were paired (i.e., given contiguously) on every trial, regardless of whether the animals made shuttle responses to the buzzer or not: b) avoidance without stimulus pairing (DC), in which the buzzer-shock interval was varied at random between 5 and 35 sec on every trial and the shocks were contingent upon omission of a shuttle response to the preceding buzzer. With both procedures, training sessions consisted of 50 trials at 10-40 sec intertrial intervals. One or seven days after training the animals were submitted to a retest session using either the same paradigm in which they had been trained, or the other one. Thus, it was investigated whether information acquired through each mode was available for retrieval only in that mode or in the other one as well, and existence of the following four possible memory channels could be tested: DP-DP, DC-DC, DP-DC, and DC-DP. In untreated animals, only the first three channels were manifest. The DP-DP channel was already in operation on day 1, and suffered no build-up or decay from then to day 7. The DC-DC channel declined between day 1 and day 7. The DP-DC channel became manifest only on day 7. Finally, animals trained in DC made no more responses in DP retests than naive animals submitted to DP for the first time. The effect of an ip. injection of d-amphetamine sulfate (1 mg/Kg), metrazol(10 mg/Kg), or nicotine (0.2 mg/Kg), given immediately after the end of the training session, was investigated. The DP-DP channel was insensitive to any of the treatments. Operation of the DC-DC channel was enhanced by amphetamine and by metrazol, but not by nicotine. Operation of the DP-DC channel was enhanced by metrazol, but not by any of the other two drugs. Finally, nicotine "unclogged" the normally "dormant" DC-DP channel. The effect on the four channels of immediate post-training hippocampal spreading depression was also investigated. This was produced by applying KCl crystals onto this structure through implanted cannulae, and was monitored electrographically. Control rats had the cannulae but received no KCl. Hippocampal spreading depression in the treated group lasted for 1-3 hs. It had no effect upon operation of the DP-DP or DC-DC channels, but it enhanced that of the other two channels(DC-DP and DP-DC). These data do not support any of the hypotheses that integrity of hippocampal function is in any way essential for memory consolidation, and suggest instead a role for this structure in the processing and sampling out of recently acquired information.

808 MORPHINE AND NALOXONE ALTER MEMORY IN THE RAT. Robert A. Jensen, Joe L. Martinez, Jr., Rita B. Messing, Vina Spiehler*, Beatriz J. Vasquez, Bernard Soumireu-Mourat*, K.C. Liang*, and James L. McGaugh. Department of Psychobiology, School of Biological Sciences, University of California, Irvine, CA., 92717, U.S.A.

The effects on memory storage of peripherally administered naloxone (Nx) and morphine (Mor) were studied. Male F-344 rats (90 days old) were trained in a one-trial inhibitory avoidance step-through task with either a 500 or 750 μA, 0.5 sec footshock. Immediately after training, the rats received an i.p. injection of either Mor or Nx. Nx was administered in divided doses, 30 min apart, of Sal, 0.1, 1.0, or 10.0 mg/kg, while Mor was given in a single dose of Sal, 1.0, 3.0, 10.0, or 30.0 mg/kg. Nx facilitated retention measured 24 hrs later. Rats that received 1.0 mg/kg Nx showed significant facilitation of retention compared to controls with either a 500 μA (χ^2=10.3, df=1, p<.01) or a 750 μA footshock (χ^2=7.02, df=1, p<.01). Rats that received Mor, trained using a 750 μA shock, showed significant amnesia with both the 1.0 mg/kg dose (χ^2=6.01, df=1, p<.02) and the 3.0 mg/kg dose (χ^2=6.72, df=1, p<.01).

To test the receptor specificity of the effects, the capacity of Mor to attenuate the facilitatory effect of Nx was examined. Rats were trained as before with a 500 μA footshock, and were given divided doses of either Sal, Nx (1.0 mg/kg), or a mixture containing both Mor (30.0 mg/kg) and Nx (1.0 mg/kg). All rats received 2 injections 30 min apart. Rats that received Nx showed significant facilitation of retention (χ^2=4.2, df=1, p<.05). However, Mor blocked the facilitatory effect of Nx since animals that reveived the mixture differed significantly from the Nx alone group (χ^2=6.04, df=1, p<.02), but not from the controls (χ^2=2.27, df=1, p>.10).

The effect of intraventricular administration of Mor was then studied. Indwelling cannulas were stereotaxically implanted above the lateral ventricle and, after a 1-week recovery period, rats were trained and given an intraventricular injection (2.0 μl) of either Ringer's solution or Mor (0.3, 3.0, 20.0, or 40.0 μg). The 40 μg dose of Mor produced significant facilitation of retention (U=166.5, z=2.14, p<.05), while the 3.0 μg treatment caused significant amnesia (U=116, z=2.38, p<.02).

These data indicate that posttraining administration of Nx facilitates memory, while Mor has a biphasic effect. The findings that Mor attenuates the Nx-induced facilitation of memory, and that intraventricular administration of Mor also affects memory suggest that the effects are mediated by central opiate receptors having a memory modulatory function. 809 THE CENTRAL NUCLEUS OF THE AMYGDALA: BULBAR PROJECTION AND INVOLVEMENT IN HEART RATE CONDITIONING. Bruce S. Kapp, Robert C. Frysinger*, and Michela Gallagher, Dept. of Psychology, and James S. Schwaber, Dept. of Anatomy, University of Vermont, Burlington, Vermont 05401.

As a part of an effort to assess the involvement of specific amygdala systems in the development of heart rate conditioning, bilateral lesions were made in the dorsomedial amygdala of eight New Zealand rabbits producing damage confined to the central nucleus and proximal fibers of passage. Two weeks following surgery the subjects received 15 presentations of the CS alone (1000Hz, 92dB, 5 sec tone) followed by 45 paired CS-US conditioning trials. The US was a 0.5 sec 2.0 mA eyelid shock coincident with the offset of the CS. The lesioned animals were significantly impaired in the development of conditioned bradycardia compared to unoperated and operated control animals (p's < .02).

Since the conditioned bradycardia response is mediated by the vagus nerves in the rabbit (Fredericks et al., 1974), the possibility was examined that a direct projection exists from the amygdala to the dorsomedial medulla, a region subserving cardiovascular reflexes and containing cells of origin of vagal cardioinhibitory fibers in this species. Bilateral and unilateral injections of horseradish peroxidase (HRP; 0.05-0.2μl, 30%) were placed in nine rabbits at the border of the medial nucleus of the nucleus of the solitary tract and the dorsal motor nucleus, both at the level of the obex and 750 micra rostral to the obex. After 24-48h the medulla and the amygdala were sectioned at 40 micra and processed using benzidine as a chromogen. HRP-labelled amygdala neurons were found to be restricted to the central nucleus, largely within the dorsomedial quadrant and in the rostral half of the central nucleus. We are now using autoradiographic and anterograde HRP techniques to determine more precisely the projections of these neurons.

Although the functional significance of this amygdala-bulbar projection is at present a matter for speculation, it is noteworthy that (1) the origin of this projection is in an area which when lesioned results in deficits in the acquisition of conditioned bradycardia, and (2) a terminal zone of this projection appears to be within a region which subserves cardiovascular reflexes and contains cells of origin of cardioinhibitory fibers.

810 ETHANOL-INDUCED FACILITATION OF INHIBITORY AVOIDANCE PERFORMANCE IN MICE. R. D. Malcolm, K. E. Lovett* and R. L. Alkana, School of Pharmacy, University of Southern California, Los Angeles, CA 90033.

It has been suggested that consolidation decrements may underly ethanol-induced memory impairment. However, recent findings in mice using post-training ethanol injections do not support this hypothesis. To further explore the effects of ethanol on memory storage, ethanol was administered to C57 Bl/6j male mice immediately after training on a "step-through", one-trial inhibitory avoidance task at a 150 μA shock level. The ethanol was given i.p. at doses of 0.75, 3.0 and 4.5 g/kg (15% w/v). A 0 g/kg control group received the 4.5 g/kg volume of normal saline. Retention was tested in the non-drug state one week after training. Latencies to step-through were recorded to a maximum of 360 sec. In this experiment, immediate post-training injection of ethanol significantly improved retention latencies at 3.0 g/kg (median - 287 sec) and 4.5 g/kg (median - 204 sec) when compared to controls (median - 77 sec) (p<0.05; 2-tailed Mann Whitney U-test). One control and 10 experimental animals reached the 360 sec ceiling. There was a non-significant trend toward increased retention at the 0.75 g/kg dose (median - 141 sec)(p<0.1). Immediate post-training injections of 4.5 g/kg ethanol in the absence of foot shock did not significantly change latencies when compared to saline controls, suggesting that the ethanol injection was not aversive. In contrast to post-training treatment, injection of ethanol 10 minutes before training significantly impaired retention. The present findings do not support the consolidation hypothesis of ethanol's acute amnestic effects. These findings agree with earlier studies suggesting that post-training administration of ethanol enhances memory storage. Further studies are necessary to replicate and extend these preliminary findings.

811 INTRAVASCULAR ERYTHROCYTE AGGREGATION AND SHORT-TERM MEMORY IN RATS AND RHESUS MONKEYS: AN EVALUATION OF THE ROLE OF BLOOD SLUDGING IN AGE-RELATED, COGNITIVE DECLINES. John G. Marriott, Raymond T. Bartus and Ronald E. Voigtman*. Pharm. Dept., Warner Lambert/Parke-Davis Research Labs, Ann Arbor, MI 48105.

Several studies tested the hypothesis that an increase in erythrocyte aggregation or blood sludging, concomitant with the aging process, is responsible for the impairment of short-term memory (STM) commonly found in aged humans. Clinical reports of the therapeutic benefits of long-term anticoagulant treatment in senile patients prompted the current investigations into the role of blood sludging in memory impairments. First, blood sludging was induced in male, hooded rats by intravenous injection of high molecular weight dextran (mean mol. wt.=370,000). Analysis of blood sludging produced by dextran as measured by erythrocyte sedimentation rate (ESR) showed profound sludging after doses of 300 m/k, which persisted for several days. In contrast to the effects on ESR, a second study showed that Dextran 500 did not affect the accuracy of STM in rats working on a delayed alternation task. Discrete trial, operant procedures were used in this study which required the animal to remember from trial to trial the position chosen on the previous trial and to respond to the opposite (alternate) side. Accuracy of delayed alternation performance, used as a measure of STM, was not affected by dextran administration. The behavioral effects of dextran under these procedures were limited to a general, dose-dependent suppression of responding. Animals completed 52% fewer trials during the session following administration of 300 m/k of dextran as compared to control performance.

To test further the hypothesis of sludging-induced STM impairments in aging, the degree of blood sludging in behaviorally impaired, aged rhesus monkeys was compared with that of normal, young monkeys. In previous studies using automated, delayed response procedures, this colony of aged monkeys was shown to exhibit significant impairment of STM similar to that reported in human, geriatric patients. Complete separation in delayed-response performance between groups of young and old monkeys was found in these earlier studies. In contrast, the comparison of young and old monkey blood showed almost total overlap in degree of blood sludging, and therefore, no significant difference between the two age groups.

Thus, blood sludging was not associated with STM impairments in rats administered IV dextran or in aged monkeys. These results do not support the notion that cognitive declines in aging, specifically in STM, are due to the effects of gross changes in blood sludging. The clinical reports of salutary effects resulting from long-term, anticoagulant therapy are likely due to actions of such drugs other than their anti-sludging properties.

812 PERIPHERAL 6-HYDROXYDOPAMINE (6-OHDA) ALTERS THE FACILITATORY EFFECT OF AMPHETAMINE ON MEMORY. Joe L. Martinez, Jr., Robert A. Jensen, Rita B. Messing, Beatriz J. Vasquez, Bernard Soumireu-Mourat*, Debora Geddes*, K. C. Liang*, and James L. McGaugh. Department of Psychobiology, School of Biological Sciences, University of California, Irvine, CA 92717, U.S.A.

We investigated, (1) the effects of peripherally administered 6-OHDA on acquisition of an inhibitory avoidance task, and (2) the effects of d-amphetamine sulphate (AMPH) on learning and retention in rats sympathectomized with 6-OHDA.

Male ARS Sprague-Dawley rats (90 days old) were trained in a one-trial inhibitory avoidance task. Rats in several groups received either SAL, 5.0, 25.0, or 100.0 mg/kg 6-OHDA, intravenously, and were then trained 24 hours later with either a 500 or 750 μA, 1 sec footshock. A retention test was given 72 hours later using a 600 sec cutoff latency. Post-mortem assay of norepinephrine (NE) concentrations in heart tissue showed that 5.0 mg/kg 6-OHDA reduced NE concentrations to about 25% of control; 25.0 mg/kg to 13%; and 100 mg/kg to 7% of control. There was no significant correlations between NE depletion of individual animals and their retention scores. Only the 5.0 mg/kg dose of 6-OHDA at 500 μA produced a significant retention deficit (U= 155.5, p<.05). Performance on the training trial was not altered by 6-OHDA since entrance latencies of rats given either SAL, 5.0, or 100.0 mg/kg 6-OHDA did not differ [$F(2,47)$= 2.38, p>.05].

In the next experiment, either SAL, 5.0, or 100.0 mg/kg 6-OHDA was administered to animals as before, and they were trained using a 500 μA footshock. Immediately following training rats received either no injection, SAL, 0.25, 1.0, or 4.0 mg/kg AMPH, i.p. A 4.0 mg/kg dose of AMPH given to rats not receiving 6-OHDA significantly facilitated retention performance [$t(28)$= 2.42, p<.05]. For rats that received 6-OHDA before training, the facilitatory dose of AMPH was decreased to 0.25 mg/kg [5.0 mg/kg 6-OHDA, $t(36)$= 2.36, p<.05; 100.0 mg/kg 6-OHDA, $t(23)$= 2.13, p<.05].

These findings are evidence that denervation of peripheral presynaptic terminals alters the facilitatory effect of amphetamine. Moreover, the results point to the importance of peripheral systems in learning and memory and suggest that part of the action of amphetamine may be peripherally mediated.

813 ELECTRICAL STIMULATION OF THE ABDUCENS NUCLEUS IN CLASSICAL CONDITIONING OF THE RABBIT'S NICTITATING MEMBRANE RESPONSE. Frederick W. Mis, f. Gormezano*, David Rosewall*, and John A. Harvey, Dept. of Psych., Univ. of Iowa, Iowa City, Iowa, 52242.

Extension of the rabbit's nictitating membrane (NM) is reliably elicited by applying electric shock to the paraorbital region (unconditioned stimulus, UCS). Movement of the NM is a passive response accompanying retraction of the eyeball into the socket. Neural control of this unconditioned response (UCR) originates within the motor neurons of the abducens nucleus. The present studies examined the ability of direct electrical stimulation of the abducens nucleus to serve as either a CS or UCS in classical conditioning of the NM response. The first experiment examined for 7 rabbits, in a within subjects design, the relationship between a variety of stimulation parameters and UCR amplitude. Our findings indicate that UCR amplitude was a function of the total energy applied via the electrode and an inverse function of the linear distance from the abducens nucleus to the electrode tip.

In the second experiment, we assessed the efficacy of abducens nucleus stimulation as the UCS. The conditioning paradigm consisted of a 200 msec tone CS followed by a 40 msec train of brain stimulation. Of the 26 rabbits which continued to manifest a UCR throughout the 20 training sessions, 16 developed substantial levels of conditioned responding (at least 50% CRs during a session). Analysis of UCR amplitude further suggested that there was an inverse linear relationship between UCR amplitude and distance from the abducens nucleus.

In the third experiment we sought to determine if stimulation applied to the abducens nucleus could effectively serve as a CS. The conditioning paradigm consisted of an 80 msec train of brain stimulation (CS) followed 120 msec later by a peripheral 50-msec paraorbital shock (UCS). Five of the six rabbits in this experiment reached asymptotic levels of conditioned responding (90% CRs) with 240 conditioning trials. Histological examination revealed that the tips of the electrodes were within 1.2 mm of the abducens nucleus.

Our findings suggest that the neural tissue necessary for integration of the sensory information related to the manifestation of a CR is located in the vicinity of the abducens nucleus.

814 ROLE OF SUPRAOPTIC DECUSSATION IN INTEROCULAR TRANSFER IN CHICKS: AGE DEPENDENCE? Nancy A. O'Connell* (SPON: R.W. Doty). Center for Brain Research, University of Rochester, Rochester, N.Y.14642

The supraoptic decussation (DSO) has been shown to be responsible for interocular transfer in birds. Meier (Psychol. Forsch. 34: 220, 1971) found that section of at least 75% of the DSO prior to training severely impaired interocular transfer of both color and pattern discrimination in pigeons. However, it was not known whether DSO actually produces a memory trace in the non-exposed hemisphere or merely provides it with access to an engram which remains in the exposed hemisphere. To test this, chicks were raised for 2 weeks monocularly in a cage where red and green colored feed was continuously available. For each chick one or the other color of feed was made aversive by adding methyl anthranilate. The DSO was then cut and eye cover reversed. Interocular transfer was considered to be present if the chick, when hungry, pecked at the previously preferred color of feed at least twice as often (and > 100 pecks) as it pecked at the other when tested for a minimum of 5 min in the presence of unadulterated feed of both colors. Of 15 chicks with > 90% of DSO sectioned, 13 showed interocular transfer (p < .01), and 5 others with >75% of DSO sectioned also showed interocular transfer. This suggests that memory was stored bilaterally, since the supraoptic decussation was unavailable for readout during testing. The possibility remained that the DSO might be unnecessary for transfer of this preference. Thus, the DSO was transected 1-2 days after hatching. These chicks were trained monocularly for 2 weeks, then tested. In this case 12 of 14 chicks with section of > 75% DSO still showed transfer. This seems to conflict with the results of Meier, but it is conceivable that newly hatched chicks can compensate for lack of an intact DSO while adult pigeons cannot. To see if newly hatched chicks differ from slightly older ones, and to have a better age-matched control for the original operated group, a third experiment was done. DSO was cut in 16-day old chicks which were then trained monocularly for 2 weeks and tested for retention and transfer. All 5 unoperated control chicks showed transfer and retention, as did all 5 chicks with anterior and pallial commissures cut but with DSO intact. All 5 chicks with > 75% of DSO cut learned color preference with the trained eye, but this preference did not transfer to the untrained eye. Thus, although the experiments are continuing, it is tentatively concluded that a bilateral engram is produced when DSO is intact, and that DSO is necessary for interocular transfer of color discrimination if the chick is raised with it intact, but that the critical role in interocular transfer is assumed by some other system if the DSO is absent during early visual experience. (Supported by USPHS Grant NS 03606 from NINCDS and NIMH fellowship MH 05257).

815 PRENATAL Co^{60} IRRADIATION EFFECTS ON GROWTH, BEHAVIOR, AND PERSISTENCE OF IMPAIRMENT IN SQUIRREL MONKEY OFFSPRING. J.M. Ordy, K.R. Brizzee, T. Beavers, P. Medart*, Tulane Univ., Delta Primate Center, Covington, LA 70433

Abnormalities of the brain are some of the more frequently cited postnatal manifestations in offspring exposed to irradiation during pregnancy. Until recently, most research on prenatal hazards, including radiation effects on the brain, has been done with rodents. High-dose effects that produce gross brain malformations are readily demonstrable in most animal models. Consequently, increased interest has been directed toward the squirrel monkey as a "diurnal primate model" for studying more subtle low-dose effects on impaired growth rates or developmental delay, sensory, learning, motor capacity, and the persistence of early damage into maturity. The specific aims of this study were to examine the effects of prenatal 0, 10, 100 and 200 rads of Co^{60} radiation on: 1) differences in postnatal growth rates between control and irradiation offspring to differentiate transient developmental delay from permanent abnormal development, 2) development of reflexes and neuromuscular coordination from birth to maturity, 3) sensory, learning, motor capacity, eye-hand lateralization, light-dark activity, emotionality, exploratory behavior and social development. Depending upon dose, significant decreases in body weight, head-circumference and crown-rump length were observed between control and irradiated offspring at birth. Comparisons of postnatal growth rates indicated developmental delay during the first six months after birth in the 100R offspring. According to the neurological evaluations, the postnatal development of reflexes and the maturation of neuromuscular coordination was significantly slower and less coordinated in the irradiated offspring from birth to two months of age. Low dose main effects on sensory-learning-motor capacity, eye-hand lateralization, emotionality, exploration, light-dark activity and social development were confounded with age, sex, and phenotype. Also, no significant differences have been observed between control and 100R irradiated offspring in sensory-learning-motor capacity from 1 to 2 years after birth. However, significant differences have been observed in visual discrimination reversal learning between control and 100R but not 10R irradiated offspring 2 years after birth. Followup studies are in progress to establish low dose 10R threshold effects and to determine if the prominent early effects of 100R and 200R persist into maturity. 816 HIPPOCAMPAL AND CORTICAL CONTROL OF PAVLOVIAN CONDITIONED AUTONOMIC AND SOMATIC RESPONSES. D. A. Powell, Shirley Buchanan,* Linda Hernandez,* Neuroscience Laboratory, VA Hospital and University of S. C., Columbia, SC 29201 and James Francis, Department of Pharmacology, University of Houston, Texas 77004.

Four experiments were conducted in which the effects of hippocampal, cortical control, and sham operate lesions were studied upon differential classical conditioning of corneoretinal potential (CRP) and heart rate (HR) changes in rabbits. Tones of different frequencies were CSs and paraorbital electric shock was the US. In the first experiment the CRP discrimination was slightly impaired during acquisition but severely impaired during reversal training. HR CRs were more accelerative in both hippocampectomized and cortical lesioned animals compared to sham lesioned Ss during both acquisition and reversal training. In addition hippocampal lesioned Ss revealed accelerative HR changes during both adaptation and extinction sessions relative to cortical and sham control Ss. However, an earlier experiment, which studied simple CRP and HR classical conditioning in hippocampal lesioned Ss, revealed enhanced bradycardiac HR CRs in the hippocampectomized Ss relative to control Ss. Subsequently experiments in the present series of investigations revealed that damage to the posteroventral hippocampus and/or damage to the cingulate cortex produced accelerative HR CRs, whereas damage restricted to the dorsal hippocampus produced enhanced decelerative HR CRs relative to control Ss. These results suggest a possible differential role of the dorsal and ventral hippocampus in modulating cardiac changes, possibly related to attentional dysfunctions. These data also implicate the cingulate cortex in mediating the cardiac inhibition accompanying Pavlovian conditioning.

817 ASYMMETRICAL STATE DEPENDENT LEARNING PRODUCED BY BENACTYZINE AND PHYSOSTIGMINE IN RATS. D. L. RICKETT* (SPON: T.-M. Shih). U. S. Army Biomedical Laboratory, CSL, APG, MD 21010.

In two separate studies using rats, 6.0 mg/kg of benactyzine or 0.6 mg/kg of physostigmine were tested for state dependent properties in a one-trial, step-through passive avoidance task. Both of the studies used the 2 x 2 factorial design with isotonic saline serving as the control condition (N state) for both drugs (D state). Twenty minutes prior to training or testing, each rat received an i.p. injection of the appropriate drug or an equivalent volume of saline. Neither benactyzine nor physostigmine had any effect on performance per se, as evidenced by comparisons of the groups trained and tested in the D state with groups trained and tested in the N state. Both benactyzine and physostigmine produced asymmetrical dissociation from the D to the N states; rats trained in the N state and tested in the D state were no different from those trained and tested in the same state, either N or D. These results are taken to support the notion that pertubation of the absolute level of cholinergic activity, regardless of direction, is more critical to retrieval of information during training than during testing. Furthermore, the pertubation in itself does not disrupt information storage and retrieval mechanisms when those changes which existed during training are redintegrated during testing.

818 ASSEMBLIES OF NEURONS IN BRAIN FUNCTION AND MEMORY--THEORY AND EXPERIMENT. Kathleen J. Roney and Gordon L. Shaw. Physics Department, University of California, Irvine, California 92717.

We discuss the possible identification of the often hypothesized assembly with the clusters of neurons that have been firmly identified neuroanatomically. Assemblies of neurons are important to brain function in that they could: maintain reverberatory firing activity for periods of the order of a second, provide stability against local brain damage, provide statistical reliability to insure a reproducible response to one stimulus presentation, and insure a reasonable memory storage capacity. This last property issues from a theory of memory developed by Shaw and Little (Shaw, Brain Res. Bull. 3:107, 1978). We note that we cannot determine the size of an assembly from the properties above; the actual dimensions must be determined electrophysiologically. From the theory, however, we envision a network of 10^3 to 10^4 highly interconnected neurons, corresponding to a cortical column (present throughout the cortex; Goldman and Nauta, Brain Res. 122:393, 1977), divided into assemblies consisting of roughly 20 neurons (the number of stimulus presentations needed to determine a reproducible post stimulus histogram (PSH)). In response to a stimulus, the network (column) will be excited into one of many different sequences of (averaged) firing patterns of the assemblies. Columns then interact, either directly or through thalamocortical pathways. The theoretical assemblies may be the "clusters" or "bundles" of apical dendrites of pyramidal cells found in the somatosensory cortex of the cat, rat, and rabbit, originally referred to by Peters and Walsh (J. Comp. Neurol. 144:253, 1972) and Fleischhauer, et al. (Anat. Entwicklungsgesch. 136:213, 1972). These clusters appear to be a fairly general feature of the mammalian brain, having been found in spinal cord, thalamus, formatio reticularis and cerebral cortex (Scheibel, et al., Exp. Neurol. 42:307, 1974). The clusters are smaller than columns and consistent with the size of our assemblies. Peters and Walsh consider it likely that the clustered dendrites have a common afferent input, consistent with the averaging of action potentials done within the theoretical assembly. It is also possible that dendrodendritic gap junctions between neurons in a cluster could serve as a basis for averaging within an assembly. Whether the clusters are electrically functional or merely developmental units needs to be determined. We propose and discuss the details of several possible experiments involving both electrophysiological and neuroanatomical measurements to determine whether these clusters are our assemblies. Though difficult, the experiments are doable; the large importance of identifying clusters as electrophysiologically functional assemblies makes the effort worthwhile.

819 BRAIN METABOLISM AND THE ACQUISITION OF NEW BEHAVIORS: EVIDENCE FOR SECRETION OF TWO PROTEINS INTO THE BRAIN EXTRACELLULAR FLUID AFTER TRAINING. Victor E. Shashoua. Mailman Research Center, McLean Hospital and Harvard Medical School, Belmont, MA 02178.

Immunochemical and double labeling experiments were used to demonstrate that at least two out of three brain cytoplasmic proteins, whose metabolism is markedly influenced by behavior, are products which are secreted into the extracellular fluid (ECF) of goldfish brain. Even after one hour of labeling, the extracts of goldfish brains with 0.32 M sucrose were found to contain highly labeled proteins. Electrophoretic analyses of the proteins, on SDS-polyacrylamide gels, indicated that an increased incorporation of [^{3}H]valine occurs for trained animals as compared to untrained controls ([^{14}C]valine) at specific protein bands migrating at 32,000 and 26,000 daltons. The proteins in the ECF gave identical precipitin bands against rabbit antisera to goldfish brain proteins whose metabolism was responsive to the acquisition of new patterns of behavior. Preliminary characterization studies of the proteins indicate that they are glycoproteins with an amino acid composition containing acidic to basic amino acid ratios of about 2/1. These results are consistent with the hypothesis that the cells which contain the proteins and whose location in the ependymal zone was determined by immunohistochemistry (L. Benowitz and V.E. Shashoua, Brain Research 136:227-242, 1977) can secrete the products into ECF. These findings also provide an explanation for our previous observations that antisera to β and γ can inhibit the formation of a long-term memory (V.E. Shashoua, Proc. Natl. Acad. Sci. USA 74:1743-1747, 1977). It is not necessary for the IgG molecules to get into cells to find their targets since the antigens are being secreted and are present in the extracellular space. It is, therefore, quite possible that the functional sites of the proteins are away from the locus of their synthesis. 820 **DEVELOPMENT OF LEARNING AND MEMORY IN MICE AFTER BRIEF PARADOXICAL SLEEP DEPRIVATION.** **P. Shiromani*, Baruch M. Gutwein* and William Fishbein. Psychobiology Laboratory, CCNY, New York, N.Y. 10031.**

Recently Bloch and his colleagues (Brain Res. 49: 367-369, 1973) have demonstrated that a brief augmentation of paradoxical sleep (PS) occurs immediately following two-way active avoidance learning. They have also shown that the retention of the learned response is impaired if the PS augmentation is prevented. In addition, Pearlman and Greenberg (Anim. Learn. Behav. 1: 49-51, 1973) have shown that selective PS deprivation (PSD), either via drugs or the 'water tank' procedure, for 3 hours immediately following two-way active avoidance or discrimination learning in the rat produces marked retention deficits; no amnesia is observed if PSD is delayed until 3 hours after training. Collectively these experiments seem to suggest a critical time period for memory consolidation. This period extends up to 3 hours after training and is characterized by PS or conditions compatible with the occurrence of PS.

The present series of experiments attempt to further elucidate the above findings. Several experiments are performed to assess, in mice, the effects of 3 hours PSD, via the 'water tank' procedure, on active and inhibitory avoidance learning. Results indicate no amnesia in experimentally treated mice. An attempt is then made to induce amnesia by administering ECS immediately after 3 hours PSD; this procedure also fails to produce amnesia. We conclude that in mice PS immediately after aversively motivated training is not essential for memory consolidation. Our results, however, do not subtract from the long-term effects of PS on memory that we have previously reported (Behav. Biol. 19:425-464, 1977).

821 EVIDENCE FOR THE SEQUENTIAL PARTICIPATION OF INFERIOR TEMPORAL CORTEX AND AMYGDALA IN STIMULUS-REWARD LEARNING. Brenda J. Spiegler* and Mortimer Mishkin, NIMH, Bethesda, MD 20014

On a test of one-trial learning of stimulus-reward associations, monkeys showed marked impairment after lesions of either the anterior part of inferior temporal cortex (area TE) or the amygdala (A). By contrast, they showed only mild loss after lesions of either the posterior part of inferior temporal cortex (area TEO) or the fusiform-hippocampal gyrus and hippocampus (FHH). Preoperatively, the monkeys had been trained to remember the reward value of an object on the basis of a single acquisition trial in which the object covered either a peanut reward (positive object) or an empty well (negative object). On the test trial, an average of 20 seconds later, the object was paired with a grey card (cf. Gaffan, JCPP 86: 1100, 1974). On this test trial the object was positive if it had been positive on the acquisition trial; otherwise the grey card was positive. A new object was used on every trial, and the trials were presented in sets of two: that is, separate acquisition trials for each of two objects preceded separate, randomly ordered test trials with each of those objects. Also, most sets consisted of one positive and one negative object. These procedures ensured that the animals could perform correctly only by remembering the objects' reward values and not by other strategies. On reaching the preoperative criterion, the monkeys received one of the four bilateral temporal lobe lesions (TEO, TE, A, or FHH) with the outcome as described above.

The finding of impairment after both the TE and the amygdala lesions fits the view (Jones & Mishkin, Exp. Neurol. 36: 362, 1972) that stimulus-reward learning in vision is mediated by a functional chain linking the visual system to the limbic system through relays in the inferior temporal area. Area TE is considered to be the last purely visual link in this pathway. A previous study (Mishkin & Oubre, Neurosci. Abs. 2: 1127, 1976) showed that damage to TE, but not to other temporal lobe structures (TEO, A, or FHH), impairs performance on a one-trial learning test of object recognition as distinguished from object-reward association. Presumably, the impairment after TE lesions in the present study was due to this same basic recognition disorder. The impairment after amygdala lesions, however, not being attributable to a recognition disorder, appears to reflect instead a disorder in object-reward association. The results thus point to object recognition and object-reward association as consecutive processes that depend in part on the sequential participation of area TE and the amygdala.

822 LOCALIZATION OF LESION IN A NOTED CASE OF CHRONIC ANTEROGRADE AMNESIA. Larry R. Squire and Robert Y. Moore. Departments of Psychiatry and Neuroscience, UCSD, La Jolla, CA 92039.

In man, chronic anterograde amnesia can result from dysfunction in the medial temporal region of the brain (case H.M.) or from neuropathological changes in the diencephalic region (Korsakoff disease). In the case of the diencephalic region the dorsal thalamus, the mammillary bodies, and the terminal aspects of the fornix have been associated with amnesia but there is disagreement as to what constitutes the minimal lesion in these regions.
