We have recently been able to obtain information about the site of injury in the chronic amnesia patient N.A. In 1960, this individual sustained a stab wound to the brain as the result of a fencing accident. Since 1960, N.A. has had great difficulty in committing day-to-day events to long-term memory. His amnesia is remarkably pure, occurring in the absence of any known cognitive defect other than memory loss. The defect is more severe for verbal than for nonverbal material.

During the past year N.A. consented to three C.A.T. scans. The results consistently demonstrated a small lucency to the left of midline, at the level of the pineal calcification, corresponding to the position of the left dorsal medial thalamic nucleus.

We cannot rule out the possibility that damage has also occurred to the adjacent anterior nucleus or to fibers of the mammillary thalamic tract. The lesion did not involve the fornix or the mammillary bodies. These findings do not exclude the possibility that lesions of the mammillary bodies may result in amnesia in some cases. The results from this patient emphasize the importance of the dorsal thalamus in memory functions.

823 A PROPOSED EXPERIMENT FOR THE INVESTIGATION OF THE "MEMORY OF SPEED". George Vroulis. Dept. Psychophysiology., TRIMS, Med. Center, Houston, TX 77030.

An experimental task is proposed for the measurement of the memory of speed of an event by human subjects. The experimental task in question involves the measurement of visual temporal behavior by having a subject to adjust a rotating disk, with a point light source attached to its periphery, ("subject's disk"), to the angular velocity of another identical reference disk (experimenter's disk") which lies right above the "subject's disk".

Small variations of the above mentioned experimental arrangement involve the use of one disk only with the subject having to memorize a reference angular velocity and be able to reproduce it 5-10 sec later.

It is speculated that saccadic and pursuit movements must mediate those tasks together with some form of short term memory which must encode and store enough angular velocity attributes during the receptive phase, which, after a rehearsive phase, must be reproduced during the executive phase.

This particular short term memory is named "Short Term Memory of Speed" (STMS) and pertains to the memory of the speed of an event.

It is assumed that this type of memory has not been coined as such by the literature and may not involve the traditional coding of information into auditory or articulatory or visual representations, but may encode and store the very eye-movement information that was necessary to perceive the angular velocity movements in the first phase.

By examining concomitantly the EOG and EEG activities, during the three separate phases of the experiment, and correlating them with the accuracy of "speed-reproduction", one may theorize about the roles of both eye movements and specific brain area activities in the STMS.

Preliminary results using the above mentioned task, (matching angular velocities) indicated that normal subjects, can replicate 3.16 Revolutions Per Minute (12 inches diameter disk) to within 9% accuracy, when they observe both the reference (top) and the subject's (bottom) disks, and to within 13% when they are exposed 20 sec to the reference angular velocity (i.e. 3.16 RPM) and they have to reproduce it 5 sec later starting at 0 RPM.

824 ENCODING DEFICITS IN ANTEROGRADE AMNESIA. C. Douglas Wetzel* and Larry R. Squire (SPON: W.T. Schlapfer). Departments of Neurosciences and Psychiatry, UCSD, School of Medicine, La Jolla, CA 92093.

Studies of the alcoholic Korsakoff syndrome have suggested the hypothesis that the amnesic syndrome may in part depend on a failure to encode information with the elaborateness characteristic of normals. Since Korsakoff disease involves some cognitive defects other than amnesia, it has not been clear whether this explanation of amnesia can be usefully applied to other examples of the amnesic syndrome. Patients receiving bilateral electroconvulsive therapy (ECT), the chronic patient N.A., and a Korsakoff patient were given verbal memory tests designed to assess their ability to encode information along graphic, phonemic and semantic dimensions. In order to induce these different levels of encoding, the subjects were queried as to whether or not the word was in upper or lower case letters, whether it rhymed with another word, or whether it was an instance of a semantic category. Results with the Korsakoff patient agreed with findings in a population of Korsakoff patients reported by other investigators. Korsakoff patients tend to fail to encode semantic dimensions of words relative to their controls except in the very simplest version of this task. In contrast, patients receiving ECT and the chronic amnesic N.A. did not exhibit a selective defect in semantic encoding. First, these patients were deficient on all dimensions of encoding. Second, they showed a pattern similar to controls that included the superiority of the semantic encoding condition. Third, the retention performance of these amnesic patients could be duplicated by normal subjects who were tested at long intervals after learning. The results lead to the following conclusions: 1) Korsakoff patients appear to have more severe semantic information processing deficits than that observed in other more pure kinds of amnesia; 2) Normal forgetting shares some similarities with the amnesias found with ECT and the patient N.A.

825 VARIATIONS ON A THEME BY LASHLEY: LESION EXPERIMENTS ON THE NEURAL MODEL OF ANDERSON ET AL. Charles C. Wood* (SPON: T. Allison). Neuropsychology Lab., VA Hospital, West Haven, CT 06516

J.A. Anderson and his colleagues (Psychol. Rev., 1977) recently presented a neural model of memory in which every neural element participates in every memory. Here I report simulated lesion experiments on neural elements in the Anderson et al. model that are similar in spirit to Lashley's classic experiments from which the concepts of "mass action" and "equipotentiality" were derived. The purpose of these experiments was twofold. The first was to examine the effects of systematic variations in lesion size and location on the performance of the model, and to compare them to lesion effects in real nervous systems. The second was to use the model to assess the degree to which principles of neural organization such as localization of function and equipotentiality can be inferred from lesion experiments. A neural model is particularly useful for this purpose because: a) the mechanisms of information processing and storage can be completely and quantitatively specified; and b) lesion size and location can be precisely controlled and systematically manipulated.

The model is represented mathematically in matrix algebra form. Each of N input neurons is assumed to be connected synaptically to each of N output neurons, and the patterns of activity in the input neurons and output neurons are represented as N-element vectors. A given pattern of input activity becomes associated with a given pattern of output activity by making the synaptic strengths between input and output neurons equal the vector product of the activity in the input and output neurons. This mechanism of association is closely related to that originally postulated by Hebb, and similar mechanisms have been proposed by Kohonen (I.E.E.E. Trans. Comput., 1972; Neurosci., 1977).

The effects of systematic variations in lesion size and location were assessed by removing specific combinations of input and output neurons and testing the model's association performance. In all, 65,024 lesions were made for each of 100 different sets of randomly selected input and output vectors. When expressed as average results over large numbers of lesions, the deficits in the model's performance provide axiomatic examples of Lashley's concepts of mass action and equipotentiality. That is, increasing lesion size produced increasing performance deficits regardless of the particular neurons removed. However, certain individual lesions produced highly selective deficits that have been widely interpreted as strong evidence for localization of function. As in the mammalian visual system, lesions including virtually the entire population of neurons were necessary to abolish performance. (Supported by the Veterans Administration and NIMH Grant MH-05286).

MONOAMINERGIC SYSTEMS

826 BEHAVIORAL EFFECTS OF LESIONS OF THE MEDIAN NUCLEUS OF THE RAPHE. Karen E. Asin, David Wirtshafter, Ernest W. Kent. Dept. of Psych. Univ. Il.-Chicago Circle, Chicago, Il. 60680.

In the past, we have demonstrated that damage to the median nucleus of the raphe (MR) results in a number of behavioral deficits which are similar to those seen following hippocampal damage. For example, we have reported that MR lesions retard extinction of a straight alley task (Neurosci. Abst.2,1976) decrease distractability and impair the acquisition of a single alternation response (Neurosci. Abst.3,1977). In the current study we further investigate the consequences of MR lesions on tasks which have been found to be sensitive to damage to limbic structures.

MR lesioned rats have been found to perseverate non-reinforced responding in a T-maze and this behavior cannot be characterized as either response or stimulus perseveration (Asin et al. Neurosci Abst. 3, 1977). To further investigate the nature of this behavior, control and MR lesioned rats were given two non-reinforced trials in a T-maze. During the first trial, one arm of the maze was blocked so as to prevent entrance into that side. During the second trial, one minute later, the block was removed and it was found that both control and MR lesioned rats responded by entering the previously blocked arm. This suggests that MR lesioned animals, similar to hippocampals, fail to perseverate forced choices.

To determine whether MR lesioned rats perseverate learned as well as spontaneous responses, the acquisition and reversal of a T-maze position habit was studied. MR animals were found to acquire the initial response as readily as controls, but were clearly impaired on its reversal. This result was obtained in animals trained to a criterion and in subjects given extensive over-training. Acquisition and reversal of a brightness discrimination task will also be discussed.

In another test, the effects of median raphe damage on a conditioned emotional response (CER) were assessed. Control and MR rats were trained for 3 days to drink water in an operant box. On the fourth day, the tube was removed and rats were shocked in the box for 30 seconds. On the following days, controls showed a significantly larger suppression of drinking than did MR animals. Impaired acquisition of a CER has also been reported following limbic lesions.

Finally, PCPA has recently been reported to eliminate latent inhibition in a shuttle box (Solomon et.al.,P&B,1978). We now report the similar observation that pre-exposure to the conditioned stimulus impairs shuttle box acquisition in control but not MR subjects. Since hippocampal lesions have been found to produce similar results, it is possible that the serotonergic projection to the hippocampus is involved in latent inhibition.

827 ALPHA-ADRENOCEPTOR MEDIATION OF ADRENERGIC-SEROTONERGIC INTERACTION IN DORSAL RAPHE. Jay M. Baraban* and George K. Aghajanian, Depts. of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06508.

Several lines of evidence indicate that the serotonergic (5-HT) cells of the dorsal raphe are subject to adrenergic influence. Drug treatments which impair adrenergic tone reduce 5-HT cell activity. For example, administration of either 1) clonidine (10 μg/kg, i.v.), which acts as a pre-synaptic α-agonist to decrease impulse flow, (Svensson et al., Brain Res., 92:291, 1975) or 2) reserpine (5 mg/kg, i.v.), which impairs noradrenergic transmission, suppresses the firing rate of 5-HT cells in the dorsal raphe.

An α-adrenoceptor is implicated in the suppression produced since the centrally active α-blocker piperoxan, but not the β-blockers sotalol and propranolol, slows 5-HT cell activity (Gallager and Aghajanian, Eur. J. Pharmacol., 39:341, 1976). Furthermore, the inhibition produced by both reserpine and low doses of clonidine can be abruptly reversed by a higher dose of clonidine (200 μg/kg, i.v.), which acts as a central post-synaptic α-agonist. In addition, we have recently found that WB-4104 (60 μg/kg, i.v., Boehringer Ingelheim), a potent α-antagonist, totally suppresses 5-HT cell firing in the dorsal raphe.

The dorsal raphe, as well as the adjacent central grey, receives a dense adrenergic input as demonstrated by biochemical, histofluorescence and immunocytochemical techniques. Thus, the α-adrenoceptors mediating the adrenergic-serotonergic interaction could be located in or near the dorsal raphe itself. This possibility is supported by the following observations from single cell recordings in chloral hydrate anesthetized rats: 1) both α-blockers, piperoxan and WB-4104 when applied iontophoretically gradually slow 5-HT cell firing; and 2) locally iontophoresed norepinephrine (NE) reverses the cessation of activity produced by either reserpine or a low dose of clonidine.

The post-synaptic α-adrenergic agonist phenylephrine is only weakly active at central pre-synaptic α-receptors located in the locus coeruleus (Cedarbaum and Aghajanian, Eur. J. Pharmacol., 44:375, 1977). In contrast, we have observed that it is equipotent to NE in its ability to restore 5-HT cell firing following the administration of either reserpine or a low dose of clonidine. Therefore, we suggest that the receptors mediating the adrenergic influence on dorsal raphe activity are of the post-synaptic α-adrenergic type.

828 **EFFECT OF SYSTEMIC APOMORPHINE ON FIRING RATES OF DOPAMINE CELLS IN RATS WITH STRIATAL KAINIC ACID LESIONS.** **M.D. Baring, J.R. Walters, E.K.Silbergeld, N. Eng*, S. DeSantis*, and J.M. Lakoski. Experimental Therapeutics Branch, NINCDS, Bethesda Md. 20014.**

Systemic apomorphine (APO) causes a rapid decrease in firing rate of nigral dopamine (DA) cells projecting to the striatum. APO, a DA agonist, may be acting both directly at DA receptors on DA cell bodies and indirectly through a striato-nigral feedback loop. To examine the effect of systemic APO in the absence of feedback from the striatum, we recorded firing rates of DA cells in rats with striatal kainic acid(KA) lesions, since KA is thought to kill cell bodies, leaving incoming axons intact. Rats were unilaterally injected with 2 μg KA in 1 μl .1 M NaH2PO4 buffer at stereotaxic coordinates (Koenig & Klippel) A 7.9, L 2.6, and 5.7 mm below skull surface. At 7 and 14 days after injection, striatal DA content and DOPA accumulation after DOPA decarboxylase inhibition had not changed significantly in the KA-injected striatum as compared to the contralateral side. Glutamic acid decarboxylase activity at 7 days had fallen to 22% of control in the striatum, and to 38% of control in the substantia nigra (SN). In the caudate-putamen, nearly complete loss of neurons was seen for 2-3 mm between A 9.4 and A 6.0. Cell loss also occurred in the globus pallidus; other areas were variously affected.

Extracellular single unit recordings were made from DA cells (one cell per rat) in 11 control and 14 KA-lesioned rats anesthetized with chloral hydrate; recordings from KA-lesioned rats were made in the SN ipsilateral to the lesion, 9-17 days after injection. APO was given at 2 min intervals in increasing amounts which doubled the previous cumulative dose; cumulative doses ranged from .32 to 320 μg/kg (.001 to 1 μM/kg). Despite major loss of striatal neurons, we saw no discernible change in the response of nigral DA cells to systemic APO at these doses. The firing of all cells was inhibited by APO; the cumulative dose at which at least half the cells showed 50% or greater inhibition of firing was 20 μg/kg for both control and KA-lesioned rats. At none of the 11 cumulative APO doses was there a significant difference in average % inhibition between control and KA-lesioned rats, nor was there a significant difference in the average dose which produced 50% inhibition. These results agree with the observation of DiChiara et al (Brain Res., 1977) that KA lesion of the striatum does not block APO's effect on DA synthesis, and our finding that APO's ability to reverse the increase in DOPA accumulation induced by γ-butyrolactone is not reduced in KA-lesioned rats.

While this study does not rule out the possibility that loss of striatal input causes subtle changes, or that changes might be seen during recovery of firing or after chronic APO, it supports the idea that the acute effect of APO on DA cell firing is predominately a direct effect on the DA cell.

829 DYNAMICS OF ENDOGENOUS RELEASE OF CATECHOLAMINES FROM RAT MEDIAL BASAL HYPOTHALAMIC (MBH) FRAGMENTS IN PERIFUSION. J. Becker* and V. D. Ramirez* (SPON: F. Delcomyn). Dept. of Physiology and Biophysics and Neural and Behavioral Biology Program, Univ. of Illinois, Urbana IL 61801.

The release of catecholamines from brain tissue in vitro has been demonstrated, but most systems use radioactively labeled monoamines or precursors as their indicator of release. We report a perifusion method in which it is possible to measure in the perifusate the endogenous concentration of DA and NE, without disturbing the initial pool of these putative neurotransmitters or the initial metabolic conditions of the neural tissue.

Adult male and female Holtzman rats were killed by decapitation, brains removed, MBH dissected out and placed in Krebs phosphate buffer glucose-albumin medium with ascorbic acid (0.1%) and pargyline (80 mM), pH 7.4, on ice. Twelve MBH's (~140 mg wet weight) are halved at the 3rd ventricle with one half going to the experimental the other to the control chamber, placed in a water bath at 37°C and medium described above is flowed in at a rate of 400 μl/4 min; air is bubbled in continuously. Perifusate is collected on ice in perchloric acid (final concentration 0.1N $HClO_4$). The tissue is allowed to equilibrate for 16 minutes. Duplicate 20 μl samples are assayed the same day using a radioenzymatic assay with a sensitivity of 32-16 pg for both NE and DA.

The spontaneous release rate (pg/mg/min) over the initial 50 min of perifusion for males is, NE: 2.67±0.28; DA: 1.79±0.13. In females, NE: 7.19±0.32; DA: 4.69±0.28. The release of both amines is irregular with occasional large NE pulses and more regular episodic DA discharges. The concentration in tissue (ng/mg) for males is, NE: 1.3±0.08(10); DA: 0.43±0.03(10). In females, NE: 1.4±0.07(2); DA: 0.35±0.02(2). In males, 60 mM K^+ triggers an immediate pulse of DA (299% of control) followed by a larger more sustained pulse of NE release (569% of control). In the absence of Ca^{++} the pulsatile secretion of NE is inhibited but not that of DA; the K^+ induced stimulation of NE is reduced and the DA surge abolished. At 0°C the mean secretion of DA and NE (control, NE: 2.83±0.31; DA: 1.58±0.08; 0°C, NE: 1.89±0.19; DA: 1.37±0.07) was reduced but pulses were still observed. The response to K^+ of the MBH's at 0°C was abolished.

In conclusion, we see sex differences in the spontaneous release of NE and DA, the latter of a magnitude consistent with values determined in vivo in the portal vessel. The endogenous secretion can be manipulated by changes in ions and T^o. Therefore, we propose the perifusion system of brain fragments as a viable in vitro technique for studying endogenous catecholamine release. Supported in part by RIAS Grant (NSF SER 76-18255).

830 SPATIAL PREFERENCE AND DOPAMINERGIC ASYMMETRIES IN THE RAT. Gregory Lucas Belenky, Claire Mays*, Richard Samaha*, G. Jean Kant, and James L. Meyerhoff. Dept. of Medical Neurosciences, Walter Reed Army Institute of Research, Washington, DC 20012.

Spatial preference, operationally defined as turning preference in a T-maze shock-escape apparatus, was determined in twenty-four female rats. The T-maze measured 62 cm by 44 cm. The grid floor of the stem delivered 0.05 watts of scrambled foot shock. The arms were shock free. Rats were given ten trials a day for ten days. Preferences emerged in the first ten trials and were highly correlated with preferences in the remaining 130 trials ($r = 0.61$, Student's $t = 3.61$, $df = 22$, $p < .001$). One month after the completion of the ten days of behavioral testing, the rats were decapitated and their brains removed. The left and right striatum, left and right nucleus accumbens/olfactory tubercle, and left and right hippocampus were dissected and separately assayed for dopamine in the case of the striatum and the accumbens/tubercle, and for norepinephrine in the case of the hippocampus. The average concentrations of dopamine (μg/gm ± SEM) were: left accumbens/tubercle 4.51 ± 0.21, right accumbens/tubercle 4.12 ± 0.14; left striatum 8.35 ± 0.40, right striatum 7.95 ± 0.49. The average concentrations of norepinephrine (μg/gm ± SEM) were: left hippocampus 0.36 ± 0.02, right hippocampus 0.38 ± 0.02. There were no statistically significant side to side differences. The ratios of assayed neurotransmitter left to right were calculated for the three paired regions and these ratios correlated with the previously determined spatial preference expressed as percent turns to the left after either ten trials or 140 trials. The ratio of dopamine left to right in the nucleus accumbens/olfactory tubercle showed a significant, positive correlation with the degree of leftward turning preference after ten trials ($r = 0.50$, Student's $t = 2.70$, $df = 22$, $p < .02$) and after 140 trials ($r = 0.436$, Student's $t = 2.27$, $df = 22$, $p < .05$). No significant correlations were found between either the ratio of left to right striatal dopamine or left to right hippocampal norepinephrine and leftward turning preference after either ten trials or 140 trials. Taken together these findings support a role for dopaminergic asymmetries in spatial preference and focus attention on mesolimbic dopaminergic asymmetries as a possible substratum of spatial preference in intact animals.

831 INCREASE IN SEROTONIN:N-ACETYLTRANSFERASE ACTIVITY FOLLOWING NEURAL STIMULATION OF THE RAT PINEAL. C.W. Bowers* and R.E. Zigmond (SPON: P.B. Dews). Dept. of Pharmacol., Harvard Med. Sch., Boston, MA 02115

The activity of serotonin:N-acetyltransferase (NAT) has a diurnal rhythm in the rat pineal gland, increasing 40 to 100-fold during periods of darkness. Pharmacological and anatomical evidence suggests that this nocturnal increase in NAT activity is related to an increase in the activity of the sympathetic nerves innervating the pineal from the superior cervical ganglion (SCG). However, attempts to measure an increase in electrical activity of these nerves in response to darkness have produced contradictory results. The magnitude of the increase in NAT activity makes the pineal gland an appropriate system for studying the neuronal control of the biochemistry of target cells. Therefore, we sought to determine whether electrical stimulation of the preganglionic trunk of the SCG would increase NAT activity in the pineal.

Albino rats were anesthetized and the cervical sympathetic trunks were stimulated bilaterally at 10 Hz, using current intensities twice that required to produce maximal exophthalamus of the ipsilateral eye. Animals were taken during the dark part of their cycle and exposed to light for 45 minutes before the beginning of the stimulation. Immediately following the period of stimulation the pineals were removed and frozen. The NAT activity increased linearly with the duration of stimulation up to 60 minutes, and by 2 hours the NAT activity had reached levels equivalent to the peak night levels seen in intact animals. Stimulation of animals during the light part of their cycle revealed that the pineal is less responsive to one hour of nerve stimulation during the day than during the night. The NAT activity (expressed in picomoles of acetylated product formed per 20 min per pineal ± the standard error of the mean) increased from an unstimulated value of 37 ± 9 to a value of 159 ± 22 following stimulation during the day, and from 278 ± 44 to 3580 ± 693 following stimulation at night. These experiments demonstrate that increases in pineal NAT activity similar to those seen in intact animals can be induced by electrical stimulation of the preganglionic trunk of the SCG. The responsiveness of the pineal to this stimulation varies during the normal light/dark cycle. (Supported by NIH grant NS 12561 and Amer. Heart Assoc. grant #76723.)

832 TOLERANCE TO THE BEHAVIORAL EFFECTS OF METHYLPHENIDATE AFTER DAILY AND INTERMITTENT ADMINISTRATION. Anne M. Brewin* and M.W. Emmett-Oglesby. Dept. Pharmacol. N.Tex. St. U./Tex. Col. Osteo. Med., Denton, TX. 76203.

This experiment tested the assumption that daily drug administration is a necessary condition for the development of tolerance to the behavioral effects of methylphenidate (MP). Thirty-two rats were trained to press a lever with water as a reinforcer and then switched to a DRL 18 second schedule, 45 minutes per session, which generated low rates of responding. After 74 training sessions, responding had stabilized, and subjects were injected with MP, twice weekly, 20 minutes pre-session. Dose-effect data were obtained for seven doses of MP ranging from 1.25 to 33.5 mg/kg. MP produced dose-dependent increases in response rate and decreases in reinforcements earned. A second series of dose-response measurements showed a reduced drug effect, and a third administration of the 10 mg/kg dose further reduced the drug effect. These data suggested that intermittent administration of MP resulted in a reduced drug effect. Therefore, the effect of daily and intermittent administration of MP were further determined for the 10 mg/kg dose. In this phase, eight rats received MP daily 20 minutes pre-session, eight rats received MP daily immediately after the session, and sixteen rats received MP twice weekly 20 minutes pre-session. The animals receiving daily MP pre-session developed tolerance to the rate-increasing and reinforcer-decreasing effects after 40 administrations; the animals receiving MP twice weekly developed partial tolerance to the rate-increasing effects after 20 administrations. Animals receiving MP post-session did not develop tolerance. After 82 sessions of chronic administration, test doses of MP, d-amphetamine, l-amphetamine, methamphetamine, and saline were given to all three groups 20 minutes pre-session. The results demonstrated tolerance to the effects of MP and cross-tolerance to the behavioral effects of the amphetamines after daily or intermittent administration of MP before the testing session. Thus, prior exposure to the behaviorally disruptive effects of a drug of the amphetamine class might subsequently decrease the effects of these drugs. (Supported by Faculty Research Grant #34150.)

833 CHARACTERISTICS OF COCAINE RESISTANT ACCUMULATION IN RAT CEREBRAL CORTEX. G.H. Burrows, M.M. Myers*, and E.D. Hendley. Dept. Physiology and Biophysics, Col. Med., Univ. Vermont, Burlington, Vermont 05401.

A major mechanism for the inactivation of extracellular norepinephrine in rat cerebral cortex is thought to be its accumulation in adrenergic nerve terminals. A sodium dependent, high affinity, transport system ($uptake_1$) has been described which saturates at approximately 0.4uM l-norepinephrine (l-NE). In view of the large (>1.0uM) concentrations of l-NE one would expect to find in central nervous system adrenergic synapses, we have directed our studies toward the characterization of a second accumulation system that is known to exist in rat cerebral cortex which saturates at concentrations much higher than 1.0uM. We have reported (Fed. Proc. 36:381, 1977) that this second system contrasts with $uptake_1$ in that it is not blocked by 10uM cocaine; it shows extremely rapid initial rates of accumulation; and it is markedly inhibited by the removal of calcium ions from the incubation medium. We have named this second system "cocaine resistant accumulation"(CRA).

We report here that when rat cortical tissue is incubated for one minute at 31°C in the presence of 1.0uM ^{3}H-l-NE, if, instead of 10uM cocaine, either 100nM desmethylimipramine or a sodium-free choline chloride medium, or both, are used to block $uptake_1$, CRA does not appear to be altered in either amount or calcium sensitivity. We have also examined this system in brain slices, crude synaptosomal homogenates, and in purified synaptosomes. The purified synaptosomes showed a 500% increase in the amount of calcium-sensitive ^{3}H-l-NE accumulation compared with brain slices, and a 60% increase when compared with crude homogenates, suggesting that CRA may, like $uptake_1$, be occurring in nerve endings. As with $uptake_1$, CRA was blocked by millimolar dinitrophenol and the regional distribution appears to follow the distribution of NE nerve terminals in the brain. In contrast with $uptake_1$, CRA did not appear to be stereo-selective with regard to l-NE accumulation. Because of the high capacity of CRA and its apparent association with NE nerve terminals, CRA may serve a major role in clearing the high concentrations of NE presumed to occur during the release of the transmitter from the nerve terminal.

834 EFFECTS OF CHRONIC MONOAMINE OXIDASE INHIBITORS ON CENTRAL NORADRENERGIC SYSTEMS. Iain C. Campbell*, Dorothy W. Gallager, Dennis L. Murphy and John F. Tallman. National Institute of Mental Health, Bethesda, MD 20014.

The effects of the monoamine oxidase inhibitors (MAOI) were examined in animals chronically treated with low doses of clorgyline (MAO Type A inhibitor) and pargyline (MAO Type B inhibitor) in a regimen which results in the inhibition of specific MAO forms. Animals treated with clorgyline showed a 25% decrease in the number of β-adrenergic receptors as measured by the binding of 1-[^{3}H]-dihydroalprenolol with no change in the affinity of the receptors. This effect persisted for at least one week following the final dose of clorgyline. By 3 weeks the number of receptors had returned to control levels. Acute clorgyline did not lead to desensitization of β-adrenergic binding. In contrast, chronic pargyline leads to a very small decrease in β-adrenergic binding (approximately 10%) and acute pargyline was without effect. These receptor effects may be corrolated with the differential effects of the inhibitors on norepinephrine (NE) levels. Consistent with desensitization observed in β-adrenergic receptor binding studies, electrophysiological data suggests that α-adrenergic function is also disrupted by chronic pretreatment with MAOIs. Twenty-four hours following the last daily dose of the inhibitor, animals were anesthesized with chloral hydrate and prepared for extracellular recording of the NE-containing cell bodies in the nucleus locus coeruleus (LC). Minimal to nonexistent spontaneous activity of the LC neurons was observed in rats chronically pretreated with MAOI in contrast to control rats (given daily saline injections) whose LC cells displayed the spontaneous firing patterns and rates typical for this region. However following the administration of the α-adrenergic antagonist, piperoxane, in chronically treated rats, a return of spontaneous activity in LC cells was observed. Electrophysiological effects of chronic MAOI treatment are also currently being investigated in a predominantly β-adrenergic postsynaptic region. This data suggests that continuous occupancy of NE receptors by NE in chronic MAOI-treated animals results in the inhibition of NE cell firing and desensitization of NE receptors.

835 COMPARATIVE EFFECTS OF SYNAPTIC STIMULATION ON TYROSINE HYDROXYLASE, DOPA DECARBOXYLASE, AND DOPAMINE BETA HYDROXYLASE ACTIVITIES IN THE SUPERIOR CERVICAL GANGLION OF THE RAT; PHARMACOLOGICAL ANALYSIS OF THE REGULATION OF TYROSINE HYDROXYLASE ACTIVITY. A. Chalazonitis*, P.J. Rice* and R.E. Zigmond (SPON: U.C. Drager). Dept. of Pharmacol., Harvard Med. Sch., Boston, MA 02115

The activities of tyrosine hydroxylase (TH), dopa decarboxylase (DDC) and dopamine beta hydroxylase (DBH) were measured in the superior cervical ganglion 72 h after electrical stimulation of the cervical sympathetic trunk in vivo. Continuous stimulation at 10 Hz for 60 min produced a significant increase in enzyme activity per ganglion (expressed as a percentage of the contralateral unstimulated ganglion ± S.E.M.) of both TH (166 ± 13%) and DBH (156 ± 14%) but not of DDC (105 ± 3%) (n = 12). Stimulation of the sympathetic trunk with trains of stimuli (40 Hz for 250 msec every sec for 60 min)--thus applying the same total number of stimuli as above--produced similar results. TH and DBH activities were increased dramatically (173 ± 9%, 153 ± 16% respectively) and there was a small (110 ± 3%) increase in DDC. These results demonstrate that direct stimulation of the preganglionic nerves innervating the superior cervical ganglion produces a significant increase in TH and DBH activities with little change in DDC activity and suggest that the increase in TH and DBH activities are more responsive to the number of stimuli applied than to the pattern of stimulation.

Nicotinic, muscarinic and α-adrenergic receptors have been implicated in ganglionic transmission. Previous experiments demonstrated that nicotinic blocking drugs, such as chlorisondamine, largely block the increase in TH activity produced by preganglionic nerve stimulation (Chalazonitis and Zigmond, Proc. Soc. Neurosci., 1977). To determine whether muscarinic and/or α-adrenergic receptors are also involved in the regulation of TH activity, animals were stimulated in the presence of appropriate antagonists at doses which block these receptors but do not interfere with nicotinic transmission. Preganglionic stimulation with 40 Hz trains (250 out of every 750 msec) for 90 min produced a similar increase in TH measured 72 h later whether the stimulation was performed in the presence (215 ± 18%; n = 4) or absence (188 ± 21%; n = 5) of atropine sulfate (125 μg/kg/min infused i.v.). In the same manner, stimulation with 40 Hz trains for 30 min produced a similar increase in the presence (156 ± 13%; n = 9) or absence (153 ± 10%) of dihydroergotamine mesylate (3.3 mg/kg injected i.v. prior to the start of stimulation). Therefore, muscarinic or α-adrenergic receptors do not play a major role in the increase of TH activity produced by synaptic stimulation. (Supported by NIH grant NS 12651 and NIH training grant NS 07009).

836 MONOAMINE-CONTAINING STRUCTURES IN THE POSTERIOR SALIVARY GLAND OF THE *OCTOPUS VULGARIS*: FLUORESCENCE HISTOCHEMICAL AND ULTRASTRUCTURAL STUDY. Tanemichi Chiba, Yuji Yaku*, and Makoto Kato*, Dept. Anat., Sch. Med., Chiba University, Chiba 280, Japan.

The posterior salivary gland(PSG) of the *Octopus vulgaris* has been paid attention by some workers due to its high content of monoamines including octopamine and the existence of chromaffin cells. Matus(1971) classified two types of epithelia(named type A and B) and identified a distinct proportion of epithelial cells of type A as chromaffin cells which also exhibited positive formaldehyde induced fluorescence.

The purpose of the present study was to clarify the localization of monoamines in the PSG by a combined histochemical and ultrastructural studies.

Two monoamine-containing structures were identified: one is a network of green-yellowish fluorescent nerve terminals surrounding tubular gland and the other is the glandular epithelial cell with brilliant granular yellow fluorescence. Spectrofluorimetric analyses revealed the existence of dopamine-like spectral pattern (excitation max. 410 μm, emission max. 480 μm and after exposure to HCl vapour for ten second, excitation max. shifted to 380 μm which persisted even after additional ten minutes exposure to HCl vapour) in the former and serotonine-like spectral pattern (excitation max. 410 μm, emission max. 510 μm) in the latter structures.

Monoamine-containing(MA) cell granules in the epithelial layer were found to be argentaffin by Bodian's stain and by Tramezzani-'s silver stain for Epon embedded sections. MA cell granules were PAS negative in contrast to surrounding most exocrine cells which stain in variable degrees for PAS.

After the observation of glyoxylic acid induced fluorescence preparation, the same specimens were processed for electron microscopy. It was confirmed that monoamine containing dense granules(0.5 to 3 μm in diameter) were embedded in the amorphous peripheral zones which were divided into many compartments by the membrane. MA cells extend their processes in both apical and basal portions and the nucleus were located in the basal portion surrounded by well developed rough endoplasmic reticulum and Golgi apparatus. Potassium permanganate seemed to preserve the cell better than glutaraldehyde or formaldehyde.

Most parts of the MA cell surface are covered by the sheath of supporting cells and occasionally axon varicosities were seen to synapse on MA cells.

The present results revealed that MA cells compose neurosecretory complex in the epithelial layer of the PSG suggesting paraneuronic nature of the cell. It is not clear whether MA cells work through endocrine, exocrine or paracrine mechanism.

837 DOPAMINE AGONIST PRETREATMENT ALTERS LSD'S ELECTROPHYSIOLOGICAL ACTION FROM DOPAMINE AGONIST TO ANTAGONIST. Greg R. Christoph* and Barry L. Jacobs (SPON: T.J. Sejnowski). Prog. in Neurosci., Dept. of Psychol., Princeton Univ., Princeton, NJ 08540.

We previously reported that low doses of LSD (25-50 μg/kg i.v.) significantly decreased the firing rate of dopamine-containing neurons in the substantia nigra of chloral hydrate anesthetized rats (Life Sciences, 21, 1585-1596, 1977). These effects were blocked, or reversed, by administration of haloperidol (100 μg/kg i.v.), and were not mimicked by brom-LSD, a peripherally active non-hallucinogenic congener of LSD. These and other electrophysiological data were supportive of the hypothesis, derived from behavioral and neurochemical experiments, that LSD can act as a dopamine agonist in the CNS. In addition, neurochemical experiments measuring dopamine specific receptor binding or synthesis of dopamine sensitive c-AMP indicate that LSD can also act as a dopamine antagonist. The present electrophysiological experiments support such an hypothesis. Dopamine-containing neurons were identified on-line by their firing rate (2-7 spikes/sec), and spike duration (> 2 msec). Histological analysis confirmed that the cells were in the substantia nigra. In contrast to the generally depressant effects of LSD alone, when LSD (50 μg/kg i.v.) was administered to rats whose nigral cell discharge had been reduced by 45% below baseline by d-amphetamine (mean dose = 1.45 mg/kg i.v.), the firing rate increased to within 7% of the original baseline. A second injection of this dose of LSD further increased the discharge rate, to a point 4% above the original baseline. A similar pattern was observed when this dose of LSD was administered to rats whose nigral unit activity had been depressed by apomorphine pretreatment (50 or 100 μg/kg i.v.). Brom-LSD, which shares LSD's dopamine antagonist, but not agonist, properties also produced these reversal effects. Finally, pretreatment with LSD (200 μg/kg i.v.) produced a 250% increase in the dose of d-amphetamine required to produce a 50% decrease in nigral discharge rate. All of these effects of LSD resemble those of classical central dopamine antagonists such as haloperidol. We hypothesize that the shift in LSD's action from that of dopamine agonist to antagonist by prior dopamine agonist treatment may be mediated by a conformational shift in the state of the dopamine receptor. (Supprted by NIMH grant MH-23433).

838 NEURAL INPUTS TO THE SELF-STIMULATION REGION IN THE SULCAL PREFRONTAL CORTEX OF THE RAT: HORSERADISH PEROXIDASE STUDY. Ronald M. Clavier and Charles R. Gerfen*. Dept. Anat., Northwestern Univ. Med. Sch., Chicago, IL 60611.

The prefrontal cortex, dorsal to the rhinal sulcus of the rat has been related to intracranial self-stimulation (ICSS). However, the anatomical substrates specific to this behavior have not been determined. While there is evidence of a causal role in ICSS for efferents from the sulcal cortex (Clavier and Corcoran, 1976), no data exist as to the possible contribution of afferents to this region.

As a preliminary approach to defining the role of sulcal afferents in ICSS, we have examined each of these systematically with the use of the retrograde transport of horseradish peroxidase (HRP). Specifically, 0.08-0.10 µl of 30% HRP (Boehringer) was injected unilaterally via a 30 g cannula over 15 min., using the same stereotaxic coordinates as those used for chronic ICSS electrode implantation. Histochemical reaction was with 3,3' diamonobenzidene or benzidene dihydrochloride (Sigma).

Labelled perikarya were seen consistently within the region of the ipsilateral medial forebrain bundle, rostral to the mesencephalic border. In view of the finding (Lindvall et al., 1978) of an A10 dopaminergic projection to the sulcal cortex, the presently labelled neurons may constitute the rostral aspect of that cell group. Lindvall's group reported A10 cells from the level of the posterior mammilar nucleus to the rostral interpeduncular nucleus after sulcal HRP injections; however, their injections showed possible spread to the caudate nucleus as evidenced by labelling in the substantia nigra (SN). A similar SN and A10 pattern was seen after HRP injections confined to the caudate nucleus (Carter and Fibiger, 1977). In the present study, there was no evidence of SN or caudal A10 labelling. Thus the presumed A10 cells referred to in our study may be distinct from those reported previously.

Labelled neurons were also seen in the dorsal raphe nucleus. These may be responsible for the sulcal serotonergic innervation described by Tassin et al. (1978).

Thalamic inputs to the sulcal cortex included a projection from the mediodorsal nucleus, as well as the ventromedial and parafascicular nuclei. Projections from the locus coeruleus and the amygdala were also seen. Each of these results confirms previous demonstrations that employed orthograde transport or neurophysiological techniques.

Ongoing studies into the possible role of each of the sulcal afferents described herein are discussed.

(Supported by NIMH Grant 1 R01 MH 30296-01).

839 SIMULTANEOUS LOCALIZATION OF LUTEINIZING HORMONE RELEASING HORMONE (LHRH) AND CATECHOLAMINES (CA) IN RAT MEDIAN EMINENCE. C.J. Clayton*, T.H. McNeill and J.R. Sladek, Jr. (SPON. K. Bignall). Dept. Anat., Univ. Rochester, Rochester, NY 14642.

Evidence indicates that CA play a role in the regulation of LHRH. Both substances are found abundantly in the median eminence (ME). In this study a technique for the simultaneous visualization of CA and LHRH in rat ME was used. Also, the distribution of LHRH reaction product in freeze-dried tissue was compared to that found in tissue fixed in Bouin's solution.

Brains from adult male Sprague-Dawley rats were divided midsagittally. Half of each brain was immersed in Bouin's solution, and the remaining half was prepared for simultaneous histofluorescence-immunocytochemistry (McNeill and Sladek, Science 200: 72-74, 1978). To eliminate possible artifacts due to immersion fixation, additional animals were perfused with Bouin's solution. Also, whole brains were prepared by freeze-drying. Primary antisera used were #38 (T.M. Nett) and 4305B (L.A. Sternberger). Staining in the ME was similar with both antisera, and absorption with synthetic LHRH eliminated staining. The distribution of granular reaction product in freeze-dried tissue was similar to that found in perfused and immersed tissue, but granules were more numerous and more distinct in freeze-dried ME.

LHRH reaction product was observed in rostral ME in both the medial and lateral portions of the zona externa. Examination of CA on the same or adjacent section revealed that CA varicosities were located in a zone external to an area occupied by the majority of the LHRH reaction product. Occasional deposits of LHRH reaction product were found in the CA-containing zone, juxtaposed to portal capillaries. LHRH reaction product in the caudal ME was heavily localized in the region of the tuberoinfundibular sulcus, and, unlike the rostral ME, the CA zone was seen to overlap a major portion of the LHRH-containing region. These data suggest immunoreactive LHRH in the ME is better preserved in freeze-dried tissue than in tissue prepared in a more routine manner. Also, the morphological relationship of LHRH to CA differs in rostral and caudal ME in the rat. Supported by Postdoctoral Fellowship HD 05668.

840 MEASUREMENT OF SEROTONIN IN HYPOTHALAMIC NUCLEI WITHIN ADULT RAT BRAIN USING A MODIFIED BRAIN PUNCH TECHNIQUE. Ric I. Cone, Gary A. Davis* and Robert W. Goy. Wis. Reg. Primate Res. Ctr. and Neurosciences Training Program, Univ. Wisconsin, Madison, WI.

Endogenous levels of serotonin were measured in several hypothalamic nuclei within brain tissue from adult male Sprague Dawley rats using the radioisoenzymatic assay developed by Saavedra in conjunction with a modification of the Palkovits brain punch technique. In contrast to results reported by Saavedra and coworkers (1), we found considerably lower values for serotonin within the suprachiasmatic portion of the preoptic area (nucleus preopticus suprachiasmatis) and throughout a major portion of the arcuate nucleus. Levels in other areas of the hypothalamus were similar to those reported by Saavedra et al. Reasons for the differences are not clear, however, our results appear to be more consistent with results based on histofluorescent staining (2;3).

Modifications developed in our laboratory have improved the anatomical specificity of the brain punch technique. Maintaining sections at -10°C on a thermoelectric cold platform (Thermoelectric Unlimited, Inc.) instead of dry ice allows for better recognition of anatomical landmarks by minimizing frost build-up, and preventing disruption of the tissue section due to excessively low temperature during removal of the punched out areas. In addition, a reliable staining procedure for 300 µ thick, unfixed brain tissue has been developed using a modification of the cresyl violet stain. Sections can be processed directly on the slide with cytoarchitectonic resolution equal to 30 µ sections stained with cresyl violet.

841 A MAP OF THE MIDBRAIN DOPAMINE SYSTEMS FOR INTRACRANIAL SELF-STIMULATION (ICSS): A FLUORESCENCE HISTOCHEMICAL STUDY. Dale Corbett* and Roy A. Wise. Dept. Psyc., Cen. Res. Drug Depen., Concordia Univ., Montreal, Quebec, Canada, H3G 1M8

Neurochemical destruction or pharmacological blockade of the brain dopamine (DA) systems results in the dramatic reduction or abolition of ICSS. These data suggest that ICSS from the region of the substantia nigra and certain prosencephalic structures is due to activation of the midbrain DA containing cell groups (A8-A10) or their efferent projections. Several questions still remain regarding the nature of the DA involvement in ICSS. First of all, despite marked anatomical differences among the nigrostriatal, mesolimbic and mesocortical DA systems, it is not known whether all of these systems participate in ICSS. Secondly, the disruption of ICSS by DA receptor blocker or DA lesions may be attributed in certain circumstances to an interference with sensory-motor abilities. Finally, it may be that a DA system located several synapses distal to the ICSS electrode is the critical DA system and not the DA fibers beneath the electrode tip. In order to answer some of these questions the A8-A10 cell groups and their efferent projections were mapped for ICSS using a moveable electrode (Wise, 1976). In 24 of the 50 rats used in this study fluorescent histochemical methods (Battenberg & Bloom, 1975) were employed to verify electrode placements.

ICSS thresholds decreased and response rates increased as electrodes were lowered ventrally towards the A10 cell group as defined by Lindvall and Bjorklund. Electrodes lowered through A10 into the interpeduncular nucleus ceased to support ICSS. The rostro-medial portion of the A9 cell group supported ICSS but only at relatively high current intensities. ICSS was not obtained from the A8 cell group, the caudal portion of the A10 cell group nor from the lateral A9 cell group. In the hypothalamus ICSS sites were distributed along the route of the DA fiber systems. Since these DA fiber systems are in close proximity to one another it is difficult to attribute ICSS to a single system.

These data clearly indicate differences within the DA cell groups with respect to ICSS. The A10 cell group supports ICSS whereas the A8 cell group does not. The present data question the view that the nigrostriatal DA system supports ICSS, since only the rostro-medial portion of the A9 cell group yielded ICSS. While it may be that the higher ICSS thresholds from the A9 region are due to the medial flow of the A9 fibers it is also possible that the ICSS instead results from current spread to the medially located A10 cell group. This latter possibility awaits further investigation.

842 ELECTROPHORETIC CHARACTERIZATION OF MONOAMINE OXIDASE IN CULTURED CELLS WITH A AND B ACTIVITIES. Maria R. Castro Costa*, Morris Hawkins, Jr.* and Xandra O. Breakefield. Department of Human Genetics, Yale University School of Medicine, New Haven, CT 06510.

Two types of monoamine oxidase (MAO, EC 1.4.3.4) activity can be distinguished on the basis of their substrate specificity and drug sensitivity. Using 5-hydroxytryptamine, phenylethylamine and tryptamine with varying concentrations of clorgyline and deprenyl, we have confirmed the presence of both types of MAO activity in living cells, homogenates and crude mitochondria from two cell lines. Rat hepatoma line MH_1C_1 expresses both A and B types of activity, while human sarcoma line Bu25 has predominantly B type activity. MH_1C_1 cells deaminate both 5-hydroxytryptamine (A substrate) and phenylethylamine (B substrate); these activities are blocked by low concentrations of clorgyline and deprenyl, respectively. Deamination of tryptamine (A and B substrate) is inhibited by clorgyline in a biphasic manner corresponding to 80% A and 20% B activity. No metabolism of 5-hydroxytryptamine can be detected in Bu25 cells; deamination of phenylethylamine is inhibited by low concentrations of deprenyl. A monophasic curve of clorgyline inhibition is seen with tryptamine.

Pargyline binds specifically and irreversibly to monoamine oxidase (Chuang et al., J. Biol. Chem. 249:2381, 1974). We have used [3-H]pargyline to label this enzyme in crude mitochondrial preparations from both cell lines. Following binding of [3-H]-pargyline, mitochondrial proteins are solubilized in sodium dodecyl sulfate (SDS) and separated by SDS polyacrylamide gel electrophoresis and isoelectric focusing (Ames and Nikaido, Biochem. 15:616, 1976). The location of labelled proteins is detected by autoradiography via fluorography. Several labelled proteins can be identified and their labelling is blocked by 0.4 mM clorgyline. The migration pattern of these proteins is similar in MH_1C_1 cells with A and B activity and Bu25 cells with only B activity. Thus the presence of A and B types of MAO activity does not appear to correlate with specific protein species.

843 EFFECT OF LOCUS COERULEUS STIMULATION ON REGIONAL BLOOD FLOW IN MICE. Richard L. Delanoy*, Wickliffe C. Abraham, Steven F. Zornetzer, and Adrian J. Dunn. Dept. Neuroscience, Univ. of Fla. College of Medicine, Gainesville, Fla., 32610.

The effects of unilateral locus coeruleus (LC) stimulation on regional cerebral blood flow were examined in mice using [^{14}C] antipyrene uptake as an index of perfusion. Both anatomical and physiological evidences have suggested that the LC is involved in the regulation of cerebral blood flow. This experiment was designed to investigate this association of LC with cerebral blood flow in various regions of unanesthesized, unrestrained mice.

Bipolar nichrome wire electrodes were stereotaxically implanted bilaterally in the region of LC in male Swiss mice. Two to three weeks following electrode implantation, a silastic cannula was inserted into the right jugular vein and threaded into the right atrium of each mouse. On the following day, each mouse was given 10 μCi of [^{3}H]2-deoxyglucose by means of a tubing extension connected to the jugular cannula, and forty minutes later, 1-5 μCi of [^{14}C]antipyrene. Concurrent with the antipyrene injection, the LC was stimulated unilaterally (75 μa, biphasic pulses for 20 sec.). These stimulus parameters were effective in altering behavior in another experimental situation. The heart was stopped with 150 ul of saturated KCl just prior to the termination of stimulation. Each animal was perfused with 0.9% saline and each forebrain hemisphere was dissected into 14 regions, in which radioactivity for both labels was determined individually by scintillation counting. The brainstem was histologically prepared for verification of electrode placement. The ratio of [^{14}C] uptake between the two hemispheres provided an estimation of differences in hemispheric blood flow consequent on LC stimulation. [^{3}H]2-deoxyglucose uptake, which was not temporally associated with LC stimulation, provided a means of normalizing the uptake of [^{14}C]antipyrene. Based on the histology, animals were divided into 3 groups: stimulated in LC (n=10), stimulated outside of LC (n=9), and sham-stimulated controls (n=6).

In no region examined were any changes in cerebral blood flow found due to the electrical stimulation. Furthermore, a comparison of the two hemispheres as a whole revealed that LC stimulation, using this paradigm, had no effect on hemispheric blood flow greater than 4% at a 95% confidence interval. These data will be discussed with regard to the existing literature describing LC modulation of cerebral blood flow.

844 HISTOFLUORESCENCE STUDY OF THE CATECHOLAMINERGIC INNERVATION OF THE AVIAN FOREBRAIN. L. Dubé* and A. Parent (SPON: L.A. Larochelle). Lab. Neurobiol., Fac. Méd., Univ. Laval, Québec,Canada.

The catecholaminergic (CA) innervation of the forebrain of birds was studied in chickens (Gallus domesticus) of 3 days to 1 month of age. Some of the animals were killed by decapitation and their brains processed either according to the Falck-Hillarp paraformaldehyde method (Falck et al., '62), or to the cryostat glyoxylic acid procedure of de la Torre and Surgeon ('76). Other birds were anaesthetized and perfused with a solution containing glyoxylic acid and a high concentration of magnesium ions. The brains of these animals were then processed according to the combined formaldehyde-glyoxylic acid method of Lorén et al. ('76).

In the diencephalon of the chicken, numerous varicose CA fibers are coursing in the lateral hypothalamus, along the medial aspect of the fasciculus prosencephali lateralis (FPL). These fibers give off collaterals to various diencephalic structures. Among those are the dorsomedial and dorsolateral anterior thalamic nuclei and the dorsomedial posterior thalamic nucleus. A very large number of CA varicosities is also found within the hypothalamic periventricular gray, especially at the level of the nucleus periventricularis magnocellularis and of the nucleus tuberis. A well-developed paraventricular organ consisting of numerous, closely-packed, CSF-contacting CA cells is also present along the ependymal wall of the hypothalamus. This cell group also contribute to the CA innervation of the hypothalamus.

In the rostral telencephalon, various structures such as the olfactory tubercle, the nucleus accumbens septi, the lateral septal nucleus and the so-called lobus parolfactorius receive a strickingly massive CA innervation. Numerous very fine CA varicosities also occur in the paleostriatum augmentatum, especially within its dorsomedial portion. In contrast, the paleostriatum primitivum contains only a few scattered varicosities although numerous patches of fluorescent material are present along its medial border, intermingled among the fibers of the FPL. The neostriatum, the ectostriatum and the hyperstriatum ventrale contain few varicose linear CA profiles that are evenly distributed. These linear profiles are much more numerous within the hyperstriatum accessorium and the hippocampal area where they are often lying just beneath the pial surface. In the caudal half of the telencephalon, the number of CA varicosities increases significantly in the neo- and hyperstriatum. In the neostriatum the CA varicosities are closely surrounding the non-fluorescent cell bodies. In the archistriatum, numerous fine CA varicosities are present in the pars dorsalis whereas the pars ventralis contains a large number of serotonin-type varicosities. (Supported by grant MT-5781 of the Medical Research Council of Canada).

845 DEVELOPMENT OF MONOAMINERGIC NEURONS IN THE ENTERIC NERVOUS SYSTEM OF THE CHICK EMBRYO. Miles L. Epstein and Michael D. Gershon, Dept. Anat., Univ. of Wisconsin, Madison,Wi.53706 and Dept Anat.,Columbia Univ., Coll.Phys. & Surg.,N.Y.,N.Y. 10032.

Both 5-hydroxytryptamine(5-HT) and norepinephrine (NE) have been found in neurites in the mammalian enteric nervous system. 5-HT has been found in intrinsic neurons while NE is the transmitter of neurons whose cell bodies lie extrinsic to the gut. In order to understand the role played by various enteric neurons in regulating the development of the system, it is important to know the order of neuronal development and the generality of this order among species. The early appearance of monoaminergic neurites can be detected by measuring the specific uptake of the respective transmitters. We have used the development of transmitter uptake as a means of detecting the appearance of incipient monoaminergic neurons in the enteric nervous system of the chick. Cells taking up 5-HT were detected by radioautography following incubation of embryonic gut in-vitro with ^{3}H-5-HT. Labeling was considered specific if it was prevented by incubation in the cold or in the presence of Lilly 11014 (50 uM). Adrenergic neurites were detected by formaldehyde-induced histofluorescence with and without prior incubation with α-methyl norepinephrine (α-M-NE). Amine uptake was correlated with fine structural observations of the enteric nervous system. Embryos were examined at 7 to 20 days of incubation. Little uptake of ^{3}H-5-HT was found prior to 9 days. At that time, and through day 13, ^{3}H-5-HT was found in cells surrounding myenteric ganglia and within the ganglionic neuropil. After 13 days ^{3}H-5-HT is confined to processes within the enteric nervous system. With the electron microscope, cells can be seen between days 9 and 13 at the periphery of the myenteric plexus apparently extending processes into the plexus. These observations suggest that cells able to take up 5-HT appear in the embryonic chick gut by 9 days and migrate into the myenteric plexus between days 9 and 13. Upon entering the plexus, uptake is observed only in cell processes. In contrast, adrenergic neurites which were rare at first could only be detected by fluorescence in tissue incubated with α-M-NE and not until days 11-12. Endogenous NE was not detected before days 13-14. This study indicates that serotonergic neurons are probably present in chicken as well as in mammalian gut. As in mammalian gut the 5-HT innervation appears before extrinsic adrenergic neurites reach the gut. In adrenergic development the transmitter uptake mechanism precedes detection of endogenous amine stores. The similarity of avian and mammalian enteric ontogeny suggests the pattern may be a general one. Supported by NIH grants #NS12969 and NS07062 and ADAMHA grant DA01772 and Univ. Wisconsin Graduate School grant.

846 RAPHE NUCLEI IN THE RAT: EFFERENT PROJECTIONS TO FOREBRAIN STUDIED USING THE HORSERADISH PEROXIDASE-RETROGRADE TRANSPORT (HRP) METHOD. J. H. Fallon and R. Y. Moore. Dept. of Neurosciences, U. Calif. at San Diego, La Jolla, CA. 92093

The ascending projections of the midbrain raphe nuclei were analyzed in the rat using the HRP technique. Injections (0.04-0.3 µl, 30% HRP) were made into basal forebrain, neostriatum, hippocampus, cerebral cortex or thalamus and HRP reaction product was localized in cell bodies of the nucleus dorsalis raphe (DR), nucleus centralis superior (CS), nucleus reticularis tegmenti pontis (NTP) and nucleus raphe pontis (NRP).

The results of this study demonstrate three principal features of the ascending projections of midbrain raphe neurons. First, DR has the most extensive projection showing heavy labeling after injections into all areas of neocortex, neostriatum, amygdala, piriform cortex, and lateral geniculate nuclei. Heavy labeling in CS occurs principally after injections in cingulate cortex, septum and hippocampus. NTP and NRP show only scattered labeled cells even after very large forebrain HRP injections. Second, although the DR, CS and NRP appear to be single, midline nuclei, they project as paired nuclei. That is, after a unilateral HRP injection, labeling is nearly exclusively found in cells in the half of the nucleus ipsilateral to the injection. Third, raphe efferents contain, in part, an amine-containing system whose distribution is intermediate in organization between the diffuse, widespread ascending and descending projections of locus coeruleus neurons and the highly topographically organized mesotelencephalic dopamine neuron projections (Fallon and Moore, 1978, J. Comp. Neur. 180 (3)). This study was supported by USPHS Grant NS-12080.

847 INTRANEURONAL FLUORESCENCE INTENSITY AS A MEASURE OF NEURONAL ACTIVITY IN THE NUCLEUS LOCUS COERULEUS. Charles Flicker*, Mark A. Geyer, and Arnold J. Mandell. Dept. Psychiatry., Sch. Med., UCSD, La Jolla, CA 92093

The Falck-Hillarp technique for the demonstration of catecholamines can be used as an index of neural activity in the norepinephrine (NE)-containing cells of the nucleus locus coeruleus (LC). Similar microspectrofluorimetric methods have been applied to serotonin-containing neurons of the midbrain raphe (Geyer et al., J. Pharmacol. Exp. Ther., in press) and to the dopaminergic neurons of the substantia nigra (Lichtensteiger et al., Brain Res. 117: 85, 1976).

Two-mm thick slices of rat brainstem are freeze-dried under vacuum for 3 weeks and then treated with paraformaldehyde vapor, which converts NE to a fluorescent derivative. Samples are embedded in paraffin after which sections 8-µm thick are cut on a microtome and mounted on slides. Slides are viewed with a Leitz microscope by red-light phase-contrast at 1150 x in order to align the 5 µm measurement aperture over the cytoplasm of LC cell bodies. Intensity readings are taken by illuminating a 40 µm diameter concentric area with light from a 1000 watt Xenon lamp, at a wavelength of 410 nm. The light emitted by the tissue specimen, filtered with a monochromator to 512 nm, is measured with a photometer.

Drugs that affect NE turnover also alter fluorescence intensity levels in LC. Pargyline, a monoamine oxidase inhibitor which increases NE levels throughout the brain, produces a dose-dependent (25, 50, and 100 mg/kg) increase in intraneuronal fluorescence intensity. Amphetamine, 2.0 mg/kg and 5.0 mg/kg, which increases release and blocks reuptake of NE, decreases intraneuronal fluorescence. Clonidine (30 µg/kg, 100 µg/kg, and 1 mg/kg), an α-adrenergic agonist which depresses LC neuronal activity presumably by activation of presynaptic "autoreceptors" (Svensson et al., Brain Res. 72: 291, 1975), increases LC neuron fluorescence. Piperoxane (0.5, 2.5, and 10.0 mg/kg), an α-adrenergic antagonist which increases impulse flow from the LC (Cedarbaum and Aghajanian, Brain Res. 112: 413, 1976), decreases intraneuronal fluorescence there.

These and related studies suggest that intraneuronal fluorescence intensity in the LC is dependent upon a transmitter pool which is increased by synthesis and reuptake of NE and decreased by release and metabolism of NE, and may therefore be considered a sensitive measure of LC neuronal activity.

This work is supported by DA-00265-07.

848 BEHAVIORAL AND ELECTROENCEPHALOGRAPHIC CORRELATES OF LOCUS COERULEUS NEURONAL DISCHARGE ACTIVITY IN THE UNANESTHETIZED SQUIRREL MONKEY. Stephen L. Foote, Floyd E. Bloom, and Andrew Schwartz*, Center for Behavioral Neurobiology, The Salk Institute, La Jolla, CA 92037. *St. Elizabeths Hospital, NIMH, Washington, D.C. 20032.

Discharge activity of individual locus coeruleus (LC) neurons was recorded extracellularly in the awake monkey. Animals were seated in a chair which allowed arm, leg, and head movements. Well-isolated action potentials were recorded through movable metal microelectrodes. EOG and cortical EEG were recorded simultaneously. Discharge activity was recorded under the following conditions: 1) sequential presentation of an array of sensory stimuli, 2) spontaneous or elicited movement, especially during orienting, 3) periods of 20 min to 1.5 hr with no imposed sensory stimulation, and 4) presentation and consumption of food. A maximum of four microelectrode penetrations was made in each hemisphere to allow unambiguous histological identification of each recording descent. Microlesions were made during the course of each penetration to facilitate accurate localization of recording sites. Unitary action potentials were considered to have arisen from an LC neuron only when the recording site was within the boundaries of the compact portion of the nucleus. LC was defined as encompassing both A4 and A6, the two large norepinephrine-containing neuronal populations in the pons (Hubbard and DiCarlo, JCN, 1973).

LC neurons responded with bursts of increased discharge activity to many auditory and visual stimuli, including the sight of food. During periods with no experimenter-induced sensory stimulation, mean discharge rate (averaged over periods of 5-30 seconds) increased during episodes of EEG desynchronization. When the monkey exhibited behavioral and EEG signs of drowsiness, LC neurons typically slowed to 0.1 to 0.5 Hz. During slow-wave sleep, periods of 5-30 seconds without any discharge activity were common. During these periods of decreased activity, presentation of a stimulus of sufficient strength or novelty to elicit EEG desynchronization and orienting movements usually resulted in a burst of 2-5 action potentials over a period of 200-700 msec. If the stimulus produced sustained alertness, LC neurons typically continued to discharge at 0.2 to 2 Hz until the animal again became drowsy or inattentive.

These preliminary observations suggest that, in squirrel monkey, LC may participate in controlling environmental surveillance. Studies supported by NIAAA Grant AA 03504.

849 CHANGES OF PROTEIN CARBOXYMETHYLASE ACTIVITY IN THE SUPERIOR CERVICAL GANGLION DURING POSTNATAL DEVELOPMENT AND AFTER AXONAL INJURY. G.M. Gilad, C. Gagnon* and I. J. Kopin, Laboratory of Clinical Science, NIMH, Bethesda, Maryland 20014

The activity of protein carboxymethylase (PCM) which catalyses the transfer of a methyl group from S-adenosyl-L-methionine to carboxyl side chains of proteins to form labile protein-methyl esters (Diliberto & Axelrod, Proc. Natl. Acad. Sci., USA, 71: 1701-1704, 1974), was examined in the rat superior cervical ganglion (SCG) and iris during postnatal development. In the SCG, PCM activity, 3.3 ± 0.3 (pmole methanol/10 min per ganglion) at birth, gradually increased reaching adult levels 28.3 ± 3, by the 30th postnatal day; an 8-fold increase which parallels the increase in protein. In the iris, one of the target tissues innervated by SCG neurons, PCM activity, 3.9 ± 0.09 at birth, has increased only about 4 fold , to 12.5 ± 0.75, during development, reaching adult levels by 40 d. The source of PCM activity in the iris is mainly in tissues other than sympathetic terminals, since 10 d after SCG removal, only 15% reduction could be detected in the ipsilateral iris as compared to contralateral controls. One day after postganglionic nerve injury (the nerve was crushed at a distance of about 5 mm from the ganglion) PCM activity has increased to 126% of control within the proximal nerve stump, suggesting an accumulation due to blockade of axonal transport or sprouting. In SCG no change in PCM activity could be detected at that time. However, 5 d after the injury, PCM activity fell to 62% of control, a decrease comparable in magnitude to that seen in the catecholamine synthesizing enzyme tryosine hydroxylase. Death of chromatolytic neurons may have contributed to the observed changes, but this is unlikely, since at 5 d postoperative protein content of the SCG has increased to 123% of control, presumably because of the net increase in (structural) protein synthesis known to occur during chromatolysis and regeneration. We conclude: (a) during postnatal development PCM activity in the SCG is gradually increased with growth to achieve adult levels 30 d after birth: (b) PCM may be localized in neurons of the SCG and transported down their axons; (c) PCM activity is reduced during the reaction to axonal injury as are other enzymes important in neuronal function, suggesting that PCM serves an active role in neuronal function.

850 ESTROGEN DEPENDENT ALTERATIONS IN TYROSINE HYDROXYLASE, GLUTAMATE DECARBOXYLASE AND LORDOSIS BEHAVIOR IN SEPTAL LESIONED MALE RATS CHRONICALLY EXPOSED TO ESTROGEN DURING THE POST LESION PERIOD. J. H. Gordon, D. M. Nance, C. J. Wallis* and R. A. Gorski. Dept. Anat. & Brain Res. Inst., UCLA, Los Angeles, CA 90024.

Septal lesions (SL) in female rats result in an increased sensitivity to the behavioral effects of acute estradiol benzoate (ACUTE-EB; 2 ug/day X 3) as measured by the lordosis quotient (LQ; number of lordotic responses X 100/number of mounts). Intact or castrated male rats do not show an enhanced LQ following ACUTE-EB unless they are chronically treated with 2 ug EB/day for 2-4 weeks immediately following a SL. The present study was undertaken to examine possible neurochemical alterations which could account for the enhanced behavioral sensitivity seen following ACUTE-EB treatment in the SL males chronically treated with EB during the post lesion period (SL-EB). The results of the LQ test (2 months post lesion, 1 month post chronic EB treatment) showed an enhanced response following ACUTE-EB in the SL-EB group (LQ = 44±6, n = 21) compared to that of SL males chronically treated with oil (LQ = 10±5, n = 16) or normal males (LQ = 0±0, n = 20). Six weeks following the LQ test the three groups were subdivided and treated with ACUTE-EB or OIL and decapitated. The brains were removed, frozen and stored at -50°C prior to dissection and assay of enzymatic activities. Tyrosine hydroxylase (TH) activity was assayed in the dopamine (DA) rich areas of the forebrain (striatum, STR; nucleus accumbens septi, ACB; and olfactory tubercle, OLT). The TH activity in the SL-EB given ACUTE-EB was significantly suppressed in both the STR and ACB relative to all other groups. The glutamate decarboxylase (GAD) activity in both the substantia nigra (SN) and ventral tegmentum (VTR) was significantly increased in the SL-EB given ACUTE-EB relative to all other groups. In summary, the SL-EB given ACUTE-EB showed 1) enhanced LQ, 2) decreased TH activity (DA terminals), and 3) increased GAD activity (DA cell bodies). These data correspond to those of SL females given ACUTE-EB which show 1) enhanced LQ, 2) decreased DA turnover, and 3) increased GAD activity, relative to sham animals given ACUTE-EB. Thus, a decrease in DA activity in both males and females is associated with an increased GAD activity in the region of the DA cell bodies (perhaps indicating greater inhibitory tone on the DA cell bodies). Since pharmacological and neurochemical data indicate that dopamine is inhibitory on the display of lordosis, it may be that the SL-EB animals acutely treated with EB have less inhibitory dopamine activity to overcome in order to display lordosis and thus, are capable of showing an enhanced behavioral response to the acute administration of EB. (Supported by HD 01182.)

851 IMMUNOHISTOFLUORESCENCE STUDY OF THE DISTRIBUTION OF EPINEPHRINE IN THE RAT CNS. L. Harvey, G.M.Brown, L. Grota. Dept. Neurosciences, McMaster Univ., Hamilton, Ont., Canada.

There is evidence in the literature that epinephrine (E) is both localized and synthesized within several regions of the CNS. This evidence stems from studies involving assay of E in tissue-punches from various brain regions and from studies on the distribution and activity of its synthetic enzyme phenylethanolamine-N-methyl transferase (PNMT).

In view of the major role played by the other catecholamines (CA) in CNS function, the potential importance of E in the CNS should not be overlooked. Unfortunately the methods currently available for visualizing the CA within nervous tissue (the Falck Hillarp & glyoxylic acid techniques) either work poorly for E or do not adequately distinguish it from norepinephrine. We are reporting an immunohistofluorescence technique which shows possibilities in this direction.

An antibody to synephrine, the mono-hydroxylated analogue of E has been prepared in our lab and has been found to cross-react with E and metanephrine but not with the other CA, including norepinephrine, and their derivatives.

We are now using this antibody in an immunohistofluorescence study of the distribution of E in the rat CNS using a double antibody technique. Rats (200-300 g., male or female) are killed by decapitation and the brains quickly removed onto dry ice. After cooling for 1 - 1½ hr., they are mounted in a cryostat and sectioned at -15°C, 10-12 μ thickness. Sections are picked up onto glass slides pre-cleaned in methanol. Slides are then incubated 30 min. with rabbit antiserum containing antibody to synephrine, washed, fixed briefly in 0.5% w/v paraformaldehyde, washed again, then incubated a further 30 min. with an antibody to rabbit γ-globulin tagged with FITC.

As controls, adjacent brain sections are incubated with normal rabbit serum at the same dilution as that containing the antibody or with antiserum pre-saturated with E.

Consistent staining has been found in several regions of the CNS on slides incubated with antiserum but not on control slides. Among them are several of the hypothalamic nuclei, the nucleus interstitialis of the stria terminalis, nucleus septi lateralis, amygdala, hippocampus, cingulate cortex and cerebellum. These results 1) tend to confirm the distribution of E as reported in the literature, and 2) do not correspond to the distribution of norepinephrine.

852 EVIDENCE FOR β-ADRENERGIC RECEPTORS IN CEREBRAL CAPILLARIES. Timothy J. Herbst*, Marcus E. Raichle and James A. Ferrendelli. Dept. of Pharmacol. and Dept. of Neurol. and Neurol. Surg. (Neurol.), Wash. Univ. Med. Schl., St. Louis, MO 63110.

There is ample evidence that adenylate cyclase is closely linked to or is a component of adrenergic and other receptors in several tissues and that cyclic AMP mediates some of the actions of neurotransmitters at specific receptor sites. Recent data indicate that cerebral capillaries are innervated by CNS adrenergic neurons. In addition, catecholamines and vasopressin modify CNS capillary function. To determine whether cerebral capillaries contain a catecholamine- and/or vasopressin-sensitive cyclic AMP system, we have studied the effects of these compounds and other drugs on cyclic AMP levels in isolated cerebral microvessels.

Microvessels were isolated from rat cerebral cortices by a standard procedure involving disruption of the neuropil, centrifugation through 25% albumin, and filtration on a bed of glass beads. The final tissue fraction, suspended in Krebs-Ringers bicarbonate buffer, contained mostly capillaries and accompanying pericytes, with slight contamination by muscular vessels, but with virtually no neural elements, as confirmed by darkfield or phase-contrast microscopy for each preparation. This tissue suspension was then incubated in the presence of various drugs, and cyclic AMP levels were measured by radioimmunoassay.

Basal levels of cyclic AMP in isolated microvessels were 2 - 3 pmoles/mg protein. Incubation of the tissue with 100 μM norepinephrine (NE) caused a 2- to 8-fold elevation of cyclic AMP levels within 5 min. In contrast, vasopressin (0.02 and 2.0 I.U.) had no effect. The effect of NE was dose-dependent with an ED_{50} of 3 μM. The phosphodiesterase inhibitor 3-isobutyl-1-methylxanthine (40 μM) increased basal levels of cyclic AMP by 50% but did not alter the response to NE. Epinephrine and isoproterenol also elevated cyclic AMP levels in cerebral microvessels, but phenylephrine, dopamine, serotonin and histamine did not. Propranolol (100 μM) completely blocked the response of NE, whereas an equal concentration of phentolamine did not alter its effect.

These results indicate that cerebral capillaries contain a cyclic AMP system which is regulated via β-adrenergic receptors and support the contention that cerebral capillary function is under neural control. The data also suggest that the effect of vasopressin on cerebral capillary function is not directly mediated by a cyclic AMP system.

853 RAPHE UNIT ACTIVITY IN FREELY MOVING CATS: CORRELATION WITH LEVEL OF BEHAVIORAL AROUSAL. Barry L. Jacobs and Michael E. Trulson. Prog. in Neurosci., Dept. of Psychol., Princeton Univ., Princeton, NJ 08540.

Single unit activity (n=51) was recorded from the dorsal raphe nucleus of freely moving cats (n=12) by means of movable 32μ or 62μ dia nichrome wires. Virtually all the cells discharged with the slow regular pattern that characterizes raphe neurons recorded in vivo and in vitro. Across the sleep-waking cycle, these cells displayed a strong positive correlation with level of arousal, as defined by both behavioral and electrographic criteria. From a mean baseline firing rate of 2.82 spikes/sec during quiet waking, the mean discharge rate of these cells phasically increased by 112% in response to an auditory stimulus. This effect rapidly habituated with repeated stimulus presentations. During waking accompanied by movement, unit activity was significantly increased by 22% as compared to quiet waking, but there was no correlation between unit activity and gross body movements. Raphe unit activity showed a significant decrease of 17% during drowsiness (first appearance of EEG synchronization) as compared to quiet waking, and then progressive decreases during the early (-34%), middle (-52%), and late (-68%) phases of slow wave sleep. During all phases of slow wave sleep, the occurrence of sleep spindles was correlated with a significant decrease in unit activity. Raphe unit activity showed decreases of 81% during pre-REM (the 60 sec immediately before REM onset) and 98% during REM, as compared to quiet waking. Unit activity reappeared 3.2 sec before the end of REM, with significant increases in unit activity of 83% and 17% during the first sec and first 10 sec, respectively, as compared to quiet waking. These data, in conjunction with a large behavioral literature, indicate that the role of CNS serotonin may be compensatory to behavioral arousal, and furthermore, that it may play a modulatory, rather than a mediative role in behavioral and physiological processes. (Supported by NIMH grant MH-23433).

854 ONTOGENY OF UPTAKE AND RELEASE OF ^{3}H-CATECHOLAMINES IN BRAINS OF RATS NEONATALLY EXPOSED TO LEAD. Kathryn M. Jason* (Spon: B. Weiss). University of Rochester, Rochester, NY 14627.

In vitro uptake and release studies were carried out in 15 and 35 day old rats that had been exposed to 0, 25, or 75 mg/kg lead acetate on postnatal days 2 through 14 by oral intubation. Striatal and cortical minces were incubated with 10^{-7} M ^{3}H-dopamine (^{3}H-DA) or ^{3}H-noradrenaline (^{3}H-NA), respectively. Lead treatment had no effect on uptake of ^{3}H-NA in the cortex. However, uptake of ^{3}H-DA in the striatum was altered by lead at both 15 and 35 days. At 15 days, less ^{3}H-DA was present in striatal tissue from the high lead group after 5 or 20 minutes incubation, indicating lead-induced changes in the properties of uptake and retention processes. At 35 days, more ^{3}H-DA was present in tissue of the high lead group animals than controls after 20 minutes incubation and may be the result of decreased competition from lower DA levels in that group. Lead treatment had no effect on potassium-induced release of tritiated amines. In the absence of calcium, however, there was a lead-related increase in spontaneous release of ^{3}H-NA from the cortex, resulting in decreased evoked release. Lead may alter intracellular binding sites for NA, or may act to replace the calcium necessary for spontaneous release.

855 CHOLINERGIC, DOPAMINERGIC AND GABA-ERGIC INTERACTIONS IN THE NUCLEUS ACCUMBENS AND GLOBUS PALLIDUS AFFECTING AMBULATORY ACTIVITY. D. L. Jones, M. Wu* and G. J. Mogenson, Dept. Physiol. Fac. Med., Univ. Western Ontario, London, Canada N6A 5C1.

The nucleus accumbens (N.Ac.) receives dopaminergic projections from the ventral tegmental area (VTA) of the midbrain which have been implicated in ambulatory activity. Increased ambulatory activity is produced by injections of amphetamine, L-DOPA or dopamine (DA) into the N.Ac., and destruction of the VTA-N.Ac. pathway attenuates amphetamine stimulated hypermotility. The N.Ac. also receives cholinergic projections and contains cholinergic and GABA-ergic neurons. There is recent evidence of an efferent GABA-ergic projection to the globus pallidus (GP). The following experiments investigated the interaction of cholinergic and dopaminergic synapses within the N.Ac. in the control of ambulatory activity. The experiments also investigated the contribution of the suggested GABA-ergic pathway to the GP to ambulatory activity.

The administration of DA (10 and 20 µg) into the N.Ac. increased ambulatory activity in an open field test. The combined administration of DA and carbachol (cholinergic agonist, 5 and 10 µg) into the N.Ac. elicited an increase in ambulatory activity which was more rapid in onset than that elicited by DA alone. However, the administration of atropine (cholinergic-muscarinic blocker, 5 and 10 µg) together with DA into the N.Ac. did not attenuate the DA-stimulated increase in ambulatory activity. Ambulatory activity was increased when picrotoxin (GABA blocker, 0.225 and 0.75 µg) was administered into the GP. The administration of GABA (2.25 µg) into the GP together with DA into the N.Ac. attenuated the DA-stimulated increase in ambulatory activity.

These data suggest the following conclusions. (1) There does not appear to be a cholinergic interneuron between the N.Ac. - DA neuron and the effector pathway responsible for the DA-stimulated ambulatory activity. (2) Cholinergic synapses within the N.Ac. appear to modulate the DA-stimulated ambulatory activity, perhaps through an inhibitory interneuron. (3) The GP plays a role in locomotor behavior and may be part of the effector pathway. (4) The N.Ac. may communicate with the GP via a GABA-ergic pathway.

856 LOCUS COERULEUS NEURONS IN FREELY BEHAVING RATS EXHIBIT PRONOUNCED ALTERATIONS OF FIRING RATE DURING SENSORY STIMULATION AND STAGES OF THE SLEEP-WAKE CYCLE. G. Jones*, S.L. Foote, M. Segal[1] and F. Bloom. A.V. Davis Ctr. for Behav. Neurobiology, The Salk Inst., La Jolla, CA 92037.

The nucleus locus coeruleus (LC) in the rat is a highly compact group of noradrenergic neurons from which a uniquely divergent efferent system of axons arises. Pharmacological, physiological and behavioral observations have generated many hypothetical functions of these neurons which can best be evaluated in the freely behaving animal. We are currently investigating the changes in discharge rate and pattern in neurons of the unrestrained albino rat LC in relation to three variables: 1) stimulation of specific sensory modalities; 2) spontaneous sleep-wake cycle alterations; and 3) freely occurring behaviors.

Single and multiple cell recordings were obtained from freely moving rats chronically implanted with cortical EEG leads, subdermal neck EMG leads, and a stimulating electrode in the ipsilateral cingulum bundle. As reported by others and confirmed in our preliminary experiments, some LC cells can be antidromically activated from the ipsilateral cingulum bundle; however the most useful criteria we have found for tentative LC neuron identification include their unique spontaneous firing and sensory response patterns. All recordings sites were confirmed by subsequent histology.

Both multi-unit and single unit data indicate that LC neurons exhibit pronounced increases in spike rate from basal resting levels of about one to ten H_z, with a latency usually between twenty and fifty msec. in response to gross auditory or visual stimulation; qualitative tactile stimulation experiments give similar results. Most LC cells showed multi-modal responsivity. The sensory evoked activation was usually followed by a transient absence of spikes with a gradual return to basal rates, over the next 200 to 1000 msec. LC cells showed no obvious correlations with overt motor behavior. Qualitative observations indicate these responses do habituate, usually beginning within five presentations of the same stimulus.

During recordings which persisted throughout sleep waking cycles, discharge rates were highest during the transitions between either slow wave sleep (SWS) and waking (W) or between rapid eye movement sleep (REM) and W, with rate increases preceding the SWS to W transition, but not the REM to waking transition. Spontaneous rates in waking rats otherwise were highest, with only occasional spikes during SWS and virtually no firing during REM.

These preliminary observations indicate the feasibility of testing hypotheses of LC function based upon studies of discharge frequency during manipulations of the freely moving rat. (Supported by NIAAA Grant AA 03504; [1]Weizmann Institute, Rehovot, Israel.)

857 INHIBITION OF THE SYMPATHETIC PREGANGLIONIC NEURONS BY CATECHOLAMINES. K. Kadzielawa. University of Florida, College of Medicine, Dep. Pharmacol. Therap., Box J-267, Gainesville, Fla 32610.

The purpose of this study was to assess the effects of catecholamines: norepinephrine (NE), epinephrine (E), dopamine (DA) and α-methylnorepinephrine (α-MNE) on the activity of the sympathetic preganglionic neurons (SPGN) located in the thoracic (T2-T4) segments of the spinal cord. These neurons are the main central sympathetic output station regulating heart rate and blood pressure.

Experiments were performed on cats anesthetized with a mixture of chloralose and urethane as well as in the cerveau isolé preparation. SPGN were identified with antidromic stimulation of the white rami of the stellate ganglion. The rate of the spontaneous or D,L-homocysteate induced firing of these neurons was analyzed. Catecholamines were applied by means of microiontophoresis from seven barrel micropipettes.

The activity of some of the SPGN was attenuated by NE, E and DA. α-MNE demonstrated a clear-cut, delayed and prolonged inhibitory action on the majority of spontaneously firing neurons and decreased the response to the excitant amino acids (homocystate and glutamate) in some of them. This inhibitory action of α-MNE may contribute to the antihypertensive action of α-methyldopa, which was shown recently to inhibit spinal sympathetic reflexes (Baum, T. & Shropshire, A. T., Eur. J. Pharmacol., 1977, 46, 259-263). Fuxe and his group (Hökfelt, T. et al., Brain Res., 1974, 66, 235-251) have demonstrated a dense net of axon terminals exhibiting PNMT activity in the areas of location of SPGN. Further study will indicate whether E may serve a role of an inhibitory neurotransmitter released from the terminals of descending axons of brain stem neurons.

The early report by DeGroat, W.C. and Ryall, R.W. (Exper.Brain Res., 1967, 3, 299-305) indicated that serotonin demonstrates excitatory action while NE inhibits the activity of some of PGN.

858 IMMUNOHISTOCHEMICAL DEMONSTRATION OF CATECHOL-O-METHYLTRANSFERASE IN MAMMALIAN BRAIN. Gary P. Kaplan*, Boyd K. Hartman and Cyrus R. Creveling*. Depts. of Psychiatry and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110 and Laboratory of Chemistry, NIAMDD, Bethesda, MD 20014.

The immunofluorescent demonstration of catechol-o-methyltransferase (COMT) (EC 2.1.1.6) was obtained in rat liver and kidney and in several areas of rat, chinchilla, and bovine brain. Tissues were fixed for 5 to 10 days in 4% formaldehyde followed by equilibration with a 15% sucrose solution. A specific antiserum prepared against rat liver COMT was used on frozen tissue sections in an indirect immunofluorescent method. Optimal immunofluorescence was obtained after a 48 hour incubation of the tissue sections in a 1:500 dilution of the antiserum, followed by incubation with fluorescein isothiocyanate conjugated anti-rabbit globulin. Controls consisted of sections prepared as described above, with normal rabbit serum replacing the specific antiserum in the first incubation. Control sections showed only trace amounts of non-specific fluorescence.

In the brain, all specific fluorescence was present in extraneuronal cellular elements. Ventricular ependymal cells and cells of the choroid plexus exhibited the greatest intensity of immunofluorescence. Glial immunofluorescence appeared most prominently in large fiber tracts including the corpus callosum and internal capsule. Interfascicular and perineuronal satellite oligodendrocytes as well as fibrous astrocytes were immunoreactive, though immunofluorescence of myelinated axons was not seen. In addition, Bergmann's glial cells in the cerebellum stained brightly for COMT. The presence of small quantities of COMT in neurons cannot be excluded. However, the pattern of localization observed in the extraneuronal elements suggests that this enzyme may function as a barrier to free diffusion of catechol compounds within the central nervous system.

859 SYNAPTIC STRUCTURES IN THE INTERMEDIOLATERAL NUCLEI OF THE THORACIC SPINAL CORD AND THE DORSAL MOTOR NUCLEUS OF VAGUS OF THE RAT, WITH SPECIAL REFERENCE TO MONOAMINERGIC ELEMENTS. Makoto Kato*, Yuji Yaku*, and Tanemichi Chiba (SPON: S. Kawamura). Dept. Anat., Sch. Med., Chiba University, Chiba 280, Japan.

Intermediolateral nuclei(IML) of the thoracic spinal cord and the dorsal motor nucleus of vagus(DMV) were examined by glyoxylic acid induced monoamine fluorescence and electron microscopy. IML and DMV are thought to be the site of localization of preganglionic sympathetic and preganglionic parasympathetic neuronal somata respectively. Both IML and DMV are well known as one of the nuclei which are densely innervated by catecholaminergic neurons and are also known as the final station of the cardiovascular reflex pathway in the central nervous system.

In the present study, synaptic structure was analysed in the following four groups of adult rats. 1) normal control 2) treated with 5-hydroxydopamine 3) treated with 6-hydroxydopamine 4) fixed by 3% potassium permanganate.

In the IML, axon varicosities with flat synaptic vesicles occupied 27.8 ± 1.0% of the total number of axon varicosities in 3,400 sq. μm area. Serial synapses were encountered in some of which the first presynaptic side was identified as catecholaminergic. Catecholaminergic axon varicosities often showed typical synaptic contacts to both dendrites and soma. Fluorescence microscopy revealed that catecholaminergic nerve bundles are seen to extend both laterodorsally and medially from the nucleus.

In the DMV, axon varicosities with flat synaptic vesicles were rarely encountered. Serial synapses were also rare. Catecholaminergic axons were found to be about 12% of total number of axons in 3,400 sq. μm area. The population of catecholaminergic nerve terminals was larger in DMV than in the nucleus tractus solitarius(2.40 ± 0.09%) in accordance with the fluorescence microscopic observations. Most catecholamine neurons(A2) were located in the latero-caudal portion of the nucleus tractus solitarius.

From the present results, it was confirmed that a considerable number of catecholaminergic axons form synapses in both IML and DMV. Modulatory(most probably inhibitory) function of catecholamine neurons to IML and DMV could be suggested as presynaptic and postsynaptic respectively from the present observations.

860 THE BEHAVIORAL EFFECTS OF AMPHETAMINE ARE CORRELATED WITH ITS EFFECTS ON cAMP IN DIFFERENT BRAIN REGIONS. Linda A. Kennedy* and Michael J. Zigmond (Sponsor: B. Dixit). Department of Pharmacology, School of Pharmacy, and Department of Biological Sciences, University of Pittsburgh, Pittsburgh, PA 15260.

In the rat, low doses of amphetamine produce behavioral activity characterized primarily by increased locomotion, while high doses produce stereotyped behavior consisting of intense sniffing and licking in a restricted area of the cage. Both of these behavioral effects appear to result from the release of dopamine (DA) since they are prevented by pretreatment with DA receptor antagonists. The two types of behavioral responses appear to result from the stimulation of dopamine receptors at two different sites in the CNS, locomotion from DA release in nucleus accumbens and stereotypy from DA release in striatum. DA stimulates adenylate cyclase in vitro, and DA agonists have been shown by some investigators to elevate endogenous cAMP levels in vivo. We therefore attempted to determine whether cAMP levels would increase in brain following amphetamine administration and, if so, whether the regional distribution of this increase would correlate with the presumed regional distribution of DA release after low and high doses of the drug. Rats injected with amphetamine were sacrificed 15 min later by 4-sec microwave irradiation (2.5 kW, 2.45 mHz). Striatum and frontal cortex were dissected from the brain and cAMP was measured using a protein-binding assay. Frontal cortex was analyzed since it receives a dopaminergic innervation from the same mesencephalic cell group as nucleus accumbens, but consists of a larger tissue mass. Following 3 mg/kg amphetamine, the concentration of cAMP in frontal cortex was increased by 27% ($p<.01$), while striatal content was unaffected. At 10 mg/kg, amphetamine increased the cAMP content of both frontal cortex (39%, $p<.01$) and striatum (32%, $p<.01$). Treatment with fluphenazine (0.5 mg/kg, s.c.) 30 min prior to amphetamine prevented the cAMP increase induced by 10 mg/kg amphetamine in both brain regions. Additional animals were given identical amphetamine treatments and behavior was monitored 30-60 min later. Rats given 3 mg/kg amphetamine showed an increase in locomotor behavior while rats given 10 mg/kg showed an increase in stereotyped behavior. Both behaviors were blocked by fluphenazine (0.5 mg/kg, s.c.) pretreatment. Thus, locomotor behavior was correlated with elevated cAMP levels in frontal cortex, while stereotypy was associated with elevated cAMP levels in the striatum. Both the cAMP increase and the behavioral effects were blocked by pretreatment with fluphenazine. These findings are consistent with the hypothesis that the two types of behaviors elicited by amphetamine may involve different brain regions. They further suggest that fluphenazine-sensitive elevations in cAMP may be useful as an index of DA release.

861 FLUORESCENCE MICROSCOPIC MAPPING OF SUBSTANTIA NIGRA DOPAMINE SOMATA AND THEIR DENDRITES: RELATION TO DOPAMINE AND NON-DOPAMINE THIONIN-STAINED CELLS IN IDENTICAL VIBRATOME SECTIONS. Haing-Ja Kim and Aryeh Routtenberg. Cresap Neuroscience Lab. Northwestern University, Evanston, Illinois 60201.

Substantia nigra (SN) dopamine cells (A9 group) have been implicated in various behavioral functions including the motor syndrome of Parkinson's disease. Distribution of these A9 cells and their dendritic varicose processes was therefore studied by taking advantage of the formaldehyde-Vibratome fluorescence method (Hökfelt and Ljungdahl, 1972). In order to identify dopamine (DA) cells amongst all SN cells, sections from various coronal levels of SN were first treated for catecholamine fluorescence and subsequently Nissl-stained as described previously (Collier and Routtenberg, 1977). This formaldehyde-Vibratome method successfully demonstrated the fluorescence of both DA cell bodies and their fine varicosity-containing processes in rats pretreated with nialamide (300 mg/kg). That the fine fluorescent varicose processes originate from A9 DA cells was clearly seen in both normal and SN-6 OH DA-treated (with desmethylimipramine pretreatment) material. Comparison of fluorescence and thionin photomicrographs prepared from identical sections disclosed that many fine fluorescent varicose processes seen in the pars reticulata (SNR) were indeed dendritic, as opposed to axonal. In the anterior third of SN, cells which stained with thionin were densely distributed in the pars compacta (SNC), while SNR cells were rather sparse. The majority of those SNC cells were dopaminergic and their ventrolaterally oriented processes formed dendritic bundles. As SN expanded caudally, there was a noticeable increase in SNR cells. SNC-DA cells tended to divide into two subgroups, namely medial and lateral. At the level of the exit of the oculomotor nerve, a considerable number of non-DA cells were observed among the medial SNC-DA cells and immediately below the DA cell layer. At this level, the medial SNC-DA cells could no longer be delineated from A10 DA cells. Those A9 DA cells, however, tended to lie parallel to the transverse course of SNC. Hence, their fine dendritic varicose processes were seen to run first dorsolaterally towards the lateral SNC cells. Some of these processes, then, turned ventrally as if to bathe small non-DA cells, presumably interneurons, which lie below the A9 DA cells. Perforating through this layer of small neurons, these dendritic processes further extended adjacent to the large deeply-stained (Nissl) non-DA cells present in the middle or ventral layer of SNR. The present results thus suggest a close association between the A9 cells and non-DA pars reticulata neurons via the long dendritic varicose processes emanating from A9 DA cells in SNC. (Supported by MH 25281 and NSF 19388 to A. R.)

862 A SERIAL ULTRATHIN SECTION ANALYSIS OF MONOAMINERGIC NERVE FIBERS IN THE SUPERIOR CERVICAL GANGLION OF THE RABBIT. Hisatake Kondo* (SPON: G.D. Pappas). Dept. Anat., Sch. Md., Tohoku Univ., Sendai, JAPAN and Dept. Anat., Coll. Md., Univ. Illinois, Chicago Illinois 60680.

It is known that fluorescent varicose fibers are present in mammalian superior cervical ganglion (SCG). Some authors consider these fibers to arise from the ganglionic SIF (small intensely fluorescent) cells and to make synapses onto the principal neuron, which participate in the generation of slow IPSP. However, this consideration has not been confirmed in electron microscopy. In the SCG of rabbits pretreated with 5-hydroxydopamine, thickened neuronal profiles packed with numerous small granular vesicles (45 nm in mean diameter) characteristic of the monoaminergic nerve fibers were found to make synapses onto principal neurons, mostly on their processes but occasionally on their soma. The proportion of synapses formed by these neuronal profiles to those by cholinergic preganglionic neuronal profiles were about 3:19 in random sections covered about 40,000 μm^2 in which about 15 principal neurons sectioned through the nucleus were present. Monoaminergic neuronal profiles and cholinergic neuronal profiles were frequently enclosed by a common Schwann cell and both formed synapses in series onto a single process of the principal neuron. Occasionally these two neuronal profiles were directly apposed to each other without any membrane specializations. These monoaminergic neuronal profiles survived the preganglionectomy. Five monoaminergic neuronal profiles were followed up to 100 μm in maximum length using 300-500 serial ultrathin sections. Following the thickened vesicle-containing portions (1.0-1.5 μm in diameter and 1.5-2.0 μm in length), the neuronal profiles changed their diameter abruptly into 0.1-0.2 μm and remained thin except for a few thickened portions along their course. The thin portions contained several neurotubules and filaments but few, if any, granular vesicles. No ribosomes were encountered in any of the monoaminergic nerve fibers. They sent no branches and received no synaptic inputs along their course and eventually extended beyond the long series of serial sections. No cytoplasmic processes showing features of SIF cell processes were seen in the present materials.

These results suggest that the monoaminergic nerve fibers are derived not from ganglionic SIF cells but from principal neurons (possibly their axons) and that these fibers are more likely candidates for the generation of slow IPSP than the ganglionic SIF cells.

863 MONOAMINERGIC CORTICAL CIRCUITRY IN AUDIOGENIC SEIZURE-PRONE MICE: A MORPHOLOGIC STUDY. Donald A. Kristt and Mark S. Shirley*. Dept. Pathol., The Johns Hopkins Univ. Sch. Med., Baltimore, Md. 21205.

Audiogenic seizures in DBA/2J mice begin postnatally (pn) and are associated with decreased brain MA levels (mostly norepinephrine, NA). We studied synapses in temporal cortex (TC), presumed primary auditory area, and somatosensory cortex (SC) at 6 dpn, when MA synapses reach (relative) peak numbers. All synapses were counted and depth recorded in 2.5μ panels extending from pia to white matter. Swiss and C57 mice were used as controls. MA synapses were identified with a cytochemical marker, 5OH-dopamine, which produces small granules in MA synaptic vesicles (SGV). MA synapses in TC were decreased in number (3-10% of total vs. 20% in controls) and lacked a specific laminar distribution as seen in DBA-SC and control TC and SC; SC MA synapses were comparable to controls (15-20% of total). In DBA the laminar distribution of all counted synapses was comparable to controls and total number of synapses was within normal limits, in both TC and SC (v. Figs.). Since systemically administered 5OHDA does not mark cortical synapses in older animals, glyoxylic acid induced histofluorescence was used to study 21 dpn (most sensitive to auditory stimuli) and adult (generally resistant) mice. In DBA the number of catecholamine fibers was dramatically reduced in most neocortical fields (caudal > rostral) at 21 dpn,but by adulthood it was comparable to controls. The neostriatum which predominantly receives a dopaminergic innervation, was equivalent to controls at all ages. Hence, there is evidence for abnormal MA (probably NA) cortical circuitry which is apparent by 6 dpn and which persists for several weeks; substantial "recovery" is seen by adulthood. We propose that since MA synapses generally inhibit neuronal excitability, the paucity of MA innervation and synapses in TC (or impaired MA uptake/storage in MA terminals) may play an important role in the susceptibility of DBA mice to audiogenic seizures. 864 **PITFALLS IN ASSESSING BRAIN MONOAMINE METABOLISM IN MAN.** C.R. Lake, M.G. Ziegler* and M.H. Ebert.* NIMH, Bethesda, MD 20014

Abnormal central nervous system (CNS) monoamine neurotransmission is implicated in several neurological and psychiatric illnesses. In an attempt to evaluate the brain activity of some of these amines, lumbar spinal taps are performed and metabolites of the amines measured, often utilizing the probenecid technique. There are several potential sources of error in interpretations of some of these studies. Recently one of these neurotransmitters, norepinephrine (NE), has been measured in cerebrospinal fluid (CSF). Probenecid, used to block active transport of acid metabolites of dopamine (DA) and serotonin (5-HT) from CSF to blood, caused a significant elevation in NE ($p < 0.005$). This implies an effect of probenecid on the synthesis, release, or metabolism of NE itself, and raises a question of the validity of the method when applied to NE or its metabolites.

There is a gradient in CSF of NE which increases 31% from the 1st 4cc out of the lumbar tap needle to the third 4 ml aliquot. However, there is no significant further rise after the 1st 12cc. For comparison of NE levels in CSF, careful control of volumes of CSF removed is required.

There were no differences between CSF levels of NE from the same individuals whether on a low- or high-monoamine diet.

Since NE levels in CSF and plasma correlate positively with age, it is important to control this variable by either age matching or age correction of the NE values.

There is a circadian rhythm in levels of NE in CSF from rhesus monkeys with significantly higher levels from 12 noon to 6 p.m. daily than from 9 p.m. to 9 a.m.

Thus when analyzing CSF for monoamine neurotransmitters or their metabolites, age of subjects, stress factors, time of removal, and volume of CSF removed must be adequately controlled.

865 MONOAMINERGIC PRECURSOR INFLUENCES ON INTERMALE AGGRESSION IN MICE. S. M. Lasley, J. B. Thurmond, and J. W. Brown*. Neuropsychopharm. Program, Univ. of Louisville, Louisville, Ky. 40208

The monoamine precursors L-tyrosine, L-phenylalanine, and L-tryptophan were administered by diet and measures of aggressive behavior, locomotor activity, and endogenous levels of the monoamines and precursors recorded. Male CF-1 mice were maintained on a semi-synthetic 12 percent casein protein diet for 2 weeks, then switched to diets modified by the addition of a 1, 2, or 4 percent L-amino acid supplement, or 0 or 4 percent casein (controls). Measures of aggressive behavior and locomotor activity were obtained before and after the dietary supplements were administered. Resident mice fed high supplements of L-tyrosine displayed a marked increase in the number of attacks on intruders and shorter attack latencies compared to controls, but their locomotor activity was unaffected. High L-phenylalanine supplements, alone or in combination with L-tyrosine reduced the latency to attack and increased motility but did not affect the number of attacks. As a whole, the group of animals fed L-tryptophan showed no changes in aggression or motility. Thus, the dietary regimens, which were designed to enhance catecholaminergic and serotonergic functioning, were found to differentially affect the territorial-induced attacks in mice.

Three days after the second aggression test half the animals in a group were sacrificed for whole brain analyses of norepinephrine, dopamine, serotonin, and the three L-amino acids in order to determine the amount of the precursor available to the monoaminergic neurons and any changes in monoamine concentration resulting from the diet treatment. Dopamine was found to be the most labile amine, increasing significantly with high supplements of tyrosine or phenylalanine and decreasing significantly with high supplements of tryptophan. Brain precursor levels generally reflected: 1) the level administered in the diet; 2) the effect of competitive uptake into the neurons as a result of having a common carrier protein. It appears then that some measures of functional activity (synthesis, turnover) may provide important additional information. (Supported in part by NIMH grant no. MH26677.)

866 DEVELOPMENTAL ORGANIZATION OF SEROTONIN-CONTAINING CELL GROUPS WITHIN THE BRAINSTEM RAPHE OF THE RAT. Pat Levitt* and Robert Y. Moore, Dept. Neurosciences, Univ. Calif., San Diego, La Jolla, Ca. 92093.

Recent autoradiographic and horseradish peroxidase studies from our laboratory (Fallon and Moore, this volume) have indicated that some cells of the fused midline raphe nuclei in the mesencephalon project ipsilaterally to forebrain structures. These same nuclei contain serotonergic neurons. Fluorescence histochemical studies were undertaken to determine whether the serotonin-containing neuron groups extending from the mesencephalon through the medulla develop as bilateral structures, and the time at which the midline cell groups eventually fuse.

A sensitive perfusion-freeze dry technique (Loren, I. et al, 1976, Brain Research 117, 313-318) was used for histochemical analysis of rat fetuses and pups. The procedure does not require drug pretreatment of the animals for the visualization of an intense serotonin fluorophore. Serotonergic cells first fluoresce on embryonic days 12-14 (Olson, L. et al, 1972, Z. Anat. Entwickl. -Gesch. 137, 301-316). At embryonic day 17, all the serotonin cell groups are arranged as paired nuclei. Most of the neurons are tightly packed and their long axis is oriented in a dorsoventral or mediolateral direction. Cell groups B3, B6, and B9 (Dahlstrom and Fuxe nomenclature) remain bilaterally oriented into adulthood, although the neurons become more loosely packed through postnatal week one. Those midline groups which are unpaired in adulthood (B1, B2, B4, B5, B7, B8) fuse in a rostrocaudal gradient. On postnatal day one (P1), the B7 group is completely fused, B8 is partially fused, while the caudal pontine and medullary cells remain paired. On P3, all the midline groups have fused except B1 and B2, which have undergone a partial fusion. The two caudal groups fuse by P6.

The results reveal that all the fused adult serotonergic neuron groups develop as bilateral structures, undergoing a primary migration from the ventricular zone to the midline prenatally, and a secondary migration to form single midline cell groups postnatally. This migration occurs in a rostrocaudal direction, comparable to the gradient of the first observable serotonin fluorescence. The bilateral origins may be maintained in the adult, as expressed by the apparent ipsilateral projections of some of the raphe neurons. Supported by USPHS Grant NS-12080.

867 EFFERENT PROJECTIONS OF THE LOCUS COERULUS. A.D. Loewy and C.B. Saper, Depts. Anat. & Neurobiol. and Medicine, Wash. Univ. Sch. Med., St. Louis, MO 63110

Although different facets of the projections of the locus coerulus (LC) have been studied using autoradiographic, immunohistochemical, and fluorescence histochemical techniques, no attempt has been made to characterize the total efferent output of this nucleus. We have placed small injections of ^{3}H amino acids in and around the LC in rats and after 5 to 7 days survival the brains and spinal cords were processed using the autoradiographic method. Ascending fibers travel primarily through the dorsal noradrenergic bundle to innervate a variety of structures in most respects similar to that described by Jones and Moore ('77). Descending fibers travel in the bundle of Probst in the dorsal part of the reticular formation ventral to the vestibular nuclei and turn ventrolaterally along the medial edge of the spinal trigeminal nucleus to descend further in the ventrolateral medulla. Other labeled fibers are seen in the paramedian reticular formation and raphe magnus nucleus, and immediately lateral to the area postrema and dorsal to the central canal. Descending fibers reach the spinal cord primarily via the lateral funiculus and seem to end mostly in the ventral horn. The projections of the LC correspond with many, but not all, of the dopamine-beta-hydroxylase containing pathways described by Swanson and Hartman ('75). Two notable exceptions are the noradrenergic projections to the supraoptic nucleus of the hypothalamus and the dorsal accessory olive which do not appear to arise from the LC. (Supported by USPHS grant #12751 and American Heart Association grant #77 797)

868 CENTRAL SEROTONINERGIC AND DOPAMINERGIC MODULATION OF RESPIRATORY DRIVE. D.B.A. Lundberg*, G.R. Breese and R.A. Mueller. Depts. Anesthesiol., Psychiat. and Pharmacol., Biological Sciences Research Center, Univ. of North Carolina Sch. Med., Chapel Hill, NC 27514.

Armijo and Flórez have reported (Neuropharmacol. 13:977, 1974) that 5-hydroxytryptophan (5HTP) depresses respiration in cats, and that this effect can be blocked by the inhibition of central aromatic amino acid decarboxylase activity. The present investigations attempted to assess the importance of central serotonin and dopamine containing neurones in the control of ventilation.

Sprague-Dawley rats, 250-300g, were lightly anesthetized with ether to permit tail artery and tracheal cannulation, and were placed in a whole body plethysmograph to permit recording of respiratory rate and depth. Anesthesia was maintained with 0.7% halothane in oxygen.

Graded doses of 5HTP (3.1-25mg/kg, i.p.) in pargyline pretreated rats (50mg/kg 40 min before 5HTP) produced a progressive depression of tidal volume and minute respiration with little change in respiratory frequency. These effects were antagonized by the administration of 10mg/kg methysergide. Pretreatment of newborn rats with 5,7-dihydroxytryptamine and pargyline to selectively reduce CNS serotonin content magnified the degree of respiratory depression produced by 5HTP administration when adult.

Apomorphine (1-10mg/kg, i.p.) produced a dose dependent increase in respiratory frequency and minute ventilation and a slight decrease in tidal volume. Haloperidol (2mg/kg, i.p.) was able to antagonize the apomorphine-induced increase in respiratory frequency. Neonatal treatment with 6-hydroxydopamine to reduce brain dopamine and norepinephrine content produced an increased response to apomorphine when adult.

These results suggest that central dopaminergic and serotoninergic neurones may modulate respiratory activity by influencing the respiratory frequency and tidal volume of ventilation.

869 2-PHENYLETHYLAMINE UPTAKE BY RABBIT RED BLOOD CELLS. Michael F. Mason* and Aron D. Mosnaim. Dept. of Pharmac., Univ. of Health Sciences/Chicago Med. Sch. & Sch. of Grad. and Postdoctoral Studies, Chicago, IL 60612.

2-Phenylethylamine (PEA), a biogenic amine postulated to play a role in central synaptic transmission, readily crosses the blood-brain barrier. Thus, variations in its free plasma concentration could result in significant changes in its brain levels and be ultimately reflected in central adrenergic and/or phenylethylaminergic mechanisms (Non-catecholic PEA's. Marcel Dekker, Inc., New York, 1978). In this work, we investigated the factors governing the PEA content of red blood cells (RBC). Rabbit blood, drawn from the carotid artery into heparin, was centrifuged (220 x g, 15 min.), the RBCs were washed with Ca^{++} free modified Ringer's and resuspended in modified Ringer's. The resultant mixture was incubated (37°C) with varying concentrations of TLC purified ^{3}H-PEA ($1x10^{-9}M$-$1x10^{-2}M$). After incubation, the RBCs were rapidly separated, digested with 70% perchloric acid, decolorized with 30% H_2O_2 and counted. The buffer fraction was also assayed for ^{3}H and ^{14}C. In all the experiments C^{14} sucrose was added as a plasma marker; all values were corrected to hematocrit of 50%. Percent uptake of PEA was relatively constant, 58% of the total recovered radioactivity over the range of 10^{-9} to $10^{-4}M$ (n=86). Lysis occurred at higher concentrations. Uptake was constant at 2', 10' and 30' incubation, showing some decrease at 180'. RBC lysates (freeze-thaw method) exhibited a $conc._{RBC}/conc._{Medium}$ ratio of 1 (n=26). In Na^{+} free medium where the Na^{+} was replaced by glucose, the percentage of recovered radioactivity in the erythrocytes was lowered to about 44% (c_{RBC}/c_{Me}=0.79). Preincubation with $10^{-5}M$ (n=38, 30 min.) iodoacetamide or $10^{-7}M$ 2,4-Dinitrophenol (n=6, 30 min.) had no effect. In a glucose free (sucrose substituted) medium the c_{RBC}/c_{Me} was unchanged. Uptake showed no temperature dependence (6° incubation compared to 37°C). In a similar manner, uptake of ^{3}H-d-amphetamine ($1x10^{-5}M$) was about 60% (n=4). This work suggests that PEA is rapidly taken up into erythrocytes by passive diffusion with a small component of Na^{+} dependent uptake. It also indicates that erythrocytes play an important role in regulating the levels of free plasma PEA. Further studies are necessary to elucidate the possible physiological importance of these findings. Supported in part by NIH General Research Support Grant FR-3566 and by Univ. of Health Sciences/Sch. of Grad. & Postdoc. Studies.

870 NORADRENALINE - ACETYLCHOLINE INTERACTIONS IN BRAIN: BEHAVIOURAL FUNCTIONS. Stephen T. Mason* & Hans C. Fibiger, Dept. Psychiatry, Univ. British Columbia, Vancouver, Canada.

It is well established that a noradrenergic-cholinergic interaction occurs in the peripheral nervous system and biochemical evidence suggests that such may also exist in the central nervous system. To elucidate the behavioural function of this interaction forbrain noradrenaline (NA) was severely depleted by intracerebral injection of 4 micrograms of the catecholamine neurotoxin 6-hydroxydopamine into the fibres of the ascending NA systems in the mesencephalon. The behavioural responses to cholinergic drugs were then assessed. The cholinergic agonists, arecoline and pilocarpine, produced a cataleptic state of behavioural immobility which was almost completely blocked by prior depletion of forebrain NA. The cholinergic blocking agents, atropine and scopolamine, induced locomotor stimulation which was potentiated by NA depletion. This was shown to be muscarinic in nature since the nicotinic antagonist, mecamylamine and the agonist nicotine were not altered in their behavioural actions after NA depletion. It is concluded that a noradrenaline -acetylcholine interaction in the central nervous system may have a behavioural function in arousal processes, with catalepsy at one extreme and locomotor activation at the other.

871 THE RAPID ACTIVATION OF ADRENAL TYROSINE HYDROXYLASE (TH) BY ELECTROCONVULSIVE SHOCK (ECS) AND ITS SUBSEQUENT IN VIVO DEACTIVATION. Joseph M. Masserano and Norman Weiner. Dept. Pharm., Univ. Colo. Med. Center, Denver, CO 80262.

Previous work in our laboratory has demonstrated that various stresses (decapitation, pain, immobilization and cold) will rapidly activate rat adrenal TH. In the present study we have examined the effects of ECS on activation of adrenal TH. Rats were shocked with a 500 mA current applied transorbitally for 0.2 seconds. This produces a consistent tonic-clonic seizure lasting approximately 30 seconds. Following ECS the animals were injected with pentobarbital (60 mg/kg) at various time intervals and the adrenals were removed surgically under anesthesia to avoid adrenal TH activation by decapitation. Approximately an 80% activation of TH was obtained at 5 minutes following ECS By one hour TH activity had decreased to 20% above control values. There was a ten-fold increase in adrenal medulla cyclic AMP twenty minutes following ECS, which rapidly declined to near control values by one hour. ECS also produced an increase in the proportion of cyclic AMP-independent protein kinase in the adrenal medulla, which slightly preceded the maximal increase in cyclic AMP. It thus appears that the activation of adrenal TH following ECS occurs rapidly and is maintained for a period of about one hour in vivo. These results suggest a possible association of tyrosine hydroxylase activation with activation of cyclic AMP-dependent protein kinase.

This research was supported by USPHS grants NSO7927, and NSO9199.

872 THE DEVELOPMENTAL COURSE OF THE RAT BLOOD BRAIN BARRIER To RO 4-4602 Clyde B. Mathura, John Marshall*, William C. Curtis* and Henry Mitchell* Dept. Psych. Howard University, and Dept. Chem., UDC, Washington, D.C. In an effort to determine the developmental course of the blood-brain-barrier to the penetration of a peripheral DOPA decarboxylase inhibitor, 4 and 10-day old rat pups were injected intraperitoneally with either RO 4-4602 (50 mg/kg) or saline in equal volumes. At 60 min. after injections, the animals were immersed in liquid CO2 and their brains excised under near freezing conditions. Whole brains were analysed for the measurement of nanogram quantities of the acidic metabolites of dopamine, homovanillic acid (HVA) and dihydroxphenylacetic acid (DOPAC). A combined GC- Mass Fragmentography assay technique (Karoum, et al.,1975) was used. The technique involved sequential HCL and ethyl acetate extraction, evaporation under N^2, methylation in lipopure methanol, derivatization of the acidic methabolites, and finally the Me/PFP derivative being injected into the apparatus, a Finnigam Model 3000 D Quadropole GC- Mass Spec employing an 8ft 1/8 inch i.d. 3% SE-54 steel column.
Preliminary data have shown both HVA and DOPAC levels to be significantly reduced in the 4 day-old but not in the 10 day-old pups. It appears as though the 4 day-old blood brain barrier is not selectively inhibiting the activity of the enzyme. Additional data on differential regional permeabilities and other developmental age periods will also be reported.
These preliminary findings have implications for the use of L-DOPA as a precursor to dopamine in providing purely central effects in the developing brain. The use of pharmacological tools (e.g. L-DOPA+RO 4-4602) established with adult animals is not readily applied to developing animals because of the immature blood brain barrier.

873 STRAIN DIFFERENCES IN RAT ADRENAL BIOSYNTHETIC ENZYMES AND STRESS INDUCED INCREASES IN PLASMA CATECHOLAMINES. R. McCarty, G.M. Gilad, V.K. Weise* and I.J. Kopin. Laboratory of Clinical Science, NIMH, Bethesda, Maryland 20014.

In an earlier study (McCarty and Kopin, Physiol. Behav., 1978), we compared the changes in plasma norepinephrine (NE) and epinephrine (EPI) of 5 normotensive rats strains following exposure to 5 min of footshock stress. The most reactive strain (Wistar-Kyoto, WKY) and the least reactive strain (Brown-Norway, B-N) were selected for additional study. A catheter was inserted into the tail artery of each rat to allow for repeated sampling of blood in conscious, unhandled rats. Two days later, basal plasma levels of NE and EPI did not differ between the two strains. However, following footshock stress, plasma levels of NE and EPI were twice as high in WKY rats as in B-N rats (Table).

Enzyme activities and catecholamine (CA) content of the paired adrenals of unstressed rats of the two strains were also examined. Activities (nmoles product/pair/hr) of tyrosine hydroxylase (TH) and dopamine-β-hydroxylase (DBH) but not phenylethanolamine-N-methyl transferase (PNMT) were significantly higher in B-N rats. In addition, the adrenal content of NE but not EPI was higher in the B-N strain (Table).

The adrenal catecholamine biosynthetic enzyme activities and CA content of these two strains were inversely related to the plasma NE and EPI levels during stress. These results suggest prominent strain differences in the rate of release of CA from the adrenal medulla and/or the rate of removal of CA from the circulation.

874 COMPARATIVE CATECHOLAMINE-NEUROPHYSIN MORPHOLOGY IN THE RAT SUPRAOPTIC AND PARAVENTRICULAR NUCLEI. Thomas H. McNeill and John R. Sladek, Jr. Dept. of Anatomy, Univ. Rochester, Rochester N.Y. 14642

The correlative morphological distribution of catecholamine (CA) varicosities and peptide-containing (oxytocin, vasopressin) perikarya in the supraoptic (SON) and paraventricular (PVN) nuclei of the rat was examined using a simultaneous histofluorescence-immunocytochemical technique. This technique allows for the simultaneous visualization of peptides and neurotransmitters in either the same section or in adjacent sections of a single tissue block. Six adult male Wistar rats (250-300gm) were prepared for simultaneous histofluorescence-immunocytochemistry following the technique of McNeill and Sladek (Science 200:72-74, 1978). Immunocytochemical analysis for peptide-containing perikarya employed antisera generated against bovine neurophysin I (NP)(provided by Dr. E. A. Zimmerman).

Only a few NP-containing perikarya appeared to be contacted by CA varicosities in the rostral SON. The heaviest innervation of CA varicosities was seen ventral to the nucleus in a zone occupied by NP-containing processes. In contrast, almost all NP-containing perikarya in caudal SON appeared contacted, often by varicosities which completely surrounded perikarya. The densest concentration of CA varicosities in the PVN was located periventricularly in the parvicellular portion of the nucleus. Periventricularly located immunoreactive perikarya were contacted by numerous CA varicosities in this part of the PVN. Some perikarya in the magnocellular portion of the PVN also were contacted by CA terminals. Many cells which did not stain positively for NP were ringed by CA varicosities in the magnocellular portion of the nucleus.

These data suggest that the major CA innervation to the SON and PVN do not coexist with the major distribution of magnocellular perikarya. It may be suggested that CA influences of PVN neurons may be via an axodendritic mechanism or possibly a parvicellular interneuronal pool. Evidence is also presented that suggests that a possible subcompartmentalization of the SON for CA-peptide interrelationships may exist. Investigations using specific vasopressin antisera are currently underway and will be presented.

875 BRAIN-STIMULATION REWARD ASSOCIATED WITH THE VENTRAL TEGMENTAL AREA IS ATTENUATED BY MICROINJECTIONS OF SPIROPERIDOL INTO THE NUCLEUS ACCUMBENS BUT NOT INTO PREFRONTAL CORTEX. G. J. Mogenson, M. Wu* and M. Takigawa*. Department of Physiology, University of Western Ontario, London, Canada.

Brain-stimulation reward was observed with electrodes in the ventral tegmental area (VTA) confirming previous findings. The role of dopaminergic neurons, which project from the VTA to the nucleus accumbens septi and the medial prefrontal cortex, was investigated by injecting spiroperidol, a dopamine antagonist, into these two forebrain sites while rats were self-stimulating the VTA. Injections of spiroperidol (1 µg in 1 µl) into the ipsilateral nucleus accumbens significantly attenuated self-stimulation of the VTA compared to microinjections of the drug vehicle. In most animals self-stimulation was reduced 1 or 2 min after the injection and was completely suppressed for 5 to 10 min; the total number of responses for brain-stimulation reward was reduced by more than 50 per cent during a 15 min test period. Spiroperidol injected into the contralateral nucleus accumbens, as a control for possible motor or non-specific effects, did not reduce self-stimulation of the VTA. These observations provide additional evidence that dopaminergic (A_{10}) neurons projecting from the VTA to the nucleus accumbens contribute to brain stimulation reward. Spiroperidol (1 µg in 1 µl) microinjected into the ipsilateral or contralateral medial prefrontal cortex did not reduce self-stimulation of the VTA. There was also no reduction in rate of VTA self-stimulation when the dose of spiroperidol into the ipsilateral and contralateral prefrontal cortex was increased to 2 µg (in 1 µl). These observations appear to be inconsistent with previous studies implicating dopamine in self-stimulation of the medial prefrontal cortex and additional investigation is needed to clarify the discrepancy. (Supported by the Medical Research Council of Canada)

876 LOCUS COERULEUS STIMULATION POTENTIATES PURKINJE CELL RESPONSES TO AFFERENT SYNAPTIC INPUTS. Hylan C. Moises, Barry Waterhouse, and Donald J. Woodward. Dept. Cell Biology, Univ. Tx. Health Sci. Ctr., Dallas, Tx. 75235.

We previously reported that excitatory and inhibitory responses of rat cerebellar Purkinje (P) cells, produced both synaptically and by microiontophoresis of putative amino acid neurotransmitters, are enhanced during norepinephrine (NE) iontophoresis. Moreover, it was shown that NE, released synaptically during activation of the noradrenergic pathway from the locus coeruleus (LC) to cerebellum, can modulate P cell responsiveness to iontophoretic applications of gamma aminobutyric acid, the basket and stellate cell neurotransmitter. In this study, we examined whether endogenously released NE could exert similar modulatory effects on P cell responsiveness to afferent synaptic inputs. Inputs to the Purkinje cell were activated by suprathreshold current stimulation (3 shocks at 500 Hz with 1-3 sec repetition rates) of the rat sensorimotor cortex and mossy or climbing fiber responses recorded extracellularly using glass micropipettes. Post-stimulus time histograms were used to quantitate the response evoked by an input when tested before and at various time intervals after preconditioning stimulation of the LC. Climbing fiber (CF) and mossy fiber (MF) evoked excitations and pure, "off beam" inhibitions were tested in 28 neurons following cerebral cortical stimulation. In 8 of 11 cells, complex spike excitations evoked by activation of CF inputs were increased (from 0.90 spikes/stimulus to 1.24 spikes/stimulus) when preceded by an LC conditioning stimulation (3 shocks of 0.1 msec duration at 100 Hz) intensity determined to be subthreshold for directly affecting P cell discharge. In 4 of 7 neurons, subthreshold LC stimulation enhanced simple spike excitations (from 0.74 to 0.88 spikes/stimulus) elicited via MF afferent input. Post-excitatory inhibitions observed after simple and complex spike excitations of the P cell were also augmented by LC stimulation in 6 of 6 and in 6 of 9 cells examined, respectively. In 5 additional neurons, pure inhibitory responses evoked by cortical stimulation, presumably mediated via MF activation of the local cerebellar inhibitory interneurons, were greatly potentiated in both duration and magnitude when preceded by LC stimulation at currents which alone elicited no depression of spontaneous discharge. Typically, this facilitating influence of LC activation on all inputs was observed when conditioning was applied 100-400 msec prior to a cerebral cortical stimulation. Stimulation in areas outside LC did not alter in 2 cells and reduced evoked synaptic responses in 3 cells. These data suggest that tonic noradrenergic input may act to facilitate the transmission of excitatory and inhibitory afferent inputs to P cells in the cerebellar cortex. (Supported by NSF BNS77-00174 to DJW).

877 EFFECT OF CHOLINERGIC AGENTS ON CATECHOLAMINE TURNOVER IN HYPOTHALAMIC REGIONS. William W. Morgan. Dept. Anat., Univ. Texas Hlth. Sci. Ctr., San Antonio, TX 78284.

Adult Sprague-Dawley female (150-175 gms) or male (130-170 gms) rats were treated with intraperitoneal (i.p.) injections of physostigmine sulfate. Because of the short term action of this compound, physostigmine was given at hourly intervals for a total of 1 to 4 hours. Control animals received a comparable number of saline injections. In all studies the rats were sacrificed by decapitation between 15:30 and 17:30. The brain of each animal was rapidly removed and immediately frozen on dry ice. The anterior hypothalamus, arcuate-median eminence and anterior telencephalon were subsequently dissected from each brain using clearly defined anatomical landmarks. The remaining brain was discarded. The contents of noradrenaline (NA) and dopamine (DA) in these areas were determined with a highly sensitive radioisotope-enzyme assay or a spectrofluorometric procedure. The decline in the content of these amines 1, 2 or 4 hours after the administration of alpha methyl-paratyrosine (αMPT, methyl ester; 250 mg/kg; i.p.) was used as an indirect method of measuring NA or DA turnover. The levels of these two amines were expressed as nanograms NA or DA per tissue or per mg protein before statistical evaluation by the analysis of variance. In male rats physostigmine (1 mg/kg) produced a statistically significant increase in NA turnover in the anterior hypothalamus within 1 hour ($p<0.05$). Statistically greater increases in NA turnover in this brain area were observed after 2 ($p<0.005$) or 4 hours of physostigmine treatment ($p<0.001$). Dosages of physostigmine of 0.5 mg to 1.0 mg per hour were equally effective. The effect of physostigmine (1 mg/kg) adminisitered for 1 or 2 hours was not blocked by atropine sulfate (40 mg/kg) given 30 minutes before the first injection of physostigmine. On the other hand, mecamylamine HCl (10 mg/kg) also given 30 minutes before the first dosage of physostigmine (1 mg/kg) blocked the effect on NA turnover in the anterior hypothalamus. Dopamine turnover in the anterior hypothalamus and the content and turnover of NA and DA in the other two brain areas were not affected by physostigmine treatment or by mecamylamine or atropine. Noradrenaline turnover was increased in the telencephalon of female rats after 4 hours of treatment with physostigmine (1.5 mg/kg), a dosage which was frequently fatal to male rats of the same weight. The data suggest that the activity of noradrenergic neurons with terminals in the anterior hypothalamus are particularly sensitive to cholinergic input probably via nicotinic receptors. Supported by NSF Grant #PCM 76-03876 and Research Scientist Development Award # 5 K02 MH00028-03.

878 CHANGES IN CATECHOLAMINE UPTAKE IN BRAIN AREAS OF THE SPONTANEOUSLY HYPERTENSIVE RAT. M.M. Myers*, E. Sukiennik and E.D. Hendley (SPON: G.D. Webb) Dept. Physiology and Biophysics Coll. Med., Univ. Vermont, Burlington, VT 05401.

The functional activity of catecholamine(CA) neurons in the central nervous system is thought to be involved in the processes responsible for central regulation of blood pressure. A number of workers have considered the possible relationship between alterations in these CA pathways and hypertension. Most research has concentrated on differences in amine content or enzyme activities in brain stem areas known to be associated with blood pressure regulation between the Spontaneously Hypertensive Rat(SHR) and the normotensive Wistar Kyoto(WKy). In a previous report we found that norepinephrine(NE) uptake in the cerebral cortex was greater in the SHR and suggested that these changes may be related to the behavioral hyperactivity which was found in the SHR(Fed.Proc. 36: 1047, 1977). In the present study we have further characterized the changes in CA uptake in three brain areas known to receive innervation from either NE neurons(cerebellum), dopamine(DA) neurons(striatum), or both NE and DA(anterior cingulate-frontal cortex).

Rates of both NE and DA uptake were measured in sucrose homogenates prepared from all three brain areas in 5 pairs of 6-8 week old SHR and WKy males. Homogenates were incubated for 4 min at 37°C in Krebs-Ringer bicarbonate buffer with either 80nM ^{3}H-NE or 80nM ^{3}H-DA. The rate of uptake into NE neurons was defined as the difference between NE accumulation with and without 400nM desmethylimiprimine(DMI). Uptake into DA neurons was measured as the difference in DA accumulation in the presence of 400 nM DMI minus the accumulation not blocked by 40uM cocaine.

In the cerebellum where no significant DA accumulation could be measured, the rate of NE uptake was greater in the SHR which is in agreement with our previous findings in the cerebral cortex. In contrast, DA uptake decreased in the striatum of the SHR. Consistent with these results, NE uptake was increased and DA uptake decreased in the anterior cingulate-frontal cortex of the SHR with the ratio of NE to DA uptake being about 50% higher in the hypertensive animals.

These data show that in the SHR 1)there are alterations in CA pathways projecting to areas of the brain not usually associated with blood pressure regulation, and 2)that although changes in both NE and DA uptake can be demonstrated they are in opposite directions such that the ratio of NE to DA uptake within an area is a more sensitive measure of the CA change than either measurement alone.

Supported by a Grant-In-Aid from the Vermont Heart Association and USPHS grant R01-25811.

879 CENTRAL CATECHOLAMINES (CAs) IN GENETICALLY OBESE MICE (obob): EVIDENCE FOR A RESERPINE (RES)-RESISTANT POOL. R. Olsauskas*, J.E. Comaty*, A.J. Vazquez, and G.A. Oltmans. Dept. Pharm., Chicago Med. School, Chicago, IL 60612.

Genetically obese mice (obob) have significantly higher levels of brain norepinephrine (NE) than their lean littermates (Lorden et al., Br. Res., 131:162, 1977). The effects of pharmacological manipulation of central CAs have not been studied in the obob. We administered saline (SAL), RES, or RES and α-methyl-para-tyrosine (α-MPT) to obob and lean littermate controls. Hypothalamic (HT) and telencephalic (TEL) NE and dopamine (DA) levels were measured after drug treatment. Although RES (2.5 mg/kg, 40 and 16 hours prior to sacrifice) reduced NE levels in the HT and TEL areas of obob, NE levels remained significantly higher than in lean controls. To determine if this persistent NE excess was newly synthesized NE, the tyrosine hydroxylase inhibitor α-MPT (300 mg/kg, 4 hours prior to sacrifice) was combined with the RES treatment. Although significant additional decreases in DA levels were produced in the areas studied (indicating that α-MPT treatment was effective in inhibiting tyrosine hydroxylase), this latter treatment did not decrease obob brain NE content to control levels. Data for the HT sections are presented in the following table ($\bar{X}$, μg/g±S.D.):

Group	Amine	SAL	RES only	RES + α-MPT
obob	NE	2.315±.248*(n=6)	.131±.038*(6)	.115±.043*(6)
lean	NE	1.930±.214 (10)	.066±.041 (9)	.050±.021 (10)
obob	DA	.634±.047 (6)	.082±.024 (6)	.034±.021**(5)
lean	DA	.671±.090 (10)	.090±.057 (10)	.038±.015**(10)

*Differs from lean, p <.01 **Differs from RES only, p <.01

In general, drug effects in the TEL paralleled those in the HT. These results indicate that in obob there is a reserpine-resistant NE pool. This pool may be the result of tighter vesicular binding of NE in the obob. The results provide additional evidence for the presence of an altered central CA function in the obob. Such abnormal CA function might contribute either directly or indirectly to the abnormal characteristics of the obob such as impaired thermoregulation, overeating, and altered pituitary function. We are currently studying the relationship of the central CAs to several of these abnormalities. (Supported by NIH grant 1RO3MH30179 and RR-05366).

880 PLASMA CATECHOLAMINES IN GOLDBLATT DOGS. Juan Parra*, A. James Blair, Jr.*, Marla Huber-Smith*, William Boyle*, Daisy S. McCann, Dept. Med., Wayne County Gen. Hosp., Eloise, Mi. 48132 and U.of Mich., Ann Arbor, Mi. 48104.

Cause and effect relationships between catecholamines and essential hypertension remain tenuous. Large amounts of norepinephrine (NE) or epinephrine (E) released from a tumor are the etiological agents for hypertension due to pheochromocytoma. Central nor-adrenergic and/or dopaminergic tracts have been implicated in the initiation, but not maintenance, of many experimental hypertension models including the Goldblatt dog, DOCA-Na induced hypertension and genetic animal hypertension. High plasma NE levels have been associated with high renin, but not normal or low renin, hypertension in humans.

We followed the pattern of plasma NE and E levels in one kidney Goldblatt dogs. Base levels obtained prior to nephrectomy, for the parameters studied were: mean blood pressure (MAP) 92 ± 2.0*; heart rate 103 ± 4; plasma NE 219 ± 25 pg/ml; E 122 ± 20 pg/ml; aldosterone 94 ± 6 pg/ml; plasma renin activity (PRA) 2.0 ± 0.1; serum sodium (Na^+) 145 ± 1.3 meq/l; plasma potassium (K^+) 4.6 ± .8 meq/l.

Of six dogs submitted to unilateral nephrectomy, 2 served as controls in whom the Goldblatt clamp was applied but not tightened; the remaining 4 developed chronic hypertension within 3 days after blood supply to the remaining kidney was reduced. The chronic MAP increase ($p<.001$) was accompanied by a chronic, statistically significant increase in NE ($p<.05$). PRA and aldosterone rose sharply immediately after application of the clamp. Both gradually returned to normal levels over the next two weeks. Pulse rate after an initial drop, rose over a two week period to stabilize at 118 ± 1 ($p<0.01$). Chronic E values did not change significantly; K^+ and Na^+ remained stable throughout the eight weeks of the study.

The data supports the concept that NE has a role to play in the development and possibly maintenance of hypertension in the Goldblatt dog.

881 NEUROANATOMY OF CATECHOLAMINERGIC SYSTEMS IN RHESUS MONKEY AND MAN. J. Pearson, L. Brandeis* and M. Goldstein. Dept. Path., Sch. Med., NYU Med. Ctr., New York, N.Y. 10016.

An antibody to tyrosine hydroxylase isolated from a human pheochromocytoma is being used with the peroxidase-anti-peroxidase immunohistochemical technique of Sternberger to map distribution of simian and human catecholaminergic neuronal perikarya and fiber tracts. Cell bodies of dopaminergic and adrenergic neurons consistently stain with greater intensity than those of noradrenergic neurons. Antibodies against other catecholamine synthetic enzymes further increase precision in neurotransmitter identification.

Catecholaminergic fibers extend backwards above the anterior part of the corpus callosum to enter superior parts of the frontal cortex. Other fibers and neurons are present in limbic cortex associated with olfactory tracts. Clustered terminals are found in the tracts. TH fibers from substantia nigra form dense bundles in the globus pallidus before spreading diffusely within the caudate and putamen. Others form a layer external to the putamen. There are periventricular and supraoptic aggregates of small TH positive neurons. Hind brain fiber tracts are clearly shown as are noradrenergic and adrenergic nuclear groups.

Dimensions and neuronal population densities of the stained structures are being determined for rhesus monkey using serial sections cut in three planes.

Knowledge of catecholamine neuroanatomy in man is crucial to the understanding of neurologic disease. A survey of the neuropathology of a variety of conditions has been initiated. Sympathetic ganglia in familial dysautonomia have approximately 90% reduction in neuron population yet present normal TH activity per ganglion by biochemical methods. TH immunohistochemistry indicates an abnormally high proportion of TH rich neurons which stain more intensely than in controls. Differential survival of a select neuronal population or functional hypertrophy of persistent neurons may occur. Increase in neuron size supports the latter possibility.

882 ANTAGONISM BY UPTAKE INHIBITORS OF α-METHYL-m-TYROSINE DEPLETION OF EPINEPHRINE, NOREPINEPHRINE AND DOPAMINE BUT NOT SEROTONIN IN RAT BRAIN. Kenneth W. Perry* and Ray W. Fuller. Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN 46206.

Epinephrine (E), norepinephrine (NE) and dopamine (DA) were measured in rat brain regions by a high pressure liquid chromatographic method with electrochemical detection [Biochem. Pharmacol. 26, 2087 (1977)]. E was detected in hypothalamus, midbrain and brain stem but not in the cerebral hemisphere. All three of the catecholamines (CA) were depleted by α-methyl-m-tyrosine (100 mg/kg, s.c.) at 6 hrs after injection. DA depletion was greater in the cerebral hemisphere (60% depletion) than in other regions, while the depletion of NE (80%) and E (50%) was about the same in all regions. The CA depletion after α-methyl-m-tyrosine (αMMT) injection was antagonized by pretreatment with various CA uptake inhibitors but was not completely prevented. Administration of an uptake inhibitor 6 hrs after αMMT injection, a time when the catecholamines were already depleted, partially reversed the depletion. However, serotonin depletion by αMMT was not altered by pretreatment with fluoxetine, an inhibitor of uptake into serotonin neurons. Apparently part of the CA (but not serotonin) depletion after αMMT injection is due to the action of amine products (α-methyl-m-tyramine and metaraminol) that enter the neuron *via* the membrane pump and whose presence within nerve terminals is maintained by the uptake pumps. Since metaraminol (MA) is localized primarily in NE neurons and α-methyl-m-tyramine (MTA) in DA neurons [Dorris & Shore, J. Pharmacol. Exp. Ther. 179, 10 (1977)], a NE uptake inhibitor would be expected to decrease MA concentration in rat brain after αMMT injection whereas a DA uptake inhibitor would be expected to decrease MTA concentration. MA & MTA were measured by high pressure liquid chromatography with fluorometric detection [Perry & Fuller, Society for Neuroscience Abstract #809, vol. III, p. 256 (1977)] 6 hrs after administration of αMMT alone or in combination with mazindol, a CA uptake inhibitor. Mazindol decreased MA concentration in brain by 90% but decreased MTA concentration only 20%, indicating that it inhibited uptake into NE neurons more than into DA neurons. This finding agrees with the order of selectivity for mazindol in antagonizing the depletion of CA by αMMT, which was NE>DA>E. Other uptake inhibitors studied and their order of selectivity were: desipramine, NE>E>>DA; imipramine, E>NE>>DA: nortriptyline, NE>E>>DA; and amitriptyline, E>NE>>DA. These studies show that αMMT is a useful tool for evaluating the selectivity of CA uptake inhibitors in vivo.

883 LITHIUM PREVENTS DEVELOPMENT OF DOPAMINE RECEPTOR SUPERSENSITIVITY. Agu Pert, Jack E. Rosenblatt*, Candace B. Pert and William E. Bunney, Jr. Biological Psychiatry Br., NIMH, Bethesda, MD 20014.

Long-term treatment of rats with haloperidol produces an increased sensitivity to the locomotor and stereotypic effects of apomorphine (APO). This behavioral dopaminergic supersensitivity is also accompanied by increased [^{3}H]spiroperidol binding in the striatum. The purpose of the present study was to assess the effects of lithium on the development of dopaminergic supersensitivity as measured both behaviorally and by striatal dopamine receptor binding. Rats were treated for 21 days with either haloperidol (1 mg/kg), haloperidol and lithium, saline or saline and lithium. Seven days after discontinuation of all treatments, some animals from each group were tested for APO (0.5 mg/kg) induced locomotor activity and stereotyped behavior. The rest of the animals were sacrificed for assay of striatal dopamine receptor binding. Freshly dissected caudates were homogenized and washed in Tris buffer. The final suspension was incubated in triplicate at 37°C with tritiated spiroperidol and either (+) or (-) butaclamol. APO-induced locomotor activity and stereotyped behavior were increased in haloperidol pretreated rats but not in rats that had been pretreated concurrently with both lithium and haloperidol. Specific binding of [^{3}H]spiroperidol was increased in caudates of haloperidol pretreated rats but not in rats that had been pretreated with both lithium and haloperidol. Lithium treatment alone did not affect behavioral sensitivity to APO or striatal [^{3}H]spiroperidol binding. Lithium also did not affect levels of haloperidol in whole brain or the caudate. Lithium was also found to prevent the development of "presynaptic" dopamine receptor supersensitivity as assessed by the ability of low doses of APO (0.05 mg/kg) to depress locomotor behavior. In addition, supersensitivity to amphetamine following depletion of catecholamines with chronic administration of α-methyl-p-tyrosine was also prevented by lithium. These findings suggest that lithium's ability to prevent recurrent manic-depressive episodes may be related, at least in part, to it's ability to stabilize dopaminergic receptor sensitivity. Work is presently in progress to ascertain whether chronic lithium also interferes with the development of catecholaminergic subsensitivity, as well as supersensitivity of other neurotransmitter systems.

884 THE EFFECTS OF BIOGENIC AMINES ON THE OCCIPITAL (VISUAL) CORTEX OF THE CAT. T.A. Reader. Centre de recherche en sciences neurologiques, Université de Montréal, Montréal, Québec, Canada.

Several evidences in favor of specific afferent pathways containing the biogenic amines dopamine (DA), norepinephrine (NE) and serotonin (5-HT) have been reported in the mammalian CNS. In an attempt to determine their functional role in cerebral cortex we examined the effects of DA, NE and 5-HT upon visually-driven neurons in the visual (occipital) cortex of the cat ("encéphale isolé" preparation). We also compared the effects of these biogenic amines to those produced by the neurotransmitters acetylcholine (ACh) and γ-amino-n-butyric acid (GABA). The amines DA, NE and 5-HT were found to inhibit the visually-evoked activity of a majority of cortical neurons. This inhibition, obtained with ejection currents of 50-100 nA during 20 to 30 s was usually of prolonged duration, lasting 4-6 min and often associated with spike hyperpolarization. The amino acid neurotransmitter GABA inhibited and hyperpolarized all the neurons tested. This effect (ejection currents of 5-30 nA) was rapid in onset and termination lasting only as long as GABA was ejected. The neurotransmitter ACh (40-60 nA for 5-15 s) increased the visually-evoked activity of the majority of cells samples below 1000 μ and this excitation could be blocked or reduced by GABA or by the biogenic amines. The blockade of the ACh-induced excitation by GABA was rapid in onset and ceased as soon as the ejection of GABA was terminated, the cell recovering immediately its sensitivity towards ACh. In contrast the blockade caused by the biogenic amines on the ACh-induced increase in evoked firing was of long duration, lasting for several minutes. The present results show that the evoked activity of a great number of visual cortical cells may be inhibited by DA, NE and 5-HT and that this inhibitory response differs markedly from that induced upon the same cells by GABA. The long duration of the effects of these amines, when compared to GABA, on the visually-evoked activity and on the ACh-induced excitations tends to rule out a simple balance between excitations and inhibitions to explain the reduction in firing and the suppression of the sensitivity towards ACh. Although the molecular mechanisms underlying biogenic amine and ACh interactions are currently in debate the interactions here reported probably call upon mechanisms closely related to the direct postsynaptic actions of these putative neuromodulators. It should also be recalled that presynaptic muscarinic and nicotinic receptors have been postulated to regulate the release of DA and NE (Reader et al., Brain Res., 111 (1976) 95). Thus different levels of interaction may coexist in cerebral cortex and account for opposite effects of biogenic amines and ACh on overall neuronal excitability. (Supported by the MRC, the CRSQ and CAFIR)

885 NUCLEAR ORGANIZATION OF THE ISTHMUS OF THE RAT: A GOLGI ANALYSIS. J. N. Riley and R. Y. Moore. Dept. Neurosciences, University of Calif. at San Diego, La Jolla, CA. 92093.

Intense interest in the organization of the isthmus has been generated by Nauta's formulation of the concept of a "limbic midbrain region" and the discovery that nuclei in the isthmus contain neurons with identified neurotransmitters. These include the nucleus locus coeruleus (LC), nucleus raphe dorsalis (RD) and nucleus central superior (CS). A Golgi analysis of the organization of these nuclei, in particular the organization of dendritic fields and relationships among nuclei would seem worthwhile to better understand the anatomical organization of this important region.

Golgi-Kopsch material was prepared from the brains of male and female Sprague-Dawley rats, ages 16-90 days old.

In the raphe nuclei, two types of neurons can be distinguished. In RD, smaller neurons located in the ventral part of the nucleus have dendrites oriented in a dorsal-ventral axis. A significant portion of neurons in ventral RD have dendrites that bifurcate in the dorsal region of the nucleus, extending into the lateral wings of the nucleus. Dendrites of cells located in the medial and dorsal regions are arranged in a less regular fashion. Some neurons in the dorsal and medial parts of the nucleus have dendrites extending for considerable distances into the central gray and dorsal tegmental nucleus (DTN). In CS, the larger neurons tend to be located nearer the midline and have a significant portion of their dendrites oriented perpendicular to the dorsal-ventral axis of the nucleus. Smaller neurons, tending to be located at the more lateral edges of the nucleus, usually have their dendrites oriented parallel to the dorsal-ventral axis of the nucleus.

The DTN appears to be composed of a relatively homogeneous population of neurons. Most of the dendrites of these neurons are strictly confined to the limits of the nucleus, in striking contrast to other isthmic nuclei. Neurons of DTN lateralis have a similar morphology to DTN neurons but have dendrites extending into DTN, RD, LC, and ventrally into the mesencephalic reticular formation. Some neurons located dorsal to RD and DTN have dendrites that run parallel and adjacent to the fourth ventricle.

Our observations on LC neurons are consistent with the descriptions of Swanson (1976). In addition, observations on the central gray, nucleus cuneiformis, and parabrachial regions will be presented. Supported by USPHS Grants NS-12080 and NS-05732.

886 AGE-RELATED DIFFERENCES IN BRAIN NOREPINEPHRINE NEURON FUNCTION IN STRESSED AND NONSTRESSED RATS. Sue Ritter and Nancy L. Pelzer*. Coll. Vet. Med., Wash. State Univ., Pullman, WA 99164.

Previous work in our laboratory has suggested that the response of brain noradrenergic (NE) neurons to severe stress is altered by age or some age-related variable. NE depletions after 6 hours of cold stress were much greater in 7-month-old than in 3-month-old rats in both hypothalamic and telencephalic regions. Hypothalamic NE concentrations immediately after cold stress were reduced to 61.5 ± 3.2% of control in older rats but to only 79.6 ± 2.3% of control in younger rats ($p<.01$). Likewise, telencephalic NE was reduced to 62.3 ± 4.6% of control in the older rats, but only 82.1 ± 3.6% of control in the younger rats ($p<.01$). If the magnitude of the NE depletion observed in these experiments immediately after stress exposure represents the size of the functional pool of NE, then our results suggest that the size of the functional pool may be altered during the aging process.

In order to investigate these possibilities in more detail, 3-month- and 7-month-old rats were subjected to 1 hour of footshock stress. We hoped to determine whether the differences in NE function observed in the two age groups after cold stress would also be present after a different type of stress. The results obtained after footshock were similar to those obtained after cold stress. Older rats sustained larger NE depletions in both brain regions analyzed than did the younger rats when compared to nonstressed controls of the same age. Hypothalamic NE was 65.6 ± 3.6% *vs* 79.2 + 2.1% of control in older and younger rats, respectively ($p<.01$). Telencephalic NE concentrations after footshock were 85.7 ± 2.7% and 99.6 ± 4.1% of control, respectively, in older and younger rats ($p<.05$). We also compared the resting levels of NE in the hypothalami and telencephalons of nonstressed rats of these two age groups. Hypothalamic NE content did not differ in the two groups but telencephalic NE concentration was 27.3 ± 1.7% higher in the older rats than in the younger rats ($p<.001$).

These results demonstrate that age-related increases in stress-induced NE depletion are not specific to a particular kind of stress but represent a general change in the function of NE neurons. Futhermore, our demonstration of elevated resting cortical NE levels in older animals, despite their greater susceptibility to depletion, suggests the possibility that the readily releasible NE pool of old rats may be increased in size in order to compensate for its increased lability. Finally, the absence of elevated resting levels of NE in the hypothalami of older animals suggests that these neurons respond differently to age-related functional changes of NE utilization than do cortical NE neurons.

887 PERSISTANT BEHAVIORAL AND NEUROCHEMICAL EFFECTS OF HYPOXIA IN RATS. M. K. Shellenberger, S. Norton* and C. L. Littlejohn*. Dept. Pharmacol. and Ks. Center for Ment. Retard. Res., Kansas Univ. Med. Center, Kansas City, Ks. 66103.

Animals were exposed to carbon monoxide (CO) at 0.52% in air to a point near respiratory failure as a model of slow onset hypoxia in which asphyxia does not occur. There are considerable data which indicate that prolonged hypoxia of this type damages predominately telencephalic structures. While there are a number of published studies concerning the acute neurochemical effects of hypoxic-anoxic episodes, little information is available concerning possible residual neurochemical alterations. Groups of male and female adult rats were used in these studies. The residual behavioral effects were evaluated in single animals over 24 hr periods in a residential maze, utilizing photocell counts, 4-6 wks after exposure.

Analysis of the data showed that as a group the female rats were significantly more active than controls during the nocturnal period and in total activity for the 24 hr period. However, it was also found that activity in the CO-exposed animals was positively correlated to the duration of exposure for both males ($r = .918$) and females($r = .946$). Females were found to tolerate longer periods of hypoxia (mean exposure = 100.3 min ± 10.5 S.E.) than males (mean exposure = 60.8 min ± 7.2 S.E.). This factor probably accounts, at least partially, for the greater number of hyperactive females.

Following behavioral evaluation the brains were taken, sampled and analyzed for dopamine (DA), norepinephrine (NE) and 5-hydroxytryptamine (5-HT). The factors noted above led to selection of animals with longer exposures for initial chemical analysis. Female rats (mean exposure = 146.7 min ± 1.5 S.E., N = 3) were found to have significant reductions in striatal DA and midbrain NE. On the other hand, male rats (mean exposure = 100 min ± 2.7 S.E., N = 3) did not show reduced striatal DA although midbrain NE was significantly lower than in controls. The data clearly indicate that periods of hypoxia, in excess of 60 min, produce behavioral alterations and neurochemical deficits which persist over long periods of time. Whether the neurochemical changes are causally related to the altered behavior cannot be determined at present.

Supported by USPHS Grant MH 27739.

888 NORADRENERGIC PROJECTIONS TO THE LOCUS COERULEUS. Michael A. Silver*, William G. Soden* and David M. Jacobowitz (SPON: L. K. Y. Ng). Lab. Clin. Sci., NIMH, Bethesda, Md. 20014.

The locus coeruleus (LC) has been described as receiving a noradrenergic (NA) innervation from the caudally situated A_1, A_2 and A_5 cell groups. Horseradish peroxidase retrograde flow studies have described cell bodies in the vicinity of these NA cell groups projecting to the LC, however, this technique does not offer neurotransmitter specificity. A retrograde flow mapping technique (in press) that is specific for dopamine-β-hydroxylase (DβH) containing neurons, has recently been developed, based upon the phenomenon of specific uptake and retrograde flow of antibody to DβH (ADβH) by noradrenergic neurons. This study reports the application of this highly sensitive and specific technique to the elucidation of the origin of adrenergic fibers terminating within the LC.

Eight adult male rats received stereotaxic injections of ADβH into the right caudal LC via a glass micropipette in volumes of 0.1 - 0.2 µl over a 15-30 minute period. Control rats received equivalent injections of pre-immune serum (PIS). The rats were decapitated after 24 hours and cryostat sections processed for immunofluorescence visualization of intraneuronal ADβH. Proper injection placement was verified in thionin-stained sections.

Following unilateral locus injection, ADβH was visualized within cell bodies of the contralateral LC, and ipsilateral A_2 NA groups. Substantial numbers of cells were labelled, bilaterally within the A_1, A_4 and A_5 groups. No other cell bodies were visualized by this technique and none were seen in the brains of PIS injected subjects. Since epinephrine releasing neurons situated within the vicinity of the A_1 and A_2 cell groups have been reported to project to the LC, it is not known whether ADβH labelled neurons within the A_1 and A_2 groups are epinephrine and/or norepinephrine releasing neurons. ADβH-containing fibers arising from the contralateral LC were seen to decussate ventral to the dorsal tegmental nuclei. Caudal to the LC, fibers were observed in and radiating from the ipsilateral ventral noradrenergic bundle. Ascending noradrenergic fibers of the ipsilateral dorsal bundle could be followed rostrally through the mesencephalon indicating anterograde transport of ADβH. This study represents the first indication that NA fibers arising from distant perikarya may innervate the NA neurons of the locus coeruleus. Since all NA cell groups were not found to innervate the LC, the circuitry of NA projections may serve as the anatomical basis for a functional organization.

889 SIMULTANEOUS VISUALIZATION OF LUTEINIZING HORMONE-RELEASING HORMONE (LHRH) AND CATECHOLAMINES IN THE GUINEA PIG BRAIN. A.I. Silverman and J.R. Sladek, Jr. (SPON: J.R. Currie). Dept. Anat., Columbia Univ., New York, NY 10032 and Univ. Rochester, Rochester, NY 14642.

There is considerable reason to believe that catecholamines (CA) and LHRH interact functionally in the reproductive cycle. Morphological studies using immunocytochemical and histochemical methods have demonstrated the existence of both substances within similar hypothalamic regions. However, these studies did not determine point to point relationships between CA and LHRH. A recently introduced method (McNeill and Sladek, Science 200: 72-74, 1978) allows the simultaneous visualization of monoamines and neuropeptides and has been used in the present study to morphologically characterize the distribution of CA and LHRH.

Adult male guinea pigs were prepared for Falck-Hillarp CA histofluorescence by freeze-drying and hot formaldehyde vapor perfusion. Serial sections were made at 10 µm and adjacent sections to those chosen for fluorescence were stained for LHRH using the unlabeled antibody enzyme technique. The primary antiserum was #4305B at a dilution of 1:500 (donated by L.A. Sternberger). The distribution of CA and LHRH was analyzed with the use of a microscope comparator bridge. Positively stained LHRH terminals and CA varicosities were observed throughout the median eminence. The distribution of LHRH terminals closely paralelled that reported previously (Endocrin. 99:30-41, 1976) in Bouin's fixed tissue. CA varicosities were seen in heaviest densities in the contact zone of the median eminence both laterally and medially. Superimposition of the CA and LHRH terminal fields revealed that the majority of CA varicosities were located external to the bulk of LHRH terminals. This finding was most prominent in caudal median eminence. Rostral median eminence was characterized by a small degree of overlap. Occasional strings of LHRH terminals appeared to penetrate the outer CA zone at all levels. LHRH containing perikarya were observed in the medial preoptic and septal regions. In the majority of instances CA varicosities appeared in juxtaposition to these perikarya at somatic and dendritic surfaces. These data indicate that LHRH and CA coexist in the median eminence in separate zones, with a small degree of overlap and that most positively stained LHRH perikarya appeared to be contacted by CA varicosities. Supported by HD 10665.

890 STIMULUS-DEPENDENT CHANGES IN PAIN-SENSITIVITY AFTER CENTRAL MONOAMINE DEPLETION: HYPERALGESIA ON THE HOT-PLATE ASSOCIATED WITH NOREPINEPHRINE DEPLETION AND IN FLINCH-JUMP WITH SEROTONIN DEPLETION. K. J. Simansky and J. A. Harvey. Dept. of Psychol., Univ. Iowa, Iowa City, IA 52242.

Electrolytic lesions which deplete forebrain serotonin (5-HT) in the rat are associated with hyperalgesia as measured by the hot-plate and flinch-jump techniques (e.g., Yunger & Harvey, JCPP, 1973, 83, 173). However, these lesions generally damage fibers of the noradrenergic (NE) and dopaminergic (DA) systems as well. The relative importance of 5-HT, NE, and DA depletion in hyperalgesia was assessed in rats given intraventricular injections of 5,7-dihydroxytryptamine (DHT), 6-hydroxydopamine (HDA), or vehicle (VC). Doses of neurotoxin employed were: 0 (VC), 120, 360, and 1080 nmol. All rats (n=8/group) were tested for both jump thresholds and paw-lick latencies by the presentation of ascending and descending intensities of shock or heat. Telencephalic 5-HT, NE, and DA content and brainstem and spinal cord 5-HT and NE content were determined.

HDA produced a dose-related decrease in paw-lick latencies but no significant change in the jump threshold. DHT produced a dose-related hyperalgesia to shock ($p < .01$) but only the highest dose of DHT lowered paw-lick latencies. The magnitude and pattern of central monoamine depletion suggested a role for NE in the hot-plate effect and for 5-HT in the lowered jump thresholds. For example, the 360 nmol dose of HDA and the highest dose of DHT both depleted telencephalic NE by 65% and DA by about 20% but the HDA failed to affect 5-HT (-7%) while DHT produced a 93% fall. Behaviorally, both groups showed equivalent decreases in paw-lick but only the DHT group had a lowered jump threshold. In a separate experiment, animals were treated with vehicle or the highest dose of DHT or HDA following pre-treatment with desipramine (DMI). DMI attenuated the NE depletion associated with each neurotoxin (e.g., HDA, no DMI -94% NE in telencephalon vs. -27% after DMI; DHT, -65% vs. -17%) and also prevented the hyperalgesia on the hot-plate without altering the magnitude of the effect on the jump threshold after DHT. These data suggest a dissociation in the central monoaminergic mediation of reactivity to "painful" stimuli that is related to the nature of the test stimulus. Supported by USPHS Grant No. MH 16841 and MH 10641.

891 CORRELATIVE DISTRIBUTION OF NEUROPHYSINS AND CATECHOLAMINES IN RHESUS MONKEY HYPOTHALAMUS. J.R. Sladek, Jr. and E.A. Zimmerman. Dept. Anatomy, Univ. Rochester, Rochester, N.Y. 14642 and Dept. Neurology, Columbia Univ., New York, N.Y. 10032.

Independent analyses using catecholamine (CA) fluorescence and neurophysin immunocytochemistry have placed both neurochemicals in similar hypothalamic loci. Physiological data indicate a possible interaction between CA and magnocellular peptides. Concurrent examination of both substances is now possible with the use of a simultaneous visualization technique which allows immunocytochemical staining of neuropeptides on tissue sections previously prepared for Falck-Hillarp fluorescence (McNeill and Sladek, Science 200:72-74, 1978). This technique was applied to the problem of morphological interrelationships between CA and neurophysin-containing neurons.

Rhesus monkey hypothalami were freeze-dried, treated with hot formaldehyde vapors, paraffin-embedded and serially sectioned at 10uM. Pairs of adjacent sections through the paraventricular (PVN) and supraoptic (SON) nuclei were examined for CA fluorescence and either human estrogen-stimulated (ESN) or nicotine-stimulated (NSN) neurophysin following PAP immunocytochemistry. Antisera to ESN and NSN appear to stain oxytocin and vasopressin neurons, respectively. Neuroanatomical maps were prepared of the combined ESN, NSN, and CA distribution patterns.

Numerous CA varicosities appeared in juxtaposition to positively-stained ESN and NSN perikarya and dendrites in the SON and PVN. Dense fields of CA varicosities were seen in PVN and SON, but the patterns of highest density were located slightly peripheral to the bulk of positively stained perikarya in both loci. A greater degree of overlap of CA fields and ESN/NSN perikarya was seen in rostral rather than caudal SON. Rostral PVN contained a high (4+) density CA field just medial to the ESN/NSN perikarya and a medium (3+) density field within the area occupied by the ESN/NSN perikarya. The 4+ field was reduced markedly at the caudal and rostral poles of PVN as the nucleus attenuated.

These observations provide evidence that CA varicosities in part overlap ESN and NSN-containing perikaryal fields. In many instances juxtaposition appears to exist between CA varicosities and neurophysin perikarya and may form the morphological basis for functional interactions. It is interesting to speculate that axo-dendritic interactions might account for the large number of CA varicosities located just to the periphery of PVN and SON, but this needs to be explored further.

892 METHIONINE ENKEPHALIN AND LEUCINE ENKEPHALIN INCREASE DOPAMINE IN THE CNS OF MYTILUS EDULIS. George B. Stefano and Edward J. Catapane. Dept. Natural Sciences, Medgar Evers College, C.U.N.Y., Brooklyn, N.Y. and The East Coast Neuroscience Foundation, Inc., Northport, N.Y.

The CNS of the marine bivalve mollusc Mytilus edulis is composed of a pair of cerebral, visceral and pedal ganglia, which have been shown to be partially composed of serotonergic and dopaminergic neurons. A variety of monoaminergic pharmacological agents have been shown to effect the metabolism of these substances in a manner similar to that demonstrated in mammalian systems. In mammals narcotic analgesics and the endogenous pentapeptide enkephalins are known to stimulated dopamine turnover and this effect can be blocked by naloxone. While the mechanism of action is as yet unknown, an opiate receptor is considered to be involved in mediating the effect. Due to the recent interest of the interactions of enkephalins with biogenic amines we investigated the interrelationships among methionine enkephalin, leucine enkephalin, dopamine, serotonin and the specific opiate receptor antagonist naloxone in the CNS of the mollusc M. edulis. Intracardiac administration of 10 µl of 5, 10, 40 and 80 µg of methionine enkephalin and leucine enkephalin were followed at 30, 90 and 180 min with assays of the CNS for dopamine and serotonin. Both enkephalins produced statistically significant increases in endogenous dopamine at the 90 min interval. 80 µg of methionine enkephalin caused a 30% increase while 80 µg of leucine enkephalin caused a 26% increase. No changes were detectable in serotonin levels as a result of these treatments. The effects of naloxone were studied to determine if an opiate specific receptor might be responsible for the effects of the enkephalins. Coadministering 10 to 80 µg of naloxone prevented the change in dopamine concentrations, while naloxone by itself produced no effects during the time course of the experiments. While high affinity opiate receptor binding has yet to be demonstrated in the invertebrates, this study suggests the possible presence of an opiate receptor in the CNS of M. edulis.

893 EFFECTS OF ELECTRICAL STIMULATION OF RAPHE DORSALIS AFFERENTS ON ACTIVITY OF RAPHE UNITS AND ADJACENT MIDLINE CELLS IN THE ANESTHETIZED RAT. Warren C. Stern, Allen Johnson* and Peter J. Morgane. D. Dix Hosp., Raleigh, NC 27610 and Worcester Fndn. Exptl. Biol., Shrewsbury, MA 01545.

Recent anatomical studies in the rat using horseradish peroxidase have shown major afferents to the raphe dorsalis (RD) from the lateral habenula (LHb) and substantia nigra (SN). In the present series of experiments we examined the effects of electrical stimulation of these afferents on the firing rates of RD units and adjacent cells in the midline. Rats were anesthetized with chloral hydrate and implanted with a concentric stimulating electrode in the LHb (n=28) or SN (n=6) and with a glass micropipette recording electrode (filled with 3M KCl and fast green dye) into the region of the RD. Stimulation consisted of trains of bipolar pulses, 0.1 msec per pulse, 0.2-1.0 mA, 1 or 10 Hz for 10-300 sec. Cellular firing rates were recorded on paper using a window discriminator and/or on FM tape. At the end of each recording the brains were perfused for histology to determine placement of stimulating and recording electrodes.

The table below summarizes the results obtained for LHb stimulation:

	Mean ± se Firing Rate			% Cells Showing*		
	Baseline	1 Hz	10 Hz	Dec.	No Change	Inc.
Raphe (n=19)	2.5±.3	1.9±.4	1.4±.3	73	27	0
Slow Units (4-10/s, n=26)	6 ± .4	6 ± .7	5 ± 2	54	27	19
Moderate Units (10-20/s, n=28)	14 ± .6	12 ± 1	13 ± 2	46	36	18
Fast Units (>20/s, n=15)	31 ± 2	25 ± 3	17 ± 4	67	33	0

* A change of 25% or greater from baseline was required for a cell to be categorized as dec. or inc. firing.

Two populations of units showed consistent inhibition after stimulation of the LHb--RD cells and midline cells with a fast baseline rate. For many RD cells the duration of inhibition following individual 1 Hz pulses was about 250 msec. After cessation of 10 Hz trains the inhibition often lasted for up to 20 sec or longer. SN stimulation also produced substantial inhibition of RD activity with less consistent effects on non-raphe units (n=14).

Thus, LHb stimulation decreases activity not only of raphe cells but also fast firing neurons in the midline area. (Supported by NSF Grant BNS 77-16512 and funds from Burroughs Wellcome Co.)

894 SPECIFIC INHIBITORS OF SEROTONIN BINDING TO SBP (SEROTONIN BINDING PROTEIN) AFFECT PAIN THRESHOLD AND BRAIN SEROTONIN LEVELS. Hadassah Tamir, Stephen E. Karpiak, Michael D. Gershon, and Meir Wilchek*, Div. Neurosci., N.Y. State Psychiatric Inst., Depts. of Anat. and Psychiatry, Columbia Univ., New York, N. Y. 10032, and Weizmann Inst. of Sci., Rehovot, Israel.

We reported[1,2,3] the presence of a protein in the 100,000 g supernatant of both CNS and myenteric plexus homogenates with high affinity for serotonin. This protein (SBP) is found in serotonergic neurons[4], binds newly synthesized serotonin, and the binding of serotonin is inhibited by reserpine. We now report strong inhibition by synthetic derivatives of 5-HTP, in particular 5-HTP-5-HTP-amide and N-acetyl-5-HTP-5-HTP-amide. In vitro, 50% inhibition is found with 0.2 and 1.0 μM, respectively. Sites of interaction of serotonin with membrane receptors were not affected by these dipeptides. Uptake of serotonin by synaptosomes was only slightly inhibited (9% at 10 μM). 5-HTP decarboxylase and tryptophan hydroxylase[5] were not affected up to 10 μM. The N-acetyl derivative was not hydrolyzed by homogenates of brain or myenteric plexus. The ^{14}C labelled peptide was taken up by an osmotically sensitive compartment of synaptosomes in a saturable manner. This peptide apparently is not transported by the serotonin carrier, since neither serotonin nor drugs affecting serotonin uptake affected the uptake of the dipeptide. Intraventricular injection of N-acetyl dipeptide into rats caused a biphasic effect depending on dose. The lower dose (10 nanomoles) induces a 40% decrease of serotonin in whole brain. The higher dose (~300 nanomoles) causes an increase of 95% in serotonin brain levels. The maximum decrease is seen at 90 min after injection. Injection of the N-acetyl dipeptide (1 nanomole) either into the periaqueductal gray or intraventricularly caused a 90% increase in pain threshold lasting for several hours, as determined by a flinch-jump test. Since N-acetyl-5-HTP-5-HTP-amide specifically affects SBP in vitro, its in vivo effects suggest that SBP is involved in serotonin storage.

895 THE INVOLVEMENT OF CYCLIC AMP AND POTASSIUM DEPOLARIZATION IN THE INDUCTION OF TYROSINE HYDROXYLASE IN NEUROBLASTOMA CELLS. A. W. Tank* and Norman Weiner. Dept. Pharm., Univ. Colo. Med. Center, Denver, CO 80262.

Considerable evidence has implicated the involvement of cAMP in the induction of tyrosine hydroxylase (TH) in neuroblastoma cells. The induction is elicited by analogs of cAMP and compounds which raise intracellular cAMP levels, such as prostaglandin E_1 (PGE_1) or the phosphodiesterase (PDE) inhibitor 4-(3-butoxy-4-methoxybenzyl)-2-imidazolidinone (RO-20-1724). In the presence of the latter two compounds, intracellular cAMP levels are elevated persistently and TH activity is increased 2-3 fold over controls 48 hours after treatment is begun. The dependence of the induction on the duration of increase in cAMP levels was investigated by incubating the cells in the presence of RO-20-1724 for 2, 6, and 12 hours. When the medium containing RO-20-1724 is removed at the times indicated and replaced with fresh medium lacking the PDE inhibitor, the elevated cAMP levels decrease to those seen in controls within 15 minutes. These transient increases in cAMP levels elicit only a 25-35% increase in TH activity measured 48 hr after the initial treatment. However, if the cells are treated with the PDE inhibitor in the presence of 56 mM KCl for 12 hours, and the medium is then replaced with that containing normal (3 mM) KCl and no PDE inhibitor, TH activity is elevated approximately 2-fold 48 hours after the initial treatment. Under these circumstances, the levels of cAMP are increased to approximately the same extent as that seen with the PDE inhibitor alone. TH activity increases by about 20% 48 hours after a 12 hour treatment with 56 mM KCl alone. We conclude that, although changes in cAMP levels may be involved in the induction of TH in neuroblastoma cells, a transient elevation in the level of cAMP is not sufficient to elicit a large increase in TH activity. However, a 2-fold induction of TH is elicited when cAMP levels are elevated in the presence of a depolarizing concentration of KCl for 12 hours.

896 NEUROCHEMICAL CORRELATES OF ISOLATION-INDUCED AGGRESSION IN DISCRETE BRAIN AREAS OF THE MOUSE. Y. Tizabi*, V. J. Massari* and D. M. Jacobowitz (SPON: R. W. Colburn). Dept. of Pharmacology, Howard Univ., Washington, D.C. 20059; and Lab. Clin. Sci., NIMH, Beth., Md. 20014.

Prolonged isolation has been shown to induce a syndrome characterized by increases in general reactivity, response to painful stimuli, vocalization and development of compulsive aggressive behavior. This study was undertaken to determine the neurochemical correlates of isolation-induced aggressive behavior. Adult male mice of Swiss-Webster (NIH) strain were kept in metallic isolation cages for 6 weeks. After this period they were tested for aggressiveness as follows: on 2 occasions 2 days apart, each isolated mouse was removed from its home cage and was introduced into a plastic cage; 3 minutes later a naïve group-housed mouse of BALB/CN strain, (the intruder), was placed in the same plastic cage. If on both occasions the isolated mouse attacked the intruder within 1 minute and continued the attack for 2 minutes, it was considered an aggressor. The isolated mice that did not initiate any attack on either occasion were used as controls. Two days after the second test period aggressors and controls were injected with 400 mg/kg i.p. of alpha-methyl-p-tyrosine, or saline. All mice were sacrificed 2 hours after injection, their brains removed, frozen on dry ice and sliced in a cryostat and 17 discrete areas were microdissected and assayed for norepinephrine (NE) and dopamine (DA). Using a 2-way analysis of variance, the NE steady state level was found to be significantly lower in olfactory tubercle and substantia nigra (zona compacta) and significantly higher in the septum of the aggressive mice. There was an increase in the turnover of NE in the A10 cell body region (ventromedial tegmentum) of the aggressive mice. The DA steady state of the aggressors showed a significantly lower concentration only in the olfactory tubercle. DA turnover was significantly reduced in the olfactory tubercle and increased in the caudate-putamen compared to the controls. It is suggested that NE inhibits the DA cells in the substantia nigra and A10 which project to the caudate-putamen and olfactory tubercle, respectively. Thus, isolation-induced aggression is correlated with an increased NE turnover in the A10 region which may produce decreased DA levels and turnover in the olfactory tubercle. A decline in NE levels in the substantia nigra may increase DA turnover in the caudate-putamen. The changes in DA turnover in the caudate-putamen and olfactory-tubercle further suggest DA involvement in motor and olfactory mechanisms associated with isolation-induced aggression.

897 EFFECTS OF LSD ON BEHAVIOR AND RAPHE UNIT ACTIVITY IN FREELY MOVING CATS. Michael E. Trulson and Barry L. Jacobs. Prog. in Neurosci., Dept. of Psychol., Princeton Univ., Princeton, NJ 08540.

Single unit activity (n=44) was recorded from the dorsal raphe nucleus of freely moving cats (n=9) via chronically implanted nichrome wires, while simultaneously quantifying LSD-induced behavioral changes (e.g., limb flicking and abortive grooming). LSD at a dose of 10 μg/kg i.p. produced a mean decrease in raphe unit activity of 15% from an active waking baseline, and produced a mean of 12 limb flicks per hour, while a dose of 50 μg/kg decreased raphe unit activity by 45% and elicited 45 limb flicks per hour. Following the 50 μg/kg dose of LSD, raphe unit activity returned to baseline levels within 4-6 hours, while the behavioral changes persisted for at least 8 hours. Twenty-four hours after the initial dose of LSD (50 μg/kg), a second injection of the same dose was virtually without behavioral effect (i.e., tolerance), but produced a 63% decrease in raphe unit activity. Administration of saline or brom-LSD (a non-hallucinogenic congener of LSD) produced no behavioral changes and no significant change in raphe unit activity. Control cells outside the dorsal raphe nucleus showed no significant change in activity following LSD administration. Although the present data provide support for a causal relationship between LSD's inactivation of central serotonergic neurotransmission and the behavioral effects of the drug, three important dissociations between raphe unit activity and behavioral changes were observed: 1) low doses of LSD produced only small decreases in raphe unit activity, but produced highly significant behavioral changes; 2) LSD-induced behavioral changes outlast the depression of raphe unit activity; and 3) raphe neurons are at least as responsive to LSD during tolerance as compared to the non-tolerant condition. (Supported by NIMH grant MH-23433).

898 Effects of Phenylalanine and Tyrosine Depletion on Serotonin Synthesis in the Mouse Brain. Thomas W. Vickroy* and Kenneth M. Johnson. Univ. Tex. Med. Branch, Galveston, TX 77550.

It has been established that the synthesis of brain serotonin is dependent on the availability of its precursor tryptophan (try) which is, in turn, dependent on the ratio of plasma try to the sum of large-neutral amino acids (including tyr and phe) which compete with try for uptake into the brain. Previously, it was demonstrated that administration of 100 units/kg of the enzyme phenylalanine ammonia-lyase (PAL, an enzyme which catalyzes the deamination of phe and tyr) to rats depletes plasma phe and tyr to trace levels by 4 hrs and they remain so for at least 24 hrs, in addition, brain 5-HT levels were tripled at 4 hrs, elevated by 42% at 8 hrs, and not different from control by 24 hrs. The purpose of the study reported here is to examine the effects of several doses of PAL on the conversion of a tracer dose of ^{3}H-try to ^{3}H-5-HT in the mouse brain during a 20 min pulse period.

Male albino mice were administered either saline, 25, 50, or 100 U/kg PAL and sacrificed by decapitation either 4 or 8 hrs later. Radioactive and endogenous try and 5-HT were separated by ion-exchange chromatography and aliquots were taken for estimation of tritium by LSC and for fluorometric determination of try and 5-HT. The specific activity (SA) of try was also estimated in liver and plasma and the incorporation of ^{3}H-try into protein was measured in both brain and liver. An accumulation index (AI) was used to estimate the synthesis rate of 5-HT in the brain. AI equals dpm ^{3}H-5-HT/g/try SA.

Four hrs after PAL administration dose - responsive increases were observed in the dpm ^{3}H-try/g and try SA in brain; however, since there was not a concomitant increase in dpm ^{3}H-5-HT/g, there was a dose-responsive decrease in the AI, suggesting a compensatory decrease in the conversion rate of try to 5-HT. We observed an approximate tripling of 5-HT levels at 25 and 50 U/kg but no change at 100 U/kg. Protein synthesis was significantly decreased in the brain but not in the liver. Liver try levels were increased at all doses of PAL, being the greatest at 25 U/kg.

Eight hrs after PAL no changes were observed in brain 5-HT or try levels, 5-HT SA, or plasma try; however, try SA was increased and the AI for 5-HT remained decreased as did brain protein synthesis. We observed a significant increase in liver try levels and a decrease in liver protein synthesis.

This study has shown that PAL is a tool which can be used to explore the effects of phe and tyr depletion on try disposition and metabolism in brain and liver and should aid our understanding of how the brain responds to daily variations in circulating levels of these important biogenic amine precursors. (Supported in part by a PMA Research Starter Grant to Kenneth M. Johnson.)

899 EFFECTS OF DOPAMINE ANALOGS ON TYROSINE HYDROXYLATION IN THE RAT STRIATUM USING AN IMPROVED ASSAY FOR TYROSINE HYDROXYLASE. W.G. Waggoner* and H.J. Leighton* (SPON: C.N. Jones). Wellcome Res. Labs., Dept. of Pharmacology, Research Triangle Park, N.C. 27709.

The rate-limiting step for the synthesis of catecholamines is tyrosine hydroxylation. An improved assay for tyrosine hydroxylase (TH), based on the formation of ^3H_2O from 3,5-^{3}H-tyrosine, has been employed to study the effects of agents on tyrosine hydroxylation in the rat striatum. The method for separation of ^3H_2O from the reactants involves a freeze-drying modification, where the product, ^3H_2O, is sublimed, collected and quantitated. This has allowed for a one-step isolation procedure from the enzyme-reaction tube to the counting vial. The technique eliminates the usual requirement for separation of ^3H_2O by column chromatography and improves the reproducibility and sensitivity of the assay. With the use of only a high efficiency vacuum pump and disposable culture tubes, approximately 60 samples/hour can be analyzed. Using this technique, derivatives of 5,6-dihydroxy-2-aminotetralins (AT), (i.e. N,N-di-n-propyl, N,N-diethyl and N,N-dimethyl) were compared with apomorphine (AP), dopamine (DA) and bromocryptine for their ability to inhibit TH in rat striatal synaptosomes. Two distinct types of TH inhibitors were identified. One type, consisting of AP, bromocryptine, and the above mentioned N-substituted AT, was antagonized by 10^{-6}M neuroleptics (N) (haloperidol, pimozide, chlorpromazine, sulpiride and fluphenazine) but not by the DA uptake inhibitor benztropine (BZ), suggesting that their major mechanism of action involves activation of dopamine receptors on the plasma membrane of the synaptosome. The second type of TH inhibitor, consisting of DA, epinine, and AT lacking amino substitution, was antagonized by BZ but not by N. The latter type of TH inhibitor was weakly antagonized by N in the presence of BZ, suggesting that these compounds have a weak affinity for the plasma membrane receptor as well as a primary mechanism of action within the synaptosome. The data suggest that TH in the rat striatum can be modulated at the local level by activation of presynaptic DA receptors. Complex neuronal feedback mechanisms are not necessarily required to observe receptor mediated inhibition of TH.

900 EFFECT OF GABA-MIMETIC AGENTS AND INHIBITORS OF GABA CATABOLISM ON THE ACTIVITY OF SUBSTANTIA NIGRA (SN) DOPAMINE (DA) NEURONS. J.R.Walters, J.M.Lakoski, N.Eng*, NINCDS, NIH, Bethesda, MD. 20014

One model which has been used to explain effects of DA receptor stimulating and blocking drugs on DA activity has postulated a striato-nigral feedback loop which tonically regulates the activity of DA neurons in the SN. GABA has been considered a possible transmitter in this feedback loop since the demonstration that some striato-nigral neurons contain glutamic acid decarboxylase. These considerations have lead to the expectation that drugs which potentiate GABA-mediated neurotransmission might attenuate the activity of SN DA neurons. Studies with γ-hydroxybutyric acid (GHB) or its precursor, γ-butyrolactone (GBL), a possible GABA agonist, and with Na valproate (VAL), an inhibitor of GABA metabolism, have tended to support this expectation. GBL has been shown to inhibit the activity of SN DA neurons in both control and haloperidol (HAL)-treated rats (Walters & Roth, N.S. Arch. Pharmacol., 1976). Administration of VAL (400 mg/kg, 45 min.) increases GABA levels by 46% in the striatum and 31% in the nigra, while significantly attenuating in vivo striatal DA synthesis (determined by following DOPA accumulation after administration of a DOPA decarboxylase inhibitor) by 30% in control rats and 40% in HAL-treated rats.

However, studies with a more active and better defined GABA agonist, muscimol, and a more effective inhibitor of GABA catabolism, aminooxyacetic acid (AOAA) have cast doubt on the idea that GABAergic mechanisms are involved in the effects of GHB and VAL on DA activity, and have suggested that the tonic activity of DA cells may not be particularly sensitive to attenuation by GABA-active agents. Thus extracellular single unit recording techniques have shown that muscimol (3.5 mg/kg, i.p.) does not inhibit the activity of SN DA neurons, and actually increases the activity of these cells when administered to gallamine-paralyzed rats. This dose also increased striatal in vivo DA synthesis by 83%. In addition, AOAA had no effect on DA synthesis nor on the single unit activity of SN DA neurons in doses (50 mg/kg, 45 min. or 5 hrs.) which caused considerably greater increases in GABA levels in the striatum and nigra (232% and 173% of control at 45 min., 482% and 331% at 5 hr., respectively) than did VAL.

On the other hand, the HAL-induced (1 mg/kg, 45 min.) increase in in vivo striatal DA synthesis was reduced to 78% of the HAL control by muscimol (3.5 mg/kg, 60 min.) and to 47% of the HAL control by AOAA (50 mg/kg, 5 hr.). AOAA also attenuated the effect of HAL on single unit activity of DA cells. Thus these agents do have some attenuating effects on the DA system. The results caution, however, against using the changes seen in HAL-treated animals as a basis for predicting how a drug might alter DA activity in the absence of neuroleptic treatment.

901 SUPERSENSITIVITY TO SEROTONIN IN THE AMYGDALA AND THE VENTRAL LATERAL GENICULATE IN 5,7-DIHYDROXYTRYPTAMINE PRETREATED RATS. Rex Y. Wang, Claude deMontigny, and George K. Aghajanian, Depts. Psychiat. and Pharmacol., Yale Univ. Sch. Med., New Haven, CT 06508.

A dense and uniform serotonergic (5-HT) input to the amygdala (AMYG) and the ventral lateral geniculate nucleus (vLGN) from the midbrain raphe has been previously demonstrated by histofluorescence and horseradish peroxidase methods; physiological and pharmacological studies have supported these findings. The aim of this study was to investigate the phenomenon of denervation supersensitivity of 5-HT receptors in these two areas. 5,7-Dihydroxytryptamine (5,7-DHT), a relatively selective neurotoxin for 5-HT neurons, injected either intraventricularly or directly into the ascending 5-HT pathway in the ventromedial tegmentum (VMT) resulted in the disappearance of 5-HT terminals in the above two areas. The response of cells to microiontophoretically applied 5-HT, norepinephrine (NE) γ-aminobutyric acid (GABA) and d-lysergic acid diethylamide (LSD) in 5,7-DHT pretreated and control (injected with either vehicle or 6-OHDA into the VMT 5-HT pathway) rats were determined by extracellular recording. The equieffective dose of these compounds was evaluated by the I·T50 values, i.e., the product of the current (I) and the time (T50) required to obtain a 50% depression from the baseline firing rate.

Enhanced sensitivity of AMYG cells to the inhibitory effect of 5-HT began to develop within 24 hours and was nearly complete between 5 to 7 days after 5,7-DHT was injected directly in the VMT. There was a marked increase in sensitivity to 5-HT and its analog LSD (which is resistant to the 5-HT uptake system) in the AMYG and the vLGN after injection of 5,7-DHT directly into the VMT and the lateral ventricle respectively. In the AMYG the sensitivity of cells to NE and to a lesser extent GABA was also increased; concurrent iontophoresis of any combination of 5-HT, LSD, NE and GABA resulted in a marked synergistic effect in 5,7-DHT pretreated rats but not in controls. Concurrent iontophoresis of chlorimipramine (which blocks 5-HT uptake) and 5-HT caused a prolongation of the inhibition by 5-HT in control rats but not in 5,7-DHT pretreated rats; presumably this is due to the fact that in the latter the 5-HT terminals and their uptake system have already been destroyed.

In conclusion, denervation supersensitivity to 5-HT has been demonstrated in the AMYG and the vLGN. The supersensitivity induced by 5,7-DHT was relatively nonspecific in the AMYG. Our results also suggest that both pre- and postsynaptic mechanisms contribute to the development of the denervation supersensitivity. (Supported in part by USPH Grants MH-17871, MH-14459, and Can. Med. Res. Council).

902 THE PRODUCTION OF MYOCLONUS BY INTRACEREBROVENTRICULAR INFUSION OF INDOLES FOLLOWING INTRACISTERNAL 5,7-DIHYDROXYTRYPTAMINE AND ATTENUATION BY SEROTONIN RECEPTOR ANTAGONISTS. John D. Warbritton III*, R. Malcolm Stewart and Ross J. Baldessarini. Mailman Laboratories for Psychiatric Research, McLean Division of Massachusetts General Hospital, Harvard Medical School, Belmont, Massachusetts, 02178; and Department of Neurology, University of Texas Health Science Center at Dallas, Dallas, Texas, 75235.

Serotonin (5-HT) is implicated as a neuromodulator in the central nervous system (CNS) with important inhibitory behavioral effects. The present work investigated the excitatory behavioral effects of intracerebroventricularly infused indoleamines in rats lesioned with a serotonin neurotoxin, 5,7-dihydroxytryptamine given after desmethylimipramine. Continuous (90 min.) intracranial infusion of 5-HT into the right lateral ventricle of male rats through a chronically implanted cannula produced intermittent jerking of head and limbs (myoclonus) as recorded with a Stoelting electronic activity monitor. This effect was dependent on the dose of 5-HT infused, over a range of 2-16 µg/min. At the higher doses toxic effects included generalized seizures and death. The approximate half-maximally effective dose (ED50) of 5HT was 6.7 µg/min. Infusion of structurally related indoles including tryptamine, indoleacetaldehyde (IAAld) and 5-hydroxyindoleacetic acid (5-HIAA) were also made. Myoclonus was not seen after tryptamine. At doses comparable on a molar basis to the ED50 of serotonin, IAAld and 5-HIAA produced similar behavioral effects to 5-HT. Acute intraperitoneal administration of the putative serotonin receptor blockers cyproheptadine and methiothepin strongly inhibited the myoclonic effects of 5-HT but only slightly inhibited 5-HIAA myoclonus. Infusion of norepinephrine 1.3 µg/min. (dose) after lesions with 5,7-DHT increased locomotor activity no more than in control animals and did not produce myoclonus. These studies suggest that indoles other than 5-HT may have strong effects on the CNS but that the effects of deaminated indoles may not be mediated by serotonin receptors.

903 NORADRENERGIC MODULATION OF SOMATOSENSORY CORTICAL NEURONAL RESPONSES TO IONTOPHORETICALLY APPLIED PUTATIVE NEUROTRANSMITTERS. Barry D. Waterhouse, Hylan C. Moises and Donald J. Woodward. Dept. Cell Biol., Univ. Tx. Health Sci. Ctr., Dallas, Tx. 75235.

In the present study we have examined whether norepinephrine (NE) in low doses can alter responsiveness of somatosensory cortical neurons to putative neurotransmitter substances. Extracellular activity of cortical neurons was recorded from halothane-anesthetized albino and hooded rats using multibarrel micropipettes. Responses to microiontophoretic pulses (8-10 sec. duration at 45-50 sec. intervals) of acetylcholine (ACH) and gamma-aminobutyric acid (GABA), putative cerebral cortical neurotransmitters, were examined before,during and after NE iontophoresis (2-40 nanoamps). Post-drug response histograms were used to quantitate effects of NE on spontaneous and drug-evoked activity.

In 21 of 25 cells, NE exerted differential effects on spontaneous activity and ACH-induced excitation. ACH responses of 8 cells were potentiated above control levels with doses of NE which had little or no effect on spontaneous rate. In 13 cells, ACH-evoked activity was preserved relative to NE suppression of background discharge such that signal to noise ratios were enhanced. These effects often lasted from one to several minutes following NE application. The ability of dopamine to enhance ACH was weak or absent in 5 of 7 cells for which NE did modulate ACH.

In 7 of 11 cells, NE at low doses augmented GABA inhibition, and this effect often persisted for one to several minutes after cessation of NE iontophoresis. Four cells showed potentiation of GABA inhibition with doses of NE which caused little or no change in spontaneous activity.

In summary, these findings suggest that NE enhances the responsiveness of cortical neurons to both excitatory and inhibitory putative neurotransmitters. These data are consistent with other evidence reported by this laboratory which suggests that NE may act in cerebellum to modulate Purkinje cell responsiveness to synaptically and iontophoretically released transmitter agents. 904 HIGH PLASMA CATECHOLAMINES PREDICT STRESS-INDUCED LETHALITY. Barton G. Weick,* Sue Ritter, Robert C. Ritter (SPON: T.A. McKean). Department of Veterinary and Comparative Anatomy, Pharmacology and Physiology, College of Veterinary Medicine, Washington State University, Pullman, WA 99164

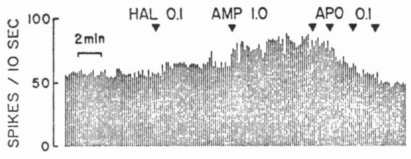
Plasma catecholamines (CA) and blood glucose concentrations were measured before, during and after footshock stress in male Sprague-Dawley rats. Adrenal CA's, liver glycogen, and splenic weight and norepinephrine (NE) content were also measured at the time of death. Of the rats tested with footshock, 60 percent died spontaneously within 5 hours after footshock (spontaneous lethality, L). Plasma CA concentrations were significantly higher in L's than survivors (S) at the termination of footshock (10.57 ± 2.07 ng/ml, L; 3.70 ± .52 ng/ml, S; $p < .05$) and 2 hours after shock (21.88 ± 8.12 ng ml, L; 3.73 ± .60 ng/ml, S; $p < .05$). The peak plasma CA levels during stress were significantly higher in L's than S's (13.72 ± 2.72 ng/ml, L; 4.91 ± .69 ng/ml, S; $p < .05$). After stress the peak plasma CA level was also significantly higher in L's than S's (27.34 ± 5.10, ng/ml L; 6.90 ± 1.69 ng/ml, S; $p < .01$). Adrenal CA content of L's was indistinguishable from that of S's (L, 60 percent of control, $p < .05$; S, 45 percent of control, $p < .01$) indicating that stress-induced lethality was not due to sympatho-adrenomedullary exhaustion. Furthermore, the fact that plasma CA levels of L's were three to four times greater than those of S's suggests that elevated CA levels may be responsible for some deleterious effects which contribute to the lethal outcome of stress. Blood glucose levels for L's and S's were not different during stress. However, blood glucose levels of L's were significantly lower than S's before and after stress. This result suggests that glucostasis in L's was impaired. Both L's and S's were similarly depleted of liver glycogen after stress ($p > .1$). Therefore, the failure of glucostasis in L's was probably not due to depletion of glycogen. S's had lower spleen weights suggesting an impairment of splenic contraction in L's. More complete splenic contraction in S's may be of adaptive value during stress and may also indicate greater sensitivity of the target organ to catecholamines.

Our results show that rats which are more susceptible to stress-induced lethality exhibit extraordinarily high plasma CA concentrations, but may be relatively refractory to beneficial CA mediated effects, such as maintenance of glucostasis and splenic contraction. Plasma CA levels appear to be predictive of susceptibility to stress-induced lethality. Furthermore, high plasma CA concentrations or reduced target organ sensitivity to CA may play a role in the pathogenesis of stress-induced lethality.

905 AMPHETAMINE-INDUCED INCREASE IN SUBSTANTIA NIGRA FIRING RATE AFTER PRETREATMENT WITH HALOPERIDOL. James J. Welch*, Jeffrey M. Liebman and Jeffrey K. Saelens. Research Dept., Pharmaceutical Div., CIBA-GEIGY Corp., Summit, NJ 07901.

Systemic administration of apomorphine (APO) or d-amphetamine (AMP) reliably reduces spontaneous firing by single cells in the zona compacta of the substantia nigra, and this effect can be reversed by subsequent administration of haloperidol (HAL). These findings are consistent with presumed local and/or neuronal loop feedback regulatory mechanisms acting upon dopaminergic neurons in this region (Bunney et al., J. Pharmacol. Exp. Ther. 185:560, 1973; Groves et al., Science 190:522, 1975). We have noted, however, other effects which cannot be attributed to presumed regulatory feedback mechanisms.

Extracellular single unit activity was recorded from chloral hydrate-anesthetized Wistar rats through single barrel micropipettes. Cell bodies in the substantia nigra, zona compacta, which are presumed to be dopaminergic, were identified by standard criteria and subsequent histological verification. Following recording of baseline firing rate, successive intravenous drug injections were administered at 5-10 min intervals. After pretreatment with HAL (0.1 mg/kg), which by itself increased firing rate slightly in most cells, AMP (1 mg/kg) did not reduce firing rate, but increased it reliably by an average of 36% over baseline, an effect which was reversed by APO (see fig.).



An even greater average increase followed injection of 5 mg/kg AMP in HAL-pretreated rats. After HAL pretreatment, APO (0.1-0.5 mg/kg), unlike AMP, consistently reduced firing rate. In non-pretreated rats, AMP never increased, but instead reduced firing rate. At a dose which elicited profound sympathomimetic effects, L-norepinephrine bitartrate (1 µg/kg) failed to alter firing rate appreciably either before or after HAL injection. The enhancing effects of AMP on firing rate after HAL are not readily predicted by a negative feedback mechanism involving dopaminergic neurons. It may be that the concurrent norepinephrine releasing effect of AMP can modulate firing rate of substantia nigra neurons when dopamine receptor blockade prevents AMP-released dopamine from activating negative feedback mechanisms.

906 ROTATIONAL BEHAVIOR IN RATS FOLLOWING NEONATAL, UNILATERAL 6-HYDROXYDOPAMINE (6-OHDA) LESIONS OF THE CAUDATE OR MIDBRAIN.
J. Wilson*, B. Pappas, R. Mailman, G. Breese and R. Mueller.
Biol. Sci. Res. Ctr., UNC Sch. Med., Chapel Hill, NC 27514.

Adult rats with unilateral 6-OHDA lesions of the nigrostriatal (NS) dopamine (DA) pathway rotate in a direction ipsilateral to the lesioned side after d-amphetamine but contralateral after apomorphine. Our examination of the results of similar lesions in newborn rats suggests that maturation affects the rotation response. Rats received unilateral injections of 10 µg 6-OHDA in 1 µl ascorbic acid/saline solution in the caudate or 5 µg in 0.5 µl in the area of the substantia nigra between 12 and 24 hours after birth. They were tested for preferred direction of rotation after apomorphine (1.0, 2.5 or 5.0 mg/kg) or d-amphetamine (1.0, 5.0 or 10.0 mg/kg) 7 and 14 days after the 6-OHDA treatment. At least 8 animals were studied for each combination of drug dose, lesion site and age of testing. Beginning at 50 days of age, each rat was also tested for rotation to d-amphetamine (2.5 mg/kg) and apomorphine (2.5 mg/kg) with a one week interval between rats.

Rotational preferences at 7 and 14 days did not differ from chance. Preferences in the adult rats after both apomorphine or d-amphetamine were contralateral to the lesion side, regardless of lesion site. The extent of DA depletion in the lesioned caudate compared to the unlesioned caudate averaged 52% in animals that had received 6-OHDA in the caudate nucleus; relative DA depletion was 45% in rats that were lesioned in the area of the substantia nigra. Some rats were treated with apomorphine or d-amphetamine and sacrificed by focused microwave irradiation. In these animals striatal and forebrain cyclic nucleotide levels showed no consistant differences between lesioned and unlesioned sides. Furthermore, the expected increases in cAMP on the side contralateral to the direction of rotation were not found.

DA receptor supersensitivity, thought to underlie the rotational response to apomorphine, did not develop by 14 days. However, it was evident that supersensitivity had developed by 50 days. This suggests that supersensitivity develops more slowly in the neonatally lesioned rat than in the rat lesioned as an adult. Furthermore, the contralateral rotation observed after d-amphetamine is inconsistent with the hypothesis that presynaptic activation of NS neurons elicits rotation contralateral to the NS terminations with highest dopamine content. (Supported by USPHS Grants HD-10570, HD-03110 and MH-00013.)

907 ROLE OF THE TECTOSPINAL TRACT IN APOMORPHENE-INDUCED ROTATION.
David Wirtshafter, Karen E. Asin, and Ernest W. Kent. Dept. Psych. Univ. Il.-Chicago Circle, Chicago, Illinois 60680.

It is well known that unilateral 6-hydroxydopamine (6-OHDA) induced distruction of dopamine-containing neurons in the substantia nigra (SN) results in contralateral circling behavior in response to apomorphine (Apo). The recent work of Marshal and Ungerstedt (Sci.,198,1977) suggests that the striato-nigral projection may be crucially involved in this response. This projection is known to be partly GABAergic, and its importance in rotation is further substantiated by our current finding that Apo-induced rotation can be antagonized by picrotoxin.

If the projection from the caudate to the SN is importantly involved in Apo-induced rotation, the question arises as to which efferents from the SN are involved. Recent anatomical and electrophysiological evidence has indicated the existence of a projection from the SN which terminates, in part, on tectospinal motorneurons in the deeper layers of the superior colliculus (SC). Therefore, this study was designed to examine the possible involvement of the tectospinal system in Apo-induced rotation.

Since the tectospinal tract decussates in the midbrain (the dorsal tegmental decussation (DTD)) interruption of this system is possible by means of a saegittal knife cut made with a retractable wire knife. DTD knife cuts were made in rats with 6-OHDA unilateral lesions of the SN (8ug/4ul). Ten to twelve days following surgery the rotational response to .5 mg/kg Apo was examined in a circular tub. Animals with DTD transections exhibited a greater than 80% reduction in rotation relative to animals with SN lesions alone. This reduction could not be attributed to hypomotility, as animals with knife cuts alone showed spontaneous and Apo-induced photocell activity equivalent to unoperated controls. Additionally, there was a virtual absence of postual asymmetry in DTD + SN rats, compared to rats with SN lesions alone.

Since it is possible that these effects on rotation may have been due to damage to non-tectospinal decussating fibers, large electrolytic lesions were made in the SC ipsilateral to 6-OHDA SN lesions. When tested with .5 mg/kg Apo, these subjects showed a marked attenuation in rotation relative to animals with nigral lesions alone. SC lesions by themselves produced only mild ipsilateral rotation, suggesting that the attenuation of contralateral rotation seen in animals with SN lesions could not have been due to simple cancellation.

In conclusion, we have demonstrated that the tectospinal system plays a major role in the contralateral rotation induced by Apo in animals with unilateral 6-OHDA lesions of the SN. It appears that a striato-nigro-tecto-spinal pathway is involved in the production of postural asymmetries by dopamine agonists.

908 HISTOCHEMICAL AND CYTOCHEMICAL IDENTIFICATION OF AMINERGIC NERVE FIBERS IN THE HUMAN MALE PELVIC/PERINEAL VISCERA.
Joe Wood, J.A. McConnell and G.S. Benson*. Depts. of Neurobiol. and Anat., and Surgery, Univ. Texas Med. Sch., Houston, Texas 77025.

Specific cytochemical mapping of the nerve distribution to the human male pelvic/perineal viscera is not in agreement with pharmacological studies; plus the anatomical literature is not supportive of the various physiologic studies conducted on such organ areas. Many agents employed pharmacologically and with some degree of success in urologic therapy are lacking of basic anatomical, neurochemical, and physiologic verification due to lack of data on the normal nerve supply to the male pelvic area.

Tissues utilized in these studies were obtained during surgical procedures for open prostatectomy, vasectomy and transsexual gender reassignment procedures. The areas studied were corpus cavernosum, corpus spongiosum and penile urethra, in addition to anterior bladder body (dome), vas deferens and epididymis. Adrenergic fibers were demonstrated by glyoxylic acid (GA) histofluorescence and electron microscopically with gluteraldehyde-potassium dichromate (GDC). Results show varying numbers of adrenergic fibers in all tissues. Such fibers are most noticeable in the vas deferens and in the corpus cavernosum. The corpus spongiosum contains a small number of adrenergic fibers. Many of the fibers are seen in the vicinity of blood vessels; however, others are in close approximation to the smooth muscle cells.

These catecholamine containing fibers are easily demonstrated with histofluorescence and lead to a better pattern distribution elucidation of sites which can be followed electron microscopically. Areas of the GCD reaction can be visualized at the light microscopic level and then tissue can be processed for fine structural study. X-ray microanalysis shows a positive confirmation of the chromium (catecholamine deposits).

These studies show that the mapping of and realization of catecholamine fibers to areas not previously definitively studied can be accomplished with the GA technique, and indicate that at the electron microscopic level confirmation of biogenic amine sites can be accomplished with GCD. X-ray microanalysis then identifies specific nerve types heretofore not assigned to aminergic systems.

909 INTERACTION OF NOREPINEPHRINE WITH CEREBROCORTICAL ACTIVITY EVOKED BY STIMULATION OF SOMATOSENSORY AFFERENT PATHWAYS IN THE RAT.
Donald J. Woodward and Barry D. Waterhouse. Dept. Cell Biology, Univ. Tx. Health Sci. Ctr., Dallas, Tx. 75235

The present study was conducted to investigate the action of norepinephrine (NE) on transmission of information through somatosensory cortical neuronal circuits. Natural stimulation of afferent pathways was evoked by suprathreshhold mechanical stimulation (500 micron punctate deformation of glaborous skin at 1 Hz.) of the contralateral forepaw. Multibarrel micropipettes were used to apply drug iontophoretically and to record extracellular activity of forelimb somatosensory neurons in albino and hooded rats lightly anesthetized with halothane. Unit responses to forepaw stimulation were examined before, during and after iontophoresis of NE. NE induced changes in stimulus bound and spontaneous activity were quantitated using post-stimulus response histograms.

All cortical neurons studied were spontaneously active and had one of the following responses to forepaw stimulation: 1) short latency excitation, 2) inhibition or 3) short latency excitation followed by a period of inhibition. In 32 of 43 (74%) neurons, NE (10-50 nanoamps) modulated differentially both stimulus bound excitation and spontaneous activity such that signal to noise ratio increased approximately twofold. Evoked spiking in 12 cells was quantitatively potentiated above control levels during NE application. These effects often persisted for several minutes following NE administration.

In 27 of 33 (82%) cells, NE augmented stimulus bound inhibition or post-excitatory suppression of activity. Potentiation of inhibition was observed in 5 cells at levels of NE which caused minimal or no change in background discharge. These changes often lasted several minutes after cessation of NE application.

In summary, these results suggest that low levels of NE may facilitate the relay of afferent information within the cerebral cortical circuitry. These data are consistent with a modulatory as opposed to a specific information transfer role for NE in cerebral cortex.

MOTOR SYSTEMS

910 PROGRAMMED RESPONSES IN HUMAN ANKLE FLEXORS AND EXTENSORS EVOKED BY FORCED ANKLE FLEXION. Gyan C. Agarwal and Gerald L. Gottlieb, Dept. of Physiology, Rush Presbyterian St.-Luke's Medical Center, Chicago, Illinois

Torques were applied to dorsiflex or plantarflex the ankles of seated human subjects. The subjects were instructed to resist the torque, assist it or to not to react at all.

Two phasic responses are evoked in the triceps surae and anterior tibial muscle EMG's. The earliest is the myotatic reflex and occurs in the stretched muscle at latencies of between 40 and 90 msec. This response is followed by the "programmed" response at a latency of between 100 and 200 msec following torque onset.

The programmed response may be characterized as follows: 1) Its latency is significantly shorter than that of a visual reaction time but comparable to a kinaesthetic reaction time. 2) The latency in a single muscle is slightly but statistically different with different instructions (ie "resist", "assist") but no one instruction always produces the shortest latency among different subjects. 3) Experiments in which the subject can anticipate neither the magnitude nor the direction of the torque do not show increases in latency. This is in marked contrast to visual reaction tasks with a simple vs choice paradigm. 4) The amplitude of the programmed response is proportional to the amplitude or the disturbing torque whenever the subject is instructed to resist and restore the foot to its initial position. The response amplitude is largely independent of the torque with most other instructions. 5) The amplitude of the programmed response is reduced by prior contraction of the extensors of flexors. 6) The instruction to not react suppresses the programmed response.

We conclude from the above that programmed EMG responses in the leg muscles at latencies between 100 and 200 msec evoked by ankle flexion are not reflex in nature. They are a form of voluntary reaction triggered by a mechanical stimulus which is dependent on prior instruction and also on peripheral input, if "appropriate".

Peripheral input is only useful in generating appropriate responses if the subject was instructed to generate proportional responses in opposition to the disturbing torque.

The relationship between the programmed responses seen in the leg and the apparantly "transcortical reflex" responses found in the upper limb is not clear at present.

911 EFFECTS OF ALTERED GRAVITY ON RHYTHMICAL HOPPING IN MAN. S.B. Backman* and D.G.D. Watt. Dept. of Anaesthesia Res. and Aviation Med. Res. Unit, McGill University, Montreal, Quebec, Canada H3G1Y6

Previous investigations have demonstrated that human subjects asked to hop up and down without external cues chose their frequency with great accuracy and consistency. It was suggested that this results from at least 3 mechanisms: a pre-programmed landing, a stretch response on contact with the ground, and a vestibular otolith response to sudden weightlessness on taking off.

The present experiments were designed to assess possible vestibular contributions by rotating the gravity vector 90° and varying the inertial accelerations experienced during hopping. Subjects were suspended horizontally, substituting for gravity with bungee cords running from the waist to the wall. Hopping at the subject's preferred frequency in the normal vertical direction was compared with hopping on the wall (horizontal) at 3 simulated g levels.

Average hopping frequencies were: vert:1.86 hops/sec, horiz(1g):1.63, horiz(.67g):1.41, horiz(.33g):1.21. The lower frequency at 1g (horiz) resulted from inadequate tension in the bungees in some subjects. The lower frequency of hopping at decreased g levels was almost entirely due to more time spent off the ground.

In the vertical direction, emg activity in gastrocnemius-soleus started on average 120 msec before contact. In the horizontal position, it maintained its relationship to the previous take-off, and so started 157 msec before contact at 1g, 246 msec before at .67g and 334 msec before at .33g. Its amplitude became smaller as g levels decreased. This early emg activity peaked about the time of ground contact and then declined.

Following contact, 2 distinct bursts of activity could be identified. One started 40-50 msec after contact and lasted about 50 msec. A later and larger burst started 100 msec after contact and lasted until 250-400 msec. The latter activity was very similar at all 3 g levels (subject horizontal) but was always significantly larger when they were vertical.

These results confirm that emg activity during a hop is triggered by the previous take-off, possibly due to an otolith-spinal reflex. After landing, there is evidence for both segmental and long-loop stretch responses. Late activity is influenced by the direction of the gravity vector, also possibly through the otoliths.

(Supported by M.R.C. Canada Grant MA-5837)

912 THE CERVICO-OCULAR REFLEX IN NORMAL HUMAN ADULTS. David E. Barlow* and William Freedman. Dept. of Rehab. Med., Temple Univ., Phila., PA 19141

The cervico-ocular reflex (COR) was examined in ten normal adults, five male and five female, ranging in age from 21 to 32. To produce neck torsion without optokinetic or vestibular stimulation, each subject underwent body rotation in the dark while his head was held fixed with respect to the environment by means of a biteplate. A hydraulically-driven rotatable platform produced passive body rotations of ±0.4 radians in amplitude at five stimulus frequencies: 0.025, 0.05, 0.1, 0.2 and 0.4 Hz. During certain trials the subjects themselves produced active body rotation using their neck muscles while standing on a ball-bearing turntable. The subjects' shoulder movement was recorded by a potentiometer and eye movements were recorded using electrooculographic (EOG) techniques.

Each experimental trial consisted of between four and twenty cycles of rotation and was analyzed by a computer as follows: individual cycles of rotation were defined, overlaid and averaged. The resulting single cycle of average shoulder movement was considered the stimulus and the resulting cycle of averaged eye movement was considered the response. The 'gain' of the response was then defined by the ratio of the amplitude of the averaged eye movement over the amplitude of the averaged stimulating shoulder movement. The 'phase angle' of the response was defined by the displacement, measured in degrees, between the corresponding points in the averaged shoulder and eye position signals.

The experimental results indicate that:

1) The amplitude of the cervico-ocular response declines with increasing frequency of neck torsion. The average gain of the response fell from 18% at 0.025 Hz to 4% at 0.4 Hz.

2) The phase lag of the response increases with increasing stimulus frequency. The average phase lag of -115° at 0.025 Hz increased to -210° at 0.4 Hz.

3) Conditions which required subject concentration and alertness (e.g., responding quickly to an audio signal or trying to maintain fixation in the dark) yielded responses that were two to three times smaller than conditions which allowed the subject to relax.

4) The COR response was found to be very variable whether analyzed cycle by cycle within an individual trial, trial by trial within an individual subject, or subject to subject. In all three methods of analysis gain differences of up to a factor of four and phase differences ranging from 60° to 120° were observed.

5) The responses produced during active body rotation were similar, in both gain and phase, to responses observed during passive body rotation.

913 STUDIES OF DESCENDING PROJECTIONS FROM THE CAUDAL MEDULLA IN THE CAT. R. M. Bowker* and J. D. Coulter, Marine Biomedical Institute and Depts. of Physiology and Biophysics and Psychiatry and Behavioral Sciences, The University of Texas Medical Branch, Galveston, Texas 77550.

The few studies of the origins of descending projections from the caudal medulla in the cat have been limited to descriptions of the dorsal column nuclei (Burton and Loewy, 1977) and of the nucleus retroambiguus (Kuypers and Maisky, 1975). In this report we describe the topographical anatomy and neurophysiology of additional descending cell groups in the caudal medulla of the cat in particular those originating in the nucleus supraspinalis and adjacent reticular formation.

Large, multiple injections of horseradish peroxidase (HRP) were made into the upper cervical spinal cord, C_2-C_3, cervical enlargement, C_6-C_8, mid-thoracic cord, T_7, and lumbar enlargement. After a 3 day survival period the animals were perfused and the tissues were routinely prepared and reacted with tetramethyl benzidine (Hardy and Heimer, 1977). In physiological experiments with chloralose anesthetized cats, glass micropipettes were used to record from identified units in the caudal medulla antidromically activated from different spinal levels. Receptive fields were characterized for these neurons.

Following injections of HRP into the upper cervical cord, medium (20-40μm) and small (<20μm) cells were labeled in the nucleus supraspinalis and the medial nucleus reticularis ventralis (NRV) beginning at the spinomedullary junction and continuing rostrally. With HRP injections covering both the dorsal and ventral spinal grey matter labeled cells were seen bilaterally in these medullary cell groups, but mainly ipsilaterally. Injections of HRP placed in the dorsal spinal grey matter resulted in labeling of neurons in the ipsilateral parts of the dorsal column nuclei and spinal trigeminal complex. Cervical enlargement injections resulted in labeled cells located more laterally in the ipsilateral NRV, while no labeled cells were seen in the nucleus supraspinalis. Only a few labeled cells were present in the contralateral nucleus retroambiguus. After thoracic and lumbar injections retrogradely labeled cells were found primarily in the lateralmost NRV with extensive labeling of cells in the contralateral nucleus retroambiguus. These results indicate that the feline supraspinal projections from the caudal medulla originate from distinct cell groups, similar to that of the primate. Furthermore, the projections from the nucleus supraspinalis and adjacent reticular formation appear to form a somatotopically organized projection system to the different spinal cord levels.

914 OPERANT REINFORCEMENT OF FTG UNITS. S. M. Breedlove*, D. J. McGinty, and J. M. Siegel. Department of Psychology and School of Medicine, University of California, Los Angeles, CA 90024 and V.A. Hospital, Sepulveda, CA 91343.

Previous studies have found that cells in the gigantocellular tegmental field (FTG) of the pontine reticular formation discharge during both waking movements and REM sleep. It was hypothesized that FTG discharge related to the motor activation common to these states (Siegel and McGinty. Science 196:676-680, 1977). In this study FTG single unit discharge in cats was increased by operant conditioning using lateral hypothalamic (LH) stimulation as a reinforcement. Behavioral changes accompanying increased FTG discharge could then be observed. This procedure provides an objective means for studying the behavioral correlates of FTG discharge.

Of 22 FTG cells studied, 16 had significantly higher mean 10 second rates during reinforcement sessions than they did in baseline sessions ($p<.05$, two-tailed, t-test). During the reinforcement of 12 experimental cells, a second, control cell was recorded simultaneously. Comparison of unit discharge change in experimental and control cells demonstrates the specificity of the conditioning procedure. Both the experimental cells and the control cells increased discharge during the early reinforcement periods, but during the final 10 minutes of reinforcement the experimental cells maintained or increased firing while the discharge of control cells was reduced. If the discharge of the entire reinforcement session was averaged, the percentage increase over baseline was not significantly different in experimental and control cells. However, the percentage increase in discharge during the final ten minutes of reinforcement was significantly greater in experimental cells than in control cells ($p<.05$, two-tailed, Wilcoxon sign-rank, matched pairs test). For all 22 reinforced FTG cells, increased discharge was accompanied by an increase in motor behavior. For most of the cells, specific, stereotyped movements accompanied the increase in unit discharge during the later portion of the reinforcement session. Typical movements included rotation of the head to the right or to the left, or lifting the head. These stereotyped movements corresponded to the behavioral correlate of discharge determined prior to reinforcement.

In summary, unit firing in most FTG cells can be readily increased by operant conditioning techniques. These operantly-conditioned increases in FTG discharge were accompanied by increased movement, often of a specific nature unique to the cell. The increased FTG firing was not accompanied by sudden REM onset in waking or by cataplexy.

915 BILATERAL CHANGES IN LIMB MOVEMENTS FOLLOWING UNILATERAL CEREBELLAR LESIONS IN HUMANS. John D. Brown and J. D. Cooke. Depts. of Clinical Neurological Sciences and Physiology, Univ. Western Ontario, London, Ontario.

Simple step-tracking movements made by patients with unilateral cerebellar dysfunction were studied. One patient was followed for one year after the development of a unilateral left hemispheric cerebellar hematoma. The second patient, with a focal left hemispheric cerebellitis, was followed for approximately 6 months. During studies the subjects were seated comfortably with their forearm supported horizontally. They grasped a handle at one end of a manipulandum which was pivoted at the other end above their elbow. The subjects were asked to perform alternating flexion/extension movements about the elbow while target and handle positions were displayed to them on an oscilloscope. No restrictions were placed on movement velocities or reaction times. When amplitudes of target movements were varied curves of peak velocity of movement vs movement amplitude showed that the larger amplitude movements made by the affected arm progressively decreased in velocity over a period of months. Smaller amplitude movements were less affected. Following this period and corresponding to the period of clinical recovery, the relation between velocity and movement amplitude moved towards the relation seen in normal subjects. Movements made with and without visual feedback of arm position had virtually identical curves of movement velocity vs amplitude. In both subjects over the course of the study movements made by the clinically "unaffected" arm had velocity/amplitude relations identical to those of the affected arm. It is suggested that, over time, the velocities in the affected limb decrease in order to help overcome the hypermetria consequent to the cerebellar lesion. Further, it is suggested that velocities in the "non-affected" limb are likewise decreased in order to maintain inter-limb co-ordination.

916 ELECTROMYOGRAPHIC RESPONSES TO SUDDEN ANKLE DISPLACEMENT IN NORMAL AND PARKINSONIAN SUBJECTS. C.W.Y. Chan, R.E. Kearney, G. Melvill Jones. Aviation Medical Research Unit, McGill University, Montreal, Quebec, Canada.

It is well known that in Parkinsonian subjects with akinesia reaction times are increased but reflex latencies remain normal. We have attempted to use this knowledge to distinguish between "reflex" and "voluntary" components of the response to ankle displacement. The electromyographic (EMG) response of tibialis anterior to three different instructions were examined in 9 Parkinsonian patients and 9 age-matched normal humans. The instructions were: as soon as possible (1) dorsiflex the ankle in response to a visual cue, (2) oppose suddenly applied and servo-controlled ankle plantarflexions, (3) relax and allow the ankle to be plantarflexed.

Two principal findings emerged: (1) 6 out of 8 Parkinsonian patients had a significantly longer visual response latency than normal subjects. In the same patients, the 'late' EMG response evoked by opposing ankle plantarflexion (termed the Functional Stretch Response, FSR) was similarly delayed. (2) The intermediate component of the response (termed the Polysynaptic Stretch Response, PSR) was significantly larger in Parkinsonian than normal subjects although its mean latency was the same. Furthermore, its amplitude increased with increases in both displacement amplitude and velocity.

The delay of the FSR in akinesic patients argued against its being a stereotyped reflex. In contrast, the findings that the PSR latency remained unchanged in akinesic patients and that its output is proportional to input characteristics support the view that the PSR is reflex in nature. The increase in PSR in Parkinsonian subjects appears to correspond to the enlarged M2 component in upper limb muscles which has been attributed to an increased gain in long-loop reflexes in Parkinsonian patients[1].

917 INTRACELLULAR AND EXTRACELLULAR EVIDENCE FOR CHANGES IN EXCITABILITY OF MASSETER MOTONEURONS DURING QUIET AND ACTIVE SLEEP. Scott H. Chandler*, Benjamin B. Chang*, and Michael H. Chase. Departments of Physiology and Anatomy, Sch. Med., UCLA, Los Angeles, CA 90024

The brainstem masseteric monosynaptic reflex is depressed during active sleep as compared to quiet sleep (Chase et al., Experientia 24: 47, 1968). Recent studies from our laboratory employing the technique of intracellular recording in chronic cats have demonstrated that the reflex suppression is accompanied by tonic membrane hyperpolarization of masseter motoneurons during active sleep (Nakamura et al., Science, 199: 204-220, 1978). In the present study we have examined the properties of the extracellular field and intracellular spike potential of antidromically activated masseter motoneurons during quiet and active sleep.

In five cats the antidromic field potential was induced by stimulation of motoneuron fibers in the masseter muscle and recorded in the trigeminal motor nucleus with 2 M NaCl glass micropipettes (tip resistance of 1-3 MΩ). During active sleep, the antidromic field potential was reduced to 50-75% of its amplitude during quiet sleep.

The excitability of individual masseter motoneurons was examined by utilizing intracellular recording techniques. Glass micropipettes filled with 2 M K citrate (tip resistance of 8-15 MΩ) were used. During quiet sleep, the intensity of the stimulus delivered to masseter motoneuron fibers was set at a level to produce consistent antidromic invasion of the neuron soma. The induced antidromic spike potential was blocked during the transition from quiet to active sleep. This conduction block was maintained throughout active sleep and was coincident with membrane hyperpolarization of 2 to 10 mV. The cessation of antidromic invasion also paralleled the decrease in neck EMG and distal limb EMG activity that is characteristic of active sleep.

The reduction in amplitude of the antidromic field potential, the blockade of the antidromic spike, and the tonic membrane hyperpolarization provide direct cellular correlates at the level of the final common pathway for the atonia of active sleep.

918 FUNCTIONAL PROPERTIES OF PRIMATE CORTICOMOTONEURONAL CELLS. P.D. Cheney and E.E. Fetz, Dept. of Physiology and Biophysics and Reg. Prim. Res. Ctr., Univ. of Washington, Seattle, WA 98195.

In monkeys making controlled wrist movements, corticomotoneuronal (CM) cells were identified by characteristic post-spike facilitation (PSF) of forelimb muscle activity detected by spike-triggered averaging. Activity of these cells, which has a directly proportional effect on motoneuronal excitability, was quantified during graded dynamic and static wrist responses. Monkeys were trained to alternately flex and extend the wrist between electronically detected hold zones against spring-like loads; thus, wrist displacement from a center zero position required proportional active torques. The same monkeys also performed isometric ramp-and-hold torque responses, alternating between flexion and extension torque zones of variable magnitude. For each cell, response averages of cell and muscle activity, wrist position and torque were compiled for different load levels. On the basis of their dynamic and static responses during the ramp-and-hold movements, all CM cells (n=135) could be classified into one of four basic types: phasic-tonic (59%), tonic (28%), phasic-ramp (8%) and ramp (5%). All CM cells fired during the static hold period, either at constant rates (tonic types) or with gradually increasing rates (ramp types). In addition, some cells of each group exhibited larger phasic responses at the onset of the torque response, with or without any associated wrist displacement. (In contrast, other precentral cells which fired only phasically at movement onset consistently failed to exhibit PSF.) The tonic activity of all CM cells adequately documented (25) was a linear function of static torque over much of the range studied. However, the load sensitivity--i.e., the increment in firing rate per increment in static torque--was consistently greater for extension related CM cells than for flexion related cells (means: 5.2 and 2.5 imp/sec/dyne-cm). Since the mechanics of wrist movements would not seem to fully explain these differences, they may reflect basic differences in the degree of cortical control of flexor and extensor muscles.

To test the participation of CM cells in postulated transcortical reflexes subserving load compensation, activity of 12 CM cells was recorded during transient loading and unloading perturbations of the wrist applied during the hold phase of both flexion and extension. All CM cells exhibited at least those responses consistent with the load compensation hypothesis--i.e., excitation by perturbations which stretched the muscles facilitated by the cell (mean latency: 24 ms). The second EMG response (M2) had a mean onset latency of 30.8 ms; the difference of 6.8 ms agrees well with the mean PSF latency of 7.2 ms for these same cell-muscle pairs. However, half of the CM cells also showed additional responses to load perturbations inappropriate for load compensation.

919 RECRUITMENT ORDER IN THREE DIFFERENT REFLEX RESPONSES ELICITED IN A HINDLIMB FLEXOR MUSCLE IN THE CAT. H.P. Clamann and A.C. Ngai*. Dept. of Physiol., Med. Coll. of Virginia, Richmond, Va. 23298

Several recent reports have suggested that cutaneous afferent inputs may be selectively directed to subsets of the motoneurons of a pool, rather than to the entire pool as predicted by the Size Principle. The organization of three distinct reflex responses of cat tibialis anterior (TA) was studied in cats anesthetized with α-chloralose and paralyzed with Flaxedil (R). TA muscle nerve was cut from the muscle, freed from surrounding tissue, and placed on bipolar electrodes for stimulation and/or recording. Stimulating electrodes were placed either on the proximal stumps of the cut L6 and L7 dorsal roots, or, when these were left intact, on the cutaneous branch of the superficial peroneal nerve, or on the sural nerve. A single stimulus applied to a dorsal root evoked a short (~3.4 msec) latency first response, presumably monosynaptic, a short latency (~4.4 msec) second response mediated by at least one interneuron, and a longer latency (~18.5 msec) third response which could be abolished by spinalization, dorsal root section, or decerebration. All three responses were evoked by homonymous or synergistic flexor muscle nerve stimulation; only the second and third responses were evoked by stimulation of a cutaneous nerve. The activity of single, antidromically identified TA motoneurons was recorded by intra-axonal recording in L7 ventral root. In all three reflex responses recruitment order was generally in order of increasing conduction velocity of axons tested. When the recruitment order of individual motoneurons was tested in the second and third responses simultaneously, a few changes in rank-order of individual cells occurred. These changes appeared to be unrelated to motoneuron size and did not significantly alter the general pattern of recruitment in order of cell size. These results confirm previous reports from this laboratory that changes in spinal afferent input can alter recruitment order of individual motor units in a manner unrelated to their sizes. However, these changes in the recruitment order of individual motoneurons did not alter the over-all positive correlation between critical firing level and conduction velocity. Thus, in response to proprioceptive and cutaneous afferent stimulation, motoneurons of TA appear to be recruited generally in order of their sizes in both spinal and supraspinal reflexes.

920 A COMPARISON OF VOLITIONALLY CONTROLLED MOTOR UNITS IN THE GASTROCNEMIUS AND SOLEUS MUSCLES OF HUMAN SUBJECTS. M.A. Clendenin and Susan P. Clarke.* Dept. of Anatomical Sciences, Eastern Virginia Medical School, Norfolk, Virginia 23501

In this investigation electromyography was used to record single motor unit activity during different types of volitionally activated movements. Single motor units were sampled from the medial and lateral gastrocnemius and the palpable portion of the underlying soleus muscle. With such extensive sampling of motor units it was anticipated that the distribution of tonic and phasic motor units would reflect the distribution of motor unit types as demonstrated by histochemical studies.

Single motor unit activity was recorded using a sterile coaxial needle electrode in fifty volunteer subjects ranging in age from twenty-one to thirty-seven years. After an initial training period using audio and visual feedback, subjects who were able to isolate and volitionally activate single motor units upon verbal command were asked to alter the firing frequencies of the unit as well as maintain motor unit activation during remote muscle activation.

The results obtained from thirty-five subjects represent motor unit activity recorded from all areas of the lateral gastrocnemius, medial gastrocnemius, and soleus muscles accessible by palpation. Twelve recordings were obtained from the medial gastrocnemius, eleven from the lateral gastrocnemius, and twelve from the soleus muscle.

The data suggests that the motor units sampled be classified as tonic units. Moreover, there appeared to be no significant difference in the properties of the motor units of the medical gastrocnemius, lateral gastrocnemius and soleus muscles. All of the motor units sampled demonstrated a low firing frequency (mean rate of 5.0 to 10.0 impulses/sec), a long interspike inverval (> 100 msec) and a similar response to remote muscle activation. When subjects performed the remote muscle activity of raising the head and shoulders, an inhibition in the firing pattern was observed in 72% of the subjects. There was no significant differences in the characteristics of the inhibition when comparing motor units from these different muscles.

These results indicate that during volitionally activated movements lower threshold tonic motor units are primarily activated. Recordings do not reflect the mix of motor unit types as reflected by histochemical studies, but rather provide an effective means of studying low threshold units.

921 ROLE OF LIMB MECHANICAL PROPERTIES IN SIMPLE HUMAN ARM MOVEMENTS. J. D. Cooke. Dept. of Physiology, Univ. of Western Ontario, London, Ontario.

Studies have been made of phase-plane trajectories (velocity vs position) of simple step-tracking movements made by normal humans. Subjects, seated comfortably with their forearm supported, grasped a manipulandum handle and performed alternate flexion/extension movements about the elbow. Target and handle positions were displayed to the subject on an oscilloscope. Subjects were left free to choose their own strategy of movement; no restrictions were placed on movement times, velocities, etc. The movements were invariably made with velocities well below the maximum possible for each subject. Phase planes of these movements were qualitatively similar to those derived from an analog model in which the arm was simulated as a simple damped spring with mass. In the model, movements were assumed to be made by a step change in the spring constant.

In random trials with the human subjects brief force pulses opposing movement were applied. Both the magnitude of the force and the point in the limb trajectory at which they were applied were varied. Over a range of force inputs the limb trajectory following the force closely resembled the trajectory of unperturbed movements. With greater forces, the trajectory following the perturbation significantly differed from control trajectories, limb velocities being consistently lower than in the control movements. Following forces which actually displaced the limb beyond its initial position, velocities remained higher than control levels over most of the rest of the movement. Application of forces in the model yielded phase planes which were again qualitatively similar to those seen in the humans. Differences between the model and the human could be accounted for by addition, in the model, of a force which mimiced a stretch reflex in response to the perturbing force. The results are interpreted as indicating that a major part of the limb trajectory during performance of some simple movements may be determined by the limb's mechanical properties.

922 THE VALUE OF UNITARY RECRUITMENT IN REFLEX REGULATION OF MECHANICAL PROPERTIES OF LENGTHENING MUSCLE. P.J. Cordo* and W.Z. Rymer, (SPON: M.M. Mozell). S.U.N.Y. Upstate Medical Center, Syracuse, New York 13210.

When the activated, areflexive m. gastrocnemius (m.g.) and soleus muscles of the cat are stretched at physiologically appropriate velocities, their force responses are grossly non-linear. This non-linearity, termed muscle 'yield' (Nichols and Houk,1976, J. Neurophysiol. 39, 119-142) or 'give'(Flintney and Hirst,1978, J. Physiol. 276. 449-465), consists largely of an abrupt decline in muscle stiffness that intervenes after the muscle has been stretched more than a fraction of a millimeter. When these muscles are subjected to similar stretches in decerebrate cats with intact stretch reflexes, the yield is no longer evident. The neural mechanisms by which the CNS is able to achieve this 'linearization' of muscle force trajectory were investigated in this study.

Examination of the motor output in the stretch reflex of the m.g. revealed several possible mechanisms for the regulation of dynamic mechanical properties. Recruitment of fresh motor units occurred throughout the observed force range (0-2000 grams) although the number of new units declined rapidly at high forces; the distribution of motor unit force thresholds was approximated by a decaying exponential curve. Initial firing rates of motor units recruited during stretch were found to be significantly greater than the rates recorded during isometric activation (using the crossed-extensor reflex). Newly recruited motor units were then observed to increase their firing rates at an average of 2.0 imp/sec/100 grams muscle force increase. Finally, recruitment during stretch was often accompanied by an uncharacteristically short inter-spike interval (< 20 msec) or 'doublet'(Burke, Rudomin and Zajac, 1976, Brain Res., 109, 515-529.

The effects of these patterns of motor unit activation on force production during stretch were then examined using groups of motor units in soleus and single, type-identified motor units in the m.g.. Preliminary observations suggest that motor units recruited during muscle stretch appear to yield only slightly or not at all. The yield is replaced by a more gradual decline in slope of the force trajectory after several millimeters of stretch. When several groups of soleus motor units are sequentially activated during muscle stretch, the trajectory of the force response is strikingly similar to that of the stretch reflex in the decerebrate preparation. The force trajectory resulting from activation of groups of motor units during stretch is noticeably steeper when a doublet is introduced at the beginning of the spike train. The mechanisms of increased initial firing rate and rate modulation appear to have much less influence than unitary recruitment on the dynamic force trajectory of lengthening muscle.

923 CLOSED LOOP CONTROL OF ELECTRICALLY STIMULATED MUSCLE FOR ORTHOTIC PURPOSES. Patrick E. Crago, Applied Neural Control Laboratory, Case Western Reserve University, Cleveland, Ohio 44106

Intramuscular electrical stimulation of paralyzed finger flexors and extensors is successfully used to provide powered grasp in the hands of C-5 quadriplegic patients*. The patient's control would be improved if the non-linear and time-varying properties of the response to electrical excitation could be regulated. This report presents open loop force modulation techniques and closed loop force feedback techniques that have been found to compensate for both non-linearities and time-dependence under isometric conditions. The experiments were carried out in soleus muscles of cats.

A single command signal controls the stimulus parameters. (In an orthosis, this signal would be derived from a non-paralyzed portion of the patient's body.) The signal must control both recruitment (at low forces) and temporal summation (at high forces). Recruitment is varied by stimulus pulse width (PW) modulation at a fixed amplitude and at the maximal interpulse interval (IPI) that allows an adequately fused contraction. However, recruitment (force versus PW) is non-linear, ie. regions of high slope are separated by regions of low slope. This is a significant problem since approximately 1/2 to 2/3 of the total force range is controlled by recruitment. For larger forces the degree of temporal summation is increased by decreasing the IPI. The command signal linearly modulates IPI instead of frequency, since force is a much more linear function of IPI. Complete linearity of force modulation has not been achieved by open loop techniques.

Closed loop force feedback systems have been studied with modulation of recruitment (PW) or temporal summation (IPI), and with modulation that switches from recruitment to temporal summation at an intermediate point. Simple proportional controllers with loop gains of about 10 cause noisy, unstable operation when modulating recruitment; this appears to be due to the discontinuous nature of recruitment. Controllers with low proportional loop gain (about 1), but with the addition of an integrator, have perfect steady state linearity, good compensation for time dependencies, and do not show the noise seen with high loop gain proportional controllers. Ratios of integral to proportional gain of about 10 yield the fastest response time with no compromise to stability. This type of controller also works well with modulation of temporal summation and at the transition between modulation of recruitment and temporal summation.

924 REFLEX MODULATION DURING ONGOING MOTOR TASKS. J. R. Dufresne* and J. F. Soechting. Laboratory of Neurophysiology, University of Minnesota, Minneapolis, Minnesota 55455.

Control systems with proprioceptive feedback are apparently utilized during a variety of motor tasks, but the manner of their engagement and regulation by central mechanisms is unresolved. This question was addressed by experiments on human subjects in which brief torque-pulse disturbances were introduced at several phases of ongoing, sinusoidal forearm tracking tasks. "Pulse responses" of biceps/triceps EMG activity were obtained by subtraction of perturbed and unperturbed task records. Integration of these responses over an interval of 50-100 msec following the pulse gave a quantitative measure of reflex EMG activity, and these data were fit by a least-squares procedure to a sinusoid at the tracking frequency.

The results of this study indicate that reflex activity leads the ongoing EMG activity of the same muscle by approximately 100° during both position- and isometric force-tracking tasks. Moreover, large phase shifts of the ongoing EMG with respect to forearm tracking velocity, obtained by using large elastic loads at different tracking frequencies (0.7 to 1.8 Hz), failed to significantly alter this phase lead of reflex activity. The results are in agreement with tendon-tap and H-reflex studies demonstrating a large increase in reflex activity prior to the initiation of movements. They suggest: (1) that changes in dynamic behavior of the spindle which depend on absolute length and velocity are not the main reason for the observed behavior, and (2) that activities resulting from the intentionally generated motion are not involved in the observed behavior. Although the mechanism responsible for the constant phase relation between changes in reflex amplitude and EMG activity are still unexplained, a tentative interpretation of its functional significance can be offered. This is the following: that the reflex gain is increased prior to the intentional activation of the muscle in order to provide for load compensation and that the constant phase lead described above will compensate for the delay introduced by the low-pass filter characteristics of the muscle.

925 ANALYSIS OF THE MOTOR UNIT POPULATION IN CAT FLEXOR DIGITORUM LONGUS (FDL) MUSCLE. R. P. Dum*, R. E. Burke and J. A. Hodgson*. Lab. of Neural Control, NINCDS, NIH, Bethesda, MD 20014.

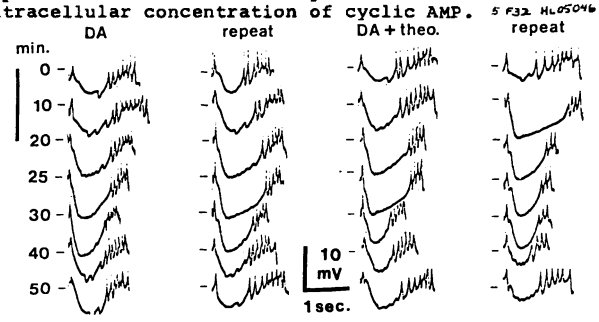
As part of a larger study, we have examined the motor unit population in the FDL muscle of normal cats. The number and location of FDL motoneurons was studied using retrograde transport of horseradish peroxidase. Labeled cells were found in a narrow column about 10 mm in length along the dorsolateral margin of the ventral horn in the caudal half of L6 and rostral third of L7. A total of about 165 cells were labeled, of which 38% fell into the gamma size range (see Burke et al., J. Neurophysiol. 40:667,1977). We used intracellular recording and stimulation methods in pentobarbital anesthetized cats to study motoneuron and muscle unit properties (initial tension for mechanical recording - 20 gm) and to record peak amplitudes of FDL and FHL group Ia EPSPs (Burke et al. J. Physiol. 234:723,1973; J. Neurophysiol. 39:447,1976). Four normal FDL muscles were studied histochemically. Motor unit types and muscle fiber types were identified according to criteria in these references. The data are summarized in the table below.

UNIT TYPES	FF	FR	S
Number and percent	25 (28.7%)	49 (56.3%)	10 (11.5%)
Axon Cond. Vel. (m/s)	99.8±7.1 (25)	98.3±6.9 (49)	84.1±8.7 (10)
FDL Ia EPSP (mV)	3.1±1.1 (14)	3.7±1.0 (26)	3.6±1.4 (7)
FHL Ia EPSP (mV)	0.8±0.3 (14)	2.5±1.0 (26)	2.2±0.8 (7)
Tw. Time to Peak (ms)	33.8±5.9 (25)	35.1±4.9 (49)	56.2±13.8(10)
Tetanus Tension (gm)	31.7±14.8(25)	5.3±3.3 (49)	1.1±1.0 (10)
(data given as means ± SD; number of observ. in brackets)			
Histochemical fiber proportions in FDL	59.1%	30.1%	10.8%

The organization of the FDL motor unit pool is fundamentally the same as found for the cat medial gastrocnemius (MG) but there are some interesting differences. The correlation between the strength of Ia excitatory input and motor unit type is much less strong than in MG. The twitch contraction times of FDL type S units are somewhat shorter than in MG. Most striking, however, is the large proportion of type FR units in the FDL pool (56%; as compared to 23% in MG), while only 30% of FDL muscle fibers have the histochemical profile characteristic of FR units. Considering the mean tetanic tensions of FDL type FF and FR units in relation to the relative frequencies of these motor unit and muscle fiber types in the FDL nucleus and muscle, respectively, we can conclude that an average FDL type FF unit must contain about 3 times as many muscle fibers as an average type FR unit.

926 DOPAMINERGIC MODULATION OF A BURSTING PACEMAKER OSCILLATION: POTENTIATION BY THEOPHYLLINE
Douglas A. Ewald Biology, U. Oregon, Eugene, OR 97403

Dopamine (DA) is localized in the stomatogastric nervous system of the spiny lobster along the input nerves to the stomatogastric ganglion (SGG) from the commissural ganglia (Kushner & Maynard, Brain Res. 129 13,'77; Barker, Kushner, & Hooper, Brain Res.in press). Electrical stimulation of this pathway increases the frequency of the pyloric rhythm generated in the SGG. Bath-applied DA mimics this effect with a slower time course (Anderson & Barker, Ns.Ab.III:522) by increasing the amplitude (A) and frequency (F) of the endogenous membrane potential oscillations of the pacemaker cells (PD & AB). Columns 1 & 2 below are individual oscillations from a PD cell at the indicated intervals during and following two consecutive 20 min exposures to 40 μM DA. Note that increases in A are due to increases in the post-burst hyperpolarization (pbh). Increases in F are due to increases in the rate of depolarization since the duration of the pbh is relatively constant. Simultaneous exposure to inhibitors of cyclic nucleotide phosphodiesterase would be expected to enhance those effects of DA which are mediated by a DA-activated adenyl cyclase. Exposure to 40 μM DA plus 1 mM theophylline (cols. 3 & 4) enhances the magnitude of the F response and decreases the time to maximal A response. Potentiation of the F response is due to an increased rate of depolarization (compare cols. 1 & 2 with cols. 3 & 4 at 30 min). It is thus proposed that the DA-induced increase in the rate of depolarization is mediated by an increase in the intracellular concentration of cyclic AMP.



927 CENTRAL PROGRAMS CONTROLLING RAPID LIMB MOVEMENT IN THE CAT.
C. Ghez and D. Vicario. Rockefeller Univ., New York, NY 10021.

In a previous study it was shown that under isometric conditions, rapid force adjustments could be described by a pulse-step model. The initial peak force was determined by the amplitude of a pulsatile command to agonist muscles of approximately constant duration and corresponding to the rising phase of dF/dt. The terminal force was controlled by a later steady output. The present study was undertaken to determine if position adjustments could also be considered to reflect a similar pulse-step control policy.

Cats were trained to position a lever with their forearm and to match a target level which was stepped at random times. The difference between the target level and the angular position of the lever determined the horizontal position of a compensatory display. Because of inertia and friction in the device, step perturbations took 200 msec to fully shift the display, but the derivatives of its motion were proportional to the size of the step. The cats responded to the perturbation by rapidly adjusting the position of the lever. The direction and extent of the initial lever displacement correlated with those of randomly varied perturbations. The peak velocity achieved was characteristically a linear function of the displacement over a large range of perturbation sizes and under different loading conditions. Increasing velocities were achieved by corresponding increases in the peak acceleration. While the duration of movement often increased as its amplitude became larger, the times from onset to peak velocity and acceleration did not.

An unexpected increase in spring load opposing movement resulted in undershoot of the first position change even when the required change in terminal force was as small as 20 gm. An increase in friction resulted in slowing of the response but a correct final position. After a few trials, the displacement, velocity and acceleration returned to control values in both conditions. These compensatory adjustments were accomplished by increases in the force output by the animal. In the case of the spring load both initial and terminal forces were increased; with friction, only the initial forces were increased.

These observations show that, in a tracking situation, position adjustments are determined by central programs which specify an intended force output in relation to derivatives of target motion. This intended output is dependent on the magnitude and configuration of anticipated loads. The different adjustments in motor output in the presence of spring and frictional loads indicates that phasic and tonic (pulse and step) components of the motor program can be controlled separately.

928 WHEEL RUNNING ACTIVITY OF RATS AFTER "FAR-LATERAL" HYPOTHALAMIC LESIONS.
W. E. Gladfelter and M. S. Shahid Salles, Dept. of Physiology and Biophysics, West Virginia University Medical Center, Morgantown, WV 26506.

In addition to producing a temporary aphagia and adipsia, destruction of the tuberal region of the hypothalamus lateral and ventral to the fornix ("mid-lateral hypothalamus") produces a permanent decrease in the wheel running activity of rats to 10% of preoperative levels. Destruction of a region lying more laterally that includes the extreme lateral portion of the hypothalamus and the medial portion of the subthalamus ("far-lateral hypothalamus") also produces aphagia and adipsia which may be more permanent than that produced by "mid-lateral" hypothalamic damage and may be caused by the interruption of fiber tracts in this region. Experiments were performed to determine whether "far-lateral" hypothalamic lesions also produce a permanent decrease in wheel running activity.

Adult male and female Sprague-Dawley rats were housed individually in activity cages consisting of a small living compartment, in which food and water were kept, and an activity wheel with a Veeder counter. These cages were kept in a room in which the temperature was maintained at 21° ± 1°C and the room lights were on a 12 hour on-off cycle. The female rats were given food ad libitum, but the male rats were kept on a restricted feeding regimen to maintain body weight constant at 280 ± 5 gms. All rats were given water ad libitum. After a control period of 8 weeks during which time wheel running activity was measured, symmetrical electrolytic lesions were placed either in the "far-lateral hypothalamus" or in adjacent regions of the brainstem of 20 rats under hexobarbital anesthesia (20 mg/100 gm). The rats were returned to their activity cages immediately after recovery from anesthesia and were force-fed until they began to eat and drink spontaneously. Their wheel running activity was measured for at least 8 weeks after placement of the lesions. At the conclusion of the experiment, the location of each lesion was verified histologically.

None of the "far-lateral" hypothalamic or subthalamic lesions produced a permanent decrease in wheel running activity comparable to that observed after "mid-lateral" hypothalamic lesions, even though each of these lesions damaged one or more of the structures and fiber tracts within the subthalamus. These data are consistent with the hypothesis that the change in wheel running activity observed after the placement of "mid-lateral" hypothalamic lesions is due to the destruction of neurons located in this area rather than to the destruction of nerve fibers coursing through this region.

929 MYOTATIC RESPONSES IN HUMAN ANKLE FLEXORS AND EXTENSORS EVOKED BY FORCED ANKLE FLEXION.
Gerald L. Gottlieb and Gyan C. Agarwal Dept. of Physiology, Rush College of Health Sciences, 1753 W. Congress, Chicago, IL 60612.

Torques were applied to dorsiflex or plantarflex the ankles of seated human subjects who were performing various motor tasks. The resulting ankle rotation evoked responses which were visible in the EMGs of the triceps surae and anterior tibial muscles.

Stretching the ankle extensors evokes brief and highly synchronized myotatic reflex in the triceps surae at a latency of about 45 msec. The magnitude of this response is highly and linearly correlated with the rate of stretch under all conditions studied. The slope of the linear regression curve characterizes part of the reflex loop "gain". We find the tonic voluntary isometric contraction of the extensors increases the extensor loop gain while contraction of the flexors decreases the extensor loop gain. Both effects are proportional to the degree of contraction.

Slow voluntary rotations of the ankle act in an analogous manner but fast plantar rotations involving strong phasic extensor contraction is associated with an often profound reduction in reflex gain.

These relationships are also characteristic of flexor responses to stretch with one important difference. The latency of the myotatic reflex in the relaxed tibial muscle is about 85 msec and less synchronized than in the extensors. Tonic voluntary isometric contraction not only increases the reflex gain but also shortens the reflex latency. A moderate contraction of 0.5 KgM. can reduce the latency to that in the extensors.

We conclude that segmental reflexes subserve a short latency, low threshold mechanism during posture and slow movement. This may provide some servolike properties to the joint. The brevity of the myotatic response and the fact that supraspinal response of only slightly longer latency will supervene in a normal, conscious subject makes the usefulness of a servo characterization for segmental load compensation very uncertain.

930 CINEMATOGRAPHIC AND ELECTROMYOGRAPHIC ANALYSIS OF STEPPING AND SWIMMING IN RATS. J.A. Gruner* and J.A. Altman, (SPON: L.F. Jaffe). Dept. Biol., Purdue Univ., W. Lafayette, IN 47907.

Although locomotion has been extensively studied in cats and dogs, and to some degree in rats, the emphasis has been primarily on stepping. Only briefly has swimming in mammalian quadrupeds has been mentioned in the literature, and no joint angle or electromyographic (EMG) data have, to the authors' knowledge, been presented. Yet a detailed study of swimming is important because many mammals do swim of their own accord, and a comparison of swimming and stepping might provide information as to the neural organization of locomotor movements. A synchronized cinematographic and EMG analysis of stepping and swimming in normal rats was therefore performed.

Limb movements and muscle activities for stepping were much the same as previously reported for cats (Engberg and Lundberg, Acta physiol. scand., 86: 92, 1969) and dogs (Tokuriki, Jap. J. Vet. Sci., 35: 433, 1973) except that (1) in cats both the knee and ankle maxima occurred at foot liftoff, whereas in rats the knee maximum occurred at foot contact; and (2) there was no evidence of a double bursting pattern in rat flexormuscles.

When swimming and stepping were compared in rats, the yield phase of stepping (flexion in knee and ankle joints following foot contact) disappeared and there were differences in the pattern of limb movement during the flexion or returnstroke phase of swimming. The altered returnstroke movements were associated with simultaneous bursts in the flexors at the end of the extension or powerstroke phase which were unique to swimming. The limits of flexion and extension of the femur were nearly identical in both cases, as were the relative onsets of extensors and flexors except for the added flexor bursts at the end of powerstroke. (Supported by USPHS Grant NS-10267 and ERDA #E (11-1)-2000).

931 THE SYNAPTIC ORGANIZATION OF THE TRIGEMINAL MOTOR NUCLEUS IN THE OPOSSUM. James E. Hamos* and James S. King, Department of Anatomy, The Ohio State University, Columbus, Ohio, 43210.

The synaptic organization of the opossum trigeminal motor nucleus was examined by utilizing Nissl preparations, Golgi impregnations, 1μm thick sections, and ultrathin sections. The cell bodies of trigeminal neurons have areas that measure from 150-2700μm^2 with a peak range from 700-1750μm^2. Sessile spines are frequently found on neuronal somata. Each neuron has 2-6 primary dendrites with a diameter of 6-10μm that extend in all planes from the cell body. Within 300μm from the soma, the primary dendrites divide into secondary dendrites and these, in turn, may bifurcate into thinner tertiary branches. Dendritic outgrowths are often present and may be sessile spines, thin-necked thorns or branched appendages. The overall diameter of the dendritic tree often extends as much as 1mm with a rare branch leaving the confines of the nucleus to enter the neighboring reticular formation.

The perikarya and initial dendritic trunks of trigeminal neurons are characterized by many synaptic contacts which cover as much as two-thirds of the cell membrane. Synaptic endings may be classified into three general categories. Small terminals, 1-3μm in diameter, which contain round synaptic vesicles account for the majority of somatic endings. Somatic spines are typically post-synaptic to this variety of bouton. Other small terminals, 1-3μm in diameter, contain pleomorphic synaptic vesicles and comprise the second most common category. Finally, there are large boutons, with round vesicles, that are 2-6μm in diameter and are always related to a subsynaptic cistern. These terminals are the least frequently encountered on the soma and proximal dendrites and very often interdigitate with adjacent synaptic endings.

Boutons en passant are typical features of the neuropil surrounding trigeminal neurons and are often seen to arise from myelinated axons. Boutons similar to the two smaller endings found on the cell bodies also typify those seen on small diameter dendrites. These data provide the basis for experimental studies designed to identify the origins of the pre-synaptic profiles in the trigeminal motor nucleus.

932 IMPROVED HEAD CONTROL IN CEREBRAL PALSY PATIENTS FOLLOWING TORQUE STEP PERTURBATIONS OF HEAD POSITION. F.A. Harris, Univ. of Wash. Sch. of Med., Seattle, WA 98195.

Torque steps were applied about the axes for head tilt in pitch and roll, using a pneumatically powered apparatus capable of influencing position of the head relative to the shoulders, in cerebral palsy patients. The patients' own head movements triggered application of torque steps opposing such movement. Application of a torque step was initiated when the head moved outside of an adjustable-width deadzone centered on the setpoint selected by the system operator (usually the gravitationally neutral head position) and terminated when the head returned to the setpoint. The apparatus delivered a maximum of 70 in-lb torque about either axis. The subjects were instructed either to yield to or resist forces thereby applied to the head, according to which of two circumstances prevailed.

Passive stabilization of the head, which facilitated self-feeding and diagnostic, hygienic and restorative dental care, was accomplished by instructing the subjects to yield to applied forces. In an attempt to strengthen the neck muscles through resistive exercise (i.e., contraction against constant or increasing load), with the goal of thereby improving voluntary head control, subjects were instructed to tilt the head in a particular direction until the deadzone limit was exceeded and then endeavor to maintain that deviated position despite the continuing application of force tending to return the head to the setpoint. This procedure was carried out for all four directions of tilt, with the number of repetitions dictated by the subject's endurance.

Stripchart and FM tape recordings of pitch and roll signals from head tilt transducers mounted on a separate headband worn during pre- and postexercise periods, and simultaneous cinematography, were carried out for comparison of voluntary head control before and after the period of "automated exercise." Those signals recorded on FM tape were digitalized; computer-plotted "scattergrams" thereby derived, representing the domain within which the head was held and the amount of time it was held at each point within that domain, were used to study alterations in head control resulting from the exercise procedure. It was determined that the range of "involuntary" head motion was narrowed, and subjects were able to hold the head at or near the setpoint for increasingly longer periods of time, following individual exercise periods as brief as ten minutes' duration. Cumulative improvement and functional carry-over were obtained with repetition at weekly intervals. Therefore, procedures used in investigation of neural mechanisms involved in postural stabilization and control of voluntary movement are applicable as well to rehabilitation of individuals with neurological disorders such as (but not limited to) cerebral palsy. 933 THEORETICAL FORMULATION RELATING INTRAFUSAL MECHANICS TO THE NONLINEAR DYNAMIC RESPONSIVENESS OF MUSCLE SPINDLE PRIMARY ENDINGS. Z. Hasan*. (SPON: R.G. Durkovic). Neurosurgery Lab., Upstate Medical Center, Syracuse, New York 13210.

For large ramp stretches, the dynamic responsiveness of primary endings varies substantially depending upon the absence or presence of γ_D or γ_S activity. However, for small sinusoidal stretches the differences in dynamic responsiveness are marginal and of unexpected direction (ref. 1,2). In order to resolve the apparent inconsistency a formulation is developed based on the following assumptions: 1.The extra tension related to movement in the polar zones of intrafusal fibers depends upon a fractional power (1/3) of the speed of movement of the polar zones. This assumption is a generalization of a property reported for extrafusal muscle (ref. 3). 2.The equatorial zone behaves as an elastic element. 3.The applied stretch is distributed between the polar and equatorial zones, and the nerve ending responds to the length of the equatorial zone and to its time-derivative.

From this formulation it is seen that large dynamic responsiveness for large stretches goes hand in hand with small dynamic responsiveness for small stretches. The result is contrary to expectations based on linear systems analysis but in the context of the nonlinear formulation there is no contradiction. Using suitably chosen sets of parameters corresponding to the primary ending when deefferented and when under the influence of γ_D or γ_S activation, the differences in dynamic properties for large stretches are explained. In particular, the slower adaptation seen in the presence of γ_D activity (ref. 4) is predicted. The 'dynamic index' varies as approximately the square root of velocity and depends upon fusimotor state. Response to a continuing stretch at constant velocity is predicted, in the steady state, to be a linear function of instantaneous length and a nonlinear function of velocity. Using the same sets of parameters the responses to small sinusoidal stretches show large phase leads at low frequencies (ref. 5), and the manner in which the predicted gain at a fixed frequency depends upon stretch amplitude in different fusimotor states is in accord with observations (ref. 2).

934 PHENYTOIN REDUCTION OF EXTENSOR TONE AND GAMMA MOTONEURON ACTIVITY IN THE DECEREBRATE CAT. N. Hershkowitz*, T. M. Mahany*, L. Baizer *, and A. Raines. Dept. Pharmacol., Sch. Med. & Dent., Georgetown University, Washington, DC 20007.

Previous work has demonstrated that phenytoin (DPH) directly suppresses deefferented muscle spindle activity (Anderson and Raines, JPET 191: 290, 1974). Because increased muscle tone in the decerebrate animal results from enhanced gamma motoneuron activity (Eldred et al., J. Physiol. 122: 498, 1953) and thus depends upon the integrity of segmental afferent input to the spinal cord (Sherrington, J. Physiol. 22: 319, 1898), we were interested in determining whether DPH would diminish decerebrate extensor tone. A midcollicular transection was performed on cats under methoxyflurane anesthesia. Anesthesia was discontinued and the extensor tone quantified by determining the force necessary to produce total flexion around ankle and knee joints when each limb was pushed against a platform affixed to an isometric force transducer. A cumulative dose-response relationship was estimated by measuring the force every ten min during an intravenous infusion of 1 mg/kg/min of DPH. DPH produced a dose dependent reduction in the extensor tone with 25% reduction occurring at 10 mg/kg and 50% reduction at about 40 mg/kg.

Because the suppression of gamma motoneuron activity may also bring about a reduction in tone, the influence of DPH on this activity was determined in decerebrate cats. A laminectomy was performed on 11 cats and the dorsal roots S_3-L_3 were bilaterally divided. Spontaneous activity of single gamma motoneurons isolated from ventral roots L_6 or L_7 was monitored. Cumulative dose-response relationships were estimated as above. DPH produced a dose dependent depression of the gamma motoneuron activity with 35% depression occurring at 10 mg/kg and 50% depression at about 20 mg/kg. To confirm the gamma nature of the muscle rigidity in our preparations a unilateral dorsal ganglionectomy (S_1-L_5) was performed on 4 untreated decerebrate cats. As expected, muscle tone was eliminated in the hindlimb of the operated side.

Thus, the capacity of DPH to suppress muscle tone in the decerebrate cat appears to be the result of the depression of muscle spindle function. This depression is produced by both a direct action on the spindle as well as a reduction of gamma motoneuron activity. It is felt that the mode of drug administration, which fails to allow time for drug effect to fully develop, underestimated DPH's potency. The observations reported here may provide a rational basis for the use of DPH in the treatment of muscle hypertonicity characterized by high gamma motoneuron tone.

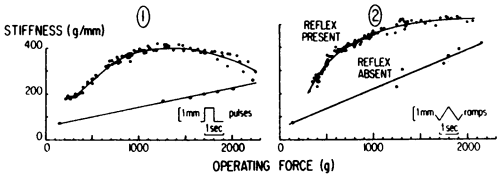
935 FACTORS AFFECTING THE GAIN OF THE STRETCH REFLEX AND SOLEUS MUSCLE STIFFNESS IN PREMAMMILLARY CATS. J.A. Hoffer and S. Andreassen*. Physiol. Dept., Univ. of Alberta, Edmonton T6G 2H7, Canada.

The role of the stretch reflex during movement has been the subject of several interpretations. Recently Nichols & Houk (J.Neurophysiol.39:119,1976) presented evidence to suggest that the stretch reflex regulates muscle stiffness rather than length. We applied incremental length changes to soleus, recorded the resulting changes in force, and used $\Delta F/\Delta \ell$= stiffness as index of gain, to investigate 1) the variability in the gain of the stretch reflex in the high decerebrate, which shows a wider behavioral répertoire than the intercollicular preparation; 2) changes in gain caused by stimulation of several peripheral and brainstem structures, and 3) the role of tendon organ pathways in the regulation of stiffness.



The reflex-mediated response to 1mm, 500ms rectangular pulse stretches was moderately dependent on the operating force (Fig.1), while the muscle response alone was markedly dependent (cut soleus nerve was stimulated at 10-50Hz to generate operating forces). Reflex responses were similar in the range ℓ_{max}-16mm to ℓ_{max}-1mm. In response to 1mm, 500ms ramps, muscle stiffness doubled, while the net reflex contribution was unchanged (Fig. 2) .

The gain of the stretch reflex was remarkably constant for each operating point (note absolute deviation of data points). The gain along spinal pathways could not be modified notably by stimulating selected peripheral and brainstem structures, although transient decreases were sometimes observed.

When the muscle was active near peak levels of contraction for $\geq$ 5 sec, stiffness values began to rise, both with reflex absent and present. Since little or no reflex-mediated compensation for muscle stiffness potentiation was observed, we concluded that the tendon organ feedback gain was low in this preparation.

Our results indicate that under these conditions the stretch reflex contribution to total stiffness is constant for each operating point, independently of type of perturbation or of changes in muscle stiffness. However, it is likely that in intact systems the stretch reflex can compensate more adequately for increased muscle stiffness during sustained high levels of contraction.

936 RESPONSES OF MONKEY PRECENTRAL CORTICAL CELLS DURING A CONTROLLED JAW BITE TASK. Donna S. Hoffman* and Erich S. Luschei* (SPON: M.A. Ruda). Dept. Physiology and Biophysics and Regional Primate Ctr., Univ. of Washington, Seattle, Washington 98195.

Single unit discharges were recorded in the precentral face area of monkeys while they exerted graded isometric biting forces across a pair of metal plates. One hundred out of 204 recorded units showed increases in discharge rate that were temporally related to, and often occurred prior to, the onset of isometric jaw force. About 25% of these task-related neurons showed a consistent relationship between their rate of maintained firing and static biting force, as force was varied between 0.1 and 7.4 kg. Such a result has been previously reported for cells recorded in the precentral arm and hand areas and is consistent with the idea that precentral cortex participates in controlling muscle tension.

The sensitivity of precentral cells to changes in jaw position and to changes in the force applied to the incisors was tested by sinusoidally moving the lower plate of the bite bar system while monkeys were applying force across the two plates. Most task-related cells examined during this procedure exhibited a sensitivity to the derivatives of positional and force stimuli applied to the jaw.

Single pulse, low intensity (<100μA) electrical stimuli applied at the end of most microelectrode penetrations produced widespread bilateral inhibition of jaw closing muscle activity at short latencies (about 7 ms). Stimuli applied in a few penetrations adjacent to the central sulcus produced short latency excitation of contralateral masseter muscle activity in addition to inhibition of activity in other jaw closing muscles bilaterally. Task-related cells were recorded only within the cortical area which could be stimulated with low currents to produce effects on jaw muscle activity.

The results of this study, together with prior studies, provide compelling evidence for a precentral role in control of jaw muscle activity. In addition, the similarity of unit firing patterns recorded in both precentral jaw and forearm areas suggests that the role of the precentral cortex with respect to movement may be common to different muscular systems.

937 ORIGINS OF CORTICAL AND CEREBELLAR PROJECTIONS TO THE RED NUCLEUS IN THE MONKEY. D.R. Humphrey, R. Gold* and D.J. Reed*. Lab. of Neurophysiology, Emory Univ. Sch. Med., Atlanta, GA 30322.

As a prelude to a study of their movement-related behavior in the conscious animal, retrograde cell labeling techniques were used to define the distribution of cortico- and cerebellorubral cells in rhesus and cynomolgous monkeys. Horseradish peroxidase (Sigma VI, 30-50 % solution) was injected (0.05-0.2 μL) into the red nucleus (RN) bilaterally in 10 animals. Survival times ranged from 48-72 hr, and after removal the brain stem, cerebellum and cerebral cortices were sectioned at 50 μ and reacted with diaminobenzidine. A cobalt chloride modification was also used to enhance visualization of the reaction product (Adams, J.D., Neurosci., 2: 141, 1977). All sections were examined under both bright and darkfield illumination.

Our major results may be summarized as follows. (1)Labeled corticorubral (CR) cells were found in the supplementary motor area and in areas 8, 6, 4, 5 and 7 on the convexity of the hemisphere. Areas 8 and 6 projected most heavily to the rostral portion of the parvocellular division of the nucleus, and areas 6 and 4 to its mid and caudal portions. Dense labeling was found in area 4 only in the region of the precentral arm area. Labeled cells were less numerous in areas 5 and 7, and very sparse in areas 3, 1 and 2. All labeled cells were small (modal transverse dia. = 13 μ), pyramidally shaped, and situated within layer V just dorsal to the row of large pyramidal cells. Maximum observed packing density was comparable to that of corticospinal tract cells (1 cell/(0.1 mm)^3 average in layer V). (2) Only a few labeled CR cells were found following injections confined to the mid and caudal regions of the magnocellular division of the RN, which is the source of rubrospinal efferents. (3) Cerebellar projections to the parvocellular division of the RN were derived principally from the dentate nuc. (ratio of 2:1 when compared to interpositorubral efferents), whereas those to the magnocellular division came principally from nuc. interpositus (ratio = 2:1).

Our findings with respect to the CR projection thus agree well with the degeneration studies of Kuypers and Lawrence (Brain Res., 4: 151, 1967), with the exception that we find little evidence for a significant direct cortical input to the magnocellular division of the RN. Our results suggest instead that the major cortical projection is to the parvocellular division. Since this division also receives a significant input from the dentate nuc., and projects back toward the cerebellum by way of the olive, it may be involved in both cortico-cerebellar and cerebello-brain stem-cerebellar loops which play some higher order role in the programming of voluntary movement. (Supported by NIH Grant NS 10183).

938 WIDESPREAD REFLEX RESPONSES TO CUTANEOUS STIMULATION IN MAN REVEALED BY EVOKED EMG. R.E. Kearney, C.W.Y. Chan, A.P. Arrott*. Aviation Medical Research Unit, McGill University, Montreal, Canada.

Animal experiments have demonstrated that cutaneous stimuli applied at a single site can elicit complex and widespread reflex responses. We have used an evoked EMG technique to study these responses in normal humans.

Stimuli consisted of electrical pulses applied to the median arch of the subject's foot at a level of about three times sensory threshold. Surface EMG's were measured from a tonically contracting muscle, full wave rectified and then band pass filtered. Stimulus related responses were extracted from noise by ensemble averaging and Wiener filtering. To date, we have succeeded in demonstrating repeatable responses in a variety of limb flexors and extensors as well as in a number of back extensors.

Limb flexor responses consisted predominantly of an early excitation followed by inhibition. Responses in limb extensors were somewhat more complex but were in general reciprocal to the flexor responses. In individual subjects, a characteristic pattern of response has been observed in the back extensors at a variety of spinal levels. An early inhibitory wave could be identified whose latency increased as progressively higher spinal levels were studied. It thus appears to be due to inter-segmental spinal reflexes. In some subjects, a later wave could be identified whose latency was shorter at higher than lower levels. This suggests a contribution from a long loop reflex such as the spino-bulbo-spinal reflex.

We conclude that, in normal man, a single cutaneous stimulus can elicit a complex, widespread reflex response which is organized reciprocally between flexors and extensors. Furthermore, some of the complexities of the response may arise from the interaction of spinal and long loop reflexes.

Supported by a grant from the Canadian Medical Research Council.

939 LOCALIZATION OF BRAIN STEM TARGETS IN THE FASCICULARIS MONKEY BY A HISTOLOGICAL X-RAY MATCHING METHOD. P. R. Kennedy, H.-G. Ross, V. B. Brooks. Dept. of Physiology, Univ. of Western Ontario, London, Ontario, Canada N6A 5C1.

Targets in the monkey's brain stem are difficult to localize mostly because they are not stationary during head movements. The short supply of Rhesus monkeys (Macaca Mulatta) makes the Fascicularis monkey (Macaca Irus) an attractive alternative. A brain atlas is available for this species in the standard prone position (1), and corrections for the sitting position can be approximated from (2). Surprisingly, however, even that cannot provide accurate stereotaxic guidance for deep targets, presumably because of the variable shape of the external auditory meati of the Fascicularis.

We have solved this problem by (a) matching sagittal brain stem sections with an outline of the brain stem visualized by contrast X-rays in 3 monkeys, and (b) locating in experimental animals the desired target in relation to bony landmarks that are also visible on X-rays taken during implantation. This method is independent of conventional stereotaxic coordinates, and is used with the monkey sitting in a modified stereotaxic frame. This is important since it is also the position during experimentation. Skull X-rays can be taken by elevating above the metal frame, holders for ears, eyes, and mouth. Ear bars are made of acrylic.

Outlines of the brain stem in 3 Fascicularis monkeys (2-2.7 kgs) were made with contrast X-ray studies using Conray (Na-Iothalamate, Mallinckrodt Canada, Ltd.) or Metrisimide (Amipaque, Nyegaard, Oslo, Norway) or air. These brain stem outlines were matched with sagittal histological brain stem sections from 1 monkey, using as matching points the interpeduncular fossa, pons, ponto-medullary junction, medulla and fourth ventricle. Then the desired brain stem target was related to bony landmarks in the composite picture. At implantation, a plain lateral skull X-ray was taken to reveal bony landmarks as well as metal markers whose projections intersected at stereotaxic zero. Using these landmarks, the desired target position was transferred to this X-ray from the composite picture to obtain stereotaxic coordinates for immediate implantation.

Accurate implantation has been confirmed with AP and lateral X-rays in one chronically prepared Fascicularis monkey to date.

940 RECRUITMENT AND DISCHARGE PROPERTIES OF HUMAN MOTOR UNITS IN LOW TO HIGH FORCE ISOMETRIC CONTRACTIONS. C.G. Kukulka* and H.P. Clamann (SPON: A.J. Szumski). Dept. of Physiol., Med. Coll. of Va., Richmond, Va. 23298

The activities of single motor units (n=46) from human biceps brachii muscle were monitored at various forces of isometric contractions (0-88% maximum contraction). Identification of single motor units at high forces was made possible through the use of an analog circuit which took the time derivative of the waveform, thereby selecting units according to the rise or fall times of their action potentials. Recruitment of motor units was observed up to 84% maximum voluntary contraction (MVC), with 36 of 46 units recruited below 50% MVC and 10 of 46 units recruited above 50% MVC. Units recruited at higher forces, on the average, had a tendency to fire at rates higher than those recruited at lower forces. Mean firing rates for grouped data, when plotted against contractile force, and analyzed by linear regression, revealed a correlation coefficient of r = 0.5 and a slope of 1 impulse $sec.^{-1}$ 3.6 kg^{-1} change in force. The maximum firing rates did not exceed 30 impulses $sec.^{-1}$, even at forces as high as 88% MVC. It appears that in brachial biceps, during isometric contraction, the two mechanisms for grading the contraction, recruitment and rate coding, have complementary roles. At low forces (below 50% MVC), a large number of motor units whose firing rates are relatively low may be recruited. As the force increases towards maximum, the limitation in firing rates of units already active necessitates the recruitment of additional units. Our findings reveal that recruitment occurs throughout most of the range of isometric forces, with the number of units recruited declining as the force of contraction increases. Previous investigations have reported that units recruited at the high forces produce greater twitch tensions than units recruited at low forces. Therefore, although fewer units are recruited at the higher forces (above 50% MVC), their larger twitch tensions would contribute a greater proportion to the total force output than the twitches of units recruited at lower forces (below 50% MVC).

941 ULTRASTRUCTURE OF CEREBELLAR AFFERENTS IN THE VENTRAL MEDIAL THALAMIC NUCLEUS IN THE CAT. K. Kultas-Ilinsky, I. Ilinsky, P.A. Young, and K.R. Smith. Depts. Anat. and Surg., St. Louis Univ. Sch. Med., St. Louis, MO 63104.

The ventral medial nucleus (VM) of the thalamus receives cerebellar projections particularly from the fastigial nucleus (Angaut & Bowsher, Brain Res., 24:49, 1970; Faull & Carman, J. Comp. Neur., 178:495, 1978). The purpose of the present study was to identify cerebellar fibers and their terminations in the VM and to compare their ultrastructural characteristics with those of previously described nigral afferents in this nucleus (Ilinsky et al., Anat. Rec., 187:611, 1977; Kultas-Ilinsky et al., Neurosci. Abstr., 3:40, 1977).

Bilateral electrolytic lesions were placed in the brachium conjunctivum by means of a precise stereotaxic technique described earlier (Ilinsky et al., Neurosci. Abstr., 3:396, 1977). The animals were allowed to survive for 3, 4 or 6 days. Numerous very large synaptic boutons (some up to 8 μm in length) and large to medium size myelinated fibers were found degenerating in the VM. At earlier stages the degeneration appeared as aggregations of synaptic vesicles into several clusters with swelling of some vesicles in the synaptic bouton. Later the cytoplasm around the clusters became filled with neurofilaments and glycogen particles. The mitochondria showed a clearing of the matrix and reduction in the number of cristae. Eventually the electron density of the boutons increased until no fine structural details could be resolved, at which stage two types of glia (an astroglia and a dark type presumably microglia) participated in the phagocytosis of the degenerating boutons. In general the pattern of degeneration may be classified as one with filamentous hyperplasia. The degenerating boutons were engaged in asymmetrical contacts with two types of dendrites: a common type and a vesicle-containing type. The majority of degenerating boutons were located in glomeruli where the same bouton contacted both types of dendrites.

It is concluded that cerebellar and nigral projections possess different types of synaptic contacts in the VM, the cerebellar being asymmetrical and the nigral symmetrical. They also differ in size and in their types of degeneration. However, the synaptic sites of both types of boutons are identical, although the cerebellar terminals seem to outnumber nigral terminals. Preliminary data on the diameters of the synaptic vesicles indicate that those in nigral terminals tend to be more elongated although both populations can be classified as pleomorphic.

(Supported in part by USPHS grant FR 05388.)

942 LOAD COMPENSATING RESPONSES OF HUMAN ABDOMINAL MUSCLES. Robert Lansing and Loren Meyerink*. Department of Psychology, University of Arizona, Tucson, AZ 85721.

Positive pressure loads (6-12 cm H_2O, 2 sec duration) were applied unexpectedly at the external airway as subjects made a constant expiratory effort against steady pressure. The latency and form of internal oblique, external oblique, and rectus abdominis EMG responses were obtained from surface recordings; data reported here were recorded over the lower anterior internal oblique covered only by the aponeurosis of external oblique. Pressure and volume changes measured at the mouth reflected the combined action of many respiratory muscles. We examined the effects of the response task, practice, and stimulus expectancy in 8 subjects. Response tasks were defined by instruction and training with a cathode ray feedback display.

When subjects did not try to oppose the load no mechanical or EMG responses were recorded in spite of rapid lung inflation. Given the task of maintaining their pre-load position in spite of the load displacement, subjects corrected to within 50-100 ml of their original volume and there was a 2-phase EMG response: an initial burst, phase I (latency 45-140 ms, duration 100-300 ms, amplitude 50-500 uV), followed by tonic activity of varying amplitude, phase II, continuing to load offset. We believe the phase I burst is a simple ballistic response of the kind conventionally recorded in simple reaction time RT tasks, serving here to oppose the initial change in pressure. The ensuing phase II potentials may represent the subject's proprioceptively guided efforts to achieve positional correction. Intercostal responses to transient loading of voluntary expiratory efforts, similar in latency and duration to our phase I burst, have been reported (Newsom Davis, J. & Sears, T.A., J. Physiol. 209: 711-738, 1970) but important differences in method make direct comparisons premature.

Our interpretation of the phase I burst is based on results obtained when subjects made a single brief response to the loads in a traditional RT task. The latency and form of these RT EMG responses were similar to those of the phase I potentials for any given subject. Practice and increased expectancy produced identical reductions in the phase I and RT EMG latencies. These practiced load RTs averaged 65 ms (range 45-120), showing that latencies of 45-70 ms do not rule out conventional RT processes. We obtained biceps RTs as short as 50 ms for 2 subjects in response to the respiratory loads, so rapid RTs in this latency range cannot be considered unique to load compensatory action in the respiratory system. The finding (Hufschmidt, H., Kilimov, N., & Linke, D., EEG & Clin. Neurophysiol. 43: 622, 1977) of voluntary biceps RTs to contralateral elbow movement of 40-70 ms supports this conclusion.

943 DIRECT SOMATOSENSORY INPUTS FROM THE THALAMUS TO THE MOTOR CORTEX. K. D. Larsen, H. Yumiya*, and H. Asanuma. Rockefeller Univ., New York, NY 10021.

Neurons in the motor cortex have somatotopically organized, somatosensory receptive fields. However, some studies suggest that not all of the somatosensory inputs to the motor cortex arrive by way of the sensory cortex. Horseradish peroxidase (HRP) and electrophysiological techniques were used to determine if some somatosensory information is transferred to the motor cortex directly from the thalamus. In HRP experiments, 0.15 µl of a 50% solution of the enzyme was injected into the distal forelimb region of the motor cortex, identified as the focus of the evoked potential elicited with radial nerve stimulation. Many HRP-containing cells were found in the ventral lateral nucleus (VL), but the rostral portion of the ventral posterior lateral nucleus (VPL) also had labeled cells. Cells in the rostral VPL were studied in electrophysiological experiments. An array of eight electrodes, implanted at a depth of one mm in the motor cortex, was used to antidromically activate cells with intracortical microstimulation. The receptive fields of the antidromically identified cells and their neighbors were examined, and the locations of projection cells were marked with electrolytic lesions. Forty cells in the VL-VPL border area were antidromically activated, each from only one cortical electrode, with latencies of 0.7-1.7 msec ($\bar{x}$ = 1.3). Thirty-two of these could be driven with natural stimulation, 12 of which had receptive fields on the skin and 20 of which were driven from deep structures. In eight cases, the cell in thalamus was recorded simultaneously with cells in the cortex using the electrode which previously activated the thalamic cell antidromically. In six of these simultaneous recordings, four of them involving cells receiving inputs from skin and two from deep structures, the receptive fields were almost identical in the thalamus and the cortical site. These results show that somatosensory inputs traveling in a thalamo-motor cortical path contribute to the formulation of receptive fields in the motor cortex.

944 DECOMPOSITION OF SUPERIMPOSED ACTION POTENTIAL TRAINS. Ronald S. Le Fever* and Carlo J. De Luca. Dept. of Orth. Surg., Children's Hosp. Med. Ctr., Harvard Med. Sch. and M.I.T., Boston, MA

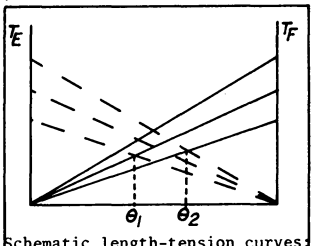
A computerized technique has been developed for the separation of superimposed action potential trains, recorded with indwelling EMG electrodes, into the individual action potential trains of each motor unit contributing to the recording. This technique is also directly applicable to extracellular neural recordings consisting of action potentials from several neurons.

The computer program which performs the decomposition may be employed in automatic or interactive modes, depending on the quality of the data to be decomposed. In the interactive mode the program seeks assistance from the operator only when it has exhausted its schemes for assigning an action potential to the appropriate train. The accuracy of the program in automatic mode is typically 95% for the decomposition of six superimposed action potential trains, but will vary with the quality of the data. Each time the program assigns an action potential to a particular motor unit it averages this new action potential into that motor unit's stored action potential form. These stored forms are compared to each successive action potential in the recorded data. The assignment decision is based on two criteria: the mean squared difference between a particular action potential and each of these stored forms, and the probability that this action potential belongs to each motor unit given the previous occurrences. The mean squared error criterion is algebraically equivalent to techniques using matched filtering, orthogonal decomposition and template matching.

The decomposition program works best when more than one simultaneously-recorded signal of the neuromuscular events is available for analysis. Our motor unit action potential recordings are obtained by using a special electrode consisting of 4 enameled 25 µm wires cemented together in close proximity. The cut ends of the wires act as the recording surfaces. This arrangement permits a very selective recording of 3 linearly independent differential signals. It was found that the quality of the recorded data could be substantially improved by proper recording and filtering techniques. The time duration of the action potentials (hence the amount of superposition) can be decreased by locating FET preamplifiers very near the recording site. This effectively increases the bandwidth of the recorded action potentials. By subsequently filtering out the lower frequencies, action potentials with time durations less than 500 µ sec may be obtained. A combination of analog and digital filtering is employed for this purpose.(Supported in part by NIAMDD grant #AM 19665, and by a joint grant from the United Cerebral Palsy Res. and Ed., the C.A. Dana and the Hearst Foundations.)

945 TRANSITION FROM MOVEMENT TO POSTURE: AN ELECTROMYOGRAPHIC (EMG) STUDY. Francis Lestienne*, Andres Polit* and Emilio Bizzi. Dept. Psychol., M.I.T., Cambridge, MA 02139.

Recent experimental evidence has indicated some characteristics of the programs which subserve limb movements and posture in monkeys (Bizzi et al., J. Neurophysiol., 1976; Polit and Bizzi, Science, 1978). In particular it has been suggested that motor programs specify, through the selection of appropriate length-tension curves in both agonist and antagonist muscles, an equilibrium point that correctly positions the arm in relation to a target (Fig. 1).



Schematic length-tension curves; T_F=Flx.; T_E=Ext.; θ=joint pos.

To further investigate this process we recorded the alpha motoneural input to forearm flexors and extensors (EMG activity) in eight adult subjects. Their forearm was fastened to an apparatus that permitted flexion and extension in the horizontal plane. 17 lights, spaced at 5° intervals, were mounted on a perimeter arc centered around the axis of rotation of the elbow. The subjects were asked to point, without sight of the arm, to whichever light was on and to hold the arm at that position for about two seconds. During the holding time we recorded the rectified and filtered EMG activity from elbow flexors and extensors. Averaged integrated EMG activity of flexors and extensors for each target indicated that (1) the transition from one position to another was attained by modulating the EMG of both agonists and antagonists. The alternative possibility that CNS would implement final arm position by specifying a new level of activity in the agonist muscles while the neural input to the antagonists remains constant was not borne out by these experiments. (2) The final level of EMG activity recorded from either flexors or extensors, while highly variable from trial to trial, was strongly correlated to position and not to such parameters as velocity, direction and amplitude of movement. Taken together these results reveal some aspect of the way in which the CNS implements the shift in equilibrium point between agonists and antagonists. They provide some idea about neural pattern of activity underlying the attainment of an invariant goal such as pointing with the forearm to a target. (Research supported by NIH grant NS09343.)

946 THE UNIT ACTIVITY OF PRIMARY AND SECONDARY AFFERENTS FROM CAT HINDLIMB MUSCLE SPINDLES DURING NORMAL WALKING. Gerald E. Loeb and Jacques Duysens. Laboratory of Neural Control, NINCDS, NIH, Bethesda, MD 20014.

Chronically implanted "floating" microelectrode wires were used to record primary afferent unit activity from the L7 and S1 dorsal root ganglia during unrestrained treadmill locomotion. Using manipulation, electrical stimulation and conduction velocity criteria, we identified 21 primary and 13 secondary spindle endings originating in various hindlimb muscles. Units were held for 1-24 days, during which period it was sometimes possible to implant EMG and/or length gauges in the muscle of origin to facilitate detailed comparison of spindle and muscle activity.

During walking, the activity of a given spindle primary was usually consistent in similar step cycles but was usually poorly correlated with absolute muscle length and was apparently unrelated to velocity of muscle stretch. It could change markedly for similar movements performed under different conditions. Secondaries appeared to be predominantly passive indicators of muscle length during walking, but could demonstrate apparently strong and rapid fusimotor modulation during other motor activities such as postural changes and paw shaking.

Spindle activity modulation not relatable to muscle length changes was assumed to be influenced by fusimotor activity. In certain muscles (particularly those not immediately causing an ongoing movement), this presumption leads to the conclusion that gamma motoneurons may be activated out of phase with homonymous alpha motoneurons as well as by more conventional alpha-gamma motoneuron coactivation. Simultaneous recordings of two spindle primary afferents from extensor digitorum longus indicated that spindles within the same muscle may differ considerably with respect to this presumed gamma motoneuron drive.

On the basis of this preliminary survey, we would propose that the various "servo-control" hypotheses regarding tightly linked pathways for the simultaneous, proportional activation of alpha and gamma motoneurons may require considerable qualification. Our data suggests that even within a given motoneuron pool, voluntary or reflex activity may significantly and independently alter the alpha-gamma relationships for a given movement. Simultaneous activation of alpha and gamma motoneurons could often be inferred under particular circumstances, but the data as a whole indicate the ability to independently control the spindles as sense organs within their parent muscles. Activity in the alpha and gamma systems generally appears correlated during use of muscles as prime movers in a task and uncorrelated when the muscles are used as stabilizers or passive sensors of limb position for a given movement.

947 POSTURAL ANALYSIS IN CORTICAL AREA 5. W.A. MacKay, H.C. Kwan, J.T.Murphy and Y.C.Wong*. Dept. Physiology, Univ. of Toronto, Toronto, Ont., Canada, M5S 1A8.

In order to evaluate the relative importance of peripheral and central inputs to area 5 in a behaving primate, one may directly compare the activity of neurons, sensitive to joint rotation, during similar active and passive movements. Such a study was undertaken in 2 monkeys trained to move a manipulandum into specific positions guided by the visual display of a cursor and a target. By flexing or extending his hand, the monkey maintained the cursor on the target line as the latter was step displaced or as step torques were applied to the hand.

The most common type of neuron found (N=358) responded dynamically to rotation of one or more joints. Only 15 cells were dominated by wrist inputs. Passive and active wrist rotations gave the same response, excitation in one direction and inhibition in the opposite direction. The cells with dominant elbow, shoulder or leg joint inputs also showed directionally selective responses which were similar for both passive and active movements. Another group of 108 neurons responded tonically to maintained joint postures. Virtually all were large cells located in deeper layers of the cortex. Again the majority behaved similarly for passively-imposed postures and active maintenance of the same joint position(s). However, a few neurons were encountered which either phasically or tonically altered their firing rate during the task, but could not be driven by passive manipulation of the arm. In spite of a lack of sensory input, the activity of these cells was often closely related to joint angle or to isometric contractions acting on the joint in the same direction. The modulations of firing rate generally preceded any movement or attainment of targets.

We conclude that proprioceptive input is a major determinant of activity in area 5, being processed in a manner which produces an accurate measure of joint angle in probable output cells. But a central input is also present and appears to monitor the 'motor drive' to specific joint vectors. It is likewise modulated into a postural signal.

948 PROPRIOCEPTIVE SHAPING OF A CENTRALLY-INITIATED MOTOR PROGRAM DURING MOVEMENT OF THE CRAYFISH CLAW. John D. Marrelli* and James L. Larimer, Dept. Zool., U. of Texas, Austin, TX 78712.

The resistance reflex is generally thought to be inoperative during voluntary movements of the crayfish walking legs.[1] However, there is evidence[2] for a large increase in the resistance reflex sensitivity (2X) during attempted movements of the restrained crayfish claw. Evidence is presented here concerning the interaction of the proprioceptive inputs from the claw with the centrally-initiated motor activity that produces movements about the merus-carpus (MC) joint. In this series of experiments all of the joints of the limb except the MC were fixed. This joint was allowed to flex and lift the limb off a rest position on one stop to a contact with another stop. The lift-off and movement to the second stop was monitored as well as flexor motorneuron activity. Sensory receptors within the limb were selectively destroyed and their effects on flexor motorneuron behavior were observed. In the intact system, the dominant behavior was complex but consistent. There was a pre-lift-off acceleration of motorneuron activity followed by a post-lift-off inhibition. Upon contact with the second stop, the motor activity again accelerated briefly then terminated abruptly. Disruption of sensory receptors distal to the MC joint eliminated the abrupt cessation of the motor program after contact, with cessation becoming variable. Destruction of the myocordotonal organ as well as the distal sensory cells resulted in long-lasting oscillations of the motorneuron activity after contact with the stop. Destruction of the remaining cordotonal organs of the joint (MC1 and MC2) eliminated the inhibition of the post-lift-off motorneuron activity. The resulting waveform of the flexor motorneuron frequency resembled a rectangular pulse with a slight overshoot at the onset. These data indicate a proprioceptive modification of a centrally-generated motor program. In particular, the inhibition of flexor motorneuron activity during flexion suggests strongly an active role of the resistance reflex in the shaping of the motor program to achieve some peripheral matching of load with central control. 949 CAN EMG ACTIVITY BE USED TO DISTINGUISH "SLOW" VERSUS "FAST" MOVEMENT? N. Mayer, S. Naylor*, and H. Rosenholtz*. Dept. of Rehab. Med., Temple U. Health Sciences Center, Phila., Pa. 19140.

By considering movement displacement and its associated integrated EMG (IEMG) as processes which go to 100%, we have derived the "delta parameter" which describes how the EMG distributes itself with respect to displacement as a function of movement velocity. Subjects were asked to move a pivoted rod forward at different self-generated rates and various accuracy controlled amplitudes. Surface EMG from the agonist anterior deltoid was integrated over the course of the movement and displacement was measured by a potentiometer. Each movement was divided into a series of ten percent amplitude bins and the corresponding percentage accumulation of IEMG was identified by computer. The value of the delta parameter was obtained by adding up the differences between percent IEMG and percent displacement occurring at each 10 percent amplitude bin of the movement. Accordingly, if the IEMG process goes to 100% more quickly than the displacement process, the delta parameter will be positive. Conversely, the delta parameter is negative when IEMG rises more slowly than the movement. Results show that the delta parameter for anterior deltoid increases linearly with velocity at each movement amplitude while the slopes of the best fit lines vary inversely with amplitude. The delta parameter changed sign (from negative to positive) at different threshold velocities depending on the movement amplitude. However, when average accelerations were calculated for each movement amplitude, the delta parameter changed sign at similar accelerations independent of differences in amplitude or velocity of movement. These findings indicate that the distribution of IEMG with respect to movement displacement is quantitatively measurable and varies with movement speed and acceleration. Orchestration of central motorneuron drive according to the acceleration requirements of a given movement might be responsible for sign and magnitude changes in the delta parameter. It is suggested that a negative delta parameter for the agonist muscle might be a useful classifier of "slow" movements while positive values would be indicative of "fast" movements.

950 EFFECTS OF LESIONS IN DIFFERENT AREAS OF SENSORIMOTOR CORTEX ON M2 AND M3 STRETCH RESPONSES IN MONKEYS. Alan D. Miller and Vernon B. Brooks. Dept. of Physiology, Univ. of Western Ontario, London, Ontario, Canada N6A 5C1.

Perturbations applied to a monkey's forearm can produce three successive EMG responses in stretched upper limb muscles (M1, M2, M3 (1). M1 peaks at 15-20 ms following perturbation onset, i.e. at the latency of a spinal stretch reflex. M2 and M3 peak at latencies of 40-50 and 65-75 ms and are thought to depend on participation of supraspinal structures that have not been fully defined. Lesions of postcentral arm region (said to have involved areas 1, 2, 3b, most of 3a, and some of 5) abolish M1 (1). Many precentral neurons discharge in response to perturbations at latencies which would permit their participation in the generation of M2 and M3 (2). We made a series of lesions through the sensorimotor cortex to determine which areas contribute to M2 and M3.

Cebus monkeys were tranquilized with Atravet, and their forearms were firmly strapped to a manipulandum handle which could be displaced along a fixed and repeatable trajectory using a torque motor (3). Biceps EMG responses, obtained with fine-wire intramuscular electrodes, were filtered, full-wave rectified, and digitized online at a sampling rate of 1000 Hz using a PDP computer; 25 trials were averaged in 5 ms bins. Unilateral suction lesions were made sequentially in 4 monkeys in the arm area of pre- or postcentral cortex, which was first mapped using surface anodal stimulation. The extent of the lesions, which were histologically confirmed, involved some underlying white matter.

Lesions down the rostral bank of the central sulcus, which included all of area 3a, the overlying part of area 4, and the bottom part of area 3b, greatly reduced M2 and M3 in the contralateral arm in 2 cases studied. In contrast, lesions of the precentral cortex sparing that part overlying area 3a had little, if any, effect on M2 and M3 (relative to M1) in 3 animals. A lesion of the postcentral cortex sparing most of the caudal bank of the central sulcus also left M2 and M3 unchanged in relation to M1.

The results suggest that area 3a and/or the immediately overlying part of area 4 is essential for the normal occurrence of M2 and M3. This region may be part of a transcortical loop which mediates M2 and M3 and/or may provide tonic facilitation for subcortical structures which in turn mediate M2 and M3.

951 PROJECTION OF THE NUCLEUS CUNEIFORMIS TO PONTINE RETICULAR FORMATION IN THE RAT. Cheryl A. Miller* and Harry M. Sinnamon. Lab. of Neuropsychology, Wesleyan Univ., Middletown, CT 06457.

The influences of the midbrain reticular formation (MRF) on behavior could be mediated by connections to the reticulospinal system. In the cat these projections have been described in anatomical and electrophysiological studies. The present study describes this pathway in the rat. Single units were recorded extracellularly in DA Agouti rats (N=16) anesthetized with halothane (0.5-0.75%). Constant current monophasic pulses (0.1-0.3 msec) were delivered through stationary, twisted pair, stainless steel electrodes. In the principle experiment the recording electrode was advanced slowly through the pons while the MRF (primarily n. cuneiformis) was stimulated at 1 Hz, 500μA. Responses and latencies were determined for various regions of the pons. Since stimulation of the n. cuneiformis could activate passing fibers originating in other structures such as the tectum, a complimentary experiment was performed. In it the range of antidromic response latencies was determined for cells in n. cuneiformis that responded to stimulation in the various pontine regions. The limits of this range, adjusted for synaptic delay, provided the criterion for classifying a response in the pons to n. cuneiformis stimulation as monosynaptic.

Cells in the ipsilateral n. cuneiformis were antidromically activated by stimulation in reticularis gigantocellularis (RG) with a latency range of 0.75 to 1.3 msec. Monosynaptic excitatory projections from n. cuneiformis to RG were seen in 4 of 23 cells ($1.45 < \text{latency} < 2.0$ msec). Multisynaptic (latency > 3.8 msec) and non-cuneiformis (latency < 1.0 msec) projections were found in 5 other RG cells. The reticularis pontis caudalis (RPC) also showed an ipsilateral projection with 4 of 27 cells having latencies compatible with the antidromic latency range (1.4 to 2.4 msec). While the reticularis paragigantocellularis (RPG) apparently receives a projection from the n. cuneiformis (antidromic latency 0.8 to 2.2 msec, 5 cells), no monosynaptic excitations have been found in 9 RPG cells tested to date. RG and RPC appear to receive a monosynaptic excitatory projection from the contralateral n. cuneiformis which is as yet unconfirmed by antidromic studies. The reticularis parvocellularis shows no indication of ipsilateral projection in 16 cells tested. In summary these results obtained from the rat suggest a major slow conducting (1 to 4 m/sec) excitatory projection to the RG and RPG from the n. cuneiformis.

952 EVALUATION OF SPONTANEOUS FUSIMOTOR EFFECTS FROM AVERAGED DORSAL ROOT NEUROGRAMS TRIGGERED BY THE ACTION POTENTIALS IN A GAMMA EFFERENT. K.S.K. MURTHY, Y. YOON*, B.M. RIGOR*, P.L. GILDENBERG, and K.G. CHATMAJIAN*. Departments of Surgery (Neurosurgery) and Anesthesiology, University of Texas Medical School, Houston, Texas, 77030.

It is possible to record the spontaneous activity of single gamma efferents, preserving the integrity of their peripheral connections. Using such a technique, a simultaneous recording of multiunit afferent activity in dorsal roots has been undertaken in this study to permit identification of the type of gamma efferent being recorded. Adult cats were studied under halothane anesthesia after induction with ketamine hydrochloride. Surgical procedures included left hind limb dissection to expose the muscle nerves for stimulation and a laminectomy (L_4 to S_1). Blood pressure was monitored through a cannula in the left common carotid artery and an intravenous drip of lactated Ringers' solution maintained through the experiment. No peripheral nerves were sectioned. No roots were severed. While recording from the ventral rootlets (L_7), the filaments were teased in continuity until a single spontaneously discharging gamma efferent was isolated. Conduction velocity and muscle of destination were established by antidromic stimulation of various muscle nerves. The dorsal root (L_7) filaments were then searched for spindle afferents from the same muscle innervated by the efferent under study.

An envelope of the multiunit afferent discharge was obtained with a ratemeter (time constant 40 msec) and averaged, with the sweep being triggered by the spontaneously occurring action potentials in the γ efferent. Two types of responses correlating with fast or slow intrafusal contractions can be obtained. The faster response presumably results from contraction of nuclear chain intrafusal fibres and causes a peak in afferent activity within 15 msec after the occurrence of the γ spike. Multiple peaks in afferent response are observed at low rates of spontaneous activity in the γ efferent, probably due to oscillations in the nuclear chain fibres (Boyd, 1976). The slower response shows maximum afferent activity about 50 msec after the occurrence of the γ spike and may correlate with contractions in nuclear bag intrafusal fibres. It remains to identify the types of γ efferents contributing to the fast and slow responses observed here.

953 ORGANIZATION OF POSTURAL ADJUSTMENT CONTROL SYSTEMS IN HUMANS. Lewis M. Nashner and Marjorie H. Woollacott. Neurological Sciences Institute, Portland, Oregon 97209.

The EMG activity of four leg muscles (gastrocnemius, tibialis anterior, hamstrings and quadriceps) was measured while freely standing humans were subjected to unexpected movements of a platform capable of six independent degrees of motion (horizontal, vertical and rotational displacements of each foot). Earlier studies have shown that a neurally programmed fixed pattern of activity occurs in the four leg muscles in response to ankle joint rotation caused by anterior-posterior sway (G-H coupling for anterior body sway and T-Q coupling for posterior body sway). This fixed pattern has been termed the sway synergy. The present data show that vertical body movements causing predominantly knee joint rotation elicit a different fixed pattern of activity in the leg muscles (G-Q coupling for downward movement and T-H coupling for upward movement), which has been termed the suspensory synergy. This fixed pattern of EMG activity among proximal and distal leg muscles also appears to be programmed neurally (and not caused independently by stretching proximal and distal muscles), since the response pattern is not altered when one of the platform bases is rotated during a vertical change in height so that the ankle motion is unexpectedly dissociated from that of the knees. The sway synergy appears to be elicited whenever movements occur largely about the ankle joints, whereas the suspensory synergy is elicited by movements about the knee joints. Two subclasses of the suspensory synergy are observed, depending on whether synchronous or reciprocal vertical motions are used. During synchronous leg motions (described above) the G-Q and T-H pairs resist the movements, whereas during reciprocal motions they follow the platform movements.

Reorganization of activity from the sway into the suspensory synergy is evident in the first trial following unexpected changes from sway to vertical perturbations. This is in marked contrast to changes in the gain of the muscle responses which, as shown in earlier studies, takes three to five trials to adapt when the relation between proprioceptive inputs and postural sway motions is unexpectedly changed.

The following hypothesis is consistent with these experimental observations: the synergic arrangement of the muscles is organized at a lower level in the nervous system, based on the pattern of proprioceptive inputs. The adaptive changes, which require several trials, involve the integrative functions of the CNS and utilize more complex combinations of somatosensory, vestibular, and visual inputs.

954 PEDALING AND THE MONKEY MOTOR CORTEX. Edward J. Neafsey, Dennis Shaw*, and Arthur A. Ward, Jr. Dept. Neurol. Surg., Univ. Wash., Seattle, WA. 98195

Single units were recorded from the leg region of one monkey's precentral motor cortex during performance of a pedaling movement. The pedaling involved reciprocal movements of the legs, and within each leg there was a cyclic activation of flexors (TA) and then extensors (G-S) as determined by EMG recordings. The monkey's arms and head were restrained. Over 80% of the 38 units recorded thus far showed some modulation of their activity related to the movement. Thirty-seven percent were activated during the flexion phase of the contralateral leg (+F), 39% during the extension phase (+E), and 5% paused during execution of the flexion-extension sequence. The remaining 19% showed no clear modulation during the movement. The modulation of some units could be explained on the basis of their observed receptive fields determined during passive movements of the leg. For example, one unit was activated during contralateral knee extension during pedaling and also responded to passive extension of the same knee. However, this pattern was not always found and many cells had no obvious receptive fields. The +F and +E cells were also studied during arm and head movements. Individual cells displayed either a consistent increase, a consistent decrease, or no change in activity during these other movements. All three types of changes were found among the +F cells, while only decreases or no change were found among the +E cells. The 25 electrode penetrations were spaced 1 mm apart and formed a 5 x 5 grid. The location of +F and +F cells were plotted on this grid. Surprisingly, the general pattern observed was that of large adjoining zones of either +F or +E cells with little overlap between zones.

(This project was supported by NIH research grant number NS-04053 awarded by the National Institute of Neurological and Communicative Disorders and Stroke, PHS/DHEW.) Dr. Neafsey is also an affiliate of the CDMRC at the University of Washington.

955 PYRAMIDAL TRACT AND RED NUCLEAR PROJECTIONS FROM THE PRIMATE SUPPLEMENTARY MOTOR AREA. C. Palmer*, E.M. Schmidt and J.S. McIntosh. Lab of Neural Control, NINCDS, NIH, Bethesda, MD 20014

There have been several investigations as to whether the supplementary motor area (SMA) has a pyramidal tract projection. Coulter et al (Brain Res. 103:366, 1976) failed to find a pyramidal projection from SMA in cats from cervical and lumbar HRP injections though Murray and Coulter (Neurosci. Abs. 3, 1977) with the same method found the projection in primates. In this study we sought neurons in the SMA projecting to the pyramidal tract (PT) and red nucleus (RN) in four rhesus monkeys using electrophysiological techniques. Neurons were found with antidromic invasion from stimulation of the pyramids or red nucleus and recorded with glass coated PT/IR microelectrodes, their impedances ranging from 1 to 2.5 Meg at 1 KHz. The criteria for antidromic invasion were a constant threshold and latency, the latency also being constant with high frequency stimulation; these ranged from 200 Hz to 500 Hz. When the cells had spontaneous activity, antidromic invasion was tested with the spike collision method. The pyramidal tract was stimulated with a bipolar coaxial stainless steel electrode 0.5 mm in diameter. The average threshold for PT cells was 365 μA; for RN neurons 401 μA (the threshold ranged from 50 μA to 650 μA for PT neurons and 80 μA to 800 μA for RN neurons, with pulse duration of 0.1 msec). RN neurons were stimulated via a similar bipolar electrode 0.2 mm in diameter or via an array of two monopolar stainless steel electrodes, 0.2 mm in diameter separated by 1 mm, with current balancing resistors in series. Stimulation occurred via an anode in the scalp. Their location was established from histological reconstruction of the electrode tracks. Fifty-eight projection neurons to the pyramidal tract were recorded and their latencies varied from 0.5 to 13 msec, 53.6% having latencies between 0.5 and 3 msec. Twenty-nine projection neurons to the red nucleus were recorded and their latencies varied from 1.2 to 6 msec. They were more evenly distributed in their range than PT neurons. Antidromically invaded neurons from the same region in the midbrain tended to be clustered together and often units with different antidromic latencies could be recorded at one electrode site. However, PT and RN neurons were rarely intermingled in this way. More RN neurons than PT neurons were recorded in laminae III and the superficial parts of laminae V. The PT neurons were generally found in the deeper parts of laminae V and laminae VI. No evidence was found of collaterals from the pyramidal tract to the red nucleus. Humphrey and Reitz (Brain Res. 110: 162, 1976) investigated PT and RN projections from the hand area of the primate motor cortex and found an average of 7 PT and 2.8 RN neurons per track. We found an average of 3.1 PT and 1.1 RN neurons per tract in the SMA.

956 CONTROLLED LATERAL PINCH AND RELEASE IN THE C6 QUADRIPLEGIC INDUCED BY ELECTRICAL EXCITATION. P. Hunter Peckham* (SPON: F.T. Hambrecht) Case Western Reserve University, Cleveland, Ohio 44106

Electrical excitation of paralyzed muscle provides a technique to elicit controlled contractions in paralyzed limbs. In this study, this approach was applied to the C6 spinal cord injury patient to provide control of lateral pinch (key grip) and release. The C6 quadriplegic retains voluntary motor control of shoulder motion, elbow flexion, forearm supination and pronation, and wrist extension, but is paralyzed otherwise. As the patient extends his wrist (without stimulation), the passive force exerted by stretching of the thumb flexor closes the thumb against the index finger (tenodesis grasp). The force is sufficient to enable him to pick up and hold large, lightweight objects.

Muscle stimulation augments voluntary tenodesis function. Chronically indwelling percutaneous coiled wire electrodes are implanted into thenar muscles (adductor pollicus and/or opponens pollicus), finger flexors, and thumb extensor. The electrodes pass through the skin on the volar and dorsal aspects of the forearm just proximal to the wrist. The force in each muscle is controlled through a recruitment and temporal summation scheme, by modulation of the stimulus pulse width and frequency respectively. A single command signal modulates the stimulus parameters according to a predetermined algorithm. Finger flexor stimulation always precedes stimulation of the intrinsic thumb muscles to provide a stable platform for lateral pinch; release is provided by stimulation of the thumb extensor. The command source for muscle activation is a two level processed myoelectric signal (MES) from a muscle which retains voluntary function. A low level MES increases or decreases the stimuli, a zero level MES maintains the stimulus, and high level MES either reverses the direction of stimulus change or deactivates the stimulation, depending upon the length of time the level is held.

Five subjects have utilized this system and have found its function beneficial in performing tonic tasks, such as eating and writing.

957 ON THE RELATIONSHIPS BETWEEN SELECTED PARAMETERS OF MOTONEURON - MOTOR UNIT "TYPE" AND THE ABSOLUTE VOLTAGE THRESHOLD OF THE MOTONEURON. M.J. Pinter*, R.L. Curtis, M.J. Hosko. Depts. of Pharm. and Anat., Medical College of Wisconsin, Milw. WI 53233

Among the indices of motoneuron-motor unit "type", an inverse relationship has been established between motoneuron size and cell membrane resistance (RES). Positive correlations have been established between membrane resistance and duration of afterhyperpolarization (AHP), between membrane resistance and twitch contraction time (TWT) of the functionally isolated motor unit and between duration of AHP and TWT. The amplitude of the maximum homonymous EPSP is positively correlated with motoneuron resistance. It has been assumed that the absolute voltage threshold (TH) and depolarization (DEP) necessary to elicit an orthodromic response in a motoneuron is independent of the above variables. This study was designed to test the validity of this assumption. We examined functionally isolated motor units of the triceps surae motoneuron pool in the anesthetized cat. Blood pressure, deep rectal, spinal and muscle oil pool temperatures were monitored. Units to be studied were identified by antidromic stimulation of lateral gastrocnemius (LG) - Soleus (Sol) and medial gastrocnemius (MG) nerves. Upon impalement of a motoneuron, the following parameters were measured: AHP duration, cell membrane RES (spike height method), DEP necessary to elicit an orthodromic spike (transected dorsal root stimulation) and resting membrane potential (RMP). Any cell whose RMP was less than 50 mV was excluded from analysis. Positive identification of the motoneuron was made by attaching the appropriate muscle tendon to a strain gauge myograph; TWT, twitch tension and tetanic tension of the motor unit were measured. 122 cells were studied. Full or partial results were obtain from 25 Sol and 97 MG-LG motoneurons.

As reported by others, we found the following pairs displayed significant positive correlations: AHP and RES, AHP and TWT and RES and TWT. We also demonstrated weak correlations among the following pairs: AHP and DEP, ($r = -.22$, $P < .01$), AHP and TH ($r = .21$, $P < .01$) and RES and TH ($r = .35$, $P < .01$). The correlations between TH and RMP ($r = .87$) and between DEP and RMP ($r = .46$) were significant ($P < .001$). Correlations between TWT and TH, TWT and DEP, RES and DEP, AHP and RMP and TWT and RMP were insignificant These data indicate that the TH and DEP of the motoneuron are tightly related to the RMP and minimally related to other indices of motoneuron-motor unit "type". 958 RELATION BETWEEN EXTRAFUSAL AND INTRAFUSAL ACTIVITY IN THE DECEREBRATE CAT MODEL: A ROLE FOR BETA FIBERS. E. Post*, W.Z. Rymer and Z. Hasan*. (SPON: C.J. Hodge). Neurosurgery Laboratory, S.U.N.Y. Upstate Medical Center, Syracuse, New York 13210.

The relation between extrafusal and intrafusal activation is presently unclear. In some circumstances (such as isometric contraction of human finger flexors (1)) the activation appears tightly coupled whereas in others (such as cat locomotion (2)) the relation is claimed to be less rigid. Furthermore, the physiological role of beta axons, whose presence is now widely confirmed in mammalian muscles, remains largely unexplored.

We have examined the relation between extrafusal and intrafusal activation in the triceps surae muscles of the decerebrate cat. The state of intrafusal activity was deduced from the discharge of identified primary and secondary endings, isolated from small dorsal root filaments. Spindle receptor properties were examined under isometric conditions, during ramp muscle stretch and during isotonic muscle shortening. The state of extrafusal and intrafusal excitation was varied using a range of stimuli, most often the crossed extensor reflex.

In most primary endings (35/42) crossed extensor activation induced a progressive increase in receptor discharge, commencing well before the onset of extrafusal force or emg activity. There was usually no further increase in discharge once extrafusal threshold was reached : in fact, at high forces receptor discharge rates sometimes fell. This sequence of activation suggests that fusimotor neurons are recruited first and saturate before or about a level of excitability equivalent to extrafusal threshold.

A smaller number of primary endings, and a significant fraction of secondary endings accelerated their discharge as force increased. Although it is possible that this acceleration of discharge was mediated via a different class of gamma fibers to that cited above, it is equally likely that beta motoneuronal discharge may have been responsible, since beta axons have been demonstrated in these muscles.

The role of beta fibers may be to increase intrafusal contraction in circumstances where gamma neuronal action is effectively saturated.

959 LARGE DISPLACEMENT ACTION TREMOR OF THE ANKLE IN NORMAL SUBJECTS. R. Pozos, D. Deetz*, and P. Iaizzo* (SPON: Alex Fedinec). Dept. of Physiol., Univ. of MN-Duluth, Sch. of Med. and Nat Polinsky Rehab. Center, Duluth, MN.

Studies concerning the mechanisms of pathological tremors which are characterized by a large displacement and a low frequency infer that the frequency and amplitude of these tremors are unique to the disease state. However, recent reports indicate that large displacement, low frequency oscillations which have been called "physiologic clonus" are induced by fatiguing the muscles. Our studies indicate the presence of an action tremor (5-6 Hz) with a large displacement (2-3 cm) in normal subjects who have not been fatigued.

Subjects were seated and an accelerometer (Gulton AVR 250) was taped to the knee. Electromyographic signals from the tibialis anterior and the soleus were amplified and recorded simultaneously with the motion. Subjects were instructed to raise their heels as high as possible and to slowly lower it.

As the heel was raised a frequency of 7-8 Hz was observed with displacement values of 20-35 micra. As the heel was lowered a frequency of 5-6 Hz was seen with a displacement value of 2-3 cm. This large displacement low frequency oscillation was position dependent in that it only occurred at a certain distance off the floor as the subject was lowering his heel and not during the full range of motion. This action tremor (tremor occurring during motion) was seen every time the subject lowered his heel. Subjects who had been fatigued by running a number of miles also demonstrated this action tremor. In some cases the action tremor in the fatigued subjects progressed into a self sustained oscillation which had the same large displacement and low frequency values as the action tremor. Similar studies were conducted on a number of Parkinsonian patients who had an overt ankle tremor. Their displacement and frequency values were similar to the action tremor seen in control subjects.

Since this study shows that the action tremor has the same displacement and frequency values as the pathological tremor, it would suggest that the mechanism for abnormal tremors is inherent in control subjects. Further since this action tremor is found in non-fatigued individuals, this finding would indicate that alteration of the properties of muscles through fatigue is not a major component of the mechanisms for these oscillations.

960 ELECTRON MICROSCOPIC CHARACTERISTICS OF FINE GRAIN DEGENERATION IN THE RAT. P.M. Ritschel, K. Kultas-Ilinsky, P.A. Young, L.C. Massopust, and R.A. Owler*. Dept. Anat. St. Louis Univ. Sch. Med., St. Louis, MO 63104.

The purpose of this investigation was to characterize, at the electron microscopic (EM) level, the fine grain degeneration seen in the ventrolateral-ventroposterior (VL-VP) and intralaminar (IL) complexes after lesions in the motor cortex of the albino rat. The Fink-Heimer technique was used to localize the areas of fine grain degeneration with light microscopy. Cores for EM were taken from areas of densest concentration of fine grain degeneration. In the VL-VP complex, a dense area first appeared at 2 days postoperatively, became heaviest at 4 days, and disappeared after 8 days. In the IL the fine grains were observed in the lateral central nucleus at 11 days and in the lateral central and paracentral nuclei at 14 days. At 21 days no fine grains were observed in these nuclei. Injections of tritiated leucine into the motor cortex were used to confirm corticothalamic terminations in these areas.

Ultrastructural studies of the VL-VP area revealed small unmyelinated preterminal axons and synaptic boutons degenerating 2 days postoperatively. The degenerating structures had a dense matrix and occasionally swollen vesicles could be seen. The degenerating boutons appeared in clusters surrounding medium sized dendrites. The number of degenerating structures increased three fold in 4 day survival animals. Only a few degenerating boutons were seen at 8 days; none were observed at day 11. No changes in neurons were observed at the survival periods studied. The same types of degenerating axons and boutons were found within the IL complex at 11 days. At day 14 larger boutons, in addition to the small ones, were seen degenerating. Fragments of large myelinated axons were also observed. There appeared to be dilatations of rough endoplasmic reticulum and a decrease in ribosomal rosettes in neurons in the IL nuclei at day 14 and later. At day 21 very few degenerating boutons were observed.

The fine grain deposits within the VL-VP are the result of small degenerating unmyelinated preterminal axons and boutons. The lack of neuronal changes indicated that alterations in thalamocortical fiber collaterals were not present. The fine grain deposits in the IL appeared to be the result of degenerating terminal axons and boutons of various sizes. However, the changes seen in the neurons here indicate the possibility of some retrograde changes in this area at the longer survival times. (Supported in part by USPHS grant FR 05388.)

961 CUTANEOUS INPUT TO NECK MUSCLE MOTONEURONS OF THE CAT. P.K. ROSE and N. SPROTT*. Department of Physiology, Queen's University, Kingston, Ontario, Canada. K7L 3N6.

Several studies have indicated a close anatomical and functional relationship between the trigeminal system and the upper cervical spinal cord. The aim of the present work was to examine the responses of identified neck muscle motoneurons to stimulation of cutaneous afferents innervating the face. Experiments were performed on adult cats anaesthetized with chloralose (70 mg kg^{-1}). Intracellular recordings were obtained from motoneurons innervating deep dorsal neck muscles (biventer cervicis and complexus, BC-C) more superficial neck muscles (splenius, S), and lateral neck muscles (trapezius, T). Stimulation of the infraorbital (IO) and supraorbital (SO) nerves consistently led to the appearance of EPSPs in ipsilateral S and BC-C motoneurons. In contrast ipsilateral T motoneurons were usually inhibited by SO stimulation and the effects following IO stimulation were mixed. Stimulation of the contralateral IO led to EPSPs in all 3 motoneuron groups although a significant proportion of T motoneurons were inhibited. The response to contralateral SO stimulation was excitatory in T motoneurons, inhibitory in BC-C motoneurons, and mixed in S motoneurons.

Additional experiments using graded electrical stimulation of the IO nerve revealed that the response of S and BC-C motoneurons usually occurred at low threshold (1-2 T) stimulation. Increasing the stimulus strength to 10 T or greater did not alter the nature of the response and led to EPSPs with latencies of 2.0 to 7.0 msec. Gentle tapping of the nose and surrounding vibrissae led to EPSPs and action potentials in S and BC-C motoneurons.

The nature and pattern of the responses of neck muscle motoneurons following stimulation of the IO nerve suggests that cutaneous input originating from the nose will result in lowering of the head to avoid the stimulus. Moreover this behaviour can be triggered by innocuous mechanical stimuli. In contrast responses to SO stimulation would suggest that a more complex movement would result, perhaps related to orientation.

962 PATTERNS OF CONTRALATERAL LIMB RESPONSES TO NOCICEPTIVE STIMULI DURING LOCOMOTION. S. Rossignol and L. Gauthier*. Centre de recherche en sciences neurologiques, Université de Montréal, Québec, Canada H3C 3T8.

When a nociceptive skin stimulus is applied on a skin nerve of a hindlimb in acute spinal cats treated with Clonidine the contralateral hindlimb extends when it is placed initially in a flexed position and conversely flexes when placed in extension (Grillner and Rossignol, Brain Res., 144: 411-414, 1978). The present study also reports on a reversal of contralateral effects but during locomotion in high decerebrate cats walking on a treadmill The stimuli (100 ms trains, 100 Hz, 1 ms pulses at or above 40X threshold for the largest fibers) were randomly delivered to the superficial peroneal nerve on one side (ipsilateral limb) at different periods of the walking cycle. The EMG activity of selected extensors and flexors was recorded bilaterally. On the ipsilateral side, the stimulus invariably evoked a flexion response irrespective of the step cycle phase. In the contralateral limb, however, increases in amplitude of either the extensor or the flexor EMG bursts were observed with stimuli occurring some time prior to or during the respective bursts and modified the ongoing limb movement. Two general patterns can thus be described. First, when the stimulus is applied during the ipsilateral swing phase, the pattern is an increase both in ipsilateral flexion and contralateral extension. Second, when the stimulus occurs during the ipsilateral extension phase, the ipsilateral extensor is inhibited and replaced by a flexion response while the contralateral flexion is enhanced. In the first pattern, the contralateral limb preserves a stable alternate gait despite the large increase of the extensor burst amplitude. In the second pattern, the alternate gait is suddenly changed to a gallop with both limbs at different degrees of flexion. The contralateral limb flexor burst is then either increased in amplitude which accelerates the swing phase or lengthened which delays the onset of extension or even resets the limb step cycle in order to rephase it properly in alternation with the other limb. This work thus emphasizes that with a nociceptive stimulus the classical pattern of crossed extension is seen only in a certain period of the locomotor cycle when its function then is to sustain the weight of the animal. In other parts of the cycle, this response is not only abolished but replaced by a facilitation of flexor muscles enabling the animal to reestablish an alternate gait pattern within one or two walking cycles.

963 SERVO-REGULATION OF MUSCLE CONTRACTION IN MAN: A REEVALUATION. W.Z. Rymer, Z. Hasan* and B.C. Corser*. Neurosurgery Lab., S.U.N.Y. Upstate Medical Center, Syracuse, New York 13210.

The early electromyogram response to abrupt muscle stretch does not serve to reestablish muscle length; rather it appears to contribute to the regulation of net muscle stiffness (1). Previously proposed mechanisms for the neural regulation of muscle have emphasized feedback servo control, using length and force signals originating in muscle to provide the required error signals. Here we address several potential inadequacies of this approach.

Forcible, constant amplitude extensions of the contracting human long thumb flexor, applied over a range of different velocities, produce virtually constant peak forces in spite of widely differing emg responses. In the extreme case, extensions completed before the onset of significant emg action (at 40 msec) produce forces similar to those observed during slower stretches, even though emg action could have made no contribution to the dynamic force trajectory. The observations suggest that intrinsic mechanical properties of muscle are responsible for much of the dynamic force trajectory.

When the mechanical properties of an adjacent, similar synergist were studied, the latter expectation was confirmed. We used percutaneous stimulation of a relaxed index flexor (FDS) to evaluate muscle behavior under 'open-loop' conditions. The deviations between electrically and reflexively activated force for this muscle were small, of late onset, and strongly dependent upon initial force. Furthermore, the most marked deviations occurred at movement cessation where electrically stimulated muscle showed significant force adaptation.

Since the length afferent signal is essentially controlled in our experimental paradigm, the only available correctional feedback signal capable of compensating for the inadequacies of intrinsic muscle force arises from tendon organs. However, tendon organ information appears to act simply as a proportional feedback signal with little dynamic component, hence such information could not be used (alone) to prevent undesirable deviations in force trajectory. This is consistent with the conclusion that the dynamic force trajectory in our subjects may rely largely upon intrinsic muscle properties. The emg response may be issued in response to a qualitative prediction of impending decline in intrinsic muscle stiffness, rather than as a correction activated by measured error.

964 REFLEXOGENIC AND PSYCHOGENIC REFLEX MODULATION: DIFFERENTIAL EFFECTS ACCORDING TO POLYSYNAPTIC AND OLIGOSYNAPTIC PATHWAYS IN HUMANS. Jerome N. Sanes*, James R. Ison, and Alice A. Adelson*. Dept. Psychology, Univ. of Rochester, Rochester, NY 14627.

Electromyographic activity recorded from orbicularis oculi in humans, was elicited by percutaneous electrical stimulation of the supraorbital branch of the trigeminal nerve. The reflex consists of an early brief ipsilateral response (R1) with a latency of about 10 msec and a more prolonged later consensual response (R2) with a latency of 30-40 msec. An oligosynaptic trigemino-facial path mediates R1, a polysynaptic path through the pontomedullary reticular formation mediates R2. The plasticity of R1 and R2 was investigated as a function of sensory stimulation preceding reflex elicitation, voluntary delivery of the shock and repetition of the shock.

In Experiment 1 brief tones (S1), at 70 dB SPL, were presented from 5 to 800 msec before the eliciting stimulus (S2). In Experiment 2 tones of intensities varying from 30 to 70 dB SPL preceded S2 at a fixed lead time of 100 msec. In each experiment S1 facilitated R1 and inhibited R2. Facilitation of R1 developed more rapidly than did inhibition of R2. The time course of facilitation had two peaks, at 50 and at 800 msec lead times, whereas inhibition had a single peak at 200 msec. Both effects increased linearly with S1 intensity. Contrary to earlier reports the reflex threshold for R1 was greater than that of R2 (11.0 mA vs. 2.3 mA). In Experiment 3 self-presentation of S2 provided reflex thresholds of R1 and R2 which were roughly equivalent. Increased S2 intensity increased both R1 and R2, but self-delivery inhibited R2 whilst markedly facilitating R1. In Experiment 4 repetition of S2 (rates of .2, .5, and 1/sec) resulted in habituation of R2 and sensitization of R1, both effects directly related to presentation rate. We note that prior experiments which have reported equivalent reflex thresholds use either self-presentation or repetitive delivery; these conditions are favorable for R1, unfavorable for R2.

We believe these collective findings reveal two processes, one reflexogenic and the second psychogenic, involved in the modification of R1 and R2. The reflexogenic process manifests itself in the time course of R2 inhibition, in the early facilitation of R1 following the tone, and in the habituation of R2. Psychogenic processes, having to do with awareness of stimulus imminence, seem responsible for facilitation of R1 at the 800 msec S1-S2 interval, for the potentiation and inhibition of R1 and R2 by self-delivery, and for the facilitation of R1 by repetitive shocks: these latter effects suggest the presence of a central reflex modulatory mechanism which is activated by warning stimuli as well as by volitional events.

965 SYNCHRONY OF VIBRISSA MOVEMENT WITH THETA AND ALPHA RHYTHMS IN RATS: NEUROANATOMICAL SUBSTRATES. K. Semba and B. R. Komisaruk. Inst. Anim. Behav., Rutgers Univ., Newark, N.J. 07102

Normal rats show two types of rhythmical vibrissa movement, one often synchronized with theta waves of the limbic system (Komisaruk, JCPP, 1970, 70, 482), and the other synchronized with what are probably alpha waves of the thalamocortical system (Semba, Szechtman, & Komisaruk, Soc. Neurosci. Absts., Vol. III, 1977, No. 889). The theta-synchronized movements occur at a dominant frequency of about 7/sec, appear during exploratory sniffing behavior, and are of large amplitude. The alpha-synchronized movements occur at a dominant frequency of about 9/sec, appear while the rat stands still, and are of small amplitude (a fine tremor). Thus the facial nucleus, which is the final common motor pathway, apparently receives input convergently from these two systems. In the present study, we have also observed that: (1) The two types of movement rarely, if ever, appear together and the same is true of the two brain wave patterns. Topographically, the predominant appearance of the alpha waves is in the anterior half of the cerebral cortex, whereas that of the theta waves is in the posterior half. (2) Bilateral ablation of either the entire neocortex or just the sensorimotor area eliminated the vibrissal alpha-tremor movement while leaving vibrissal theta-exploratory movement normal. The tremor movements showed a slight recovery (short irregular bouts of very small amplitude) 7 weeks after surgery in a few rats. Unilateral neo-decortication eliminated normal contralateral tremor movement for 3-6 weeks in some rats, whereas in some rats, no detrimental effect of this operation on tremor was observed. (3) Sensory feedback from the tremor movement to the CNS does not seem to play a critical role in generation or maintenance of the tremor, for cutting the maxillary division of the trigeminal nerve did not abolish the tremor. The transection did not affect the exploratory vibrissa movement, either. (4) Depletion of monoamines with tetrabenazine (10 mg/kg, i.p.) induced the alpha-tremor and the associated synchronized EEG activity, but not theta-exploratory vibrissa movements or theta activity. We are currently investigating the effect on the alpha-tremor activity of septal lesions, which disrupt exploratory vibrissa movement and theta waves. Preliminary results with cerebellar ablation indicate that it selectively abolishes the alpha-tremor of the vibrissae, but not the theta-exploratory movement of the vibrissae.

966 PERIPHERAL, SPINAL AND SUPRASPINAL MECHANISMS OF SUSTAINED CLONUS. Arthur M. Sherwood* and Milan R. Dimitrijevic. Dept. Clin. Neurophysiol., Tex. Inst. for Rehab. and Res., Houston, TX. 77030.

Sustained ankle clonus can be described as a repetitive stretch reflex, elicited by activation of stretch receptors during the relaxation period of the cyclically stretched muscle(Hagbarth et al, J. Neurol., Neurosurg., Psych., 38: 636-641, 1975). The persistence of the clonus rate in spite of changing loads led Walsh to conclude that a central pacemaker played a key role in controlling the clonus rate(Walsh, J. Neurol., Neurosurg., Psych., 39: 266-274, 1976).

Testing which of the two mechanisms, peripheral or spinal, is the predominant factor in controlling the rate of clonus in spinal cord injury patients, we used EMG, position and force measurements of the effects of additional afferent volleys applied at various phases of the clonus cycle. The afferent volleys, whether from electrical stimuli(H-reflexes), phasic stretch(T-wave) or tonic stretch(tonic vibratory reflex), produced an output only if their arrival coincided with the stretch afferent volleys producing the next clonus cycle. We have found that the frequency of clonus is constant within $\pm$ 1 Hz, and that this frequency cannot be altered appreciably by modifying the peripheral or central experimental conditions. This constant frequency is not determined by peripheral factors, but rather by the centrally determined period of unresponsiveness to additional proprioceptive volleys between two successive contractions.

We have also found that the contribution of supraspinal facilitation of segmental reflex mechanisms is essential to sustained clonus. This facilitation maintains the state of segmental excitability, which in turn governs the incoming stretch receptor volleys. Examining 27 incomplete and 39 paralyzed spinal cord injury patients for the presence of clonus in the quadriceps and triceps surae muscles bilaterally, 14% of the incomplete but only 4% of the paralyzed patients showed sustained clonus, although both groups exhibited clonus(50% of incomplete and 57% of paralyzed).

967 DYNAMIC PROPERTIES OF CAT TENUISSIMUS MUSCLE. J. F. Soechting and Sofia Sanchez Robles* (SPON: C. K. Knox). Laboratory of Neurophysiology, University of Minnesota, Minneapolis, Minnesota 55455.

The dynamic characteristics of the tension generated by an isolated tenuissimus muscle-nerve preparation were evaluated under several experimental conditions with the aim of providing a general model description for this muscle incorporating some of the non-linear features of its behavior. Average muscle twitch was calculated by randomly stimulating the muscle nerve at different mean frequencies under isometric conditions. Mechanical stiffness of the muscle was determined by imposing sinusoidal changes in length while stimulating the muscle at a constant frequency. The interaction between mechanisms responsible for generating active tension and the mechanical stiffness was evaluated by simultaneously imposing random changes in muscle length and random electrical stimulation. In agreement with the 3-element model for muscle, the average twitch response under this condition was identical to that obtained under isometric conditions. The effect of immediate past history of muscle activation on the active tension was ascertained from 2nd order Wiener kernels characterizing the incremental active tension due to two stimuli separated by various times. A model for this muscle incorporating some of these non-linear features will be presented. (Supported by NIH Grant NS-02567.)

968 MUSCLE RECEPTOR RESPONSES TO CONTRACTIONS OF SMALL GROUPS OF CONCURRENTLY AND INDEPENDENTLY ACTIVE MOTOR UNITS. E. K. Stauffer, R. A. Auriemma* and G. P. Moore. Univ. Minn.-Duluth Sch. Med., Duluth, MN 55812 and Dept. Biomed. Engr., USC, Los Angeles, CA 90007.

Responses of single muscle receptor afferents to contractions of motor units in the cat tibialis posterior were studied in order to derive how the response of a receptor to any given motor unit was modified as additional independently stimulated motor units were activated.

Single motor units were functionally isolated from ventral rootlets at the L_6-L_7 level. Single spindle group Ia, group II and tendon organ afferents were identified and isolated from corresponding dorsal root filaments.

Responses of each afferent were recorded during periodic (1/sec) stimulation of every motor unit individually, and PST histograms were constructed to show the average behavior of the afferent spike train to the motor unit contraction. Average motor unit contraction profiles were also calculated using force measurements from the tendon. Following this, the same afferent was tested as two or more motor units were stimulated at mean rates of 5-10 pulses/second by concurrent and independent Poisson pulse trains obtained from Geiger counter-triggered stimulators. In every instance the form of the PST histogram describing the average behavior of the afferent response during the motor unit contraction changed qualitatively and quantitatively as additional motor units were activated, usually revealing a striking relationship between the time course of the afferent PST histograms and each averaged motor unit tension record.

A new two-dimensional cross-correlation technique was used in addition to determine whether responses to summed motor unit contractions could be predicted from the response to single contractions, or whether non-linear interactive effects occur between successive contractions of a single motor unit or between motor units known to effect a common receptor.

969 CHANGES IN THE RECRUITMENT THRESHOLD OF MOTOR UNITS PRODUCED BY SKIN STIMULATION DURING SLOWLY INCREASING VOLUNTARY MUSCLE CONTRACTIONS IN MAN. J.A. Stephens* and R. Garnett* (SPON: D.G. Stuart). Sherrington Sch. of Physiol., St Thomas's Hosp. Med. Sch. London ENGLAND

The force of abduction of the index finger produced by contraction of first dorsal interosseous muscle (1DI was recorded using a strain gauge placed against the lateral side of the proximal interphalangeal joint. Motor unit action potentials were recorded using a mono polar concentric needle electrode inserted into 1DI.

Once a single motor unit action potential had been isolated, the subject was required to make repeated isometric contractions following a target on an oscilloscope screen. The task was so arranged that for each contraction the subject's force rose linearly with time until it reached approximately twice the level at which the motor unit first started to fire. The subject then relaxed. Each ramp contraction lasted approximately 10 sec and was repeated every 18 sec.

After at least 6 control contractions, the index finger was stimulated via ring electrodes placed on either side of the proximal interphalangeal joint (50 pps, pulse width 0.1 ms). Stimulus strength was set at 4x threshold for perception. Such stimulation is not painful but elicits a sensation similar to having the finger firmly gripped. With one exception, the recruitment threshold of units gradually changed during stimulation reaching a new level after some 2-4 min. Low threshold units (control recruitment threshold < 150 g or approximately 6% maximum;n=17) had their recruitment threshold raised by skin stimulation. Increases in threshold ranged from 21 to 188 g or 0.31 to 72 times control values. High threshold units (control threshold > 150 g; n=7) had their recruitment threshold lowered. Reductions in threshold ranged from 13 to 418 g or 0.28 to 0.95 times control values. For the majority of units recruitment threshold returned to control within 1-2 min after the end of stimulation.

We conclude from these results that cutaneous stimulation alters the recruitment order of motor units during normal voluntary muscle contractions in man. This finding coupled with previous observations in the decerebrate cat (Kanda et al, 1977) lends further support to the view that the recruitment order of motor units is not fixed but depends in part on the nature and distribution of input to the motoneurone pool.

Kanda, Burke & Walmsley. Exp Brain Res 29 57-74 1977

970 STABLE OSCILLATIONS OF A SKELETAL MOTOR CONTROL SYSTEM. Robert N. Stiles, Dept. of Physiology and Biophysics, Univ. Tenn. Cntr. Hlth. Sci., Memphis, TN 38163.

Postural tremors of the hand are suggestive of an instability of the neuromuscular system controlling that structure. However, these continuous oscillations may also reflect the transient responses of a stable system to continuous internal disturbances. According to R.W. Jones (Principles of Biological Regulation, Academic Press, NY, 1973, pp 240-244), the possible operating points of a physical system are of two kinds, either stable or unstable. If a system is unstable, any disturbance will cause the system to move away from a steady-state level and never return. Therefore, any kind of disturbance can be used to "test" the system for stability. In the present study, a pulse of force (an external disturbance) was repetitively (about one/sec) imposed upon the outstretched hand of a normal human subject. This was done over different 16-sec periods during a 40-60 min period that the subject continuously maintained the hand extended against gravity. During this 40-60 min period, postural hand tremor occurred having root-mean-square (rms) displacement amplitudes ranging from 30 to 4500 micra. Hand motion was detected with an AVR-240 accelerometer mounted 16 cm from the wrist, and the voltage analog of acceleration was digitized at 64/sec. Bipolar, surface EMG's from a wrist extensor muscle were digitized 1024/sec, rectified and smoothed, resulting in amplitude demodulated EMG records with an equivalent sampling rate of 64/sec. Auto- and cross-spectral analyses were performed on the simultaneously obtained 16-sec records of EMG's and postural hand oscillations. When applied between recordings of tremor of different rms displacement levels, the pulse disturbances consistently resulted in damped (die-away) oscillations of the outstretched hand. These results indicate that the system producing both large- and small-displacement amplitude hand tremors should be considered stable. High coherence values were obtained between the amplitude demodulated EMG and hand tremor for tremors with amplitudes above about 100 micra. Similar coherence values were obtained between the EMG's and damped oscillations of the hand. Therefore, the presence of amplitude modulation of wrist extensor EMG's which is highly coherent with the postural hand tremor is not sufficient for the maintenance of these stable oscillations. (Supported in part by USPHS Grant NS-08692.)

971 MULTIPLE REPRESENTATION IN THE PRIMATE MOTOR CORTEX: A NEW CONCEPT OF INPUT-OUTPUT ORGANIZATION FOR THE REPRESENTATION OF DISTAL FORELIMB. Peter L. Strick and James B. Preston. Depts. of Neurosurgery and Physiology, SUNY, Upstate Medical Center, and V.A. Hospital, Syracuse, New York 13210.

The motor output and somatosensory afferent input of area 4 were mapped in the squirrel monkey using microstimulation and unit recording. The squirrel monkey was chosen because none of its forelimb area of motor cortex is buried within a sulcus. Animals were initially anesthetized with pentobarbital sodium (25 mgm/Kgm). Ketamine HCl (5-10 mgm/Kgm) was given as needed to maintain anesthesia. Glass-coated, platinum-iridium microelectrodes (approx. 1 MΩ) and a closed chamber system were used for microstimulation and unit recording.

The results from microstimulation showed that there are two, spatially separate hand-wrist representations in area 4. Stimulation in area 4 just rostral to area 3a evoked movements of the hand (thumb and fingers). Rostral to this hand region was a zone from which wrist movements were evoked. Moving further rostrally in area 4, there was an abrupt transition to a second zone of hand representation and anterior to this a second zone of wrist representation. The hand and wrist movements evoked and their thresholds were similar in the two motor representations. We have termed the hand and wrist representation adjacent to area 3a the caudal motor representation, and the second, more anterior hand and wrist representation, the rostral motor representation.

The results of single unit recording in area 4 demonstrate that the caudal and rostral motor representations receive different patterns of somatosensory afferent input. Units driven by cutaneous stimulation were concentrated in the caudal representation while units driven by joint and/or muscle stimulation were concentrated in the rostral representation.

On the basis of these observations, we believe that the two motor representations reflect two motor systems in area 4 which are designed to control different aspects of distal forelimb motor behavior. (This study was supported in part by funds from the Veteran's Administration Research Fund and USPHS Grant N502957.)

972 NUCLEUS OF THE CRUS CEREBRI (NCC): A PREVIOUSLY UNDISCOVERED CELL GROUP FORMING A RETICULUM AROUND MOTOR SYSTEM FIBERS DERIVED FROM THE CEREBRAL CORTEX AND NEOSTRIATUM. Konrad Talbot (1) and Larry L. Butcher (1,2). Dept. of Psychology (1) and Brain Research Inst. (2), U.C.L.A., Los Angeles, California 90024.

The cellular group we term NCC, a neuronal cluster embedded in the rat and cat pes pedunculi between the caudomedial tip of the subthalamic nucleus (Sub N) and the rostrolateral tip of the substantia nigra, pars compacta (SN,pc), receives no mention in the neuroanatomical literature. It cannot, however, be grouped with neighboring structures; for example, the NCC is not continuous with the Sub N or the SN,pc, and its neurons are readily distinquished in Nissl preparations from nerve cells in those structures. In this context, we summarize our studies on the rat NCC.

Compared to most brain nuclei, the NCC is certainly small: its approximately 700-1000 neurons are located within A-P, M-L, and D-V dimensions of 0.545, 0.884, and 0.545mm, respectively. Nissl material and especially pharmaco-histochemical preparations for acetylcholinesterase (AChE) reveal that the neuronal somata (1) range in maximum diameter from 8-37um (85% are 15-26um), (2) exhibit a wide variety of shapes most of which are ovoid or triangular, and (3) possess 1-4, but usually 2-3, enzyme-reactive processes. Most NCC neurons demonstrate appreciable but not intense AChE activity (unlike Sub N and SN,pc), many display appreciable NADH-diaphorase activity (again unlike Sub N and SN,pc), and none fluoresce for catecholamines (unlike SN,pc) even after nialamide (100mg/kg) treatment.

Characteristic of the NCC is the aggregation of its somata and processes, especially at caudal levels, to form a reticulum through which course bundles of peduncular fibers. This is particularly interesting since silver degeneration studies (e.g., Rinvik, 1968, Exp. Br. Res., 5, 129) and our own autoradiographic investigations indicate that the NCC in both the rat and cat is so situated that many, if not all, those bundles consist of motor system fibers projecting from the motor cortex to midbrain and thalamic nuclei and from the rostro- and centro-lateral neostriatum to the SN. Although gating mechanisms come to mind, further work is clearly required to elucidate the possible functional significance of the close association between NCC neurons and motor system fibers.

973 EVIDENCE FOR A MULTISYNAPTIC STRETCH REFLEX OF THE JAW ELEVATOR MUSCLES IN THE CAT. Anthony Taylor*, Michael J. O'Donovan and Kwabena Appenteng*. (SPON: Mary Wetzel). Dept. Physiol., St. Thomas's Hosp. Med. Sch., London SE1 7EH, England.

The monosynaptic connections of jaw elevator muscle spindles to elevator motoneurones are sparse and weak. Thus by spike-triggered averaging from spindles, individual monosynaptic EPSPs were found in only 15% of motoneurones and their mean amplitude was 18μV. In spite of the weakness of this projection, powerful stretch reflexes of the jaw elevators can be obtained under certain conditions. This may be explained by the existence of multisynaptic components, for which we have some evidence. First, there are interneurones close to the motor nucleus specifically excited by spindle input, and since there is no Ia antagonist inhibition of jaw muscles, these interneurones could be excitatory to the motoneurones. Secondly, ramp and hold jaw opening generates synaptic noise in elevator motoneurones which is seen to continue to increase into the hold phase, when spindle output is declining rapidly. This could be due to progressive build-up of activity in an interneurone pool. Thirdly, naturally evoked spindle afferent volleys can generate late excitation of motoneurones which is abolished by small doses of barbiturate. In addition it is noted that IC records from jaw elevator motoneurones commonly show ongoing individual EPSPs related to jaw stretch with amplitudes up to 10 times the average monosynaptic individual EPSP. These seem likely to be due to interneurones driven by spindles and suggest a potentially powerful pathway. A weak stretch reflex of the elevators may indeed by greatly enhanced by other intra-oral stimulation which could be explained by convergence on to excitatory interneurones.

974 FORELIMB FUNCTION AFTER DORSAL COLUMN NUCLEI LESION OR DORSAL RHIZOTOMY. D. E. Teodoru*, T. Tran* and A. J. Berman. Dept Neurosurg., VA Hosp., Bronx, N.Y. 10468

Four monkeys were subjected to unilateral lesion of dorsal column nuclei (DCN) and four to dorsal rhizotomy C2-T3 (DR). Postoperatively, spontaneous behavior was systematically observed and forelimb movements compared on two tasks. One task required limb movement forward into a cylinder. Latency from presentation of the container until hand entry was a measure of coarse reach; time from entry to grasp and withdrawal with food was a measure of coarse grasp. The second task required reaching and grasping a food pellet from one of three positions atop a narrow cylinder. This task yielded measures of fine reach and grasp as well as allowing detailed evaluations of the movements involved.

DCN lesion was followed by ataxia in the immediate postoperative period. At the time of testing, however, 6 mos after surgery, reach latency was unaffected but an impairment of grasp was evident. The form of coarse grasp was similar to that of the intact limb, consisting of a prehensile movement with all the fingers opened and closed together. Fine grasp was initially unsuccessful, apparently due to incoordination of thumb-index opposition. When grasp became successful, it consisted of scooping movements involving all fingers or independent scooping by thumb or index. When vision was occluded with the precision test, reach time of the lesioned limb continued to be comparable to that of the intact limb, but grasp was never successful. DR monkeys failed to contact the target with their operated limbs in the fine test. On the coarse task, however, one monkey was successful. In this case, reach time was considerably longer than for the contralateral intact limb. Grasp time was greater than for the intact limb, but, despite severe injury to two fingers on the denervated hand, was far less than for animals with DCN lesions.

The proximal to distal pattern of recovery observed after DCN lesion is in contrast to the distal to proximal recovery seen after DR in this and previous experiments. After DCN lesions there is chronic deficit in coordinated finger movements with only transient involvement of proximal limb musculature. After DR, fine finger movements recover before movements involving the shoulder. We suggest that DCN lesion interrupts afferent input to motor cortex modules mediating finger coordination. In addition, non-pyramidal inputs which can interfere with finger coordination are released from the pyramidal inhibition normally supported by afferent input ascending via DCN. Thus a distal deficit predominates. DR interrupts gamma loops through which non-pyramidal influences operate, resulting in a proximal deficit, with the pyramidal system free to recover its control over distal musculature. Supported by NIH Grant #2 RO1 NS12330 to A.J.B.

975 EFFECTS OF FOCAL INJURY IN AREA 6 ON THE ACTIVATION OF NEURONS IN THE AREA 4 MOTOR CORTEX. Floyd J. Thompson and Joseph J. Warner* Dept. of Neuroscience, College of Medicine and College of Veterinary Medicine, University of Florida, Gainesville, Fla.

The activation patterns of motor cortex neurons were investigated to determine the nature of physiological changes which occur subsequent to focal injury in area 6. The fundamental question investigated in these experiments was: Do injury related changes in sensory transmission to the motor cortex involve mechanisms intrinsic to the cortex or to subcortical systems which contribute to cortical neuron excitability?

The motor cortices of cats were exposed and covered with a closed chamber. Bipolar concentric electrodes were inserted into the contralateral dentate nucleus, in the ipsilateral medullary pyramidal tract, and into the ipsilateral entopeduncular nucleus. A bipolar concentric electrode was also placed in the posterior intermediate sulcus in the upper cervical spinal cord to activate the contralateral gracile and cuneate tracts. These electrode placements provided activation of cortical neurons by four functionally different but powerful sources. Cortical neuron activation patterns were studied by analysis of laminar and single unit evoked activity. Focal injuries were made in area 6 using a silver ball electrode to deliver radiofrequency to the cortical surface. Histological examination of the studied neural tissue revealed exact locations of cortical lesions and electrode tracts.

These studies have shown that evoked activity of motor cortex neurons can be enhanced, diminished, or abolished for several hours in a spatially widespread manner, following a focal lesion in area 6. However, within the same animal, these changes in the evoked activity were different depending on the input tested. For example, in one animal, the evoked activity in the lateral postcruciate gyrus elicited by dentate stimulation was reduced by 50-60% for 3 hours following the production of the lesion. However, in the same region, the evoked activity elicited by entopeduncular nucleus stimulation was increased by 20-50% for five hours following the injury. Changes of this nature have been observed to persist for up to]2 hours, then return to control values. In a different experiment, single unit activity was evoked by stimulation of the gracile and cuneate tracts following focal area 6 injury. In the same recording region, however, dentate stimulation evoked no activity during that time.

The experiments to date strongly suggest that even focal injury to the cortex may have profound effects on subcortical systems which contribute to the excitability of the motor cortex. (Supported by The American Heart Association, Suncoast Chapter, 7/77 AG 613)

976 EFFERENT PROJECTIONS OF THE DEEP MESENCEPHALIC NUCLEUS OF THE RAT. Randolph B. Veazey*, (SPON: C.M. Severin). Department of Anatomy, University of Texas Medical Branch, Galveston, Texas 77550.

Efferent projections from the deep mesencephalic nucleus were examined using autoradiographic and horseradish peroxidase techniques. In one series of rats unilateral injections of tritiated leucine were made and confined to either the medial or lateral part of the deep mesencephalic nucleus (DMN). Following injections of tritiated leucine into the lateral part of the DMN two groups of fibers were observed. One group coursed ventrally above the substantia nigra to enter the ipsilateral zona incerta. Some of these fibers entered the subthalamic nucleus where mesencephalic terminations were observed in its ventromedial part. Other fibers within the zona incerta coursed anteriorly to enter and pass through the internal capsule into the entopeduncular nucleus where mesencephalic terminations were observed. The remaining fibers passing through the internal capsule entered and terminated in the medial portion of the globus pallidus. The second group of fibers arising from the lateral part of the DMN coursed dorsally and rostrally to enter and terminate in the dorsomedial nucleus of the thalamus. Following injections of tritiated leucine into the medial part of the DMN two groups of fibers were observed. One group coursed ventrally and posteriorly to enter the ventral tegmentum of the pons. Some of these fibers terminated in the caudal part of the pontine reticular nucleus. Other fibers in the ventral tegmentum of the pons passed posteriorly through the ventral portion of the medullary reticular formation to enter the spinal cord. Some of these fibers terminated in the gigantocellular nucleus of the medullary reticular formation. The second group of fibers arising from the medial part of the DMN coursed dorsally and posteriorly through the dorsal portion of the pons and medulla to enter the spinal cord. To verify the findings of the autoradiographic study, another series of rats received injections of 33% horseradish peroxidase confined to the terminal areas demonstrated by autoradiography. The DMN was then examined for the presence of HRP-positive labelled cells. Based on the autoradiographic and HRP studies, the lateral part of the deep mesencephalic nucleus projects to the ventromedial portion of the subthalamic nucleus, the entopeduncular nucleus, medial portion of the globus pallidus, and dorsomedial nucleus, whereas the medial part of the deep mesencephalic nucleus projects to the caudal part of the pontine reticular nucleus, the gigantocellular nucleus of the medullary reticular formation, and the spinal cord.

977 CORRECTION OF ONGOING MOTOR OUTPUT IN THE CAT. D. Vicario, T. Blunk* and C. Ghez. Rockefeller Univ., New York, NY 10021.

We have previously shown that rapid isometric responses made by cats tracking sudden target perturbations, using a compensatory display of their force error, are controlled by a pulsatile neural signal of constant duration and variable amplitude (Ghez and Vicario, Soc. Neurosci. Abstr., 3: 271, 1977). The peak force achieved under these conditions is a linear function of the peaks of its first and second derivatives. Thus, the responses were scaled from their onset and the peak of the force derivative (dF/dt) was predictive of the intended final force. In the present study, we have investigated the cat's ability to make corrections in the force it applies following a second target perturbation presented at varying interstimulus intervals (ISIs) after a first.

As previously described, cats were trained to apply force isometrically to a strain gauge with their forearms to match a target force level which was stepped at random times. On random trials a second target step followed the first at controlled intervals. The motor effects of changes in the neural output could be detected rapidly under isometric conditions, where mechanical delays and reflex effects are minimized. Latencies in this task are very short; mean daily latencies measured from the perturbation to the onset of dF/dt were 60-80 msec. The peak dF/dt is reached after another 30-55 msec.

When the second perturbation preceded the peak dF/dt (of the response to the first) by more than a reaction time, and required a reduction in force applied, the peak dF/dt decreased progressively with shorter ISIs. Peak forces were proportionally reduced. The cat could abort its response entirely with the shortest ISIs (10-20 msec), though in such cases EMG activation of remote synergistic muscles was still occasionally present. Accompanying these reductions in amplitude were reductions in the time from onset to peak dF/dt, indicating that the output pulse had been shortened in its duration. These data, obtained under isometric conditions, are not consistent with intermittent sampling models which imply central refractoriness. The timing of the observed corrections in ongoing motor output suggests that responses may be updated by newly acquired sensory information with no detectable increase in reaction time.

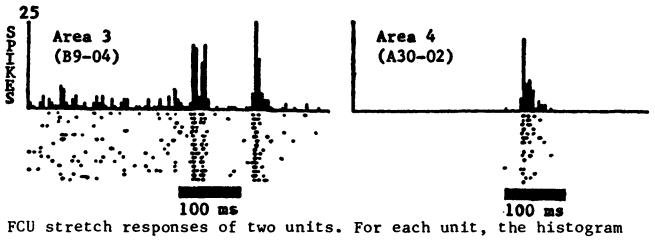
978 UNIT RESPONSES TO ELECTROMAGNETIC MUSCLE STRETCH IN PRIMATE SENSORIMOTOR CORTEX DURING SKILLED ACTIVITY. Jonathan R. Wolpaw. Laboratory of Neurophysiology, NIMH, Bethesda, Md. 20014.

Motor cortex units respond to limb displacements delivered during limb movements or maintained postures. Such displacements activate skin, joint, and muscle receptors. The present study assessed response to relatively pure muscle receptor activation.

Monkeys working for liquid reward grasped a torque motor handle and held it in mid-position, wrist neither flexed nor extended, against a range of steady-state torques. Stimuli given at pseudo-random intervals were of two kinds: (1) 50 ms DC torque pulses(TP), flexor or extensor, superimposed on the steady state torque and producing a hand displacement;(2) 100 ms 70 gm DC stretch of the muscle flexor carpi ulnaris(FCU), achieved by applying force via an external electromagnet to a 2 gm coated iron slug chronically imbedded in the distal musculotendinous junction (Wolpaw and Colburn, Br Res 141 (1978) 193-196). The latter stimulus was presumed to produce relatively selective activation of muscle stretch receptors for it caused no detectable change in handle position and monkeys appeared to ignore it.

In two monkeys (Macaca mulatta) 307 units in areas 4, 3(a & b), and 1 responded to flexor and/or extensor TP, the primary search stimuli. Of 259 units which responded within 60 ms of TP onset, 45% of those in area 4 and 63% of those in areas 1 and 3 also responded to FCU stretch. In all three areas FCU stretch responses were predominantly phasic ("on" or "on-off"), and units with short response latencies (10-20 ms) occurred.

Studies in anesthetized primates show that, while unit responses to muscle afferent stimulation are strongest and earliest in area 3a, responses also occur in area 4. The present study indicates that in awake behaving primates there is widespread short latency sensitivity to muscle stretch in area 4, as well as in areas 3 and 1, even when the ongoing performance is not disturbed.



FCU stretch responses of two units. For each unit, the histogram gives the sum of the 16 individual trials shown in the raster. The bar represents 100 ms FCU stretch.

979 COMPARISON OF LOAD COMPENSATION BY NORMAL AND DEAFFERENTED MONKEYS. Richard M. Wylie and C.F. Tyner. Dept. Med. Neurosci. Walter Reed Army Inst. Res. Washington, D.C. 20012.

Three normal and two operated (unilateral forelimb dorsal rhizotomy) monkeys were trained to perform a weight compensation task. The task required flexion of the forearm (held in a restraint which limited gross movement to rotation at the elbow in the vertical plane) from a horizontal rest position through a criterion arc of about 40 degrees and return to the rest position. No external cue signaled crossing the criterion level: reinforcements were delivered only after return of the arm to the rest position. After initial training with no external load, external loads were suspended from the arm restraint. Flexion through the criterion arc lifted the load against gravity about 16.5 cm. When the load was held constant over many one and one half hour sessions, the average height reached was independent of load. The loads were then varied between short blocks of responses within a daily session. On the first lift of each trial, both normal and deafferented monkeys generated load dependent lifts: acceleration and velocity measured during the rising phase of the lift and peak height achieved were all inversely related to the load. After the first few responses, the normal animals generated lifts in which acceleration, velocity and peak height were all independent of load. Although on successive lifts within a trial, the deafferented animals reduced the effect of load on position, the effect remained sufficient to appear in trial averages.

Comparison of the waveforms of acceleration generated by the two groups of animals reveals a striking difference between groups. On all lifts, including the first of each trial, the normal animals generated acceleration curves which rose monotonically to a maximum early in a lift and then fell smoothly to the maximum deceleration near the top of the lift. In contrast, deafferented animals generated acceleration curves with multiple relative maxima which indicate discrete increments of force during the rising phase of the lift. The increments of force are assumed to be corrections the animal makes in the trajectory of his arm. The corrections appear at latencies of more than 100 msec. from the start of movement and at heavier loads are seen on many lifts through the trial. The corrections are not a generalized ataxia because they were not seen when the animal was run on the same load in repeated sessions. The latencies of the corrections indicate that deafferented monkeys lack servo loops with rapid feedback. The contrast in the smoothness of regulation between the two groups suggests that servo loops with short loop delays contribute, in the normal monkeys, to the performance of this task.

980 THE CELLS OF ORIGIN OF INTERHEMISPHERIC CONNECTIONS IN THE PRIMATE MOTOR CORTEX. Julius D. Zant* and Peter L. Strick. (SPON: E.G. Keating). Depts. Neurosurg. and Physiol., S.U.N.Y., Upstate Med. Center and Veterans Administration Hospital, Syracuse, N.Y. 13210.

Multiple injections of 30-50% HRP (Sigma, type VI or Boehringer-Mannheim I, in saline) were made unilaterally into the motor cortex of 3 rhesus and 2 cynamolgus monkeys. In some animals the primary somatic sensory area was also injected for comparison. After a 1-3 day survival, the animals were sacrificed, perfused with an aldehyde-phosphate fixative and their brains processed for retrograde HRP transport using benzidene as a substrate (Mesulam, J. Histochem. Cytochem. 24: 1273, 1976).

There was a clear relation between the intensity of HRP retrograde labeling and the size of labeled neurons in the motor cortex on the side opposite the HRP injections. This was particularly evident for neurons in layer III, where large callosal neurons were more heavily labeled than small ones.

There are a number of marked differences in the laminar distribution and topographical organization of callosal neurons of the motor and somatic sensory cortices. First, callosal neurons are found in all layers of the motor cortex, except layer I. These neurons are most concentrated, however, in layers III, V and superficial layer VI, forming a distinct bilaminar pattern. In contrast, most callosal neurons in the somatic sensory cortex are found in layer III and only occasional callosal neurons are seen in layer V. Second, the mediolateral strips of labeled neurons which are a prominent feature of the somatic sensory cortex (jones, et. al. Science 190: 572, 1975) sre not as distinct in motor cortex. Third, many more callosal neurons are found in the arm and leg areas in the motor cortex than in the arm and leg areas of the somatic sensory cortex.

Finally, while the representation of the arm in area 4 lacks distinct strips of callosal neurons it does contain two "holes" in which callosal neurons are not found. On "hole" is buried in the central sulcus and the other is located on the cortical surface near the central sulcus. Current concepts indicate that callosal "holes" are found in regions of sensory cortex containing the representations of distal musculature. Recently, Strick and Preston (Brain Res. in the press) have demonstrated that there is a double representation of the hand in area 4 of the squirrel monkey. Therefore, the callosal "holes" in the arm area of area 4 suggest that a double representation of the hand also may exist in the motor cortex of the rhesus monkey.

981 DO INSECT MUSCLE CELLS SERVE AS SENSORY-MOTOR INTEGRATORS? Sasha N. Zill* and David T. Moran* (SPON. W.E. Hahn). Dept. Anat., Sch. Med., Univ. of Colorado, Denver, Colo. 80262

Insect locomotor patterns are widely assumed to be generated by the central nervous system and modified by peripheral feedback. Our studies of cockroach leg reflexes suggest that one level of integration of the effects of sensory feedback with centrally generated patterns occurs at muscle cells that, in insects, are multiply innervated and non-spiking.

The posterior trochanteral flexor (coxal levator) muscle lifts the leg in walking. It is innervated by both inhibitory (axon #3) and slow excitatory (axons #4,5,6) motoneurons. Pearson and Bergman (J. Exp. Biol. 50:445, 1969) studied this innervation and found that the inhibitory axon, a branch of the widespread common inhibitory neuron, was most effective in reducing tension produced by axon #4 - the smallest excitatory axon - but had little effect on tensions produced by the larger excitatory axons (#5,6).

Pearson and Fourtner (J. Neurophysiol. 38:33, 1975) have characterized an interneuron that depolarizes during rhythmic leg movements and is believed part of a central flexor burst generator in locomotion. It excites a group of flexor motoneurons - specifically axons #3,5,6 but not axon #4.

We have studied the effects of stimulation of a variety of leg sense organs upon trochanteral flexor motoneurons. Campaniform sensilla are sense organs that monitor cuticular strain caused by external load and muscular contraction. Chordotonal organs monitor joint angles. Stimulation of distal tibial campaniform sensilla and coxal chordotonal organs excites the trochanteral flexor. In both cases activity in axon #4 is increased with little effect on the other flexor motoneurons (#3, 5,6).

These results suggest that trochanteral flexor motoneurons may be divided into two groups, those driven predominantly by central interneurons (axons #3,5,6) and those driven by proprioceptive feedback (axon #4). Since the inhibitory axon (#3) most effectively eliminates tension produced by axon #4, the interaction between these axons on the muscle cell membrane would effectively integrate centrally generated patterns and proprioceptive feedback. We are presently testing this hypothesis by simultaneously recording sensory and motor activity in walking animals. (Supported by NSF Grant BMS-73-06766 and NIH Anatomy Training Grant GM-01981.)

NEUROCHEMISTRY

982 BIOCHEMICAL CHARACTERIZATION AND IN VITRO MAINTENANCE OF NEURONS FROM ADULT RAT BRAIN ISOLATED BY THE PERFUSION METHOD. H.H. Althaus*, W.B. Huttner*, P.J. Gebicke*, V. Neuhoff* and J.D. Lane. Max-Planck-Institut für exp. Medizin, Forschungsstelle Neurochemie, 3400 Göttingen, FRG

Recently a method has been developed to isolate neurons from adult rats which retain a reasonable part of their processes (Althaus, et al., Hoppe-Seyler's Z. Physiol. Chem. 358, 1155, 1977). These neurons have a preserved plasma membrane to which synaptic complexes are attached (Huttner, et al. in preparation; abstract, this meeting). Scanning and transmission electron microscopy of the preparations will be presented. In these isolated neurons, the composition of lipids, amino acids and several enzyme activities have been evaluated, as well as the uptake and incorporation of (^{3}H)-uridine and (^{14}C)-leucine into nuclear and protein fractions. The protein composition of cytoplasmic and particulate fractions of the neurons at different ages have been studied by SDS microgel-electrophoresis and pathological conditions such as experimental hyperphenylalaninemia result in changes in membrane-bound proteins. Moreover these neurons can be maintained in culture and are capable of regenerating their fibers. (supported in part by SFB 33).

983 EFFECTS OF CHRONIC ANTIPSYCHOTIC DRUG TREATMENT ON DOPAMINE METABOLITES IN PRIMATE BRAIN. N. G. Bacopoulos*, D. E. Redmond, J. Baulu* and R. H. Roth. Departments of Pharmacology and Psychiatry, Yale Univ. Sch. Med., New Haven, CT 06510

Haloperidol, 0.5 mg/kg, i.m., (chronic maintenance dose) was given daily for 19 days to adult male and female feral vervet monkeys (Cercopithecus aethiops) trapped and maintained in group outdoor cages on the island of St. Kitts, West Indies. On the 20th day chronically treated and untreated (control) animals were injected with 1.0 mg/kg haloperidol i.m. (acute challenge dose) or saline. Four hours later brains were removed under nembutal anesthesia and dissected into regions that were frozen in liquid nitrogen and kept in a -80° C freezer. Dopamine metabolites (3,4-dihydroxyphenylacetic acid-DOPAC- and homovanillic acid-HVA) were measured by mass fragmentography. The acute challenge dose of haloperidol increased DOPAC and HVA in basal ganglia of previously untreated animals but had lesser effects in chronically pretreated animals. Conversely, chronic pretreatment with haloperidol enhanced the HVA-elevating effects of the acute challenge dose in dorsal frontal, orbital and cingulate cortex. In the temporal, parietal and occipital cortex, the acute haloperidol challenge dose had the same effects on HVA concentration in chronically pretreated and previously untreated control animals. HVA was quantitatively the principal metabolite of dopamine in cortical regions, with DOPAC constituting less than 5% of total metabolite. No significant amount of the conjugated forms of these metabolites were found in any of the brain regions analyzed.

These observations demonstrate that following chronic haloperidol treatment the responsiveness of dopamine neurons in the basal ganglia to the HVA-elevating effects of haloperidol is diminished, whereas the responsiveness of frontal cortical and cingulate neurons is enhanced. These regional differences in the response of central dopamine neurons to chronic haloperidol treatment may be relevant to the clinical action of this drug. Clinical studies have indicated that tolerance develops to the sedative and extrapyramidal effects of haloperidol while the therapeutic antipsychotic effects of this drug require one or more weeks of continued treatment to be manifested. (Supported in part by USPHS grant MH-14092, the Guggenheim Foundation and postdoctoral fellowship USPHS 1-F32-MH07146-02 to NGB.)

984 EFFECTS OF SPINAL CORD TRAUMA ON MYELIN (NEUROSCIENCE ABST.). Naren L. Banik*, James M. Powers* and Edward L. Hogan. Depts. Neurology, Biochemistry and Neuropathology, MUSC, Charleston, SC 29403

The essential role of descending fiber tracts in the mediation of motor paresis following spinal cord trauma warrants study of the biochemical events occurring in these myelinated axons. In this study the effects of trauma on the myelin sheath have been examined after experimental spinal cord trauma was produced in rats by dropping a 10 g weight 30 cm upon surgically exposed and dura-invested spinal cord. Specimens of normal and traumatized spinal cord were removed at 1, 2, 3, 4, 8, 12, 24 and 72 hrs. after injury and myelin was prepared. Hemorrhages, necrosis and edematous swelling in the lesion area were evident on light microscopy, while electron microscopic study revealed that dissociation of the myelin lamellae with the formation of vesicular structures and damaged axons were most prominent between 4 and 12 hrs. Granular degeneration of axons preceded vesicular damage to myelin which occurred first in the innermost myelin lamellae. After 12 hrs., aggregates of vesicular myelin debris were scattered throughout the lesion and by 72 hrs. the vesicular distortion of myelin was diminished but still present. The predominant morphologic lesions at the latter stage were axonal degeneration including mineralization and clusters of lipid-laden macrophages. The yield of myelin was reduced by 15 and 30% at 4 and 8 hrs. respectively following trauma. At 72 hrs. the yield was decreased to 50% of the normal value. No significant change in the level of adenosine 2', 3' cyclic phosphohydrolase (CNP) activity was found in myelin at 4 hrs. after trauma. At 8 and 72 hrs. the CNP activity was decreased by 15 and 20% respectively compared to control. Myelin proteins were separated by SDS-PAGE; striking reductions in all myelin proteins were observed in samples from the lesion. The main loss was in myelin basic protein with reductions of about 65% large basic and 45% small basic proteins while the losses were 15% for the proteolipid and 10% for the Wolfgram proteins from myelin (at 4 hrs.) compared to control. Greater decreases of these proteins were found at 24 and 72 hrs. following trauma. For example, at 24 hrs. there was a loss of 85% large B.P., 70% small B.P., 30% PLP and 35% WP. The relevance of these results to the pathophysiology and ultimate functional disability of spinal cord trauma will be discussed.

This study was supported by NIH-NINCDS Grant No. NS11066.

985 EFFECT OF WALLERIAN DEGENERATION ON MYELIN PROTEIN SYNTHESIS IN SCIATIC NERVE OF RAT. Margaret E. Bell and Richard C. Wiggins. Dept. Neurobiol. and Anat., UTMS, Houston, Texas 77025.

We used a double isotope procedure to compare the in vitro incorporation of glycine into myelin protein synthesis in control sciatic nerves and in nerves undergoing Wallerian degeneration. Wallerian degeneration was induced in rats by surgically performing a unilateral left neurotomy at the level of the sciatic notch. Each rat whose left sciatic nerve was cut also received a sham operation on the right side. At 1,3, and 5 days after surgery, we removed the distal stumps of the sectioned nerves and the contralateral sham operated nerves. In addition to the contralateral control, for each experimental rat there was a control rat (no surgery) whose intact sciatic nerves were removed at the same time as the experimental nerves. All nerves were transferred into screw-top test tubes containing 0.3 ml Krebs-Ringer-bicarbonate buffer, pH 7.4, 3 mg/ml glucose, radioactive glycine, and an atmosphere of 95% O_2 and 5% CO_2. Nerve sections undergoing Wallerian degeneration and the contralateral control nerves were placed in buffer containing 5 μCi of 3H glycine. Sciatic nerves of control rats were placed in buffer containing 10 μCi of 14C glycine. At the end of a 3 hr incubation period at 37°C with continuous shaking, the tissues were rinsed 3 X in cold buffer. Each 3H-labelled nerve was combined with a 14C-labelled nerve from a control rat, and the two were homogenized together in 0.29M sucrose. Purified myelin was prepared according to Wiggins et al. (Brain Res. 89:99, 1975). The myelin pellets were delipidated 3 times with ether-ethanol (3:2, v/v), solubilized in Protosol, and prepared for liquid scintillation counting. The sciatic nerve 3H/14C ratios (degenerating/control and sham operated/control) at 1,3, and 5 days are shown in Table 1 (sample size in parentheses):

Table 1	1 day	3 day	5 day
3H/14C = degenerating / control	1.15±0.18(9)	1.35±0.12(8)	0.75±0.10(5)
3H/14C = sham operated / control	1.15±0.19(7)	1.06±0.09(6)	1.32±0.47(3)* 1.12±0.16(2)*

As can be seen from the data, no significant increase or decrease in myelin synthesis appears at 1 day following initiation of degeneration. By 3 days post transection, however, myelin synthesis appears to be increased by about 30% in response to injury. At 5 days after surgery, this transient stimulation of myelin synthesis in the cut nerves has attenuated as a result of nerve degeneration, and myelin synthesis has decreased by 45%. (The high value at 5 days for the sham control results from a single sample; by omitting this number one gets a mean of 1.12.)*

986 EXTRACELLULAR PROTEINS OF THE VERTEBRATE BRAIN. Larry I. Benowitz and Victor E. Shashoua, Department of Biological Chemistry, Harvard Medical School. McLean Hospital, Belmont, MA 02178.

Several types of nervous system cells are known to depend upon extrinsic proteins for their development and function (e.g., Levi-Montalcini and Angeletti, Physiol. Rev. 48:534, 1968; Lim *et al.*, Science 195:195, 1977). Assuming that analogous factors play a role in the functional development of many other CNS elements, we have begun to survey proteins of the brain's extracellular and cerebrospinal fluid (ECF). In the fish, chick, and mouse, the ECF, obtained from perfused brains either by sucrose extraction or by directly drawing off the cerebrospinal fluid, was found to contain proteins markedly different from those appearing in serum or in the cytoplasmic fraction of whole brain. Polyacrylamide-SDS gels of the various protein fractions were compared in terms of staining patterns (Coomassie blue and PAS glycoprotein stains) and isotope incorporation profiles. Our primary evidence for the selective secretion of proteins was obtained by a double-labeling method. ECF proteins labeled with ^{3}H-valine from one animal were combined with ^{14}C-labeled cytoplasmic or serum proteins from another animal. The mixture was separated electrophoretically on gels, which were then cut and counted for ^{3}H and ^{14}C. High ^{3}H:^{14}C ratios, indicative of a relative enrichment in the ECF, were found predominantly for low molecular weight proteins. In the goldfish, the ECF was found to be particularly enriched in β and γ (see Abstract: Shashoua, this volume), proteins whose metabolism is altered by training (Shashoua, Science 193:1264, 1976). The β protein derives from a family of astrocyte-like cells of the brain's matrix zone (Benowitz and Shashoua, Brain Res. 136:227, 1977). In the chick, nearly 1/3 of all the precursor incorporated into ECF proteins after 1 hr of labeling appears in a 17,000 dalton molecular weight product. Tremendous animal-to-animal variations were noted in the labeling only of the 17,000 dalton secreted protein. The mouse brain was also found to have proteins which are rapidly labeled and secreted into ECF. We are now attempting to localize the origin of various secreted brain proteins and to study their relationship to brain function. 987 IN VIVO PHOSPHORYLATION OF POSTSYNAPTIC DENSITY PROTEINS. Robert F. Berman*, William J. Kinnier*, John P. Hullihan* and John E. Wilson. Department of Biochemistry, University of North Carolina, Chapel Hill, North Carolina 27514.

Protein phosphorylation, a possible mechanism modulating synaptic transmission, was examined in postsynaptic density-enriched fractions isolated from rat brain. In vivo phosphorylation was carried out by injecting rats intraventricularly with 1 mCi of ^{32}P-orthophosphate in 20 µl saline. After a 30 minute isotope incorporation period, the rats were decapitated, and postsynaptic densities (PSD) were isolated from pooled cerebral corticies as described by Cotman, Banker, Churchill & Taylor (J. Cell Biol., 1974, 63, 441-455). In vitro phosphorylation was attempted by incubating unlabeled PSD's, isolated from non-injected rats, with 5 µM [$\gamma^{32}P$]ATP as described previously (Hullihan, Wilson & Williams, Biochim. Biophys. Acta, 1977, 499, 139-149). In vivo and in vitro treated PSD's were then fractionated by SDS-polyacrylamide slab gel electrophoresis, stained with Coomassie blue, and scanned for absorbance at 600 nm. The Coomassie blue protein banding pattern was typical for PSD's, and identical for in vivo and in vitro treated PSD's. The principal polypeptide component occurred in a single band at an apparent molecular weight of 51,000, and did not co-migrate with purified tubulin or actin. The gels were dried and placed in contact with X-ray film. The resultant autoradiograph showed a major peak of radioactivity associated with the 51,000 M.W. component for the in vivo labeled PSD fraction. Additional minor peaks of radioactivity were also observed. In contrast, no ^{32}P incorporation into PSD proteins was observed following the in vitro ^{32}P-labeling procedure. These results indicate that proteins associated with the postsynaptic density, although difficult to phosphorylate under in vitro conditions, readily incorporate phosphate in vivo and may represent a major class of phosphoproteins. They also open the possibility that the phosphorylation state of these proteins may play a role in their suggested function as modulators of synaptic transmission (Blomberg, Cohen & Siekevitz, J. Cell Biol., 1977, 74, 204-225). (Supported by NIH Grant NS-07457).

989 CYCLIC GMP LEVELS IN THE CEREBROSPINAL FLUID AND CEREBELLUM OF THE MONKEY: EFFECTS OF MORPHINE. G. N. Catravas, S. J. Wright, Jr.* and J. B. Katz*. Armed Forces Radiobiology Research Institute, Bethesda, MD 20014.

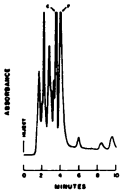
Silastic Pudenz catheters were chronically implanted in the fourth ventricle of monkeys and were connected to compressible polyethylene Ommaya reservoirs placed subcutaneously over the occiput for aspiration of cerebrospinal fluid (CSF). Administration of morphine (20 mg/kg IM) to the awake animal significantly elevated the levels of cGMP in the CSF. Following hemicraniectomy biopsies of cerebral and cerebellar cortex were taken from monkeys under anesthesia, given 20 mg/kg (IM) morphine sulfate. Only cerebellar cGMP levels were found to change significantly showing a more than 30% decrease compared to anesthetized controls. Naloxone (0.3 mg/kg IM) blocked the changes observed in both CSF and cerebellar cGMP levels. Although the controlling factors of brain and CSF cGMP levels are not well understood, our results indicate that, under some conditions, a reciprocal relationship may exist between cGMP levels in certain brain regions and in CSF.

990 KINETIC AND MECHANISTIC STUDIES OF CHOLINE ACETYLTRANSFERASE FROM BOVINE BRAIN. L. P. Chao* and L. L. Hsu* (SPON: D. Leelavathi). TRIMS, Houston, Texas 77030; Dept. Neurol. Sch. Med., UCLA, Los Angeles, Ca. 90024

Choline acetylthransferase (acetyl-coenzyme A: choline O-acetyltransferase, EC 2.3.1.6., CAT) from candate nuclei of bovine brains was purified to homogeneity according to the procedure previously reported by Chao and Wolfgram (J. Neurochem. 20, 1075-1081, 1973). The CAT activity was determined by measuring the radioactive acetylcholine produced from acetyl-coA and choline (Brandon and Wu, personal communication; Fonnum, J. Jeurochem 24 407-409, 1975). Kinetic studies of the purified brain CAT at varying acetyl-CoA concentrations and fixed excess choline concentration or vice versa resulted in linear double reciprocal plots. The Km values obtained from Lineweaver-Burk plots are 30uM and 1mM for acetyl-CoA and choline chloride respectively. Our kinetic data also indicate that product inhibition by acetylcholine is competitive with respect to choline and noncompetitive with respect to acetyl-CoA while product inhibition by CoA is competitive with acetyl-CoA and noncompetively with choline. Initial studies of effects of neurotransmitters,neuroleptics and psychotomimetics on the CAT activity showed that r-aminobutyric acid, dopamine, bufotenine, ipronia zid and 1, 2, 3, 4 - tetrahydro-B-carboline slightly inhibited the CAT activity at 0.1mM concentrations whereas norepinephrine, serotonin, cAMP, haloperidol, chozapine and mescaline did not affect the CAT activity to a significant degree. The possible kinetic mechanism(s) of CAT and the drug reaction mechanism(s) will be discussed.

991 HIGH PERFORMANCE LIQUID CHROMATOGRAPHY (HPLC): NEW INSIGHT INTO CYCLIC AMP METABOLISM. Major L. Cohn, Maria I. Chitas* and Joseph A. Feldman*, Dept. Anes., Magee-Womens Hosp., Univ. Pgh. Sch. Med. & Univ. Duquesne, Pittsburgh, PA 15213.

The metabolic pathways regulating the degradation processes of adenosine 3':5' monophosphate (cAMP) are well established. Cyclic nucleotide phosphodiesterase (PDE) converts cAMP to adenosine 5' monophosphate (5'AMP). Subsequently 5'AMP is rephosphorylated to ATP or further metabolized to adenosine and then adenine. By an alternate pathway, 5'AMP may be deaminated to inosine monophosphate (5'IMP) and converted to inosine by the catalyst 5'-nucleotidase. The removal of ribose converts inosine to hypoxanthine. We are now reporting a new HPLC technique by which we separate, identify and quantify cAMP and its metabolites in rat brain tissue. The retention times for 5'AMP, cAMP, adenine and adenosine were recorded at 2.87; 6.40; 8.46 and 9.60 min. respectively. When beef heart PDE was added to standard cAMP solutions in tris buffer pH 7.4 (0.06 M) three absorbance peaks appeared, the first at 2.87 min. which corresponds to the retention time of 5'AMP; the second and third (labeled C and F) at 3.37 and 3.84 min respectively. Thus, C and F retention times do not correspond to those of adenine and adenosine whose peaks did not appear. When rat brain slices were incubated at 30°C in tris buffer, pH 7.4 (0.06 M) with cAMP, C and F as well as 5'AMP and adenosine appeared at their usual respective retention times. With prolonged incubation cAMP and 5'AMP peaks disappeared while C and F peaks significantly rose. Next, we tested whether C and F peaks appear only under anaerobic conditions by sacrificing groups of rats in a microwave oven set at 5 sec. time exposure. The removed brains were homogenized in perchloric acid (0.4 N), centrifuged and the supernatant neutralized with 3M tris. The ultra-filtered samples were chromatographed. The major peaks of 5'AMP, cAMP, adenine, adenosine, C and F appeared at usual retention times (Fig). Interestingly, C and F peaks have the same retention times as inosine and hypoxanthine. Mass spectral studies are in progress to confirm the identification of all peaks. (NIDA 00605)



992 GANGLIOSIDES ASSOCIATED WITH ISOLATED NEURITES AND SOMATA OF SENSORY AND SYMPATHETIC NEURONS IN VITRO. Carson Cornbrooks, Richard P. Bunge and David Gottlieb. Dept. Anat. and Neurobiol., Wash. U. Sch. of Med., St. Louis, MO 63110.

The superior cervical ganglion (SCG) and the dorsal root ganglion (DRG) of the embryonic or neonatal rat can be cultured as explants which generate a profuse network of fibers (neurites) in vitro. It has been established that these neurons express in culture many of their known in vivo characteristics: 1) When grown with supporting cells the neurites of the larger DRG neurons, but not those of SCG neurons, become myelinated in culture; 2) The SCG neurons receive cholinergic synapses from cocultured spinal cord (Ko et al., 1976a, Brain Res., 117: 437) and provide synapses to cocultured target (fat) cells, and to one another (O'Lague et al., 1974, PNAS, 71: 3602; Ko et al., 1976b, Brain Res., 117:461). These ganglia may be taken for culture after the embryonic period of neuroblast proliferation, but before a large number of supporting cells have been generated. If these cultured explants are then treated with several pulses of antimitotic agents, they may generate a profuse outgrowth of neurites free of all supporting cells (Estridge, 1977, Nature, 268: 60). Because it is thus possible to obtain neurites free of contaminating elements (Schwann cells and fibroblasts) they offer a model system for axonal biochemistry. We have used this system to study the cellular distribution of gangliosides. Established cultures with neuritic halos 3 mm or more in width were incubated with ≃ 5 μCi of ^{3}H-glucosamine for 48 hours. Neurites and somata were separated by dissection, and mixed with approximately 1 gram of fresh rat brain. Gangliosides were extracted by the method of Tettamanti (1973, BBA, 296: 160), followed by chromatography on Sephadex G25-80 to remove traces of labeled precursors. Ninety-five percent of the labeled material was TCA-PTA precipitable. Mild acid hydrolysis released approximately 80% of the label which comigrated with authentic sialic acid when assayed by column chromatography on AG1-X8 resin. Radioactive gangliosides were analyzed by thin layer chromatography. In the case of both SCG and DRG somata and neurites labeled material comigrated with GM1, GD1a, GD1b and GT. A large amount of label migrates in the disialo-region but does not correspond to GD1a or GD1b. Small amounts of label are associated with GO, GM2 and GM3. These results indicate that numerous gangliosides are associated with both the cell somal region and the neurites of two different types of PNS neurons.

993 CENTRAL MYELINATION IN VITRO: EFFECT OF REDUCED CALCIUM AND MAGNESIUM. William Craelius, Nicki A. Newby and Frances C. Thomas* Dept.Biol. Sci., Stanford U., Stanford, CA 94305.

It has been suggested that deficiencies in calcium and magnesium experienced during infancy may lead to improper development of myelin (Goldberg,1974;Intern. J. Envir. Stud.,6,121). This hypothesis has been tested in vitro using slices of spinal cord from 10 to 12 day old chick embryos. Control culture media contained approximately 2.0 mM Ca and 1.0 mM Mg, and test media was identical except that the concentrations of Ca and Mg were approximately 0.7 and 0.4 mM. After one to three weeks incubation at 37 C, cultures were fixed and prepared for electron microscopy. Central type myelination, in various stages of growth, was readily observed in both control and test spinal cord slices after 7 days of culture. In the control tissue, at 7 days, many axons were tightly myelinated with 50 or more layers of lamellae. Myelin grown in the reduced Ca and Mg media, however, usually appeared loose and irregular, and was not as well formed as control myelin.

The optimal ionic requirements necessary for the proper growth of myelin have not been explored previously, and these results suggest that there may be certain minimum levels of calcium and/or magnesium that promote adequate myelination. Since only a moderate reduction in calcium and magnesium produced a noticeable deficiency in myelin growth, these results may be physiologically relevant. As suggested by Goldberg, the demyelination experienced by victims of multiple sclerosis may occur as a result of improper early development of myelin, due to shortages of calcium and magnesium. Published lipid analyses of myelin taken from multiple sclerosis victims have found developmental abnormalities, among which are increased unsaturation in fatty acids, particularly in cerebrosides, and decreased fatty acid chain length (Woelk & Borri,1973:Europ.Neurol. 10,250; Fewster et al,1976:J. Neurol. 209,119). Both of these abnormalities would render myelin unstable as predicted by O'Brien (1965: Science,14,1099).

Demyelination in multiple sclerosis may be partially a result of improper myelination; the present results suggest that deficiencies in calcium and/or magnesium could be responsible for the developmental errors.

994 ISOLATION OF MANNOSE-CONTAINING OLIGOSACCHARIDES IN HYPERPLASTIC GINGIVA FROM A CASE OF MANNOSIDOSIS. Peter F. Daniel* and Ira T. Lott* (SPON: Marjorie B. Lees). Eunice Kennedy Shriver Center for Mental Retardation, Inc., 200 Trapelo Road, Waltham, MA 02154.

We have reported an unusual case of mannosidosis (Kistler et al., Arch. Neurol. (1977) 34, 45-51) with massive gingival hyperplasia. The gingiva was infiltrated with histiocytes containing large amounts of storage material staining positively for carbohydrate. Gingival tissue was excised from this patient for dental indications, and 3.4 g were available to us for analysis. The tissue was homogenized in distilled water and sonicated to release any water-soluble material. Proteins were precipitated by addition of trichloroacetic acid (5% final concentration), and the supernatant was fractionated on Sephadex G-50 and Biogel P-2, followed by ion exchange chromatography on Dowex 50 to separate oligosaccharides from glycopeptides. Oligosaccarides represented the major storage material; very little carbohydrate was present as glycopeptides. Six oligosaccharide fractions were obtained by chromatography on an analytical Biogel P-2 column (-400 mesh) at 55° C and were analyzed by TLC on silica gel G with n-propanol/H_2O 8:3 as solvent; sugars were visualized by spraying with orcinol. Fraction 1 did not migrate; fraction 2 contained only minute amounts of orcinol positive material and was not further analyzed; fraction 3 contained at least four slow-migrating components; fractions 4-6 each contained one major component. Fraction 6 co-migrated with standard Man α 1, 3 Man β 1, 4 GlcNAc, which is the major sugar isolated from mannosidosis urine. Carbohydrate analysis of the crude fractions from Biogel P-2 by GC-MS revealed that fraction 1 contained only glucose and was presumably a dextrin. Fractions 3-6 each contained mannose and glucosamine together with small amounts of glucose. The molar ratio of mannose to glucosamine in fractions 4-6 was determined to be 5, 3, and 2 respectively. Control tissue (4.5 g) obtained from hyperplastic gingiva associated with phenytoin administration showed no components corresponding to the mannose containing fractions. The sole orcinol positive peak in the control co-eluted with fraction 1.

In comparison with published compositional data (Strecker et al., Biochimie (1976) 58, 579-586) on mannosidosis urine, the present results from gingival tissue show a striking absence of an oligosaccharide containing 4 moles of mannose.

995 BRAIN NUCLEAR PHOSPHOPROTEIN METABOLISM WITH BEHAVIORAL STIMULATION. S. Diane Davis* and John Eric Wilson (SPON: D.L.McIlwain). Neurobiology Program & Dept. Biochem., UNC, Chapel Hill NC 27514.

The effects of electric footshock and footshock avoidance training upon the incorporation of 32P into rat brain nuclear proteins were studied in 100 day old Wistar albino rats. After 35 min of labeling and 5 min of avoidance training (preceded by 5 min of acclimation to the apparatus) rats were killed by decapitation, the brains homogenized, and the nuclei sedimented through 2.4 M sucrose containing CaCl2 and Triton X-100. Nuclei were further fractionated into nucleoli, heavy chromatin, and light chromatin by sonication and density gradient centrifugation. Avoidance training caused an alteration of the distribution of the label between the two chromatin fractions studied, with a relative increase in the fraction sedimenting through 2 M sucrose compared to the fraction that did not sediment through 2 M sucrose. Electric footshock alone caused increased incorporation into the chromatin proteins of both fractions studied. No significant findings were observed in the nucleoli, the nonchromatin nuclear proteins, or the 10% CCl3COOH soluble proteins of the nucleus. Preliminary work indicated that ACTH administration duplicated the effects of electric footshock.

996 EFFECTS OF SOME MONOAMINE OXIDASE INHIBITORS (MAOI'S) ON THE DEAMINATION AND UPTAKE OF meta-TYRAMINE (m-TA), para-TYRAMINE (p-TA) AND DOPAMINE (DA) BY RAT STRIATUM in vitro. L.E. Dyck* and A.A. Boulton. Psychiatric Research Division, University Hospital, Saskatoon, Sask., Canada S7N 0W8.

During recent investigations on the uptake of m-TA, p-TA and DA into rat striatal slices; nialamide was included in the medium at all times and appeared to inhibit MAO. However, in release studies it became evident that the MAO was active and the deaminated metabolites were being washed into the bathing medium. Deamination occurred in the decreasing order: p-TA>m-TA>DA. In order to determine whether this differential rate of deamination was a consequence of an innate substrate selectivity of MAO, a substrate selective inhibition by nialamide, or a selective protection from MAO by intraneuronal storage; the ability of rat striatal homogenates to deaminate m-TA, p-TA and DA were assessed with and without the addition of MAOI'S. Their effect on uptakes was also evaluated.

MAO activity of striatal homogenates was assayed by measuring the decline in amine substrate concentration and the production of acid metabolites. Preincubation (20 min, 10 μM MAOI) and incubation (37 min, 10 μM MAOI, 10 nM tritiated amine) were performed at 37°C. After the incubation, the amines were extracted into di-2-ethyl-hexyl-phosphoric acid, while the acids were extracted at pH 1.0 into ethyl acetate. In the absence of drugs, homogenates deaminated p-TA and m-TA faster than DA. Approximately 75, 50 and 10% of the p-TA, m-TA and DA were converted to p-hydroxyphenylacetic, m-hydroxyphenylacetic and dihydroxyphenylacetic acids, respectively. The efficacy of the MAOI'S in inhibiting MAO with all three substrates in increasing order was nialamide, iproniazid, pargyline, clorgyline, catron and parnate.

Uptake of 10 nM amine into slices was assessed after a 5 min incubation. MAOI (10 μM) was included during preincubation (20 min). Nialamide, iproniazid, pargyline and clorgyline did not exhibit any significant effect on uptake of the amines; however, catron and parnate, whose chemical structures most clearly resemble the amines themselves, significantly reduced the uptake of m-TA and p-TA. Parnate significantly reduced DA uptake.

It is clear that at this concentration of nialamide and iproniazid no interference with uptake of the three amines occur, but little protection of p-TA and m-TA from MAO occurs. Catron and parnate which are the best inhibitors of MAO for all three amines, unfortunately also inhibited, markedly, their uptakes. Pargyline and clorgyline, which are good inhibitors of MAO for all three amines, did not interfere with their uptakes and they therefore appear to be suitable for use in transport studies.

Supported by the Department of Health, Province of Saskatchewan and the Medical Research Council of Canada.

997 CYCLIC NUCLEOTIDE-MODULATED PHOSPHORYLATION OF PROTEIN THAT IS SPECIFIC TO PHOTORECEPTOR CELLS OF RETINA. Debora B. Farber and Richard N. Lolley. Depts. Ophthalmology and Anatomy, UCLA School of Medicine, Los Angeles, CA 90024, and Devel. Neurology Lab., V.A. Hospital, Sepulveda, CA 91343.

Rod photoreceptor cells of dark-adapted retinas possess high levels of cyclic GMP. Upon bleaching of rhodopsin by light, cyclic GMP-phosphodiesterase is activated, and the concentration of cyclic GMP falls rapidly. Cyclic GMP activates a protein kinase from rod outer segments (ROS) and modulates preferentially the phosphorylation of a soluble, 30,000-dalton (30K) protein. In order to confirm that the 30K protein is localized specifically in photoreceptor cells of rodent retinas, we studied its phosphorylation in vitro, as a function both of visual cell maturation during postnatal life and visual cell degeneration in selected inherited disorders of mice and rats. In dark-adapted retinas of control animals, the incorporation of phosphate into the 30K protein increases at the time during postnatal life when photoreceptor cells are differentiating and developing ROS. Thereafter, the phosphorylation of this protein increases slightly, reaching its highest level by adulthood. From early postnatal life to adulthood, phosphorylation of the 30K protein is enhanced by exogenous cyclic nucleotides. C3H/HeJ mice are affected with an inherited disorder that causes photoreceptor cell degeneration beginning about 10 days postnatally. Prior to 10 days, when C3H visual cells are viable, basal and cyclic nucleotide-dependent phosphorylation of the 30K protein is demonstrable and similar to that of control retinas. However, after 10 days, when rod visual cells are degenerating, phosphorylation of the 30K protein diminishes and is undetectable by 20 postnatal days. A different type of inherited blindness occurs in Royal College of Surgeons (RCS) rats, and visual cells degenerate later in life. In retinas of RCS rats, basal and cyclic nucleotide-dependent phosphorylation of the 30K protein proceeds normally until morphological pathology is demonstrable. As photoreceptor cell degeneration occurs, the phosphorylation of the 30K protein is reduced, and it disappears when visual cells are depleted from the retina. These data indicate that the soluble 30K protein is localized selectively in photoreceptor cells of the retina and perhaps exclusively in ROS. (Supported by NIH Grant EY00395 and the Medical Research Service of the Veterans Administration.)

998 METHODS FOR MEASURING BLOOD GABA CONTENT. J. Ferkany*, L. Smith*, W. Seifert*, R. Caprioli* and S.J. Enna (SPON:I.J. Butler). Depts. Pharmacol., Neurobiology and Anat., and Biochem., Univ. Texas Med. Sch., Houston, Texas 77025.

Several recent studies have indicated that the ability to measure blood levels of putative neurotransmitters may provide useful clinical and basic scientific information. While there is little evidence that GABA serves a transmitter function in peripheral nerves, the ability to detect this agent in blood may provide new insights into the biological role of this amino acid in mammalian systems. While previous attempts to measure blood GABA have been unsuccessful, the present report describes two methods which are capable of accurately determining the content of GABA in mammalian blood. For the study, whole blood was withdrawn from a variety of mammalian species into syringes containing 15% EDTA, and 1-3 ml portions were added to tubes containing 7% perchloric acid, then vortexed and centrifuged. The resultant clear supernatant was neutralized with 4N KOH, then analyzed for GABA content using a previously described radioreceptor assay (J. Neurochem. 28:1121, 1977) or by gas chromatography-mass spectrometry (GC/MS). For the latter assay, the neutralized supernatant was lyophilized, redissolved in 0.1 M ammonium acetate buffer and the GABA eluted from a Sephadex G-15 column. For GC/MS assay, the GABA in the eluate was converted to a N-pentafluoropropionyl, methyl ester derivative and GABA content quantified using d_2-GABA as an internal standard. Analysis of rat blood samples using both procedures indicated that the two assay methods yield virtually identical results, with whole blood GABA levels varying from 500 to 1000 pmoles/ml. Using the radioreceptor assay it was found that blood GABA content is stable for up to 24 hrs at room temperature and that the amino acid is found in both formed elements and plasma. Whole blood GABA concentrations range from 500 to 1300 pmoles/ml in 8 mammalian species with human values averaging about 900 pmoles/ml. In vivo administration of aminooxyacetic acid increases both blood and brain GABA levels to a similar extent. Thus, blood GABA determinations may be a useful tool to correlate clinical response to the biochemical effect of GABA transaminase inhibitors and for investigating the physiological function of this amino acid in peripheral tissues. (Supported in part by the Pharmaceutical Manufacturers Association, the Huntington's Chorea Foundation, Merck Sharp and Dohme, and USPHS grants RCDA NS-00335 (S.J.E.) and MH-29739.)

999 ONTOGENIC DEVELOPMENT OF TRITIATED WATER FORMATION DURING LEUCINE METABOLISM IN RAT BRAIN. G. N. Fuller and R. C. Wiggins, Dept. Neurobiol. & Anat., Univ. of Texas Med. Sch. Houston, TX 77025

Following the injection of tritiated amino acid a large portion of brain soluble radioactivity is in the form of tritiated water (TH_2O), and we show here that the portion increases with postnatal age. Long Evans female rats at various ages were injected intraperitoneally (IP) with L-(4,5-^{3}H(N))-leucine (50uCi/100g body wt.). After 10 min animals were sacrificed and cerebral cortex, liver, blood and sciatic nerve tissue samples were quickly excised and homogenized immediately in a deproteinizing solution of 10% trichoroacetic acid (TCA). The TCA precipitable fraction was then pelleted by centrifugation at 700g for 10 min. Two equal aliquots were taken from the resulting supernatant of each sample. Total soluble radioactivity was determined in one aliquot by adding Biofluor directly to the sample followed by liquid scintillation couting. The other aliquot was dried under nitrogen at 50°C and resolubilized in the original volume of water before determining the evaporative loss of radioactivity (TH_2O). The TH_2O percentage of total radioactivity, that is, the percentage of radioactivity lost through evaporation of the acid soluble fraction was:

	% TH_2O ± SEM			
AGE(d)	CEREBRAL CORTEX	LIVER	BLOOD	SCIATIC NERVE
1	7±0.49	7±0.58	9±1.47	-
8	13±1.54	6±0.48	9±1.28	8±0.82
15	17±0.82	7±0.37	14±1.1	6±0.97
20	22±1.8	9±1.6	18±1.7	11±1.0
25	30±1.4	12±1.3	16±1.3	17±10
30	37±2.1	12±1.7	19±2.3	14±3.3
ADULT	45±1.6	14±0.60	25±1.2	28±3.17

The proportion present as TH_2O is either constant or increases slightly during the first two postnatal weeks. However, during the 3rd and 4th postnatal weeks hydrogen exchange from leucine to water increases markedly, and reaches essentially adult values at this time. A less striking increase is observed in liver and blood. Results for L-(4,5-^{3}H)-valine at 10 and 40 days are comparable to those for leucine. At least for the case with leucine, the percentage of radioactivity present as TH_2O was the same in brain cerebellum, cerebral cortex, and medulla. This work was supported by U.S. Public Health Service Grant NS-14355.

1000 EFFECT OF A CLASS OF NATURALLY-OCCURRING TETRAHYDROISOQUINOLINES ON CATECHOLAMINE METABOLISM IN RAT ADRENAL MEDULLA; IMPORTANCE OF METHYLATION. Matthew P. Galloway*, William J. Burke*, Alex Kosloff*, Deborah L. Lieberman*, John Mitchell*, and Carmine J. Coscia* (SPON: H.B. Sarnat) Departments of Biochemistry and Neurology, St. Louis Univ. Sch. Med., St. Louis, MO 63104.

Two tetrahydroisoquinoline derivatives, 3'-O-methylnorlaudanosolinecarboxylic acid (MNLCA) and 3',4'-desoxynorlaudanosolinecarboxylic acid (DNLCA) have been shown by computerized mass fragmentography to be trace constituents of normal human and rat brain. Norlaudanosolinecarboxylic acid (NLCA) is a condensation product of dopamine and 3'-4'-dihydroxyphenylpyruvate. Its methylation product, MNLCA, is elevated upon administration of L-dopa (C.J. Coscia et al., Nature 269, 617, 1977). To determine the effects of NLCAs on enzymes of catecholamine metabolism in vivo, an investigation was undertaken using rat adrenal medulla explants maintained in culture. In preliminary trials it was demonstrated that tritiated MNLCA, DNLCA as well as dopamine were taken up by medullae. At the end of the incubation concentrations of the NLCAs within the tissue approached that of the media (0.5 mM). In subsequent experiments medulla explants were cultured in the presence of 0.5 mM MNLCA, DNLCA or NLCA and [1,2-^{3}H]dopamine. After 12 h the medullae were removed from the media, carefully washed and homogenized. Upon addition of carrier catecholamines and their various catabolites, the mixture was subjected to paired-ion reversed-phase high pressure liquid chromatography which afforded complete resolution of the compounds examined (J. Mitchell and C. J. Coscia, J. Chromatogr., 145, 295, 1978). The metabolites were collected and counted. Catecholamine levels were increased over controls in the presence of all three NLCAs and concomittantly, levels of dopamine catabolites (3,4-dihydroxyphenylacetic and homovanillic acids) were depressed by MNLCA. These results suggested inhibition of monoamine oxidase by MNLCA which was also observed in vitro using crude adrenal medulla homogenates. NLCA was not inhibitory. Similarly metanephrine and normetanephrine were elevated over controls in the presence of MNLCA but not NLCA. Previous in vitro data indicated that NLCA is a competitive inhibitor of catechol-O-methyltransferase (COMT)-catalyzed methylation of dopamine and norepinephrine. Metabolism of NLCA upon intravenous injection into mice appeared to occur predominantly by methylation. NLCA is converted into MNLCA, the 7'-O-methyl isomer and the 3',7-O-dimethyl derivative. Thus both in vitro and in vivo effects on catecholamine metabolism by NLCA will depend on the extent of its methylation. (Supported by NIH Grant NS 12342.)

1001 PRESENCE, METABOLISM AND UPTAKE OF PIPECOLIC ACID IN THE MOUSE BRAIN. Ezio Giacobini, Thomas Schmidt-Glenewinkel*, Yasuyuki Nomura*, Y. Okuma* and Tomio Segawa*. Dept. Biobehav. Sci., UConn, Storrs, CT 06268 and Dept. Pharmacol. Inst. Pharmac. Sci., Hiroshima Univ., Sch. Med., Kasumi 1-2-3, Hiroshima, Japan.

Pipecolic acid, an iminoacid related to lysine metabolism, has recently been identified in the mouse brain in our laboratory by means of TLC and mass spectrometry. Endogenous levels of 18±4 nmoles/g pipecolic acid were found in whole brain homogenates of adult mice. Several organs of the adult mouse, including brain, showed in vitro formation of pipecolic acid from L-lysine. The kidney demonstrated the highest rate followed by the brain (Schmidt-Glenewinkel et al., Neurochem. Res. 2: 619-637, 1977). The synthesis of pipecolic acid from L-lysine was studied in whole embryo and brain of mouse and chick. In the mouse brain formation of pipecolic acid could be detected as early as at day 17 of gestation and in the chick embryo head at day 5 of incubation. Synaptosomes isolated from mouse brain showed temperature dependent uptake of (^{3}H)-pipecolic acid at a concentration of $2x10^{-7}$M. The uptake was Na^+ dependent, ouabain sensitive and showed at $K_m=4.17x10^{-6}$M. Structural analogues of pipecolic acid showed a significant inhibitory effect on uptake at a concentration of 10^{-4}M. Release of pipecolic acid could also be demonstrated in rat brain slices. The demonstration of presence, biosynthesis in adult and embryonal brain and high affinity uptake of pipecolic acid, suggests a physiological role of this substance in the central nervous system of the mouse.

1002 PINEAL GLAND PRODUCES ITS OWN S-ADENOSYLMETHIONINE. Ras B. Guchhait and James E. Grau, Jr.* Dept. Epidemiol., Sch. Hyg. and Pub. Hlth., Johns Hopkins University, Baltimore, MD., 21205.

Transmethylation requires S-adenosylmethionine which is catalyzed from ATP and L-methionine by S-adenosylmethionine synthetase (S-adenosyltransferase, EC 2.5.1.6). It is demonstrated that the pineal gland, a tissue highly active in biogenic amine transmethylation, from rat and various other species, contains S-adenosylmethionine synthetase. The synthetase is also present in rat Harderian gland and retina besides other tissues. A product of the enzymatic reaction has been characterized as S-adenosylmethionine which serves as the methyl group donor for the formation of melatonin by the pineal extract. The specific activity of rat pineal S-adenosyltransferase is at least eight times greater than that of the brain, and one-half that of the liver enzyme. Km for L-methionine and ATP has been determined as 6.2×10^{-5} and 6×10^{-4} M respectively. Magnesium at a concentration of 25 mM is required for maximal catalysis, higher concentration is found to be inhibitory. 50 mM potassium ion increases the activity by 30%, however, unlike Mg^{2+}, higher concentrations of K^+ up to 200 mM do not show any inhibition. Omission of a sulfhydryl compound from the reaction mixture causes an insignificant change in overall catalysis.

1003 A SENSITIVE AND SPECIFIC ENZYME LINKED IMMUNOSORBENT ASSAY FOR THE Ca^{2+}-DEPENDENT REGULATOR PROTEIN OF PIG BRAIN. I. Hanbauer, J. Gimble* and H.-Y. T. Yang*. Section on Biochemical Pharmacology, NHLBI, NIH, Bethesda, MD 20014 and Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

The heat stable Ca^{2+}-dependent protein regulator (CDR) from brain was purified according to the procedure of Klee (Biochemistry 16: 1017-1024, 1977). Our CDR preparation was homogenous in 20% polyacrylamide gel electrophoresis in presence of 0.1% SDS. For the production of immunoglobulins directed toward CDR, the purified protein was coupled to hemocyanin with 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide. The CDR-hemocyanin conjugate emulsified in complete Freund's adjuvant was injected intradermally into the back of rabbits. The injection was repeated 7 to 8 times at 2 week intervals.

Partially purified immunoglobulins [50%$(NH_4)_2$ SO_4 precipitation] were coupled with various concentrations of CDR or unknown CDR. The mixtures were then transferred to CDR coated microplates and incubated for 2 hours. Horseradish peroxidase labeled anti-rabbit globulin was then added and allowed to react. Reaction with o-phenylenediamine produced a colored compound which was measured in a spectrophotometer (488 nm). The enzymatic immunoassay could detect as little as 500 pg CDR. The immunoglobulins directed against CDR were highly specific; the cross-reactivity with Troponin C from rabbit muscle (a gift from Dr. D. M. Watterson) was about 0.5% and that with the Ca^{2+}-dependent activator protein from human erythrocytes (a gift from Dr. F. F. Vincenzi) was 1%.

1004 CHOLINE ADMINISTRATION INCREASES RAT BRAIN DOPAMINE METABOLISM Dean R. Haubrich and A. Barbara Pflueger* Merck Institute for Therapeutic Research, West Point, Pa. 19486

Administration of choline increases the concentration of ACh in brains of laboratory animals [see Life Sciences 20, 1465 (1977)], and alleviates the symptoms of tardive dyskinesia in humans [N. Engl. J. Med. 293: 152 (1975); Ann. Neurol. 1, 418 (1977)]. This neurological disorder is also reversed by administration of the acetylcholinesterase inhibitor physostigmine. These findings suggest that choline administration stimulates the formation and neuronal release of ACh to elicit an increase in central cholinergic function.

To test this hypothesis, central cholinergic function was assessed indirectly by measuring changes in metabolism of dopamine in the corpus striatum of rats. Oral administration of choline Cl (20 mmol/kg, fed rats) enhanced the rate of depletion of striatal dopamine induced by simultaneous administration of α-methyltyrosine (α-MT, 1.2 mmol/kg, i.p.), a tyrosine hydroxylase inhibitor (α-MT alone→50% decrease; α-MT with choline→68% decrease measured 2 hr after treatment). In addition, treatment of fasted rats with two doses of choline (10 mmol/kg, p.o., 1 hr apart) caused an increase (22-54%) in the concentration of the dopamine metabolite, homovanillic acid (HVA) measured 30 min after the second dose. A similar increase in HVA concentration also occurred 30 min after the second of two oral doses of physostigmine sulfate (2.5 μmol/kg, 1 hr apart). Administration of atropine sulfate (8.6 μmol/kg, i.p.) lowered the concentration of HVA measured 90 min after treatment, and this decrease was prevented by simultaneous oral administration of two doses of choline. Treatment of rats with a dose of atropine (2 μmol/kg) which did not affect levels of HVA partially antagonized the choline-induced increase in concentration of the metabolite. These findings show that administration of choline elicits an increase in the metabolism of brain dopamine by a central cholinergic mechanism.

To assess the role of ACh synthesis in mediating this increase in dopamine metabolism, fasted rats were treated with 4-(1-naphthylvinyl)pyridine (NVP), (0.37 mmol/kg, i.p.), an inhibitor of choline acetyltransferase, followed 10 min later by either choline or physostigmine (as above). Treatment with NVP lowered the concentration of HVA and antagonized the choline-induced increase in concentration of the metabolite, but did not prevent the increase in HVA levels induced by administration of physostigmine. This latter finding indicates that choline and physostigmine produce their central cholinergic effects by different mechanisms, and suggests that choline stimulates central cholinergic function by an increase in the rate of synthesis and release of ACh from its presynaptic terminals.

1005 cAMP-DEPENDENT ACTIVATION AND PHOSPHORYLATION OF TYROSINE HYDROXYLASE (TH). John W. Haycock, Michael D.Browning, John A. Meligeni and Jack C. Waymire. Dept. of Psychobiology, University of California at Irvine, Irvine, CA. 92717.

Dopamine synthesis from radiolabeled tyrosine in cultured bovine adrenal chromaffin cells underwent a rapid (less than 2 min.), dose dependent (1.0 mM optimal), pH dependent (pH 5.5 optimal), reversible (20 min. at 37°C) stimulation in response to 8-bromo-3',5'-cyclic adenosine monophosphate (8BrcAMP). TH isolated from activated cells exhibited a higher V_{max} for tyrosine (28.8 vs. 18.6) and pterine cofactor (14.5 vs. 12.6) and a lower K_m for pterine (0.58 vs. 0.36); and TH from control cells exhibited a similar pattern of kinetic alterations when exposed to in vitro conditions optimal for cAMP-dependent phosphorylation. Preincubation of chromaffin cells in the presence of $^{32}PO_4$ to label ATP, followed by 8BrcAMP stimulation and immunoprecipitation with TH specific antisera, revealed a marked stimulation of ^{32}P incorporation into bands which comigrate with more highly purified TH on polyacrylamide slab gels. A similar stimulation of ^{32}P incorporation into immunoprecipitated material occurred upon incubation of TH from the supernatant of control cells with ^{32}P-ATP under cAMP dependent phosphorylation conditions. These results indicate that dopamine synthesis and TH activity may be elevated in situ by a mechanism which involves cAMP dependent phosphorylation of TH molecules.

1006 INVOLVEMENT OF LSD-INDUCED HYPERTHERMIA IN THE DISAGGREGATION* OF RABBIT BRAIN POLYSOMES. John J. Heikkila and Ian R. Brown
Dept. of Zoology, Scarborough College, Univ. of Toronto, West Hill, Ontario, Canada, M1C 1A4.

We have previously reported that the intravenous administration of LSD to young rabbits induces a transient, organ-specific disaggregation of brain polysomes (Holbrook & Brown, J. Neurochem., 27, 77, 1976). The LSD-induced shift of brain polysomes to monosomes is mediated by the interaction of the drug with neurotransmitter receptors (Holbrook & Brown, Life Sci., 21,1037,1977) and the extent of polysome disaggregation can be accentuated by mild stress and blocked by pre-LSD sedation (Heikkila et al., Life Sci. 22, 757, 1978; Holbrook & Brown, J. Neurochem., 29, 461,1977). We now report that LSD-induced hyperthermia may be involved in the disaggregation of rabbit brain polysomes.

Rectal temperature measurements were taken in conjunction with the examination of brain polysome profiles 1 hr after LSD (10-100 ug/kg i.v.) administration. High rectal temperatures (41-42°C+) prior to sacrifice were always associated with a massive disaggregation of brain polysomes while lower rectal temperatures were correlated with slight polysome shifts. Rabbits given LSD (1-25 ug/kg) plus stress (restraint) consistently showed more extensive brain polysome disaggregation and higher rectal temperatures than animals administered LSD without stress. Pretreatment with neurotransmitter receptor blockers which inhibit the LSD-induced disaggregation of brain polysomes also prevents LSD-induced hyperthermia. If hyperthermia was involved in the series of events leading to brain polysome disaggregation then one might expect that hyperthermia would precede brain polysome disaggregation. Rabbits given 25 ug/kg of LSD showed marked elevations in body temperature within minutes after injection, whereas brain polysome disaggregation is not detectable until 15-30 min later. The administration of 2-bromo-LSD, which does not disaggregate brain polysomes also did not elevate body temperature. These results suggest an involvement of hyperthermia in the LSD-induced disaggregation of rabbit brain polysomes.

1007 REGULATION OF AEROBIC METABOLISM IN STIMULATED GARFISH OLFACTORY NERVE. L.A. Hershey, S.H. McDougal*, R.V. Dargar*, and D.B. McDougal,Jr.*, Dept. Pharm., Wash. U. Medical School, St. Louis, Mo., 63110.

Metabolic flux is known to accelerate during nerve stimulation. It is not clear how this flux transition occurs in aerobic nervous tissue. Neither is it known how sodium pump activity influences such a transition. Garfish nerve was chosen for this study because the monotonous homogeneity of its non-myelinated fibers assures uniformity in measuring both electrical and metabolic events.

Oxidative metabolism was shown to be necessary in supporting the action potential during repetitive stimulation and in maintaining optimal levels of high energy phosphates in stimulated garfish olfactory nerve. Levels of lactate, pyruvate, acetyl-CoA and α-ketoglutarate were measured fluormetrically in extracts of nerves that had been stimulated in air for various intervals. Changes in the levels of these intermediates during metabolic flux transition gave some clues about control points in oxidative metabolism in this preparation.

When metabolic flux is increased by nerve stimulation, pyruvate dehydrogenase appears to be the first rate-limiting step in the Kreb's cycle. Pyruvate levels increased by 40% after 120 impulses, while acetyl-CoA levels remained unchanged. Next, α-ketoglutarate levels increased by 45% (after 180 impulses), suggesting a second control step beyond this point in the cycle.

There is a fall in the lactate/pyruvate ratio with nerve stimulation that appears to be commensurate with a fall in the ATP/ADP·P_i ratio (maximal after 180 impulses). These ratios return to resting levels in parallel with one another during continued stimulation. This suggests a close association between sodium pump activation and metabolic flux transition in garfish olfactory nerve.

1008 THE ROLE OF pH IN THE ISOLATION OF NERVE ENDING PARTICLES WHICH TRANSPORT GABA. Robert J. Hitzemann* (SPON: Enoch Callaway) Depts. of Pharmacology and Psychiatry, University of California, San Francisco, CA 94143.

Nerve endings were prepared from the whole rat brain using sucrose and sucrose-ficoll solutions buffered to pHs ranging from 6 to 8.2 with 5 mM HEPES. Briefly, a crude mitochondrial fraction was prepared by standard centrifugation techniques using 0.32 M sucrose + 5 mM HEPES (S-H) as the homogenizing medium. After washing the mitochondrial fraction twice with S-H, the pellet was resuspended and layered on a discontinuous S-H-Ficoll gradient containing steps of 15, 12, 8 and 6 percent Ficoll. The gradient was centrifuged for 45 min x 83,000 g. Five fractions (A to E) were harvested from the gradient; each fraction contained the interfacial material plus the material suspended in the layer above each interface. Increasing the pH from 6 to 7.8 resulted in a 460 percent increase in the total [^{3}H]GABA transport appearing in the combined five gradient fractions. Even increasing the pH from 7 to 7.8 significantly increased [^{3}H]GABA transport 60 percent. Changes in pH also affected the distribution of transport sites within the gradient. Below pH = 7, the majority of the transport activity was found in the mitochondrial fraction (fraction E), whereas at a pH of 7 or above the highest density of transport sites was found in fraction C. In fraction C, which is the most enriched in nerve endings, increasing the S-H pH from 7 to 7.8 increased total transport activity 85 percent and transport specific activity 41 percent. A similar effect was observed for [^{14}C]glutamate transport. Total transport activity increased 92 percent and transport specific activity increased 50 percent. Using succinic dehydrogenase and NADPH cytochrome C reductase, respectively, as mitochondrial and microsomal marker enzymes, it was found that increasing the S-H pH to 7.8 did not significantly increase the contamination of fraction C. Finally, it was found that increasing the S-H pH increased the total number of [^{3}H]ouabain binding sites but did not increase binding specific activity in fraction C since the increase in binding was not greater than the increase in protein which occurred in this fraction. Overall, the results of the present study suggest (1) that the pH of the sucrose solutions used to process brain tissue is a critical factor in isolating viable nerve endings, and (2) that when isolating nerve endings to be used for GABA or glutamate transport studies the pH of the sucrose solutions should be about 7.8.

This study was supported in part by Grant NS-13398.

1009 IS THERE ACETYL-COENZYME A HYDROLASE OR CHOLINE ACETYLTRANSFERACE IN MAMMALIAN BLOOD? L. L. Hsu* and J. Claghorn (SPON: T. Samorajski) Texas Research Institute of Mental Sciences, Houston, Texas 77030

In the course of establishing the radiochemical assay for choline acetyltransferase (acetyl-coenzyme A: Choline O-acetyltransfuase E.C. 2.3.1.6., CAT) in mammalian blood, we found that Triton X-100 treated whole blood, red blood cell (RBC) or plasma, catalyzed the hydrolysis of (C^{14}) - or (H^3) - acetyl-CoA either in the presence or in the absence of choline chloride. We have therefore further studied the acetyl-CoA hydrolase in blood fractions. Both the methods of Fonnum (J Neurochem 24, 407-409, 1975) and Brandon and Wu(personal communication) were used. The latter method employs activated charcoal to absorb the unreacted labeled acetyl-CoA leaving products in the supernatant. Whole blood, plasma and RBC from mammals including humans, Rhesus monkeys, rats and mice were homogenized in equal volumes of 0.5% Tritm X-100 and 1 tenth volume of 3M NaCl (Massarelli et al, Neuroscience Letters, 5, 95-101, 1977). Aliquots of blood fractions were incubated in 0.5M potassium phosphate buffer containing 0.2mM (1-C^{14}) - or (H^3) - acetyl-CoA, 2 mM EDTA, 0.1 or 1mM physostigmine, and varying concentrations of choline chloride in a final volume of 0.15 or 0.2 ml at 37° C for various time intervals. At the end of incubation, either 10% acetic acid or 0.01 M potassium phosphate was added to stop the reaction. Either charcoal or Kalignost in acetonitrile (15 mg/ml) was added respectively and radioactivity of the product was measured. The radioactive product is identified by TLC analysis. The enzyme activity is linear with whole blood and plasma up to 50 ul and with RBC up to 25 ul; linear with incubation time up to 1 hr. The enzyme activity is pH dependent and optimal at pH 8.0. The enzyme activity was 2.5 times as high in RBC as that in the plasma fraction. Coenzyme A (0.08 mM) competitively inhibited the enzyme activity in both RBC and plasma. Acetylcholine (0.1 M) slightly inhibited the enzyme activity in RBC but markedly inhibited that in plasma. On the other hand, choline chloride at 4mM did not affect the hydrolase activity. The distribution of acetyl-CoA hydralase in brain has been reported (Matsuda and Yoshida, J. Neurodhem, 26, 817-822, 1976).

1010 DIRECT PHOSPHORYLATION OF TYROSINE HYDROXYLASE BY cAMP-DEPENDENT PROTEIN KINASE: A MECHANISM OF ENZYME ACTIVATION. T.H. Joh, D.H. Park, M.J. Brodsky*, and D.J. Reis, Laboratory of Neurobiology, Cornell University Medical College, New York, NY 10021.

Over the past several years the demonstration that the activity of tyrosine hydroxylase (TH) is altered by cAMP has raised the question as to whether TH may be regulated by phosphorylation, and if so, whether the enzyme itself is phosphorylated. In the present study, we have sought to determine: (a) if TH in rat brain and adrenal medulla can be directly phosphorylated by cAMP-dependent protein kinase (PK); (b) if such phosphorylation increases the catalytic activity of the enzyme; and (c) what the kinetic mechanism is for the increase in the enzyme activity. TH was highly purified from rat brain and adrenal gland by homogenization, centrifugation, and ammonium sulfate fractionation, followed by sequential chromatographies of Phenyl-Sepharose, DEAE-cellulose (stepwise), DEAE-cellulose (gradient), CM-cellulose and Sepharose 4B columns. The highly purified TH was then subjected to conditions for protein phosphorylation, using PK purified from rat heart, and phosphorylated TH (P-TH) isolated. Addition of cAMP to the reaction mixture was necessary for phosphorylation of TH. For the isolation of P-TH, polyacrylamide gel electrophoresis was substituted for the aforementioned final two column chromatographic steps. On a polyacrylamide gel, authentic TH and P-TH showed a single protein band. On an SDS-gel, three protein subunits were seen with MWs equivalent to 52,000, 62,000 and 68,000; the protein band of MW 62,000 represents the catalytically active unit while the other bands probably represent structural or regulatory subunits. When ^{32}P-ATP was used in the phosphorylation mixture, ^{32}P was detected only in the subunit of MW 62,000, indicating that the catalytically active subunit was phosphorylated. The specific activity of the P-TH was two times higher than that of authentic TH. Kinetic analysis of P-TH demonstrated that the increase in TH activity is due to an increase in Vm without change in Km for either substrate or cofactor, reflecting an increase in the amount of enzyme. Since in our system the total amount of TH was fixed, an increase in the amount of enzyme must therefore represent an increase in the amount of the catalytically active enzyme from an inactive form of the enzyme. This concept implies that in tissue the pool of native TH is composed of a mixture of enzyme in both active and inactive forms, that the active form is phosphorylated, and the phosphorylation produces an active form of enzyme at the expense of the inactive form. Interconversion of the forms may be an important mode of regulation of catecholamine biosynthesis in vivo. (Supported by NIH grants HL 18974, MH 24285; and NASA award NSG 2259.)

1011 THE EFFECTS OF LEAD POISONING ON CALCIUM TRANSPORT BY THE BRAIN IN 30-DAY OLD ALBINO RABBITS. C. S. Kim*, L. A. O'Tuama, S. L. Cookson*, and J. D. Mann*. Depts. of Neurology, Pediatrics, Medicine, and the Biological Sciences Research Center. Sch. Med. Univ. N. C., Chapel Hill, N. C. 27514.

We have shown that the extraction of ^{45}Ca from plasma by cerebral gray matter is reduced in lead intoxicated albino rabbits compared to controls. This finding indicates that Pb poisoning may disrupt systems for transport of ^{45}Ca at the blood-brain barrier (Soc. Neuroscience Abs. 3:311, 1977). To investigate the possibility that this effect might also exist at the cellular membrane level, we have studied the uptake and efflux of ^{45}Ca in control and lead treated 30-day old albino rabbits. The clearance of ^{45}Ca from CSF, measured by ventriculo-cisternal perfusion, was sufficiently slow that a ratio between inflow and outflow concentrations of only 0.8 was reached at steady state. These findings are compatible with those of Graziani et al (Am. J. Physiol. 208:1058-1064, 1965) who had likewise noted an extremely slow exchange of ^{45}Ca across the brain-CSF interface. In Pb poisoned animals receiving 165 mgs of $Pb(CO_2)_3$ daily for 5 days, no significant difference was noted in the rate of clearance of ^{45}Ca from the ventricle. The uptake of ^{45}Ca was also studied in brain slices that were preincubated for 30 min in artificial CSF only and then transferred to experimental medium. The T/M ratio was 0.65 $\pm$ 0.08 for controls and 0.86 $\pm$ 0.12 for brain cortex exposed to lead nitrate (5×10^{-6}M) (NS). For the study of ^{45}Ca efflux, brain cortex, paraventricular tissue (PVT) and choroid plexus (CP) slices were rapidly removed and incubated for 30 min in a medium containing ^{45}Ca 350,000 cpm/ml (sp. act. 17.9 mCi/mg). The slices were washed in cold artificial CSF, transferred to unlabeled CSF at 37° and incubated for different periods of time (5 to 45 min). The intracellular retention of ^{45}Ca at 5 min was increased 75% in animals treated in vivo with lead carbonate ($P < 0.01$), 69% in tissues incubated in vitro with Ouabain (10^{-4}M) ($P < 0.01$), and 48% with Sodium Azide (3mM) ($P < 0.05$). However, such treatment did not increase ^{45}Ca accumulation by CP or PVT. The entry of Ca into the cells is down an electrochemical gradient and efflux is by active transport. This study indicates the possibility of interaction of lead and Ca with carrier complexes in the process of active transport. A resultant imbalance of intracellular Ca levels may influence Pb Neurotoxicity. Supported by a grant from the NIH #RO1-ES01151.

1012 IN VITRO INHIBITION OF RABBIT BRAIN MONOAMINE OXIDASE BY NITROBENZENOID COMPOUNDS. Alane S. Kimes and Daniel O.Carr* Dept. Biochem., Ks. Univ. Med. Cen., Kansas City, Ks. 66103.

Several soluble flavoenzymes are known to be inhibited by nitrocompounds. In addition, monoamine oxidase (MAO) from rabbit liver, a membrane bound flavoenzyme, has been shown to be inhibited by nitroaromatic compounds. In the present study, MAO was partially purified and solubilized from rabbit brain and then subjected to inhibition by several nitrobenzenoid derivatives. The results were compared to the inhibition of the rabbit liver enzyme by the nitrobenzenoid compounds in this laboratory. As with the liver enzyme, the nitrobenzenoid compounds were competitive inhibitors of the rabbit brain enzyme when p-dimethylaminobenzylamine, a type B substrate, was used. The nitrobenzene derivatives tested included those with the following substituents: p-carboxy, p-chloro, p-carboxamide, p-carbomethoxy, p-formyl, p-acetyl, p-cyano, m-nitro, and p-nitro. The K_i's ranged from 5.2×10^{-7}M to 1.8×10^{-4}M. The inhibition was greater when the electron withdrawing power of the substituent, as measured by its Hammett sigma value relative to unsubstituted nitrobenzene, increased. p-Dinitrobenzene was the most potent inhibitor and had the most electron deficient ring system. These results were similar to those found for rabbit liver MAO. Some differences were noted, i.e., p- chloronitrobenzene was much more potent with the liver enzyme than with the brain enzyme which may indicate some slight differences in MAO from the two organs.

1013 ANALYSIS OF MAJOR RNA CLASSES IN THE MAUTHNER AXON. Edward Koenig. Dept. Physiol., SUNY at Bflo., Sch. Med., Buffalo, NY 14214.

Work in this laboratory over the years has indicated that myelinated vertebrate axons are capable of a low level of protein synthesizing activity that is extramitochondrial. Recent studies (Frankel and Koenig, 1977, Exp. Neurol., 57:282; 1978, Brain Res., 141:67) have suggested that those few products which appear to be synthesized indigenously in vitro may relate in part to axoskeletal components (e.g., neurofilaments). A major objection to attributing protein synthesizing activity to the axon has been the lack of morphological evidence of ribosomes. A method has been developed for extracting and purifying on a microscale undegraded RNA from myelin-free Mauthner axons of the goldfish. Microextracts were fractionated by microelectrophoresis and showed the presence of major RNA classes indistinguishable from ribosomal classes of fish brain; i.e., 26 S_E and 18 S_E. There was no apparent 5 S_E class and the 4 S class was disproportionately large compared to that of brain tissue. In addition, axonal extracts contained an apparent 15 S_E nonribosomal class that was neither evident in brain extracts, nor in extracts from Mauthner axon myelin sheath samples. Myelin sheath extracts also exhibited a disproportionately large 4 S class. Electron-microscopy showed that the technique of axon isolation yielded samples that were free of significant contamination by myelin. In addition, comparisons between equivalent-sized samples of isolated axons and myelin sheath showed that axon samples yielded significantly more RNA than myelin sheath samples. It is concluded that the Mauthner axon contains a protein synthesizing machinery, which, because of its dispersed deployment, shows relative enrichment of nonribosomal 15 S and 4 S classes.

Supported by P. H. S. Public Health Grant No. 04656 from the NINCDS.

1014 STUDIES ON THE ENZYMATIC DEPHOSPHORYLATION OF TYROSINE HYDROXYLASE. Mitchell A. Lazar*, Joachim D. Raese*, Arthur M. Edelman*, and Jack D. Barchas.

We have previously found that purified tyrosine hydroxylase from bovine corpora striata is a substrate for cAMP-dependent protein kinase. Tyrosine hydroxylase can incorporate 0.7 to 0.9 moles of phosphate per mole of enzyme, and is activated by phosphorylation. We report here that high speed supernatants from rat tissue homogenates can dephosphorylate ^{32}P-labeled tyrosine hydroxylase. The specific activity of tyrosine hydroxylase phosphatase is several-fold greater in corpora striata than in liver, muscle, or kidney. Dephosphorylation of ^{32}P-labeled tyrosine hydroxylase by rat striatal extract is not inhibited by addition of excess unlabeled phosphohistone to the incubation medium. In contrast, unlabeled phosphohistone competes efficiently with ^{32}P-labeled histone as a substrate for phosphohistone phosphatase in rat striata. The data suggest the existence of a phosphatase with higher specificity for phosphorylated tyrosine hydroxylase than for phosphorylated histone.

1015 COMPARISON OF MICROWAVE IRRADIATION AT 986 VS 2450 MHZ FOR IN-VIVO INACTIVATION OF BRAIN ENZYMES IN RATS. Robert H. Lenox, James L. Meyerhoff, Om P. Gandhi*, and John H. Jacobi*, Depts. of Medical Neurosciences and Microwave Research, Div of Neuropsychiatry, Walter Reed Army Inst. of Research, Washington, DC 20012 and Dept. of Electrical Engineering, University of Utah, Salt Lake City, UT 84112.

Our laboratory has previously observed that heat deposition as well as the pattern of enzyme inactivation in the rat brain at 2450 megahertz (MHz) is non-uniform, and that energy distribution is markedly affected by rotation of the rat head. Accordingly we find it necessary to immobilize animals prior to sacrifice by microwave irradiation. Because immobilization is a potent stressor which can cause neurochemical and hormonal changes, a technique of irradiation that was independent of orientation of the rat would be extremely useful if it eliminated the present requirement to immobilize the rat prior to sacrifice. The present study was undertaken to compare the effects of rotation on the geometry of energy distribution in rat brain during exposure at different microwave frequencies. The pattern of energy deposition can be inferred from the pattern of enzyme inactivation using a cytochemical technique. Male 300 gram Walter Reed strain rats were anesthetized with sodium pentobarbital and inserted into a plexiglass cylinder which was placed in one of four degrees of rotation (0^{o}, 90^{o}, 180^{o}, or 270^{o}) within the waveguide chamber. The rats were then exposed to either of two microwave frequencies: 2450 or 986 MHz. An exposure duration was deliberately selected to produce a gradient of enzyme inactivation in the brains of rats exposed to either frequency. Four animals were studied under each of the eight combinations of frequency and rotation. Following exposure to microwave irradiation the rats were decapitated, the brains removed, frozen on dry ice, and 10μ sections cut in a cryostat at -2^{o}C. The pattern of enzyme inactivation was revealed by the cytochemical technique of Nachlas which stains for succinic dehydrogenase activity. The pattern was markedly rotation-dependent at 2450 MHz: absorption of energy was markedly reduced at 90 and 270 degrees of rotation. At 986 MHz, however, the dorsal portion of the brain absorbed most of the energy at all four angles of exposure, and degree of rotation produced almost no effect on the pattern of enzyme inactivation. These data suggest that further exploration of frequency parameters would contribute to development of a microwave inactivation technique more applicable to neurochemical studies in behaving, freely-moving rats.

1016 PURIFICATION OF CHOLINE ACETYLTRANSFERASE FROM CHICKEN BRAINS. Kelvin Ma*, and S.C. Sung. Div. of Neurol. Sci., University of B.C., Vancouver, B.C., Canada, V6T 1W5.

Choline acetyltransferase (CAT), the enzyme responsible for the synthesis of acetylcholine (ACh), has been extensively purified from chicken brains which had their cerebellums removed. Purification procedures included ammonium sulfate fractionation, DEAE-Sephadex (A-25) chromatography, protamine sulfate fractionation, chromatography on hydroxyapatite, sephadex G-150, and affinity chromatography on agarose-hexane-Coenzyme A column. CAT activity was measured radiochemically. Due to the instability of the enzyme in the course of purification, the most active fraction obtained after agarose-hexane-Coenzyme A chromatrography showed a specific activity of only 560 nmoles ACh formed/min./mg. protein which corresponded to a 1000 fold purification from homogenate. However, on non-denaturing polyacrylamide gel electrophoresis at pH 8.8, the highly purified CAT preparation showed 2 distinct bands, and CAT activity was recovered by slicing and assaying the gel, and corresponded to the position of the faster moving band. The same preparation showed 1 major band and 3 minor bands on SDS gel electrophoresis. The estimated MW of the major band was 63500. The lack of carnitine acetyltransferase in the enzyme preparation was indicated by the low specific activity of carnitine acetyltransferase of 0.17 nmoles acetylcarnitine formed/min./mg. protein compared to 24 nmoles/min./mg. in crude extract. The presence of eserine sulfate in the reaction mixture had no effect on the CAT activity of the preparation indicating that it was free of acetylcholinesterase. Studies on the inhibition of ACh on the CAT preparation showed that the CAT activity was not inhibited up to 50 mM ACh (14% inhibition) and that only a 28% inhibition was obtained with 200 mM ACh. The CAT preparation also showed species specificity. By the Ouchterlony double immunodiffusion test, both the highly purified CAT preparation and crude extract from chicken brains diluted to different concentrations did not cross react with rabbit serum (of different dilutions) prepared to purified human CAT. (Supported by the MDAC).

1017 INORGANIC PHOSPHATE AS A REGULATOR OF BRAIN GLUTAMATE DECARBOXYLASE. S.B. Martin* and D.L.Martin* (SPON. A.T.Campagnoni) Chemistry Dept., University of Maryland, College Park, Maryland 20742.

Previous studies have suggested that inhibition of brain glutamate decarboxylase (GAD) by nucleotides results in the formation of the inactive apoenzyme. The present results suggest that physiological concentrations of P_i oppose this inhibition, at least in part, by promoting the reactivation of apoGAD. In most experiments apoGAD was prepared by incubating GAD preparations with $2x10^{-5}$ M aminooxyacetic acid for about 30 min at room temperature followed by exhaustive dialysis against 0.05 M imidazole-acetate buffer, pH 7.2 containing 1 mM aminoethylisothiuronium bromide. Reactivation of apoGAD by pyridoxal-5'-phosphate (PLP) was studied by incubating apoenzyme at 37° under various conditions. The amount of holoenzyme was then measured by incubating for 5 min with 1 mM 1-^{14}C-glutamate and collecting the $^{14}CO_2$. Incubation of apoGAD with PLP in the absence of P_i resulted in an initially rapid but incomplete reactivation which stopped after 20 min of incubation. The amount of holoenzyme formed after 20 min was proportional to log [PLP] over the range 0.03 to 250 μM. Half-maximal activity was reached at about 10 μM PLP. Addition of 1-10 mM P_i stimulated reactivation. This effect was observed whether P_i was present initially or added after 15 min indicating that incomplete reactivation in the absence of P_i was not due to depletion of PLP. Incubation with 1 μM PLP and 1 mM P_i resulted in partial reactivation which stopped after 10 min. Addition of 10 mM P_i reduced the concentration of PLP giving half-maximal activity to about .07 μM; full activity was reached by about 10 μM PLP. P_i also stimulated reactivation of apoGAD prepared by treatment with glutamate or hydroxylamine or from vitamin B_6 deficient rats. The IC_{50} for several nucleotides including ATP, ADP, GTP, ITP, UTP and CTP is less than 200 μM suggesting that GAD is under continuous strong inhibitory pressure in vivo. In view of this, variations in the level of P_i may be important in controlling GAD activity.

1018 CHOLINE UPTAKE IN THE NEUROBLASTOMA X GLIOMA HYBRID, NG108-15. R. McGee* (SPON: K. L. Dretchen). Dept. Pharmacol., Sch. Med. & Dent., Georgetown University, Washington, DC 20007.

NG108-15 cells possess many neuronal properties, including the ability to form neuromuscular synapses in culture following prolonged exposure to dibutyryl cAMP (Bt_2cAMP). Previous experiments have shown that cells grown in the absence of Bt_2cAMP are unable to release acetylcholine in response to depolarization but gradually develop this capacity during Bt_2cAMP treatment. Since the ability to accumulate choline is essential for the functioning of cholinergic neurons, the choline uptake systems of NG108-15 cells and the effects of Bt_2cAMP on these systems were studied. Cells grown in the absence of Bt_2cAMP exhibit 2 choline uptake systems: a high affinity system, Km = 3.4 µM, Vmax = 40 pmol/min/mg protein, and a lower affinity system, Km = 76 µM, Vmax = 2500 pmol/min/mg protein. The high affinity uptake system (uptake at 0.5 µM choline) was inhibited about 50% by replacement of Na^+ by Li^+ but was unaffected by omission of Ca^{++} or K^+. A tenfold elevation of Ca^{++} or K^+ inhibited uptake by about 20%. In sharp contrast to the high affinity uptake system of brain synaptosomes the high affinity uptake system of NG108-15 cells was not Na^+ dependent since replacement of Na^+ with isosmolar sucrose increased uptake by 60-100%. However, this increased uptake was blocked by elevation of Ca^{++} from 1.8 mM to 18 mM. Also in contrast to syanptosomes, a high concentration of hemicholinium-3 (50 µM) was required to cause 50% inhibition of the high affinity uptake system (0.5 µM choline).

NG108-15 cells cultured with 1 mM Bt_2cAMP for 7 days appeared to no longer possess 2 uptake systems but rather a single system with Km = 46 µM and Vmax = 1800 pmol/min/mg protein. In spite of these changes in kinetic parameters, high affinity uptake at 0.5 µM choline still was increased 60-100% by the replacement of Na^+ with isosmolar sucrose, and 50 µM hemicholinium-3 still inhibited uptake by 50%. Whether or not the changes in kinetic parameters following Bt_2cAMP treatment are involved in the development of depolarization-dependent release of acetylcholine by these cells remains to be determined. However, Bt_2cAMP-treated NG108-15 cells do not appear to have the Na^+-dependent high affinity choline uptake system thought to be associated with cholinergic neurons. Since these cultured cells can form neuromuscular synapses, the results suggest that the Na^+-dependent system is not required for synaptic function. An alternative explanation that cannot be ruled out at this time is that the presynaptic endings of NG108-15 cells do have the Na^+-dependent uptake system but its activity cannot be observed when measuring uptake with intact cells having a high background activity of other choline uptake systems. (Supported by BRSG RR05360 and the PMAF.)

1019 INHIBITION OF MITOCHONDRIAL RESPIRATION BY 3-QUINUCLIDINYL BENZILATE. Brian Melamed* and John J. O'Neill, Temple University School of Medicine, Department of Pharmacology, 3420 North Broad Street, Philadelphia, Pa. 19140.

Potent anticholinergic glycolate esters, in particular the compound Ditran^R (or 30-70% mixture of N-ethyl-3-piperidyl cyclopentyl-phenyl glycolate and N-ethyl-2-pyrrolidyl-methyl cyclopentyl-phenyl glycolate), have marked inhibitory effects upon respiration in stimulated rat brain cortex slices (O'Neill, et al, Adv. Bioch. Pharm. 6: 203, 1972). Furthermore, it was shown that these compounds inhibit mitochondrial respiration when glutamate (10 mM) is the sole substrate; no inhibition of respiration was seen with succinate (10 mM). It was concluded that inhibition occurred at substrate-level phosphorylation. In the present study the effects of Ditran^R on mitochondrial respiration were confirmed.

In light of the current interest in the use of the potent muscarinic antagonist 3-quinuclidinyl benzilate (RO2-3308, QNB) as a marker for muscarinic receptors, we have undertaken an investigation of the effects of this compound on mitochondrial respiration. Mitochondria were obtained from rat brains by a modification of the method of Clark and Nicklas (JBC, 245: 4724, 1970). In these experiments we demonstrated a profound inhibition of state III respiration when QNB was present at similar concentrations to those of Ditran^R in the experiments cited above. Inhibition was observed when glutamate (10 mM) was the sole substrate. No inhibition was seen when either succinate (10 mM) or glutamate (10 mM) plus malate (2.5 mM) were the substrates. Further experiments are planned to elucidate the detailed mechanism of this inhibition. (Supported by NIMH Fellowship 1 F31 MH0733-01.)

1020 EFFECTS OF MILD METHYLMERCURY POISONING ON THE LIPID METABOLISM OF THE DEVELOPING RAT BRAIN. Nirmala K. Menon*, Richard R. Lopez* and R.A. Pieter Kark. Reed Neurol. and M.R. Research Centers, N.P.I., Sch. Med., UCLA, Los Angeles, CA 90024

Injecting CH_3Hg^+ in low doses to pregnant rats on the 4th day of gestation results in inhibition of the incorporation of label from (DL)-3-OH[3-^{14}C] butyrate, but not from [U-^{14}C] glucose, into total extractable brain lipids during the period of active myelination in the virtually asymptomatic pups. Mercury levels and radioactivity of lipids in this model of congenital intoxication have been studied further. Mercury concentrations of the brains, kidneys and livers of the pups were 3.6±0.5µg/g, 5.7±1.0 and 8.0±1.1, respectively, on postnatal day 1; and 0.6±0.2, 1.0±0.3 and 0.6±0.2 on day 21 vs. the asymptomatic dams' concentrations of 20.6±0.3, 42.7±4.0 and 3.0±0.8 in those organs on day 1, and 1.0±0.2, 20.2±4.0 and 2.3±0.9 on day 21. Of the initial mercury, 12% left the pups' brains over the first 21 days vs. 67% from the dams' brains. These data are consistent with evidence of others that the fetus may be more susceptible to methylmercury than are the mothers, and the brain more susceptible than are other organs.

Brain slices from methylmercury-treated pups incorporated significantly less label from 3-OH-butyrate into cholesterol, free fatty acids, phosphatidyl choline and phosphatidyl serine but ten fold more into sphingomyelin at the onset of rapid myelination (day 14), but there were no differences from controls by day 21. However, the inhibition of incorporation into the individual classes of lipids was not enough for changes in any one class to account for the decreased incorporation into total extractable lipids. The data therefore suggest a) inhibition of early steps between the uptake of 3-OH-butyrate by brain slices and its conversion via acetyl- and malonyl-CoA to lipids and b) either inhibition of the conversion of cytidine diphosphate choline to phosphatidyl choline or a defect in the myelination process itself with secondary changes in the metabolism of phospholipids related to myelin.

1021 HYPERTHERMIA IN INFANT RATS: EFFECTS ON IN VIVO PROTEIN SYNTHESIS, ORNITHINE DECARBOXYLASE ACTIVITY AND FREE AMINO ACID LEVELS IN BRAIN AND HEART. N.M. Millan* and F.L. Siegel. Depts. of Pediatrics and Physiological Chemistry, Center for Health Sciences, University of Wisconsin, Madison, WI 53706.

Acute hyperthermia was previously demonstrated to produce a reversible disaggregation of brain polyribosomes and a reversible increase of free amino acid levels in brain (L.L. Murdock, S. Berlow, R.E. Colwell and F.L. Siegel, Neuroscience, In Press). Injection of large amounts of amino acids also produces brain polyribosome disaggregation, but no inhibition of brain protein synthesis occurs in vivo, suggesting that polyribosomes disaggregate only when tissue is homogenzied. In the present investigation, we have determined the effects of hyperthermia on in vivo protein synthesis, ornithine decarboxylase activity and free amino acid levels on 7 and 21 day old rat brain, heart and liver. Our results indicate that pool-corrected in vivo protein synthesis is inhibited by 50% in both brain and liver following a 45 min period of hyperthermia (39.5°C), in 7 day old rats, but no inhibition is produced by hyperthermia in 21 day old rats. Protein synthesis returns to control levels when hyperthermic 7 day old rats are allowed to recover for 2 hr under normothermic conditions. Inhibition of protein synthesis occurs in cortex, midbrain, cerebellum and brain stem and also recovers in all brain areas. Acute hyperthermia for 45 min results in a total loss of ornithine decarboxylase (ODC) in all brain areas and a 39% loss of heart ODC activity. After 2 hr of recovery from hyperthermia, ODC activities in cortex and cerebellum were increased 100% over control; brain stem and midbrain ODC was 30-40% over control, whereas heart ODC activities were 400-600% greater than control values. Cycloheximide administration prevented the increase in heart ODC during the recovery period, suggesting that enzyme induction mediated the increase in enzyme activity. Similar increases in brain free amino acid levels were seen after hyperthermia and cycloheximide administration, suggesting that the increased amino acids result from, rather than contribute to, brain polyribosome disaggregation. β-adrenergic stimulation has been shown to increase heart ODC (J. Bartolme, C. Lau and T.A. Slotkin (1977), J. Pharm. Expt. Therap. 202, 510-518); in the present study pretreatment of infant rats with propranalol (10 mg/kg) or phenoxybenzamine (2.5 mg/kg) failed to prevent the ODC induction during recovery from hyperthermia suggesting that the effects described here do not result from adrenergic stimulation.

Supported by NIH grant HD09045.

1022 BRAIN MEMBRANE PROTEIN PHOSPHORYLATION EXAMINED BY IN VITRO AND IN VIVO LABELING: A FUNCTIONAL ROLE FOR BAND F? Joan C. Mitrius,* David G. Morgan,* Richard G. Conway,* Gary Benson,* and Aryeh Routtenberg. Cresap Neuroscience Laboratory, Northwestern University, Evanston, ILL 60201.

Previous reports from our laboratory have characterized by SDS polyacrylamide gel electrophoresis and autoradiography several synaptosomal phosphoproteins (bands $D_{1,2}$ (MW~83K), D_3 (~67K), E (~53K), F (~47K), G (~34K), and $H_{1,2,3}$ (~18-13K), using in vitro phosphorylation (Conway and Routtenberg, Brain Research, 139, 1978, 366-373) methods. It has been found that band F appears to be especially sensitive to various functional manipulations.

Passive avoidance training affects the in vitro phosphorylation of band F. An increase in band F phosphorylation was found in an osmotically shocked P_2 fraction of rat frontal cortex as a result of experience. Rats were handled daily prior to being trained in a simple learning task. A second group served as yoked-shocked controls, while a third group were handled controls that received no shock. Both trained and yoked-shocked animals displayed significantly greater in vitro phosphorylation of band F than the unshocked controls when sacrificed 24 hr after the experience.

A second approach to assess the functional significance of synaptosomal phosphoproteins was to examine which phosphoproteins were labeled in vivo and the extent of in vivo labeling. Animals with indwelling chronic cannulae injected with 25-100 μCi ^{32}P-orthophosphate into neostriatum were sacrificed by focused microwave radiation (3.0 sec, 2.5 Kw) 2 min to 24 hrs after initiation of the ^{32}P injection. Although the pattern of in vivo phosphorylation varied with time of incorporation, phosphoproteins labeled in vivo were found to co-migrate with phosphoproteins labeled in vitro. Band F demonstrated the most rapid and extensive phosphate incorporation at short time intervals. Indeed, at the shortest time points band F was the major phosphate acceptor.

Finally, subcellular studies indicate that band F is located, at least in part, in the synaptic complex.

Collectively, these data suggest that a synaptosomal substrate, band F, rapidly labeled in vivo and affected by experience may be involved in neuronal function, perhaps at synaptic locations. (Supported by MH25281 and NSF19388 to A. R.)

1023 PHENYLACETIC ACID IN BLOOD AND CEREBROSPINAL FLUID. Aron D. Mosnaim Dept. of Pharmac., Univ. of Health Sciences/Chicago Med. Sch. & Sch. of Grad. and Postdoc. Studies, Chicago, IL 60612 and Daniel L. Feingold* (Sponsor Vel Nair) Dept. of Biol. Sci., Univ. of Illinois, Chicago, IL 60612.

The levels of acid metabolites of biogenic amines have been extensively used to estimate their rate of metabolism. This approach may prove particularly helpful when studying some of the noncatecholic phenylethylamines in view of the relative analytical difficulties found in measuring these substances in biological fluids. We now report the presence of phenylacetic acid (PAAc) in rabbit and human blood and in rabbit, cat and human cerebrospinal fluid (CSF). Using a technique involving solvent extraction-PAAc purification, this acid was reacted with N,N-Bis (Trimethylsilyl acetamide) (BSA) (Madubuike, U., M.Sc. Thesis, UHS Sch. of Grad. & Postdoc. Studies) (1975) and the derivatives estimated by GLC. Radioactive PAAc was added to the initial samples and carried throughout the experimental procedure as internal standard for recovery (PAAc recovery range, as PAAc-BSA, 17-34%). This method provided a detection limit of about 2 ng of PAAc as PAAc-BSA and allowed differentiation of PAAc-BSA (retention time (RT) 18.4 min.) from the BSA derivatives of other possible interfering biogenic acids, e.g., mandelic, homovanillic, benzoic, m-methoxy PAAc and 3,4-dihydroxy PAAc, RT of 13.2, 17.5, 7.4, 27.2 and 17.5 min., respectively. Rabbit and human plasma showed a PAAc concentration of 11.3 ± 2.2 and 13.8 ± 2.7 ng/ml ± S.E.M., respectively. No PAAc could be detected in red blood cells. The levels of PAAc in rabbit, cat and human CSF were 1.13 ± 0.11, 1.17 ± 0.15 and 0.83 ± 0.10 ng/ml ± S.E.M., respectively. Each CSF samples, approximately 10 ml fluid, was obtained by pooling several (3-5) individual samples. Measurement of PAAc could be of importance as one of the parameters used in elucidating the postulated role of PEA in a number of disease conditions, including phenylketonuria and affective and extrapyramidal disorders. Supported in part by NIH General Research Support Grant FR-3566 and by Univ. of Health Sciences/Sch. of Grad. & Postdoc. Studies.

1024 EVIDENCE FOR THE UTILIZATION OF EXTRACELLULAR [γ-^{32}P]-ATP FOR THE PHOSPHORYLATION OF INTRACELLULAR PROTEINS IN SQUID GIANT AXONS. Harish C. Pant*, Susumu Terakawa* and Ichiji Tasaki (SPON: Stuart Judge), Lab of Neurobiology, NIMH, Bethesda, Md. 20014.

The squid giant axons provide a unique model system for the study of biochemical events related to electrogenesis. Some of the special features of this experimental preparation for biochemists is that the sheath can easily be separated from the axoplasm by extrusion.

With this preparation, the radioactive substrate [γ-^{32}P]-ATP, can be applied directly to extruded axoplasm in vitro under rigorously controlled conditions, or alternatiavely it can be injected into the axoplasm in situ, namely, in the excitable axon. In the present studies, we have analyzed the labeled proteins in axoplasm by the polyacrylamide gel electrophoresis method in sodium-dodecyl sulfate (SDS), after phosphorylation in vitro and in situ. The two major phosphorylated regions on the gel had molecular weights of 400,000 and 200,000 daltons. These two peaks appear to be neurofilament proteins of squid axoplasm. In addition, we have made a series of observations which yielded somewhat unexpected results indicating that the same set of proteins were phosphorylated in the axoplasm regardless of whether the [γ-^{32}P[-ATP was applied intracellularly or extracellularly. These results suggest that ATP in the extracellular space is, by some ATP-translocation mechanism, utilized in the process of intracellular phosphorylation. Measurements of the apparent influx of ATP across the squid axon membrane yielded results consistent with the view that ATP in the extracellular fluid could be transported into the axoplasm.

1025 REGIONAL CEREBRAL GLUCOSE METABOLISM DURING HYPOXIA. William A. Pulsinelli and Thomas E. Duffy, Dept. Neurology, Cornell University Medical College, New York, N.Y. 10021

Hypoxic-ischemic insults to the brain usually produce damage to vulnerable areas. Whether such variability reflects regional differences in blood flow or the tissues' metabolic responses remains unclear. We assessed qualitative differences in regional glucose metabolism by the ^{14}C-2-deoxyglucose (2-DOG) technique under conditions of moderate hypoxia in the physiologically-controlled "Levine" rat. Male rats weighing 250-300 gm were paralyzed and ventilated with 70% $N_2$0-30% O_2. The right common carotid artery was ligated and the FiO_2 of the inspired gas lowered to produce an arterial PO_2 of 28-32 mm Hg; arterial blood pressure was maintained above 100 mm Hg. After 10 min of equilibration, 50 uCi of ^{14}C-2-DOG was injected i.v. and the animal decapitated 30 min later. The brains were processed for autoradiography. Because blood flow to both cerebral hemispheres increases (greater contralaterally) in this model (Ginsberg et al. 1976) the insult to brain is one of uncomplicated hypoxia.

Autoradiograms of control rats (normoxic, right carotid ligated) showed no right-left asymmetries and gray matter appeared darker than white matter. Autoradiograms of hypoxic rats revealed alternating light and dark bands of activity in the right cerebral cortex which were not demonstrable in the left cortex. Compared to the left, there was increased activity in the right striatum and hippocampus. Hypoxia induced bilateral increases in 2-DOG metabolism in white matter (corpus callosum, internal cap., anterior commisure) such that they appeared as dark or darker than gray matter.

To determine the relationship of the alternating light and dark cortical columns to the cortical vasculature, hypoxic rats were perfused with black plastic microspheres (15 ±5 u) via the ascending aorta just prior to sacrifice. When the ^{14}C-2-DOG autoradiograms were superimposed upon the brain sections from which they were derived, the microsphere-laden arteries lined up over the light cortical columns; the dark columns were most distant from the arteries. If areas of cerebral cortex between penetrating arteries represent "microwatershed" zones (Welsh et al. 1977), then the cortical columns of higher 2-DOG phosphorylation correspond to regions of lowest tissue oxygen tension.

The hypoxia-induced changes in regional 2-DOG phosphorylation may reflect an increase in energy requirements and/or anerobic glycolysis. If anerobic glycolysis were increased only to meet normal energy demands, one would expect an identical increment rise in 2-DOG phosphorylation in both gray and white matter. The greater degree of 2-DOG phosphorylation noted in white versus gray matter during hypoxia suggests that energy requirements are increased, at least, in white matter structures.

1026 EFFECT OF METAL CHELATES OF L-DOPA ON THE CEREBRAL AND PERIPHERAL METABOLISM IN RATS. K.S. Rajan, R.D. Wiehle*, IIT Res. Inst., Chicago, Ill. 60616, and J.M. Davis, Ill. State Psych. Inst., Chicago, Ill. 60612.

In continuation of our earlier finding regarding the potential application of the metal chelation approach for improved replenishment of the dopaminergic pools of rat brain, studies were undertaken on the metabolic patterns of the tritiated DOPA in the brain and circulating blood after i.v. administration of ^{3}H-L-DOPA and a number of metal-^{3}H-L-DOPA chelates. Among the systems examined, Cu(II)-L-DOPA-ATP chelate was found to be the most satisfactory and consistent one yielding an increase of 130-150% in the overall transport into the brain, a similar increase in the brain catechol amines and a 50% increase in the aromatic aminoacids when compared to the ^{3}H-L-DOPA controls. On the basis of time course studies on L-DOPA, Cu(II)-L-DOPA (1:2), Cu(II)-L-DOPA-ATP (1:1:1), Zn(II)-L-DOPA-ATP (1:1:1) and the combination drug, L-DOPA + RO4-4602, it was found that the Cu(II)-L-DOPA-ATP chelate showed the largest increases in the brain levels of the aromatic aminoacids over long periods of time.

Whereas the brain levels of the aminoacids effected by the combination drug dropped drastically beyond 30 minutes, those of the Cu(II)-chelate remained steady beyond 90 minutes. Detailed results of the metabolic patterns and the time course studies of the different metal-L-DOPA chelates are presented and discussed in terms of the metal chelation approach.

1027 MORPHOLOGICAL LOCALIZATION OF ENHANCED BRAIN ACID PHOSPHATASE RESULTING FROM HYPOCHOLESTEROLEMIC DRUG ADMINISTRATION. R.B. Ramsey and V.W. Fischer. Depts. of Neurology, Anatomy, and Pathology, Saint Louis University, Saint Louis, Missouri 63104.

Previous study has demonstrated that the administration of hypocholesterolemic drugs to developing rats not only affects the lipid metabolism within the central nervous system (CNS) of these animals, but also alters the activity of certain hydrolytic enzymes within the CNS (Ramsey, abs. 6th Int'l Meeting Int'l Soc. Neurochem., Copenhagen, Denmark, 1977, p.42). When two hypocholesterolemic drugs, zuclomiphene (50mg/kg) and AY-9944 (5mg/kg), were used in combination, a pronounced increase in brain acid phosphatase was observed. Neither drug, used individually, was able to elicit a similar response. The response to the drug administration was rapid (within 24 hr), very large (four-fold increase in enzyme activity within 24 hr), and was accompanied by an equally rapid increase in brain total protein. Only minimal numbers of membranous cytoplasmic inclusion bodies were present in the CNS of these animals (Acta Neuropath. 36: 91, 1976), hence, the nature of the cellular and subcellular location of the enhanced acid phosphatase activity was of interest. The CNS of animals 6 days of age (24 hr after treatment) and 20 days of age (treated for 16 days) was examined by electron microscopy for acid phosphatase localization. Ultrathin sections of cerebral and cerebellar tissue of acute and chronically treated rats showed markedly the presence of numerous macrophages within perivascular spaces. These phagocytic cells were conspicuously identifiable by their cytoplasmic vacuolar and electron-dense inclusions, as well as an intense deposition of enzymatic reaction products. Examination of the parenchymal tissue did not reveal the presence of such products to a greater degree than was seen in sections of untreated animals.

Our observations would indicate that when the two drugs, zuclomiphene and AY-9944, are administered together to developing rats, they not only disrupt CNS sterol metabolism, but they also alter the tissue in or around the CNS vessels in such a way that an infiltration of macrophages results. The mechanism by which these drugs bring about this infiltration is yet to be determined.

1028 BRAIN RESISTANCE TO PROTEIN LOSS ON RESTRICTED PROTEIN INTAKE IN WEANLING RATS. Richard R. Rebert, Robert L. Chronister, Herbert E. Longenecker and L. Preston Mercer* Univ. So. Ala., Mobile, AL. 36688

Weanling rats (21 days old) were starved for 24 hours, then put on an ad.lib. standard diet (Purina Rat Chow, 23% protein) for three days. The white male rats were then assigned to one of 12 groups, each group with a different protein level. Six animals were assigned to each group: 0%, 1%, 2.5%, 4%, 6%, 8.5%, 12%, 16% 20%, 24%, 28% and Purina Rat Chow of 23%. Feeding and drinking were ad lib. with each animal in its own cage. Body weights, food and water intake were measured dach day. The diets were isocaloric in that carbohydrate made up any deficiency in caloric intake due to protein deficiency. The protein source was lactalbumin. Twenty-one days after the start of the study the animals were sacrificed. The brains were rapidly removed and prepared according to the procedures outlined for the Falck-Hillarp fluorescent technique. Each brain was sectioned at sacrifice into a frontal one-third, a mid one-third and a hind one-third. Brains from the 0%, 1%, 2.5%, 12%, 24% and 28% were randomly chosen for amino acid analysis. Brain weights did not show any great variation from that of the rats on the 24% or "normal" dietary protein intake. There were variations in free amino acid patterns which could not be statistically validated because of the small number of the sample. The general patterns of brain weights and of free amino acid patterns were within the limits of "normal". Body weights did show a significant change as did the food and water intake of the dietary protein restricted rats. The findings in this study are in accord with the known resistance of the brain to protein loss after the weanling period (e.g. after day 21) when the maturation of the rat brain is more or less completed. The significance of the brain maintenance of weight and general free amino acid patterns compared with that of the body in general under dietary protein limitations is emphasized.

This study was supported by an Intramural Grant (#22610) from the University of South Alabama.

1029 BRAIN ALDEHYDE METABOLISM IN ALCOHOLISM AND IN AFFECTIVE DISORDER. Eli Robins, Evelyn M. Cochran* and Juanita L. Carl.* Dept. of Psychiatry, Sch. of Med., Washington Univ., St. Louis, MO 63110.

The activities of the enzymes responsible for the metabolism of the "biogenic" aldehydes, aldehyde reductase and aldehyde dehydrogenase, have been measured in 12 regions of human brain. These activities were compared in subjects with affective disorder, subjects with alcoholism, and in matched controls. Aldehyde reductase was determined using p-nitrobenzaldehyde as substrate and NADPH as cofactor. Aldehyde dehydrogenase activity was determined using heptaldehyde as substrate and NAD^{+} as cofactor. The activities were determined by measuring the change in fluorescence of the nucleotide. In 11 of the 12 regions, the activity of the aldehyde reductase averaged higher in the alcoholics than in the controls ($p<0.0002$ for the series). These differences reached significance for three individual regions: rostral hippocampus ($p<0.02$), head of caudate ($p<0.05$) and tegmentum of pons ($p<0.05$). The range of activities among controls varied from 52.7 µmol/g/hr for frontal white to 30.5 µmol/g/hr for tegmentum of pons, a 1.7-fold range. For aldehyde dehydrogenase, the activities averaged lower in alcoholics as compared to controls for 10 of the 12 regions ($p<0.02$ for the series). This difference was significant for one individual region, temporal gray ($p<0.01$). The range of activities among controls varied from 5.8 µmol/g/hr for frontal white and for centrum semi-ovale to 16.4 µmol/g/hr for putamen, a 2.8-fold range. These enzymes are involved in the metabolism of the biogenic amines via oxidative (to carboxylic acids) or reductive (to alcohols) pathways. The relatively high levels of aldehyde reductase in white matter suggest that the glial cells play a role in the reductive pathway probably at the expense of the oxidative pathway.

1030 AN AEROBIC AND ANAEROBIC CONTROL OF OXIDO-REDUCTION OF MITOCHONDRIAL NICOTINAMIDE ADENINE DINUCLEOTIDE IN NEURONS OF FROG DORSAL ROOT GANGLION.
Carlos Rodríguez-Estrada. Cátedra de Fisiología, I.M.E. Fac. Med. U.C.V. Caracas, Venezuela.

A preliminary report (Rodríguez-Estrada, Soc. Neuroscience vol III Abs #1032) showed that steady state level of reduced nicotinamide adenine dinucleotide (NADH) was changed in vitro preparations of dorsal root ganglion neurons by rising the carbon dioxide partial pressure. This change was similar to that observed in isolated mitochondrial preparation (J.M. Lowenstein & B.Chance, J.Biol.Chem 243:3940,1968) after rising the hydrogen ion concentration. This work studied the effect of changes of hydrogen ion concentration on the steady state level of NADH, it was expected that the protonated form of NADH~X inhibit less the respiratory enzymes components and in anaerobiosis inhibit less its oxidation in the glycolytic stage. Fluorometric determinations of NADH were performed on in vitro preparations of dorsal root ganglion neurons as previously reported. pH change was measured continuously and it was decreased 0.8 unit with any CO_2 mixture used. CO_2/O_2 (2.5%/97.5%), CO_2/N_2 (2.5%/97.5%), N_2, replaced temporarily the O_2 of the chamber. NADH level showed an inmediate and fast decreased (2-3%) after O_2 was replaced with CO_2/O_2 and the NADH level returned slowly after CO_2/O_2 was replaced with O_2. NADH level showed an inmediate and fast decreased (2-3%) after O_2 was replaced with N_2 and the NADH level showed what has been mentioned before and on a prolonging of N_2 after 2-3 minutes a large increase of NADH level (10-20%) was observed. Now replacing N_2 with CO_2/N_2 the NADH level showed an inmediate and fast decrease (10-20%) followed by a later increased that reached a new level which is smaller than that observed in N_2. If CO_2/N_2 is replaced with CO_2/O_2 an oxidation of NADH was observed. When O_2 replaced CO_2/O_2 the level of NADH increased (2-3%). After 2-3 min of CO_2/N_2 replacing O_2 the NADH level increased, this change was smaller than that observed in N_2. The changes observed with CO_2 mixtures are attributed to changes of H^+ ion concentration and H^+ ion concentration controls the steady state rate of oxidation. This results indicate that mitochondrial NADH intervenes in the respiratory chain as well as in the anaerobic stage of glycolysis.

1031 GENETIC REGULATION BETWEEN NEUROBLASTOMA AND GLIOMA CELLS IN CELL CULTURE AS MEASURED BY THE SYNTHESIS OF SPECIFIC PROTEIN SPECIES.
Roger N. Rosenberg, Carol K. Vance*, Marcelle Morrison*, Nagindra Prashad*, Julianne Meyne*, and Fred Baskin. Dept. Neurology, Univ. Texas, Southwestern Med. Sch., Dallas, Tx. 75235.

Neuroblastoma, glioma and hybrids of neuroblastoma-glioma cell lines were grown in cell culture and protein species were separated and identified in the first dimension initially utilizing isoelectric focusing gels and proteins were separated further in the second dimension by SDS acrylamide gels. Proteins were identified which were dominantly expressed in neuroblastoma and also in hybrid cells and proteins were expressed dominantly in glioma and also hybrid cell cultures. Specific proteins were identified which were significantly expressed in neuroblastoma cells and much reduced in glioma cells, and also conversely so. The hybrid cell line expressed many of the neuroblastoma type proteins and relatively few of the glioma type proteins. Proteins labelled as H, K and E were dominant in neuroblastoma and hybrid cultures and proteins labelled as G, g and gs were dominant to glioma and hybrid cell cultures. A specific protein species (z) was identified in hybrid cells and was not present in either parental neuroblastoma or glioma cultures. Protein z was expressed however by the co-culturing of neuroblastoma and glioma cells strongly suggesting its induction may be dependent on a soluble factor. The z protein is 53,000 dalton and migrates near the tubulin subunits on a two-dimensional gel. Protein z in hybrid cells was demonstrated in both stained gels and by autoradiography. Chromosome analysis of hybrid cells confirmed the presence of both rat and mouse chromosomes. Recently, the protein z species was identified to be present also in homogenates obtained from the Ajax mouse brain. These studies emphasize the point that the determination of an enzyme activity or protein concentration in a homogenate of brain is in actuality the summated expression of both neurons and glia monitoring and regulating the genetic expression of the opposite cell. Biochemical neuronal-glial interaction is in operation in the intact brain as suggested by the finding of the z protein in Ajax mouse brain and may be a central mechanism of differentiation within the mammalian brain.

1032 TURNOVER OF THE FREE GLUCOSE POOL IN BRAIN.
H. E. Savaki*, L. Davidsen*, C. Smith*, and L. Sokoloff. Lab. of Cerebral Metabol., NIMH, Bethesda, MD 20014

The recently developed autoradiographic deoxyglucose method can be used to determine quantitatively the rates of glucose utilization in localized regions of the central nervous system. The operational equation of the method originally derived is limited by the requirement that the plasma glucose concentration remain constant throughout the experimental period. A new operational equation has been derived that is free of this restrictive constraint, but it requires knowledge of the half-life of the free glucose pool in brain. A method has, therefore, been developed to measure the turnover rate constant of the free glucose pool. It is based on a kinetic model of the equilibration of the specific activity of the free glucose pool in the tissue with that of the plasma during an infusion of radioactive glucose. With the assumption of a constant arterial plasma glucose concentration during the short experimental period, the following equation has been derived:

$$(SA)_B(T) = Ke^{-KT}\int_0^T (SA)_P\, e^{+Kt}\, dt$$

where $(SA)_P$ = specific activity of the arterial plasma glucose content; $(SA)_B$ = specific activity of the free glucose pool in brain tissue at the time of killing; T = the time of killing; t = the variable, time; and K = the rate constant of the turnover of the free glucose pool in brain.

During a continuous intravenous infusion of [2-^{14}C]glucose over a measured interval from 2 to 3.5 minutes, timed arterial blood samples are drawn. At the end of the interval the animal is killed by microwave radiation. The protein of the blood and plasma samples and the brain tissue is removed by acid precipitation, and the free glucose in the acid-soluble fractions is isolated by ion-exchange chromatography, checked for purity by TLC chromatography, and assayed for glucose specific activity. The rate constant is computed from the equation after correction for the contribution of the glucose in the blood content of brain. The half-lives of the free glucose pool determined thus far in 6 normal conscious rats and 5 rats lightly anesthetized with thiopental are 1.2 (S.D. = ± 0.2) and 1.9 (S.D. = ± 0.4) minutes, respectively. The difference is significant at the $p < 0.005$ level. These results demonstrate that the free glucose pool of brain turns over with a significant half-life that varies with the functional and metabolic state of the brain.

1033 OCTOPAMINE AND SEROTONIN NERVE ENDINGS IN THE LOBSTER.
Susan F. Schaeffer*, Margaret Livingstone* and Edward A. Kravitz. Dept. Neurobiol., Harvard Med. Sch., Boston, MA 02115.

Octopamine is synthesized and released from nerve cells in the proximal region of the second roots of thoracic ganglia in the lobster. Structures in the same region have now been found to contain, synthesize, store and release serotonin (5-HT). Tryptophan is taken up by the roots by two processes; one a high affinity (K_m = .3 μM) sodium-independent mechanism and the second a low affinity mechanism. Ninety percent of the tryptophan taken up by the high affinity system is immediately converted to 5-HT unless the synthesis of 5-HT is blocked by a decarboxylase inhibitor. In the latter case, the tryptophan is still taken up and partially converted to 5-HTP. A high affinity (K_m = .8 μM) sodium-dependent uptake of 5-HT is also found in the roots. When animals are treated with 5,7 dihydroxytryptamine, the endogenous 5-HT content and the ability to synthesize and store 5-HT are lost. In addition, the high affinity component of tryptophan uptake disappears while octopamine synthesis from tyrosine or tyramine is unaffected. This suggests that separate systems for the synthesis, storage and release of octopamine and 5-HT are found within the same region of the roots.

To determine what structures might contain the amine systems, electron microscopic studies were performed. Groups of cell bodies having the typical appearance of neurosecretory cells surrounded by numerous granule-filled endings were found in the proximal regions of the roots. We have identified four types of endings: Type 1 contains large (200 nm) dense-core granules and clusters of small (50 nm) round, clear vesicles; Type 2 contains large (200 nm) granules with a distinct crystalline substructure and small clear vesicles; Type 3 is filled with large (200 nm) granules with a pale homogeneous matrix; Type 4 contains small pleiomorphic clear vesicles and abundant glycogen granules.

To determine which type of ending is associated with each amine, roots were incubated with either 2μM ^{3}H-tyramine or 0.2 μM ^{3}H-tryptophan under conditions in which nearly all of the radioactive precursor was converted to either octopamine or 5-HT. The tissues were then processed for EM autoradiography. Newly synthesized octopamine was confined to the Type 2 endings whereas newly synthesized 5-HT was found in the Type 4 endings. When tissues were incubated in low concentrations (0.1 μM) of 5-HT, radioactivity was found again in the Type 4 endings. In animals treated with 5,7 dihydroxytryptamine, a selective degeneration of the Type 4 endings was seen. Thus, our studies indicate that octopamine and 5-HT are synthesized in morphologically different types of endings.

1034 ACETYLCHOLINE AND SEROTONIN CONTENT IN BRAIN AREAS OF RATS DURING PERIOD OF BEHAVIORAL DEPRESSION FOLLOWING D,L-5-HYDROXYTRYPTOPHAN ADMINISTRATION. P.A. Shea, J.N. Hingtgen* and M.H. Aprison.
Depts. of Psychiatry and Biochem. and Institute of Psychiatric Research, Indiana U. School of Medicine, Indianapolis, IN 46202.

It has been found that administration of D,L-5-hydroxytryptophan (5-HTP) to pigeons working on a food-reinforced operant schedule produces a period of behavioral depression (response rates less than 50% baseline) that is temporally related to increased levels of total serotonin (5-HT) in the telencephalon and diencephalon plus mesencephalon of the brain (Aprison et al., FED. PROC. 34: 1813, 1975 for review). To study serotonergic changes in smaller areas of the rat brain following 5-HTP, as well as possible cholinergic changes associated with this type of depression, injections of D,L-5-HTP (50 mg/kg s.c.) or saline were given to rats working on a VI 1 schedule (milk reinforcement for lever pressing) to establish the average period of suppressed responding. Subsequently, rats were given 5-HTP 15 min after the start of a VI session and were killed at a time equivalent to 30% of their total period of depression (when the response rate had decreased to 0) or at a period when their responding had returned to normal levels following depression. Other trained rats were given saline and killed at times comparable to the 5-HTP treated rats. The method of killing was the modified near-freezing technique of Shea and Aprison (ANALYT. BIOCHEM. 56: 165, 1973). However, instead of the animals being removed from the lever-pressing apparatus and dipped into liquid nitrogen in a separate cage, a new device permitted the entire behavioral chamber to be submerged at any time during the VI session. The following brain areas were dissected at -10°C and were assayed for 5-HT and acetylcholine (ACh) content (Smith et al., ANALYT. BIOCHEM. 64: 149, 1975): hippocampus, striatum (ST), telencephalon minus hippocampus and striatum (TEL), diencephalon, mesencephalon and pons plus medulla oblongata (P+M). Levels of 5-HT were significantly elevated (25% to 84% over controls) in all brain areas except P+M during behavioral depression with levels in the TEL returning to normal by the time response rates had returned to within the normal range. ACh was significantly elevated during depression in the ST (+34%) and P+M (+16%). As in the pigeon studies, 5-HT changes in at least one brain area of the rat appear to be correlated with the behavioral depression following 5-HTP. The observed changes in ACh content during 5-HTP induced depression reported in this study are supportive of the concept of cholinergic involvement (Hingtgen et al., SCIENCE 193: 332, 1976) in certain types of behavioral suppression. (Supported in part by research grant MH-03225-18 from NIMH).

1035 DIFFERENCES IN TURNOVER OF THE BIOGENIC AMINE AND AMINO ACID PUTATIVE NEUROTRANSMITTERS CONCURRENTLY MEASURED IN THE CEREBRAL CORTEX AND STRIATUM OF RAT BRAIN. J. E. Smith, C. Co*, T. R. Mote* and J. D. Lane. Dept. of Psychiat, Louisiana State Univ. Med. Ctr., Shreveport, LA 71130.

The turnover rates of the putative neurotransmitters in various brain regions may be a better measure of the activity of these neuronal systems than are measures of content alone. The turnover of acetylcholine (ACh), dopamine (DA), norepinephrine (NE), serotonin (5-HT), aspartate (Asp), glutamate (Glu), gamma-aminobutyric acid (GABA) and glycine (Gly) were concurrently measured in the cerebral cortex and striatum after injections of radioactive precursors. Ten rats were injected with 0.5 mCi ^{3}H-tryptophan, 1.0 mCi ^{3}H-tyrosine, 0.5 mCi ^{3}H-Choline and 0.2 mCi ^{14}C-glucose through chronic jugular catheters. Five rats were sacrificed by near freezing in liquid nitrogen at 60 min after the administration of ^{3}H-tryptophan, ^{3}H-tyrosine and ^{14}C-glucose and 4 min after ^{3}H-Choline. Five rats were sacrificed at 90 min after the administration of ^{3}H-tryptophan, ^{3}H-tyrosine and ^{14}C-glucose and 7 min after ^{3}H-Choline. The brains were removed and dissected at -18°C into the cerebral cortex (CC) and striatum (Str). The tissue samples were individually pulverized in liquid nitrogen and the biogenic amines (ACh, DA, NE and 5-HT) extracted from one portion of the tissue powder into 1N formic acid-acetone (v/v-15:85) (FA/A). DA, NE and 5-HT were separated from a portion of this FA/A extract using a cation exchange resin, assayed fluorometrically for content and then isolated and assayed for radioactivity with alumina columns and TLC using a previously described procedure (Lane et al, Life Sci 21, 1101, 1977). Acetylcholine was assayed for content and radioactivity by a radioenzymatic method and paper electrophoresis using a previously described procedure (Shea and Aprison, Anal. Biochem. 56, 165, 1973) from another portion of the FA/A extract. The amino acid putative neurotransmitters were extracted into 5% TCA from a 10 mg portion of the powdered tissue samples and their respective dinitrophenyl derivatives separated by two dimensional TLC (Brenner et al, Exper. 17, 145, 1961) and assayed for content and radioactivity. DA turnover in the Str (197.0 pmoles/mg protein-hr) was ten times that seen in the CC (18.9 pmoles/mg protein-hr) while 5-HT turnover was four times higher in the CC than in the Str (28.9 and 8.9 pmoles/mg protein-hr respectively). Asp and Glu turnover in the CC was twice that in the Str (Asp 40.8 and 23.8 pmoles/mg protein-hr; Glu 159.4 and 87.6 pmoles/mg protein-hr). Gly turnover in the Str (24.5 pmoles/mg protein-hr) was three times that in the CC (9.6 pmoles/mg protein-hr). NE turnover in the Str appears to have a completely different time course than the other neurotransmitters investigated. (This project was supported in part by USPHS Grant DA-01999-02.)

1036 MEMBRANE FLUIDITY AND SYNAPTOSOMAL ATPASES. Albert Y. Sun.
Sinclair Comparative Medicine Research Farm and Department of Biochemistry, University of Missouri, Columbia, MO 65201

Several experimental data have indicated the dependency of synaptosomal ($Na^{+}+K^{+}$)-ATPase and Ca^{++}-ATPase on the integrity of membrane structure. Low concentrations of detergents and phospholipases treatment interfered with the activities of both enzymes. However, the biphasic response to various concentrations of ethanol was observed only with ($Na^{+}+K^{+}$)-ATPase. At low concentrations (0.1-0.5%) ethanol enhanced ($Na^{+}+K^{+}$)-ATPase, probably as a result of an increase in membrane fluidity. At higher levels of ethanol (1-4%), both ($Na^{+}+K^{+}$)-ATPase and Ca^{++}-ATPase activities were inhibited, probably due to a disturbance of the membrane structure through hydrophobic alcohol-membrane interaction. A sharp decrease in the energy of activation was also observed with the ($Na^{+}+K^{+}$)-ATPase when membrane lipids changed from liquid crystalline state to a more fluid state at transition temperature. It is concluded that ($Na^{+}+K^{+}$)-ATPase may be more sensitive to the microenvironmental changes than Ca^{++}-ATPase. (Supported in part by USPH Grant #AA02054).

1037 INACTIVATION OF BRAIN GLUTAMATE DECARBOXYLASE BY ALKALINE PHOSPHATASE. P.Y. Sze, B.J. Hedrick* and R. Alderson*. Dept. of Biobehavioral Sci., Univ of Connecticut, Storrs, CT 06268

Alkaline phosphatase (AP) is known to dephosphorylate a variety of phosphoproteins as well as low molecular weight phosphate esters. In this study, the effect of the phosphatase on brain L-glutamate decarobxylase (GAD) was examined. GAD was prepared mainly as ammonium sulfate precipitate (30-70% cut) from 100,000g supernatant of mouse brain homogenate. The GAD preparation was incubated in the presence of purified calf intestine AP at 37°C in 50 mM Tris acetate, pH 7.4. The AP was then removed by DEAE-cellulose chromatography, and the activity of GAD was measured radiometrically from 1-^{14}C-L-glutamate. Alternatively, GAD activity was determined directly in the incubation mixture after the AP activity was completely inhibited by 0.2 M phosphate.

Incubation with AP is found to produce a rapid loss of GAD activity. The inactivation follows second order kinetics, with a half-life estimated as 30 min. at the concentration of AP used (80 ug/ml). The ability of AP to inactivate GAD, like its ability to dephosphorylate p-nitrophenyl phosphate, is dependent on zinc and inhibited by inorganic phosphate, EDTA, or arsenate. From Lineweaver-Burk plots, the inactivation of GAD leads to a decrease in V_{max}, with no change in the apparent K_m either for glutamate or for PLP. There is no difference toward AP inactivation between GAD preparations from cell cytosol and synaptosomes, or from various brain regions.

Two possibilities are considered for the action of AP on GAD. First, AP may act on the enzyme-bound cofactor PLP. This possibility, however, does not seem to be compatible with the following data: (1) The inactivated GAD cannot be reversed to activity by PLP; and (2) the inactivation by AP cannot be prevented by the addition of PLP at high concentrations. The other possibility is that AP may act by hydrolyzing protein-bound phosphate, leading to inactivity of GAD. Both possibilities are being tested.

(Supported in part by MH-29237)

1038 MYOSIN ISOLATED FROM BOVINE BRAIN. Michael Toma*, C. Mahendran* and Soll Berl. Dept. Neurology, Mount Sinai School of Medicine, New York, New York 10029.

Kinetic studies have been initiated on myosin isolated from bovine brain. The protein was prepared in the following sequence (modified after Pollard, T.D., et al., Anal. Biochem., 60:258, 1974.):one hour extraction at high ionic strength in 0.6M KCl, 1.6mM $MgCl_2$ and 10mM PPi, precipitation by dialysis to low ionic strength (0.03M KCl), 25-55% ammonium sulfate fractionation, and column chromatography on Biogel A-15M, 200-400 mesh. Fractions having K^+-EDTA ATPase activity were pooled and subjected to low ionic precipitation in the presence of 10mM $MgCl_2$. When treated with sodium dodecyl sulfate (SDS) and 8M urea, this protein reveals a similar electrophoretic pattern to skeletal muscle myosin on SDS polyacrylamide gels. Dialysis at low ionic strength results in the formation of bipolar filaments observed on carbon coated grids stained with uranyl acetate in the electron microscope. These filaments coalesce in a head to head fashion to form periodic arrays. At pH 7.0 and 0.6M KCl, in the presence of Ca^{2+}, the specific activity is 0.406 - 0.600 μmoles inorganic phosphorous mg^{-1} min^{-1}, and in the presence of 2mM EDTA, 0.836 - 1.100 μmoles inorganic phosphorous mg^{-1} min^{-1}. The K^+-EDTA activity of this enzyme reveals typical Michaelis-Mentin kinetics for substrate saturation, and a Km of 10^{-4}M as determined by the Lineweaver-Burke and Eadie-Hofstee plots. The data will be compared with that of rabbit skeletal muscle myosin. Supported in part by NIH Grant NS 11824, The Clinicial Center for Research in Parkinson's and Allied Diseases, NINCDS Grant NS 11631.

1039 NERVOUS SYSTEM CARBONIC ANHYDRASE. Michael C. Trachtenberg and Victor S. Sapirstein*. Neurol. Svc., VA Hosp., Neurol. Dept., BU Sch. Med., Boston, MA 02130 and Dept. Biochem., E.K. Shriver Ctr., Waltham, MA 02154, Dept. Biol. Chem., Harvard Med. Sch., Boston, MA 02115

The activity of carbonic anhydrase (CA) was examined in a wide variety of well defined structures in both the CNS and PNS of the rat. The activity of CA in white matter from forebrain regions (e.g. subcortical white matter, optic nerve) is uniformly higher than that in cortical gray matter (e.g. occipital and parietal corticies). However, retinal-choroid preparations have the highest activity of the structures examined. The difference in activity between gray and white is evident in both the membrane bound and soluble fractions, with membrane bound activity accounting for approximately 60% of the total. By way of a competitive binding procedure utilizing ^{3}H-acetazolamide, it was found that the differences observed in the activity reflects differences in the moles of enzyme present and not differences in the state of activation. The activity in predominantly white matter regions (spinal cord, myelencephalon, pons, mesencephalic tectum and subcortical white) is characterized by a neuraxial progression with activity increasing rostrally. Preliminary evidence suggests that these differences in activity reflect differences in enzyme levels as determined by displacement of ^{3}H-acetazolamide. In gray matter regions from metencephalon to telenecphalon relatively little variation in enzyme activity is seen suggesting that the CA content of glia in gray matter (astrocytes) is constant throughout these areas of the CNS. However, oligodendroglia and astrocytes from white matter differ in their expression of CA along the neuraxis with greater activity in the later developing structures. Our previous report (Neurosci. Abst. 3:1034, 1977) of marked differences in CA in purified myelin derived from spinal cord, lower and upper brain stem suggests that the neuraxial distribution is attributable to variation in the oligodendroglial enzyme. The CA activity in PNS is uniformly low with comparable activity in sciatic nerve, spinal roots, superior cervical and trigeminal ganglia. The values obtained are equal to or lower tan those for spinal cord, lowest of all CNS regions.

1040 EFFECTS OF SODIUM OCTANOATE ON BLOOD-BRAIN BARRIER TRANSPORT. Doris A. Trauner. Dept. of Neurosciences, Sch. Med., UCSD, San Diego, CA 92103.

Short chain fatty acids (SCFA) produce coma, hyperventilation, and seizures in experimental animals within 5-10 minutes after a single intraperitoneal injection. The rapidity of action suggests a direct effect of SCFA on the nervous system, and leads to speculation about changes in blood-brain barrier transport as a potential mechanism. In the present pilot study, effects of the SCFA sodium octanoate on two aspects of blood-brain barrier transport, passive diffusion and active transport, were examined using a double tracer technique.

Experimental rats were given intraperitoneal injections of 1 molar sodium octanoate, pH 7.4, 1 mM/100 gm body weight, at 30, 60, 90, 120, and 240 minutes before sacrifice. Control rats received either normal saline or no injection. Animals were anesthetized with ether and the carotid artery isolated. In the first group, ^{14}C-tryptamine, which crosses the blood-brain barrier by passive diffusion, was injected into the carotid artery simultaneously with ^{3}H-water, which is freely diffusable into brain. The animals received a total volume of 0.2 ml solution. They were then decapitated in 5 seconds, the brains quickly removed, and sections prepared for scintillation counting. The ratio of ^{14}C to ^{3}H in brain compared with the ratio of these isotopes in the original injection mixture provides an index of brain uptake (BUI) of test substance (1). A second test group was given ^{14}C-tyrosine and ^{3}H-water using the same procedure described above. Tyrosine crosses the blood-brain barrier by an active transport mechanism.

The BUI of control animals was 16.1% in the tryptamine/water study. 30 minutes after octanoate injection, the BUI rose to 27.7%, $P<.05$. The peak increase occurred at 1 hour (36%, $P<.01$) and was still elevated at 4 hours after injection (34%, $P<.05$). Similar increases in BUI occurred with tyrosine. A BUI of 43.6% was found in controls, while in experimental animals the BUI rose to 57.7% in 60 minutes and to 56.7% by 2 hours.

These preliminary studies suggest that both passive diffusion and active transport mechanisms which normally protect the blood-brain barrier may be altered in the presence of octanoate. Such alterations in transport would provide one explanation for the rapidity with which coma and electroencephalographic changes occur after injection of sodium octanoate into experimental animals.

1041 EFFECTS OF CATECHOLAMINE METABOLITES AND THEIR OXIDATIVE PRODUCTS ON THE UPTAKE OF ^{3}H-NOREPINEHRINE BY A CRUDE SYNAPTOSOMAL FRACTION OF RAT BRAIN. Anthony D. Vanker and Frank L. O'Brien*. Depts. of Biology and Chemistry, Georgia State University, Atlanta, Georgia 30303.

There is evidence that at least some of the effects of 6-hydroxydopamine (6-OHDA) are due to its oxidation to the corresponding quinone which is thought to subsequently undergo nucleophilic reactions (Sachs, C. & Jonsson, G. (1975). Biochem. Pharmacol. 24, 1). The inhibitory effects of 6-OHDA on norepinephrine (NE) uptake into presynaptic elements is well known. Similar quinones could be formed from normal catecholamine metabolites (CAMT). It is, therefore of considerable interest to investigate the effects of CAMT and their oxidative products on the uptake of NE. Controlled potential coulometry was chosen as a means of oxidizing selected CAMT because: 1) there was no contamination by oxidizing reagents 2) there was exact control of potential 3) the corresponding quinone can be formed in the presence of synaptosomes without greatly affecting the synaptosomes. The forebrains of adult female Sprague-Dawley rats were used to isolate a crude synaptosomal fraction which was then resuspended in 0.32 M sucrose. A portion of this suspension was mixed with a physiological salt solution containing 25 mM TES (N-tris [hydroxymethyl]-methyl-2-aminoethane sulfonic acid) at pH 7.4 (NEP). Different portions were then used in each of the following experiments: 1) NEP + stirring 2) NEP + stirring + CAMT 3) NEP + stirring + CAMT + electrolysis. The time interval for each experiment was 10 min. Immediately following each experiment, standard procedures were employed to measure the uptake of ^{3}H-NE into the synaptosomes found in NEP. The effects of the oxidation products of CAMT varied from essentially complete inhibition at 10^{-4} M to almost no inhibition at 10^{-6} M. The corresponding CAMT exhibited considerably less inhibition at most concentrations. At the higher concentrations studied, the electrochemical data indicate substantial secondary oxidation reactions occur in the presence of synaptosomes.

1042 A SENSITIVE METHOD FOR THE SEPARATION AND MEASUREMENT OF S-ADENOSYLMETHIONINE AND S-ADENOSYLHOMOCYSTEINE IN MAMMALIAN TISSUE.

Dona L. Wong*, Alfred W. Sandrock, Jr.* and Roland D. Ciaranello.
Dept. Psych., Stanford Med. Ctr., Stanford, CA 94305.

Relative levels of S-adenosylmethionine (SAM) and S-adenosylhomocysteine (SAH) may provide local modulation and regulation of the methyltransferases, t-RNA methyltransferases, protein methyltransferases, and catecholamine methyltransferases. We have been studying the regulation of the catecholamine methyltransferases and have recently found that an endogenous stabilizing factor exists which protects adrenal medullary phenylethanolamine-N-methyltransferase (PNMT) from thermal and tryptic degradation. This stabilizing factor is a small molecule which is dialyzable and has an absorption maximum of 265 nm. Preliminary evidence suggests that this factor may be S-adenosylmethionine. Moreover, while SAM does protect PNMT, SAH does not render protection against thermal and proteolytic denaturation. Our current thinking is that the interconversion of SAM to SAH may modulate PNMT levels *in vivo* by increasing the susceptibility of the enzyme to proteolysis.

Since the endogenous levels of SAM and SAH may be critical to the understanding of PNMT regulation, a sensitive assay system must be developed which allows for the physical separation of SAM and SAH and their subsequent quantitation. Separation of these two compounds is critical, since SAH is an extremely potent inhibitor of SAM-dependent methyltransferases. We have devised an appropriate separation system combined with a sensitive enzymatic assay and have used it to measure tissue levels of SAM. SAM and SAH are separated on an ion-exchange column (DOWEX 1 X 8). SAM is not bound to this column, while SAH is retained and can be eluted with NaCl. The levels of SAM are estimated by reaction with purified hydroxyindole-O-methyltransferase and N-acetylserotonin, modified from a procedure described by Baldessarini and Kopin. This isotope-dilution assay is linear from 0-1.96 nmoles SAM. Tissue levels of SAH are measured by direct inhibition of HIOMT. This assay is linear from 0-0.12 nmoles SAH. Recoveries of both SAM and SAH average 70-75%, with only 1-2% contamination of SAM by SAH.

NEUROCYTOLOGY

1043 DOES APOCRINE SECRETION OCCUR IN THE CHOROID PLEXUS? W.F.Agnew, T.G.H. Yuen*, Cheng, J.T.* and R.B.Alvarez*. Neurological Research Laboratory, Huntington Institute of Applied Medical Research, Pasadena, California, 91105.

Apical blebbing of the choroid plexus has been observed in 8 species in a comparative ultrastructural study which included amphibian, reptilian and mammalian forms. A secretory function for the apical protrusions was suggested by ultrastructurally observed stages including attached and free-floating profiles which underwent swelling and eventual rupture in the CSF space. Membrane dynamics studies using ruthenium red and alcian blue markers, the observation of bleb formation in tissue culture preparations of choroidal epithelium and the stimulation of bleb formation by paracentesis speak against the artefactual origin of these protuberances.

Protein synthesis studies utilizing intravenously administered C^{14}-phenylalanine demonstrated that incorporation of this amino acid in the choroid plexus exceeded that observed in either liver or brain parenchyma. Light and electron microscope autoradiographs following H^3-leucine and H^3-phenylalanine administration have demonstrated preferential intracellular labelling in choroidal epithelium as well as blebs, both in vivo and in tissue culture preparations. These findings, together with previous reports, suggest that the apical blebbing phenomenon represents a physiologically significant source of CSF proteins.

1044 INTRAVENTRICULARLY ADMINISTERED PUROMYCIN: AN APPLICATION OF THE SWITZER-GOLGI TECHNIQUE TO THE STUDY OF NEUROSECRETORY AND OTHER NEURONS. William E. Armstrong, Steven Warach* and Glenn I. Hatton. Depts. Psychol. and Zool. and Neurosci. Program, Michigan State Univ., E. Lansing, MI 48824.

Switzer's (Neurosci. Lett. 2:301, 1976) technique of puromycin induced argyrophilia was investigated as a means of staining hypothalamic neurosecretory neurons, long noted for their resistance to impregnation with Golgi methods. Injections of 5µl puromycin dihydrochloride (0.1M) into the right lateral ventricle of rats were followed by survival times of 6-48 hours, after which the brains were fixed and sections stained with a modification of De Olmos' (Brain Res. 33:523, 1971) cupric silver technique for degenerating neurons. Optimal impregnation of neurons in several hypothalamic nuclei was observed at 12-18 hr survival. Included were the following neurosecretory nuclei: paraventricular nucleus (PVN), anterior commissural nucleus (ACN), and nucleus circularis (NC). The locations of cells in these nuclei corresponded with those of HRP-labelled neurons in other rats following injections into the neurohypophysis. Thus, they are probably neurosecretory. There is little doubt that our argyrophilic neurons in ACN and NC are neurosecretory, but we are less certain about those in PVN since many unlabelled cells are present there in the HRP material. The results show that, contrary to previous investigations, the neurons across these nuclei are of a heterogeneous morphology. For example, some cells of NC appear monopolar while several of those in PVN and ACN are multipolar with many processes oriented perpendicular to and encroaching upon the third ventricle. A variety of cell types exhibiting a great range in size and number of processes were found in PVN.

Additionally, extensive staining was observed in thalamus, hippocampus, caudate, cerebral cortex, septum, and non-neurosecretory hypothalamic areas, making this approach valuable for impregnating neurons of various types and locations. However, the staining observed in thalamus and hypothalamus is selective, as some areas (e.g., anterior hypothalamus, ventromedial hypothalamic nucleus) stain while others (e.g., suprachiasmatic nucleus, arcuate nucleus) do not. Whether this selectivity is a result of selective availability of puromycin or of its particular interaction with certain neurons has not been determined.

Supported by research grant no. NS09140 from NINCDS.

1045 DIGITIZER ASSISTED QUANTITATIVE STUDY OF BOUTONS CONTACTING NEURONS IN THE SACRAL PARASYMPATHETIC NUCLEUS. H. Keith Brown and Michael F. Nolan. Dept. Anat., Col. of Med., Univ. of So. Fla., Tampa, Fl., 33612.

Methods for quantitative determination of synaptic connections are essential for studies of synaptic reorganization and plasticity. Such methods are already contributing much to the understanding of synaptic population dynamics on spinal motoneurons (Bernstein and Bernstein, J. Neurocytol. 6:85-102 and Conradi and Ronnevi, J. Neurocytol. 6:195-210). The purpose of this study is to describe the frequency of occurance and postsynaptic coverage of each type of bouton found in the spinal nucleus responsible for urinary bladder function.

Adult male and female cats were anesthetized with pentobarbital and perfused through the heart with aldehydes for fixation. Sacral spinal segments were removed and processed for electron-microscopy. The sacral parasympathetic nucleus (SPN) was identified and a total of 455 micrographs (7,100X) were made of the neuropil. The cursor of an Hewlett-Packard 9864A digitzer was used to measure the diameter and perimeter of each dendrite or soma and the length of postsynaptic membrane covered by each bouton profile. These data as well as the number and type of each bouton present were recorded by the interfaced Hewlett-Packard 9815A calculator. This information was subsequently tabulated and provided the following observations.

Boutons which contain clear spherical vesicles (S boutons) occur at the same frequency on somata, large dendrites (>1 µm dia.) and small dendrites (<1 µm dia.). These S boutons average 19 per 100 µm of postsynaptic membrane (19 btn/100 µm). Bouton profiles which contain spherical vesicles and three or more dense core vesicles (GS boutons) are present on somata (3 btn/100 µm) but show a higher frequency on large dendrites (8 btn/100 µm) and small dendrites (10 btn/100 µm). Boutons with flattened vesicles (F boutons) are more numerous on large dendrites (3.19 btn/100 µm) than on the somata (0.9 btn/100 µm). Boutons cover 18% of the surface of somata and 30% of the surface of dendrites. These results demonstrate specific population differences on postsynaptic structures in the SPN and show that GS boutons are primarily applied to small dendrites while most F boutons are associated with large dendrites.

1046 APPARENT PRESYNAPTIC ELEMENTS FORMED ON POLY-BASIC COATED BEADS. Richard W. Burry and John G. Wood, Department of Anatomy, University of Tennessee Center for the Health Sciences, Memphis, Tenn.

In the developing CNS, neuronal processes grow to target neurons and form synaptic contacts. The precise mechanisms that guide these processes and allow selection of proper target neurons are not known. Surface groups of neuronal processes must contain at least some of the information required for establishment of synaptic contacts. We have investigated the effect of modifying surface charges of developing neurons. During synaptogenesis, compounds with different charges were added to cell cultures of the CNS.

Dispersed cell cultures of 2 day old rat cerebellums were prepared as described by Lasher (Brain Res., 69 (1974) 235). In order to stabilize the compounds added to the living cultures, proteins of different charge were coated on to cyanogen bromide activated sepharose 4B beads. The coated beads were then added to cultures at 7 days in vitro, when synaptogenesis had already begun. The cultures were followed using phase optics or fixed for electron microscopy. Beads coated with poly-basic proteins (histone or poly-lysine) attached to the cultures while beads coated with neutral proteins (BSA) or poly-acidic proteins (polyglutamate) did not attach. Beads coated with Con A also attached to the cultures apparently via a sugar binding mechanism and not by the electrostatic mechanism of the poly-basic compounds.

Within 24 hrs., both neuronal and non-neuronal cells had grown up onto the attached beads. Electron microscopic observations showed swellings of neuronal processes which were closely applied to the poly-basic protein coated beads. These swellings contained aggregates of vesicles the size of synaptic vesicles (20 nm) close to the attachment site with the bead. The morphology of this swelling resembled that of a presynaptic element but in place of the postsynaptic element was the protein coated bead. These swellings were called apparent presynaptic elements.

The apparent presynaptic elements were found only as parts of neuronal processes attached to the poly-basic protein coated beads and were not seen with neuronal cell bodies or glial cells attached to the beads. In addition Con A coated beads had many neuronal processes running over them, but no apparent presynaptic elements were seen adjacent to the Con A coated bead.

These results suggest that charged groups on the surface of neuronal membranes carry some of the required information necessary to establish synaptic contacts.

1047 NUCLEAR INVAGINATIONS IN DEVELOPING HAMSTER NEURONS. MB. Tank Buschmann and A. LaVelle. Dept. Anat. & Gen. Nursing, Coll. Med. & Coll. Nursing, Univ. Ill. Med. Ctr., Chicago, IL 60612.

Deep nuclear invaginations have been frequently observed in rapidly growing and in adult neurons undergoing the retrograde reaction. For example, in large motor neurons, as of cranial and spinal nerves, nuclear invaginations appear during the intense, early phase of perikaryal growth when the nucleolar apparatus is also increasing in size; with leveling off of this growth activity, in maturity, the invaginations disappear or are greatly diminished (LaVelle & LaVelle; Tennyson, Dev. Neurobiol., Himwich, ed., 1970). In the retrograde reaction membrane "folding" or invagination has been particularly noted during the peak of chromatolysis (Lieberman, Int. Rev. Neurobiol. 14: 49, 1971). On the basis of such observations, it has been indicated that the invaginations may function in nuclear-cytoplasmic exchange (Hydén, Acta Physiol. Scand., 6: 1, 1943) and their increase may be related to enhanced neuronal metabolism (Lieberman, Int. Rev. Neurobiol. 14: 49, 1971).

In the case of the hamster, in pyramidal cells of layer V, the period of very rapid perikaryal growth is from newborn to 10 days of age by which time adult nuclear and perikaryal volumes are reached. At about 5 days, nuclear invaginations became apparent and their depth and frequency increased progressively with age in the pyramidal cells. However, instead of gradually diminishing following cessation of this rapid perikaryal growth as observed in certain other neuronal types, the depth and frequency of the invaginations continued to increase and persisted at all ages up to 18 months. Illustrations of this sequence of nuclear invaginations of pyramidal cells in layer V of hamster motor cortex will be presented.

It would appear that in these hamster pyramidal cells the persistence of invaginations with age through maturity may indicate a continuation of high metabolic activity which was established during the early growth period. This speculation has yet to be confirmed by more direct metabolic studies.

1048 DEVELOPMENT OF SUPRAEPENDYMAL NEURONS ASSOCIATED WITH THE MEDIAN EMINENCE OF THE HAMSTER. J.P. Card*[1] and J.A. Mitchell, Dept. of Anatomy, Wayne State University School of Medicine, Detroit, Michigan.

In a previous study (Card and Mitchell, Anat. Rec. 187: 544, '77) of the infundibular recess of the adult hamster a well organized cluster of intraventricular nerve cells and processes was consistently found associated with the nonciliated ependyma of the median eminence. The following study was undertaken to examine the developmental features of this cluster during the perinatal period. Brains were collected and fixed with Karnovsky's aldehyde fixative on days 11-15 of gestation and on days 1,2,5,8 and 10 post partum. The floor and walls of the third ventricle in the region of the infundibular recess (IR) were exposed by microdissection and subjected to routine processing for scanning electron microscopic (SEM) examination. Selected specimens at each stage of development were subsequently processed for correlative transmission electron microscopic (TEM) examination. SEM examination of the ventricular surface at 11 days of gestation revealed that the majority of the ependymal lining was undifferentiated, exhibiting only occasional cilia and microvilli. However, in a localized area overlying the anlage of the IR, accentuated convexities clearly demarcated individual cell borders. Correlative TEM confirmed the undifferentiated nature of ependyma and neuropil at this stage of development and demonstrated that the convexities seen in the area of the IR were apical surfaces of individual cells. No intraventricular nerves or processes were present in 11 day specimens. On ensuing days, the ependymal lining was characterized by a progressive differentiation, and supraependymal neuronal elements were encountered with increasing frequency. Independent supraependymal cells and processes were first visible on day 12 of gestation, and a well organized neuronal cluster such as that consistently observed in the adult was observed as early as day 13 of gestation and was always present by parturition (day 16) and thereafter. The ultrastructural characteristics of such clusters closely resembled those seen in the adult. Specifically, each mass consisted of a group of nerve cell perikaria situated peripherally with respect to a central core of nerve cell processes. Studies are in progress to determine the origin of these clusters. [1]C. DeVlieg Fellow.

1049 LARGE FLUCTUATIONS OF MEMBRANE POOLS IN ROD AND CONE TERMINALS OF CHICK RETINA. A THIN SECTION ANALYSIS. Nigel G.F. Cooper* and Barbara J. McLaughlin. (SPON: R. R. Mize). Department of Anatomy, University of Tennessee Center for the Health Sciences, Memphis, Tennessee 38163

Long term light or dark adaptation of chick photoreceptors causes wide fluctuations in certain membrane pools, (not evident in short term in vitro experiments) which may affect the overall performance of the synaptic terminals, and that are suggestive of a finite lifespan for localised membrane recycling before complete renewal is necessary. 1-2 wk old White Leghorn chicks were dark or light adapted for 1-4 days, the retinas of which were fixed by perfusion and processed for E.M. In the larger cone terminals (first row - double cones) after 48 hours dark adaptation, there is an increase in the numbers of coated vesicles observed, especially along the plasmalemma and also throughout the cytoplasm, but there appears to be an overall reduction in the total number of vesicles per unit area of terminal. This is particularly noticeable in smaller cone terminals (second row - straight cones) where there are few vesicles of any type and where synaptic ribbons can be seen without their usual full complement of synaptic vesicles. In long term light adapted cone terminals there is a significant increase in the amount of internalised plasmalemma that folds around on itself and encloses portions of terminal cytoplasm containing vesicles. Loosely packed membrane whorls form, from which vesicles are gradually excluded. Even after the longest experimental periods of light adaptation significant numbers of synaptic vesicles remain in all terminals examined. There is not such a large population of coated vesicles as seen in the dark adapted state, although some are still evident. In dark-adapted rod terminals there are several complex changes, one of the most noticeable being an increase in the number of densely stained multivesicular bodies. In long term, light-adapted rod terminals there is an increase in the number of large vesicles and dense cores are discernable, especially in these larger vesicles.

In conclusion, there appears to be a loss of synaptic vesicle membrane from cone terminals in long-term dark adaptation when membrane recycling is probably maximal. Coated vesicle re-uptake appears not to lag behind synaptic vesicle release in this condition. There is a maximal internalisation of plasmalemma in cone terminals during long term light adaptation, when coated vesicle re-uptake may be minimal or lag behind synaptic vesicle release. These observations suggest that there may be a diurnal pattern of membrane fluctuations impressed upon terminals which we are currently investigating. 1050 ADAPTATION OF THE DEOXYGLUCOSE METHOD FOR USE AT CELLULAR LEVEL. Michel H. Des Rosiers* and Laurent Descarries, Centre de recherche en sciences neurologiques, Université de Montréal, Montréal, Québec, Canada H3C 3T8.

To make the deoxyglucose (DG) method (Sokoloff et al., 1977) applicable at cellular and possibly subcellular levels, a histological procedure compatible with high resolution radioautography after administration of [^{3}H]DG was developed. In adult rats, vascular perfusion of all products required for primary fixation, post-fixation, dehydration and resin embedding of CNS tissue was carried out through the aortic arch, 30-45 min after an i.v. injection of 1-[^{3}H]-2-deoxy-D-glucose. 600 ml of 3.5% glutaraldehyde in 0.05 M phosphate buffer (3-4 min), 500 ml of 1% OsO_4 in 0.15 M phosphate buffer (3-4 min), 3-4 l of absolute acetone (45-60 min) and 3 x 200 ml of acetone-Epon mixtures at increasing concentrations of resin (20-30 min) were perfused in sequence. The whole brain and upper spinal cord were then dissected out, immersed in pure Epon (3-4 hr) and polymerized in toto. One-µm-thick sections were prepared for radioautography according to standard dipping techniques. To evaluate the global retention of [^{3}H]DG and/or its metabolite [^{3}H]DG-6-phosphate, measurements of radioactivity were obtained from several rats in which tissue proteins had been previously labeled with [^{14}C] leucine. Comparable [^{3}H]/[^{14}C] ratios were found in homologous brain regions removed before and after the entire histological processing by perfusion, indicating minimal loss of [^{3}H] radioactivity. In light microscope radioautographs of the cervical cord, the tracer was found to be more concentrated in grey than white matter, and more so in anterior than in posterior horn. The ratios of concentrations between these various areas were nearly identical when determined by grain counts in the Epon embedded sections and by optical densitometry in film radioautographs of fresh frozen samples. Moreover, within given nuclei or tracts, adjacent cellular elements such as neuronal cell bodies, glial cells and myelinated axons exhibited differential labeling. These results strongly suggest that the tracer was retained in situ, which should allow visualization of cellular if not subcellular sites of energy consumption in CNS tissue adequately preserved for light and electron microscopy. Since DG and DG-6-phosphate are water soluble and rapidly lost from brain slices immersed in fixative solutions or acetone, even after primary fixation by perfusion with glutaraldehyde, their retention in situ during the course of histological processing by vascular perfusion might be related to the preservation of unbroken cell membranes in morphologically intact tissue. This histological approach could also be useful for high resolution radioautography of other diffusible compounds. (Supported by the Conseil de recherche en santé du Québec and Medical Research Council of Canada).

1051 IMMUNOPEROXIDASE LOCALIZATION OF MYXICOLA NEUROFILAMENTS (10 nm) AT THE LIGHT AND ELECTRON MICROSCOPIC LEVELS. L. F. Eng, R. J. Lasek, J. W. Bigbee* and D. L. Eng *Dept. Path., VA Hosp. and Stanford U. Sch. Med., Stanford, CA 94305, and the Neurobiology Center and Dept. Anat., Case Western Reserve U., Cleveland,O 44106

Antibodies prepared in rabbits against Myxicola neurofilaments (Lasek and Wu, Neurosci. Abst., 2: 40, 1976) have been employed to stain immunohistochemically neurofilaments in intact Myxicola nervous tissue. The marine polycheate was fixed in 5% buffered paraformaldehyde for 4-5 hours. Paraffin-embedded and frozen sections (5-6 μ) were examined at the light microscopic level with Sternberger's peroxidase-antiperoxidase method, and frozen (5-6 μ) and Vibratome (20-40 μ) sections were studied at the ultrastructural level with Nakane's conjugated peroxidase method. The neurofilament antibody stained only neurons and axons at the light microscopic level. The staining pattern at the electron microscopic level corresponded to the neurofilaments within axons and neurons. Neurons, neurofilaments, glial cells, glial filaments, and non-nervous tissue showed no peroxidase staining when preimmunization rabbit serum, specific antiserum absorbed with neurofilaments, and antiserum to the glial fibrillary acidic protein of mammalian CNS astrocytes were utilized.

Glial cells which surround the axons contain large bundles of filaments which resemble astrocytic filaments in mammalian astrocytes. These filaments do not stain with the anti-neurofilament antibody. This indicates that neurofilaments and glial filaments of Myxicola have different immunologic properties.

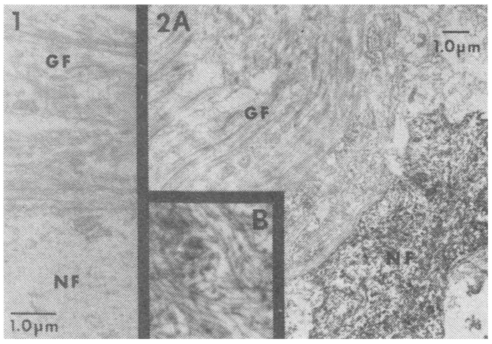

Fig.1,Control section treated with antiserum absorbed with neurofilaments (NF).NF and glial filaments (GF) are unstained.Fig.2A, NF antiserum treated section (1:1000). GF negatively and NF positively Stained.Fig.2B, NF positively stained. High Magnification.

1052 EFFECTS OF SOME MAYTANSINOIDS ON THE CENTRAL NERVOUS SYSTEM NEURONS. B. Ghetti, Dept. of Pathology, Div. of Neuropathology, Indiana University School of Medicine, Indianapolis, IN 46202

Maytansine (MYT) and Maytanprine (MYTPR) belong to a class of naturally occurring ansa macrolide derivatives, the maytansinoids.

MYT binds to tubulin and possesses stathmokinetic properties; it also inhibits DNA synthesis. In nerve cells, in vivo, MYT induces neurofibrillary degeneration (Ghetti, Brain Res., 1978, in press), while in axons, in vitro, it induces a reduction of microtubules and blocks axoplasmic transport (Ghetti and Ochs, Abst. Soc. Neurosci., 1977). The aims of the present communication are 1) to describe the neurocytological changes induced by MYTPR, 2) to analyze the changes preceding and following the appearance of neurofibrillary changes in neurons exposed to these drugs, 3) to describe the topography of the central nervous system (CNS) lesions.

Histological and ultrastructural studies were carried out on the CNS of rabbits sacrificed between 18 hours and 6 days following intrathecal injection of 25, 50 and 100 μg of either MYT or MYTPR. The retina of rabbits intraocularly injected with 3 μg of MYT was studied between 40 hours and 15 days following injection. The results are as follows: 1) MYTPR induced severe neurofibrillary degeneration in neurons of the cervical spinal cord, medulla and pons between 48 and 72 hours following injection. Dendrites were extensively involved; axons were focally distended and filled with neurofilaments. Axonal and dendritic microtubules were drastically reduced. 2) The cell groups known to respond with neurofibrillary degeneration displayed, between 18 and 48 hours, severe loss of microtubules. The cytoplasm showed clumping of the Nissl substance, composed of aggregates of short cisterns of rough endoplasmic reticulum with a large number of ribosomal rosettes. The cytoplasm outside these areas showed clumping of the mitochondria, complete loss of microtubules, dispersed ribosomes and ribosome rosettes, numerous membrane-bound vesicles, rare bundles of neurofilaments and an amorphous floccular material. Also, the retinal ganglion cells responded with neurofibrillary degeneration. The local intraocular injection provided a useful system to study the time course of the cellular changes. 15 days after intraocular injection a large number of retinal ganglion cells had disappeared. The remaining ganglion cells contained scattered neurofilaments and rare microtubules. 3) The neuropathological changes were severe in the cervical cord, in the medulla and pons. Neurofibrillary changes were also present in the Purkinje cells; their axons showed numerous focal swellings. Few neurons with neurofibrillary changes were present in the hippocampus and cerebral cortex.

(Supported by grant IN-46R of the American Cancer Society.)

1053 A RAPID GOLGI STAINING TECHNIQUE FOR BRAIN TISSUE LESS THAN 0.5 mm THICK. Kristen M. Harris. Neural and Behavioral Biology Program, Univ. IL, Champaign, IL 61820.

Recent advances in the use of in vitro preparations to study neuronal plasticity have prompted the development of a golgi technique to stain small pieces of brain. While the technique has not yet been used on tissue maintained in vitro, it has been used successfully on freshly perfused tissue.

All tissue used in the staining procedure is fixed in buffered (0.43% NaOH and 1.88% NaH_2PO_4, pH 7.2-7.4) 4% paraformaldehyde solution for at least 24 hours. The small piece of tissue (0.3-0.5 mm) is then sewn with white polyester thread between two pieces of similarly fixed brain tissue (2 mm). The preparation is then wrapped in cotton gauze and placed in 0.16% OsO_4 and 2.3% $K_2Cr_2O_7$ solution for 5 days. The gauze and tissue is then rinsed in distilled water and 1% $AgNO_3$ solution and placed in 1% $AgNO_3$ solution for 5 days. At the end of this period, the tissue is dehydrated (1:1 acetone-ethanol for 3 hours; 100% alcohol for 30 min; and 1:1 ether-ethanol for 30 min). Then the tissue is carefully unwrapped and the threads are cut so that the small piece of brain tissue can be separated and embedded in celloidin. Tissue is permeated with 8% (W:W) celloidin for 3-8 days, and then transferred to 16% celloidin for approximately 3 days. The small sections are embedded in 16% celloidin and hardened over chloroform vapor for 36 hours. The blocks of embedded tissue are mounted on wooden blocks and microtomed at 60-100 micron thickness. These 60-100 micron sections are mounted in permount under cover glass.

This method has been found to fully stain neurons in preparations from adult rat cortex and hippocampus with sufficiently low staining density to permit qualitative and quantitative analysis. Staining other regions of brain or brains of other animals may require different concentrations or times.

1054 THE ORDERED TRANSVERSE BRIDGE LATTICE SYSTEM ASSOCIATED WITH NEUROFILAMENTS AND MICROTUBULES IN AXONAL CYTOPLASM OF LOLIGO AND HERMISSENDA. Alan J. Hodge* and W. J. Adelman, Jr. Lab. of Biophysics, IRP, NINCDS, NIH, Woods Hole, MA 02543.

Slender transverse projections radiating from microtubules (mt) and neurofilaments (nf) have been described in thin sections of neural tissue prepared for electron microscopy. In favorably oriented specimens, these projections appear as bridges between parallel neurofilaments and microtubules. This study utilized thicker sections (0.1-0.3 μm) for stereoscopic study of neural networks in conventional TEM (Philips 300) where the upper limit of section thickness is determined primarily by loss of resolution resulting from inadequate imaging of inelastically scattered electrons and by problems associated with heavy metal staining. Improved fixation was observed for squid neural tissue (including giant axons) and for the CNS of Hermissenda crassicornis when the initial glutaraldehyde (2-4%) phosphate-buffered fixative (pH 7.2) contained EGTA (2-40 mM) and Mg^{++} (1-5 mM) with the total osmolarity adjusted with sucrose to not less than 1100 mosm. Initial fixation (30 min.-2 hours) was followed by cold OsO_4 treatment (30 min.-2 hrs.). Specimens were dehydrated and embedded using Epon 812. Specimens were stained en bloc with either aqueous or alcoholic solutions of uranyl acetate, sometimes followed by alcoholic PTA. Often these thicker sections required further staining, usually alcoholic uranyl acetate and aqueous lead citrate for adequate contrast.

When thicker sections (0.1-0.3 μm) of longitudinally oriented axons were examined, a distinct transverse striation could be discerned in the mass of parallel neurofilaments. Close stereoscopic inspection revealed an extensive ordered network of thin (3 nm) transverse elements arranged in planes approximately normal to the fiber axis and spaced about 40 nm apart along this axis. Thin elements often appear to bridge neighboring neurofilaments and to connect the lattice to axolemmal membrane surfaces. It thus appears that neurofilaments and microtubules together with thin transverse elements form a highly ordered lattice structure or gel intimately connected to the neurolemmal surface. This ordered lattice was confirmed by image enhancement using multiple image superposition techniques. The neuronal lattice system is presumably the equivalent of the microtrabecular system found by Porter and colleagues in cultured cells. The ordered lattice system might be involved in axoplasmic flow and in the transport mechanism proposed by Schmitt for transmitter substances and enzymes. The small diameter (2-3 nm) of transverse elements suggests the possibility that they may be composed in part of a tropomyosin-like protein, which, in striated muscle, acts as a bridging component, at least in Z-bands.

1055 CYTOPLASMIC CHANNELS OF THE MAMMALIAN SCHWANN CELL: A FREEZE-FRACTURE STUDY. Lawrence Kruger and Aidan S. Breathnach*. Dept. Anat. and Brain Research Inst., UCLA Med. Center, Los Angeles, CA 90024, and Dept. Anat., St. Mary's Hosp. Med. Sch., London, W 2, England.

The distribution of Schwann cell cytoplasm was examined in spinal and trigeminal nerves and dorsal roots of rat, rabbit and human fetus preserved in aldehyde mixtures or unfixed and using a variety of cryoprotective agents before rapid freezing for purposes of electron microscopic examination of freeze-fracture replicas.

The surface plasmalemma displays broad cytoplasmic bulges extending beyond the perikaryal region and is extensively studded with caveolae, although these are less numerous in the region of the outer mesaxon. The outer layers of "semi-compact" or "loose" myelin are permeated by an interlacing network of trabecular cytoplasmic channels of approximately 0.1 μm diameter. Channels of similar diameter can be followed through "compact" myelin layers, as Schmidt-Lanterman incisures, some ending blindly, others continuing as longitudinal tubules terminating as loops at the paranodal zone.

The inner surface of the Schwann cell contiguous with the axolemma usually consists of a single "semi-compact" layer with less regular expanses of trapped cytoplasm except for zones containing a uniform spiraling multiple tubular network corresponding to the "axon-Schwann" network described in thin sections by Berthold. The similarity in diameter for the inner tubules, paranodal terminal loops, nodal microvilli, incisural channels and the outer Schwann trabecular network, suggests a parsimonious principle. This form of sequestration in Schwann cells might underlie the specialized needs of cytoplasmic communication in a cell with large domains in which cytoplasm has been extruded to form compact myelin.

1056 PROLIFERATION OF FIBROUS ASTROCYTES IN RESPONSE TO BRAIN INJURY: SIMULTANEOUS LOCALIZATION OF GLIAL FIBRILLARY ACIDIC PROTEIN BY IMMUNOPEROXIDASE TECHNIQUE AND OF ^{3}H-THYMIDINE UPTAKE BY RADIOAUTOGRAPHY. Norman Latovitzki*, Gajanan Nilaver*, Earl A. Zimmerman, Ann-Judith Silverman, William G. Johnson*, Richard Defendini*, and Lucien Cote. Departments of Neurology, Anatomy and Neuropathology, College of Physicians and Surgeons, Columbia University, New York City, N.Y. 10032.

Astrocytes proliferate and hypertrophy in response to many different kinds of CNS injury. The acutely reactive astrocyte develops large numbers of intracellular gliofibrils and is rich in glial fibrillary acidic protein (GFAP). Since the production of GFAP by an astrocyte denotes a further degree of cell specialization or differentiation and since highly differentiated cells often cease proliferating, the ability of the GFAP-containing astrocyte to undergo division was examined by combining radioautography of radiolabelled thymidine with localization of GFAP by immunoperoxidase technique.

A needle stab wound in the cerebrum was produced transcranially in mice. Three days later 100μCi of ^{3}H-thymidine/animal was injected intraperitoneally and the animals sacrificed one hour later. Formalin fixed, paraffin embedded, 6 μm brain sections were immunostained by the peroxidase-antiperoxidase bridge method using rabbit antihuman GFAP antiserum as the first antibody. Large numbers of GFAP reactive cells were present in the lesion, while only occasional ones were encountered in normal tissue. ^{3}H-thymidine radioautographic products on the subsequently emulsion coated sections were located in a significant number of nuclei of GFAP reactive astrocytes in the lesion. These findings suggest that astrocytes sufficiently differentiated to produce GFAP retain the ability to divide and that such cell division may be a significant source of astroglial proliferation in response to tissue injury.

1057 IMMUNOHISTOCHEMICAL LOCALIZATION OF ACTIN IN IDENTIFIED NEURONS OF *APLYSIA*. Beverly W. Lubit, Ariel A. Sherbany*, and James H. Schwartz. Dept. Physiol., Div. Neurobiol. & Behav., Columbia Coll. Phys. & Surg., New York, N.Y. 10032.

Because contractile proteins are likely to be involved in the intracellular movement of neuronal components by axonal transport, we have developed a radioimmunoassay for *Aplysia* actin and have used rabbit anti-actin antiserum for immunohistochemical localization. Actin was extracted differentially from *Aplysia* body wall muscle and purified by Mg^{++}-polymerization, ion-exchange chromatography on DEAE-cellulose or affinity chromatography on bovine pancreatic DNase I-Agarose. Rabbits were immunized for 4 weeks with 30 μg per week of the actin contained in a suspension of polyacrylamide from a final purification by slab gel electrophoresis in sodium dodecyl sulfate. Antibody was first detected by Ouchterlony immunodiffusion a week after the last immunization.

Immunofluorescence studies were initially carried out on squashes of the isolated cell body of R2, the giant neuron dissected from the abdominal ganglion. In these whole mount preparations, actin was found in fluorescent strands along the surface of R2's cell body. Because the neuron is so large (0.5-1mm in diameter), 10-μm cryostate sections were necessary to reveal a granular cytoplasmic localization *within* the cell body and axon. Although the perinuclear area was the brightest, the nucleus itself was only faintly fluorescent. Connective tissue and glial cells appeared to contain only small amounts of actin, if any. As expected, cryostat sections of muscle from body wall, buccal mass and heart were highly fluorescent. Incubation of sections in the presence of 0.2% *Aplysia* tropomyosin did not affect the patterns observed. A similar distribution of actin was obtained using Sternberger's PAP-immunoperoxidase method.

The specificity of the anti-actin antibody was assessed by immunoadsorption and by radioimmunoassay. Fluorescence was not obtained with antibody from which anti-actin had been removed by passage through actin-AH Sepharose; after elution, the adsorbed anti-actin provided strong fluorescence. The antiserum contained a negligible cross-reacting activity to tropomyosin detected by radioimmunoassay using the double antibody method to precipitate actin labeled by reaction with ^{3}H-acetic anhydride or with the ^{125}I-Hunter-Bolton reagent. The latter probe is of sufficiently high specific radioactivity to permit assay of actin in isolated nerve cell bodies.

1058 ULTRASTRUCTURAL LOCALIZATION OF CALCIUM BY ELECTRON PROBE ANALYSIS IN PRESYNAPTIC NERVE TERMINALS. C.F. McGraw, A.V. Somlyo*, and M.P. Blaustein. Dept. Physiology and Biophysics, Washington University Sch. Med., St. Louis, MO 63110, and Pennsylvania Muscle Institute, Philadelphia, PA 19104.

Presynaptic nerve terminals (synaptosomes) were isolated from adult rat brains according to the method of Hajos (Brain Res. 93: 485, 1975). Saponin-disrupted synaptosomes were incubated in Ca-containing, K-rich media in order to load the intraterminal Ca-sequestering sites with Ca (Blaustein, et al., J. Gen. Physiol., in press); the incubation solutions all contained 10-30 mM K oxalate. Some preparations were fixed with aldehydes and postfixed with OsO_4; all fixatives contained oxalate. Other synaptosome preparations were processed by a freeze-substitution method. All tissue samples were dehydrated and embedded in plastic; unstained, thin sections were examined in the electron microscope. Many of the terminals contain flattened cisternae and tubular profiles which resemble smooth endoplasmic reticulum; these structures are frequently observed adjacent to mitochondria. In the aldehyde-fixed preparations, electron-dense deposits, probably calcium oxalate, are localized in the structures resembling smooth endoplasmic reticulum. Electron probe X-ray microanalyses of these structures verify the presence of calcium at a significantly higher concentration than in the cytoplasm. Mitochondria, and synaptic vesicle-rich areas of the cytoplasm, also contain significant concentrations of calcium. Electron probe analyses of the freeze-substituted preparations confirm that the flattened cisternae in these terminals also contain calcium at a higher concentration than is observed in the cytoplasm.

Presynaptic nerve terminals contain non-mitochondrial, ATP-dependent calcium storage sites; the uptake of calcium by these sites, which are exposed in disrupted terminals, is enhanced in the presence of oxalate (Kendrick et al., Nature 265: 246, 1977). The cisternal and tubular structures in which calcium has been localized by electron probe analysis may be the organelles which are responsible for the non-mitochondrial, ATP-dependent calcium storage. 1059 CYTOCHEMICAL EVIDENCE FOR PHAGOCYTIC CELLS UNDERLYING THE CEREBRAL VENTRICLES. Olivia C. McKenna. Department of Biology, City College, City University of New York, New York, N.Y. 10031

A population of cells which rapidly incorporate extracellular material has been identified lying immediately beneath the ependymal cells of the cerebral ventricles of the toad (Bufo marinus). The ventricular system was perfused with 1% horseradish peroxidase (HRP) in Ringer's solution and tissue sections processed for electron microscopy using the DAB cytochemical method. It was found that HRP readily penetrates the ependymal lining filling the extracellular spaces of the underlying tissue. More notably, within two minutes after the perfusion reaction product is incorporated into subependymal cells where it is found within cisternae, vesicles and multivesicular bodies. These cells characteristically contain membrane-limited dense bodies of various sizes and shapes, long strands of granular endoplasmic reticulum, lipid bodies and nuclei with clumped chromatin. Microtubules and filaments are notably absent. The cells also give rise to many pseudopodia which contain a uniformly dispersed flocculent material and are free of organelles. Cells with similar cytoplasmic components but lacking clearly defined pseudopodia are found in untreated tissue. Other cells also incorporate HRP but to a much lesser degree than the subependymal cells. As a result of the presence of pseudopodia and dense bodies and the ability to incorporate HRP the subependymal cells are readily distinguished from other central nervous system cell types.

The finding of a population of cells with phagocytic activity beneath the ependymal lining suggests that, although a barrier equivalent to the blood brain barrier does not exist at the cerebrospinal fluid brain interface, the brain has a population of cells which function to protect the brain by engulfing foreign materials entering the brain tissue from the cerebrospinal fluid.

1060 KAINIC ACID LESIONS OF THE SUPERIOR COLLICULUS: HISTOLOGICAL CHARACTERISTICS AND INCIDENCE OF INFARCTIONS. Björn H. Merker*. (SPON: R. Held). Dept. Psychol., M.I.T., Cambridge, MA 02139.

Kainic acid (KA) was injected into the anterior part of one superior colliculus (SC) of 17 adult Syrian hamsters via a modification of the Eide et al. (Neurosci. Lett. 2: 51, 1976) thermal microinjection method (0.15 or 0.2 ul of 2.5-10ug KA/ul in normal saline). After 6 to 15 days survival, brains were studied by light- and darkfield microscopy on adjacent serial sections stained for Nissl substance by cresyl violet, myelin by the Loyez hematoxylin stain, and normal axons and degeneration products by modifications of the Fink-Schneider and Fink-Heimer I methods, respectively. KA injections produced a remarkably benign tissue reaction characterized by drastic though subtotal neuronal destruction in the absence of severe gliosis, fibrosis or macrophage invasion. Neuronal destruction around the injection site tended to be more severe in the deep layers of the SC than in the superficial grey (SG). Central grey was always conspicuously spared even when drastic SC cell loss extended to its borders. In the SC large neurons were invariably destroyed. The density of surviving medium and small neurons was somewhat variable, but in the deep SC it approached complete neuronal destruction in some cases. Though the region of cell loss included the stratum opticum, the distribution of optic tract and other fibers throughout the SC behind the lesion was indistinguishable from the control side in the myelin and normal axon stains. The sparing of fibers of passage was further supported by cases in which both eyes were injected with ^{3}H-leucine and ^{3}H-proline 24 hr prior to killing. In 2 of these cases autoradiographically assessed labelling of the SC was bilaterally symmetrical throughout its extent, though a substantial portion of the optic tract passed through the region of cell loss. Within the region of cell loss a number of cases showed loss of variable amounts of fibers in the SG, particularly when cell loss there was more severe. This might represent a secondary reaction on the part of afferent fibers to loss of terminal sites. In 5 of the 17 animals, local elongated patches of total necrosis with the radial orientation of the collicular vascular system were associated with the lesion, and could extend beyond the region of cell loss into the central grey. Such damage, apparently caused by vascular infarction, was virtually nonexistent in 77 animals injected with a variety of metabolic inhibitors, though many of these cases had tissue reactions far more severe than those induced by KA. This incidence of infarctions therefore appears to be associated with the tissue effects of KA rather than with the injection procedure or nonspecific reactions to tissue damage.

1061 GENETIC ENZYME VARIANTS AS CELL MARKERS IN STUDIES OF NERVOUS SYSTEM DEVELOPMENT. Mary Lou Oster-Granite and John Gearhart*. Dept. Anat., Univ. Md. Sch. Med., Baltimore, MD 21201.

Glucosephosphate isomerase (GPI, E.C. 5.3.1.9) is a ubiquitous soluble, glycolytic enzyme which is expressed early in mammalian embryogenesis. The structure of this enzyme is specified by a single autosomal locus with at least four different alleles (Gpi-1^{a}, Gpi-1^{b}, Gpi-1^{c}, and Gpi-1^{d}) in mice. These alleles are expressed as electrophoretically distinct allozymes of GPI (GPI-1A, GPI-1B, GPI-1C, and GPI-1D). We have isolated and purified two of these allozymes, GPI-1A and GPI-1B, from mouse liver, brain, and skeletal muscle. The GPI-1A allozyme was isolated from Balb-c and AKR mice, the GPI-1B allozyme from C57Bl/6J, C57Bl/6J (pcd), and C57Bl/6J (bg^{J}) mice. Purified allozymes have been used in xenogeneic, syngeneic, and allogeneic immunizations involving goats and mice. Goat antisera to GPI have been absorbed with allozyme-conjugated Sepharose columns and the allozyme specificity of these absorbed antibodies determined by radioimmune assay. Such purified allozyme-specific antibodies have been used in an indirect fluorescent assay to determine the presence of GPI in paraffin sections of various parts of the immature and mature nervous system to test the usefullness of this enzyme as a genotype specific cell marker. We are currently extending this procedure to the EM level by use of an indirect staining procedure utilizing a horseradish peroxidase (HRP)-antibody conjugate. Such allozyme-specific antibodies may be very useful for studies of the developing nervous system examining 1) cell interactions between various populations of neurons or between neurons and glia; 2) the origins of various cell populations in the nervous system; 3) the locus of action of mutant genes which produce neurologically mutant mice; 4) the circumstances necessary for the expression of mutant phenotype by genetically mutant cells; and 5) aspects of regeneration and plasticity in the immature nervous system in combinations of both genotypes in chimeric mouse systems. The usefullness of this enzyme as a marker of cell genotype is illustrated primarily in the spinal cord and cerebellum, but its general applicability to other areas of the nervous system will be demonstrated.

1062 PERSISTENT CELL MULTIPLICATION IN THE SPINAL ROOTS OF ADULT DYSTROPHIC MICE. C. Suzanne Perkins*, Garth M. Bray and Albert J. Aguayo. Department of Neurology and Neurosurgery, McGill University and the Montreal General Hospital, Montreal, Quebec, Canada.

In spinal roots of dystrophic mice, there are bundles of large, unensheathed axons (J. Neurol. Sci. 18:227, 1973). This abnormality is associated with a neonatal deficit of Schwann cell multiplication (J. Neurol. Sci. 32:203, 1977). In the present study, adult dystrophic (C57BL/6J dy^{2J}/dy^{2J}) and control (C57BL/6J +/+) mice were injected with tritiated thymidine (4μCi/g body weight) daily for 10 days and sacrificed on the 10th day by systemic perfusion of fixative solution. Labelling indices in the lumbar ventral roots were determined by radioautography.

No labelled nuclei were observed in the spinal roots from control animals but in dystrophic roots, up to 20% of nuclei were labelled. This abnormal cell proliferation could be caused by myelin debris which is present in the dystrophic roots. Thus, in addition to the initial deficiency of axonal ensheathment, there may also be a failure to sustain myelin in the abnormal segments of these nerves.

1063 NEURONAL UPTAKE OF HORSERADISH PEROXIDASE IN MECHANICALLY BRAIN INJURED CATS. J.T. Povlishock,* D.P. Becker, and J.D. Miller* (Spon: J.A. Astruc). Departments of Anatomy and Neurological Surgery, Medical College of Virginia, Richmond, Virginia 23298.

Recently in an analysis of central nervous system vascular permeability alterations in response to low-grade concussive injuries uncomplicated by either microscopic intraparenchymal hemorrhages or other relevant neuropathological change, we have described at both the light and electron microscopic level an increased vascular permeability to intravenously injected horseradish peroxidase within the raphe and reticular core. In these animals the protein apparently reached the parenchyma through a dramatic form of transendothelial vesicular transport (Brain Research - In Press). Concomitant with the spread of the peroxidase into the brain stem parenchyma, numerous neurons became inundated with the tracer and as such appeared reminiscent of cells visualized in Golgi preparations. In that such inundation with peroxidase most probably reflects altered neuronal membrane permeability, the question arises as to what is the fate of these neurons.

Toward the resolution of this question these flooded neurons were studied in serial ultrathin sections over a 24h period following mechanical brain injury. Immediately after injury ultrastructural examination of the flooded neurons demonstrated peroxidase diffusely spread throughout their cytoplasm as well as being localized within vesicles and vacuoles. Careful examination of the neuronal cell membranes failed to reveal any evidence of physical damage, and all other aspects of cellular morphology appeared unremarkable. Within 6h of brain injury, no neuronal flooding with peroxidase was observed. No evidence of cellular degeneration was noted and thus, the fate of the flooded neurons appeared questionable. However, in those same loci, which immediately after trauma displayed inundated neurons, numerous neurons displayed a cytoplasm laden with peroxidase containing vesicles. Within these same group of neurons, after 12h of survival, the peroxidase containing vesicles assumed a perinuclear orientation and within 24h of the injury the peroxidase reaction product was observed to be both diffusely spread in the nucleus as well as being selectively sequestered within nucleolar vacuoles. In conjunction with this nuclear and nucleolar peroxidase uptake, no ultrastructural manifestation of any cellular alteration was observed.

Such neuronal peroxidase uptake appeared to be directly related to the traumatic injury and was not secondary to various traumatic hemodynamic episodes.

1064 DEPLETION OF DENSE-CORED VESICLES IN AXON TERMINALS OF CAT SUPERIOR CERVICAL GANGLIA FOLLOWING ELECTRICAL STIMULATION. J.J. Pysh and Daniel G. Nehls*. Dept. Anat., Northwestern Univ. McGaw Med. Ctr., Chicago, IL 60611.

Cholinergic nerve terminals in sympathetic ganglia contain small numbers of large dense-cored vesicles (LDCV's) dispersed amongst the larger population of small clear-cored vesicles. The function of LDCV's in cholinergic nerve terminals is unknown. The objective of this study was to determine whether the concentration of LDCV's in nerve terminals of cat sympathetic ganglia is altered during synaptic activity.

Cervical sympathetic trunks of cats were stimulated electrically at 10 Hz for 2, 5, or 30 minutes and nictitating membrane contractions were recorded to monitor the effectiveness of stimulation. Animals were perfused intra-aortically with an aldehyde fixative. Subsequently, stimulated and contralateral control ganglia were processed simultaneously for electron microscopy.

A morphometric analysis was carried out on electron micrographs of randomly selected axo-dendritic synapses identified by the presence of characteristic synaptic densities and the presence of clear-cored vesicles. The concentrations of LDCV's in axon terminals ($\#/\mu^2$) was computed from counts of LDCV's and measurements of terminal profile areas. Paired comparisons between control and stimulated ganglia were made to obtain percentage differences of LDCV concentration for each animal.

The mean concentration of LDCV's in presynaptic terminals decreased significantly after 5 minutes of stimulation and continued to decline to reach a concentration 31% of controls after 30 minutes of stimulation. In ganglia allowed to rest for 1 hour after 30 minutes of stimulation, the concentration of LDCV's in axon terminals recovered to 47% of controls, whereas the concentration of clear-cored vesicles completely recovered as shown in a previous study (Pysh and Wiley, 1974).

The present data offers evidence that the contents of LDCV's may be released from cholinergic nerve terminals during functional activity.

1065 INCORPORATION OF NEWLY FORMED ETHANOLAMINE PHOSPHATIDES INTO PERIPHERAL NERVE (PN) MYELIN: AN ELECTRON MICROSCOPE (EM) AUTORADIOGRAPHIC ANALYSIS. F.A. Rawlins, Dept. Biophysics, IVIC, Apartado 1827, Caracas 101, Venezuela.

Recent EM autoradiographic studies indicate that PN shows different mechanisms of uptake for various of its lipid components. Thus, cholesterol rapidly enters the forming myelin sheath (MS) almost simultaneously through its inner an outer edges. A movement of cholesterol from axon into MS was also suggested (Rawlins, F.A. J. Cell Biol. 58: 42, 1973). Uptake of newly formed lecithin by the adult MS occurs almost exclusively through its outer edge (Rawlins, F.A. 8th Int. Cong. Elect. Micros. 2: 288, 1974: Gould and Dawson, J. Cell Biol. 68: 480, 1976). Phosphoinositides are first concentrated within the axon and afterwards appear incorporated into the MS and Schwann cell (SC) (Gould, R.M. Brain. Res. 117: 169, 1976). In the present work we have studied the site of synthesis of ethanolamine phosphatides, one of the major myelin lipid components, in PN and its route of incorporation into the MS of young and adult mice. The animals were injected i.p. with 500 µCi of ethanolamine hydrochloride (1,2-^{14}C), sacrificed at various times after injection and the sciatic nerves processed for EM autoradiography. The autoradiograms were analyzed following the method of Salpeter et.al. (J. Cell. Biol. 41: 1, 1969). Each nerve fiber (cross and longitudinal sections) was divided into 3 main compartments: myelin, axon and SC. Each compartment was subdivided into several subcompartments of 2000 Å wide (one ^{14}C half distance). The results indicate that in both young and adult mice, the label was initially concentrated in the SC cytoplasm mainly over the smooth endoplasmic reticulum. In the young animals "filling" of the MS was attained by two radial movements of the labelled molecules: one from the SC cytoplasm through the outer edge and another from the adaxonal SC cytoplasm through the inner edge. In the adult mice only the first type of movement could be detected. Although some label was confined to the axon, no evidence of an axon to myelin movement of molecules was obtained. It is suggested tha while growth of the MS implies a simultaneous incorporation of molecules at the outer and inner mesaxon, maintenance of the adult MS is achieved mainly through its outermost lamellae.

1066 ABNORMALITIES IN THE PLASMA MEMBRANE OF CENTRAL MYELINATED AXONS OF "QUAKING" MICE AS SEEN IN FREEZE-FRACTURE REPLICAS. Jack Rosenbluth. Departments of Physiology and Rehabilitation Medicine New York University School of Medicine, New York, N.Y. 10016.

Previous freeze-fracture studies of myelinated nerve fibers have shown that the axolemma is regionally specialized in relation to the surrounding myelin sheath. Paranodal junctional membrane specializations are prominent, and nodal intramembranous particle accumulations may represent ion channels important in saltatory conduction. "Quaking" is a mutant mouse strain which exhibits "hypomyelination" as well as a variety of irregularities in myelin sheath structure. Thin sections of central nervous system white matter reveal thin myelin sheaths whose lamallae often terminate irregularly along the internode. The paranodal region may appear normal, but irregularities in the pattern of the terminal loops occur here as well. "Transverse bands" are present at some paranodal regions, but are absent or only partially present at others. The "radial component" of myelin is conspicuous even in very thin sheaths,and myelin debris occurs commonly as well as redundancies and aberrant formations around cell bodies and processes other than axons. In freeze-fracture replicas the outer leaflet of the paranodal axolemma sometimes exhibits a faint diagonal pattern characteristic of the axoglial junctional specialization normally found in this region. However, in the quaking animals the paranodal membrane specialization is neither consistent nor regular. This is particularly evident in etched preparations where the pattern in the specialized axolemma stands out distinctly and exhibits a rope-like configuration. Abnormal angulations in the pattern occur in which the orientation of the component strands changes abruptly forming ~30, 60, or 90° angles, and islands of non-specialized axolemma are also present. Large intramembranous particles, like those normally found concentrated in the nodal axolemma, are found in the axolemmal E face within the broad areas between paranodal "grooves" to a much greater extent than normally, and the concentration of large particles in the outer leaflet of the nodal axolemma is sometimes reduced markedly below normal. The P face of the membrane of the paranodal glial loops facing the axolemma often exhibits discoid aggregates of closely packed large particles instead of the regularly spaced diagonal rows of particles seen normally in the junctional membrane. Freeze-fracture analysis thus shows that in addition to the previously described abnormalities of myelin, the quaking nervous system exhibits abnormalities in both glial and axonal membranes in the region of the paranodal axoglial junction and in the nodal axolemma as well. These alterations in structure in the axonal plasma membrane, whether secondary to glial abnormalities or not, could account in part for the neurological deficit seen in these animals. Supported by grant NS 07495 from the NIH.

1067 RAPID RETROGRADE DEGENERATION IN THE OLFACTORY BULB OF MICE. David W. Samanen* and P.P.C. Graziadei. Dept. Bio. Sci., Florida State Univ., Tallahassee, FL 32306.

Axotomy of the olfactory mitral cells was performed 1) in the lateral olfactory tract (LOT) at the level of the caudal margin of the anterior olfactory nucleus, or 2) by direct lesion of the olfactory bulb with a wedge-shaped lesion in the coronal plane at its mid-length. Animals at postoperative intervals of 12 hrs - 180 days were sacrificed and the brains serially sectioned and stained by the Nissl and Holmes methods. Several changes in the arrangement of Nissl substance and the argyrophylia of the neurons were observed. These changes occurred very rapidly, as early as 12 hrs postoperatively in the animals with bulbar lesion and at 48 hrs for animals with LOT lesion. Disappearance of the lesioned neurons occurs from both lesions thereafter.

The distribution of the mitral cells undergoing retrograde degeneration was different between the two lesions. It was rather diffuse, as observed in coronal sections, scattered about the entire perimeter of the mitral cell layer, in animals with LOT lesions. It was restricted to a rather discrete sector of the bulb in animals with the direct bulbar lesion.

The mitral cells caudal to the direct bulbar lesion also sustained degenerative changes. While these neurons were not affected by axotomy, the axons of their associated primary neurons may have been cut during the surgery performing the wedge-shaped lesion. We believe that their degeneration may have been induced by the deafferentiation of their apical dendrite at the glomular level. It is interesting to observe that the time course of this putative transneuronal degeneration follows the same rapid temporal pattern of the retrograde degeneration observed in the mitral cells rostral to the lesion.

Supported in part by NSF grant BNS 77-16737 to P.P.C. Graziadei and by NIH training grant 5T32NS 07010.

1068 THE EFFECT OF HYPERGLYCEMIA ON BRAIN CAPILLARY PERMEABILITY IN A LIZARD, ANOLIS CAROLINENSIS. A FREEZE-FRACTURE STUDY. Richard R. Shivers. Dept. Zoology, Univ. Western Ontario, London, Canada

The anatomical basis of the blood-brain barrier in the American chameleon, Anolis carolinensis, is the tight junction system that "seals" brain capillary endothelia to systemically injected horseradish peroxidase (HRP) and trypan blue. These inter-endothelial junctions, when examined in freeze-fracture replicas, consist of a highly complex network of anastomosing continuous PF membrane face ridges and complementary EF membrane face grooves. Many experimental protocols and pathological states are known to alter brain capillary permeability and are assumed to act by disrupting the structure of brain capillary endothelial tight junctions. In the present study, systemic injection of 5 mg of glucose into lizards resulted in increased brain capillary permeability as evidenced by escape of trypan blue or HRP (Sigma Type VI), which were included in the glucose injection, into the intercellular spaces of central neuropil. Freeze-fracture analysis of brain capillaries of glucose-hyperglycemic lizards showed no alteration in the ridge and groove construction of endothelial tight junctions, indicating that although the blood-brain interface becomes leaky during hyperglycemia, the capillary occluding junctions are not affected. Evidence obtained in this study strongly supports the notion that the increased capillary permeability is the result of amplified trans-endothelial transport that is facilitated by and manifest as formation of chains of pinocytotic vesicles derived from the luminal surface of the endothelial cells, which then fuse to create open trans-endothelial channels. It is likely that formation of open conduits across the brain capillary endothelial cells, as a response to hyperglycemia, could allow unrestricted passage of a wide range of molecules, some potentially toxic, into the CNS extracellular milieu. Careful examination of the EF fracture face from many control and experimental brain capillary endothelia failed to show any increase in the number or distribution of pinocytotic vesicles as a response to hyperglycemia. This is the first report to unequivocally document, with freeze-cleave techniques, that abnormally elevated levels of blood sugar can affect blood-brain barrier permeability, and because of this, suggests that similar consequences probably result from diabetic hyperglycemia in humans. Results of this study also suggest that amplification of pinocytotic activity,with formation of trans-endothelial channels,may constitute the usual consequence of most of the experimental and disease-related insults known to affect the barrier.Further studies are required to determine if this condition contributes to impairment or death of CNS neurons and their processes. (Supported by the National Research Council of Canada)

1069 MORPHOLOGICAL BASIS FOR CROSSED MOTONEURONAL INTERACTIONS IN FROG SPINAL CORD. R. W. Soller* and S. D. Erulkar (SPON: G. B. Koelle). Department of Pharmacology, University of Pennsylvania, School of Medicine, Philadelphia, Pa. 19104.

Recently, we reported that lumbar motoneurons on opposite sides of the frog spinal cord show electrically- and chemically-mediated synaptic interactions (Soc. Neurosci. Abst. III: 514, 1977). In order to identify the morphological substrates of these crossed interactions we used LM and EM methods to examine spinal cords whose ventral roots were loaded with horseradish peroxidase (HRP).

HRP was applied topically to the cut ends of ventral roots of segments 7-10. After two days spinal cords were prepared according to the HRP-diaminobenzidine method. Dendritic processes were identified at the EM level by the presence of synaptic input, endoplasmic reticulum and microtubules.

At the LM level the distribution of HRP-positive processes confirmed the motoneuronal dendritic profile described in Golgi studies (Liu and Chambers, Anat. Rec. 127: 326, 1957). In addition, medially-directed dendrites were seen to terminate in an ipsilateral field that was ventrolateral to the central canal or to cross the midline in the anterior commissure and terminate in the ventral gray matter or, in some cases, the lateral funiculus. Crossing dendrites emanated from both lateral and medial motor groups of segments 7-10, but were most numerous in segments 7 and 8. A notable specialization of these processes, particularly in the anterior commissural region of rostral lumbar segments, was the appearance of localized enlargements (8-15 um in diameter).

At the EM level, HRP-positive processes, presumably motoneuronal dendrites, were observed in (1) the anterior commissural region as localized enlargements that receive synaptic input and that appear in close apposition (17 nm separation) to non-reactive dendritic processes, (2) dendritic thickets (see Stensaas and Stensaas, Brain Res. 31: 67, 1971) of the ipsilateral gray matter, where they closely apposed other HRP-positive processes, (3) otherwise non-reactive dendritic thickets of the contralateral gray matter and (4) close apposition to neurons of unknown origin on the contralateral side. As yet, we have not seen gap junctions associated with HRP-positive processes.

These results suggest that motoneurons of lumbar segments receive contralateral synaptic inputs on their crossed dendrites and that crossed interactions between lumbar motoneurons may be mediated at sites where dendrites from one side are closely apposed to dendrites and neuronal perikarya of the other side.

(Supported by USPHS grant NS 12211)

NEURO-ENDOCRINOLOGY

1070 PINEAL INFLUENCE ON ADRENOCORTICOTROPIC HORMONE (ACTH) SECRETION IN THE RAT. J.P. Allen, G.M. Vaughan* and P. Starr*. Dept. Neurosci., Peoria Sch. Med., Peoria, IL. 61605, and Dept. Med., Un. TX. Hlth, Sci. Ctr., San Antonio, TX. 78284.

Because the pineal gland may modulate pituitary-adrenal function in the rat, we measured plasma ACTH and corticosterone (B) in pineal-stimulated (blind-anosmic) and pinealectomized male Sprague Dawley rats housed in a 12-hr light/12-hr dark environment. We compared these data to plasma testosterone (T) levels in the same groups. Rats were sham-pinealectomized (ShPx), pinealectomized (Px), optic-enucleated olfactory-bulbectomized (blind-anosmic [BA]), or a combination BAPx in the fifth week of life. Five weeks later, half of each group was adrenalectomized (Adx), and after three more weeks the animals were decapitated under basal conditions 100 min after the onset of the light phase. Trunk blood was collected and analyzed for ACTH, B and T using sensitive and specific radio-immunoassays. The inter-assay and intra-assay variations for each radioimmunoassay was <5%. In the non-adrenalectomized groups, plasma B levels were significantly higher ($P<0.01$) following either BA or BAPx compared to either ShPx or Px. Significant ($P<0.01$) suppression of mean plasma T levels occurred only in the BA group. In contrast, mean plasma ACTH levels were slightly but significantly elevated ($P<0.05$) in the BA group compared to the ShPx, Px or BAPx groups. In the adrenalectomized groups, the post-Adx rise in mean plasma ACTH level was significantly higher ($P<0.01$) in the BAPx animals than in ShPx, Px or BA groups.

Our data suggest that in the male rat: (1) deprivation of sight and smell either stimulates B secretion or alters its circadian rhythmic secretion. Moreover, there is possible non-concordance between basal ACTH and B concentrations after this dual sensory deprivation; (2) either the pineal gland or intact sight/smell can separately inhibit the post-Adx rise in plasma ACTH levels with release of this inhibition after the combination of pineal ablation, optic enucleation and olfactory bulbectomy; (3) intact sight and smell facilitates T secretion. In marked contrast to the pineal-adrenal inter-relationships, the effect of sight/smell on the testes is through the blocking of inhibitory influences from the pineal on the gonads. However, in both pineal-adrenal and pineal-gonadal systems, the pineal acts as an inhibitory influence.

1071 LOCALIZED UPTAKE OF (^{14}C) DEOXYGLUCOSE BY THE PREOPTIC AREA OF FEMALE RATS IN RESPONSE TO VAGINOCERVICAL STIMULATION. Theresa O. Allen* and Norman T. Adler, Dept. Psych., Univ. Penn., Phila. PA 19104.

Stimulation of the vagina and cervix by the intromissions of the male rat during copulation is required to initiate the neuroendocrine events (progestational state) necessary for successful pregnancy (Adler, J. Comp. Physiol. Psychol. 69:613, 1969). In the present study, we used the (^{14}C)-2-deoxyglucose (2DG) method (Kennedy, DesRosiers, Jehle, Reivich, Sharpe & Sokoloff, Science 187:850, 1975) to identify brain areas which increased functional activity in response to vaginocervical stimulation.

Unanesthetized, behaviorally receptive female rats were gently restrained and stimulated with a smooth metal rod attached to a vibratory engraving tool. The vaginocervical stimulation was intermittent (on for 15 sec/min) and was applied for 5 minutes preceding and for 45 minutes following the 2DG injection. The pulse of 2DG was delivered intracardially via a chronically implanted jugular catheter. There were two groups of control animals: (1) females receiving no vaginocervical stimulation, and (2) females receiving the stimulation after cervical denervation by bilateral excision of the pelvic nerves.

In the experimental animals, x-ray autoradiographs revealed increased concentration of the label in the medial preoptic area of the hypothalamus. Autoradiographs from both groups of control females did not show this activation. Nonspecific activation of other brain areas (e.g., auditory structures) was similar in all three groups. These results confirm the involvement of the preoptic area in the response to vaginocervical stimulation (Carrer & Taleisnik, Endocrinol. 86:231, 1970) and reveal the value of the 2DG method to investigate neuroendocrine events.

1072 SEXUAL DIFFERENCES IN PATTERN OF HORMONE ACCUMULATION IN THE BRAIN OF A SONG BIRD. Arthur P. Arnold and Albert Saltiel*. Dept. Psychol., UCLA, Los Angeles, CA 90024.

The autoradiographic method was used to determine the distribution of hormone-accumulating cells in brain after injection of tritiated testosterone into gonadectomized adult male and female zebra finches (Poephila guttata). Significant sex differences in accumulation are found in two brain regions involved in control of song: Hyperstriatum ventrale pars caudale (HVc), and magnocellular nucleus of the anterior neostriatum (MAN). In the female HVc, only a very small number of cells are labelled, many fewer than in the male. Since the female HVc is much smaller than the male HVc, the paucity of hormone-accumulating cells in female HVc may be a reflection of the small number of female HVc cells in general. However, in female MAN, there are cells which appear to accumulate a small amount of radioactivity, but this accumulation is strikingly less in amount per cell than in male MAN. This suggests that hormone-accumulating cells are present in both male and female MAN, but the MAN cells differ between the sexes in their ability to accumulate testosterone or its metabolites. The implications for mechanisms of sexual differentiation in the brain will be discussed.

In certain other brain areas, including regions related to song, we did not detect sexual differences in distribution of hormone-accumulating cells. The following areas contain labelled cells in both sexes: the hypoglossal motoneurons controlling the muscles of the vocal organ (syrinx), nucleus intercollicularis of the midbrain (related to vocalization), medial preoptic area, periventricular magnocellular nucleus of the hypothalamus, and infundibular nucleus of the posterior hypothalamus.

1073 EFFECTS OF CASTRATION AND ESTRUS CYCLE STATE ON MONOAMINE-STIMULATED ADENYLATE CYCLASE ACTIVITY IN RAT HYPOTHALAMUS AND AMYGDALA. G. A. Barr, H. S. Ahn*, J. L. Gibbons, and M. H. Makman*. Depts. of Psychiatry, Biochemistry and Molecular Pharmacology, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

There is increasing evidence that both normally occurring and surgically induced changes in endocrine systems can alter hypothalamic monoamine functions. For example, castration of male rats increased dopamine (DA) turnover, tyrosine hydroxylase (TH) activity, and steady state serotonin (5-HT) levels in certain hypothalamic nuclei. In the cycling female rat, dopamine turnover is lowest and norepinephrine (NE) turnover highest during proestrus, while steady-state levels of DA and NE peak during proestrus.

Adenylate cyclase (AC) activity in homogenates of rat anterior and medial hypothalamus or amygdala was measured as ATP dependent formation of cyclic AMP as previously described (Brain Res., 138, 125-138, 1977). In castrated males, there was significant stimulation of adenylate cyclase in the medial hypothalamus by both DA (100 μM) and 5-HT (100 μM) that did not occur in either intact or sham operated controls. In addition, there was no significant stimulation by NE (100 μM) or by the NE agonist methoxamine (100 μM) for any group. Using GPP(NH)P, a nonspecific stimulator of AC, there were no differences between groups. There was no significant stimulation in the anterior hypothalamus except for GPP(NH)P. In the amygdala, stimulation of AC by DA was unaffected by the endocrine status of the males.

In cycling females, AC was stimulated in the medial hypothalamus by dopamine, 5-HT, and isopropylnorepinephrine (100 μM) only during proestrus, and not during other stages. Furthermore, in the anterior hypothalamus, only GPP(NH)P stimulated AC. Amygdaloid AC activity was increased by several amines and GPP(NH)P but this stimulation was unaffected by differences in estrus cycle.

In summary, we have shown changes in monoamine stimulated AC activity in the medial hypothalamus due to alterations in endocrine systems for both male and female rats. These effects on AC systems are anatomically specific, occurring only in the medial hypothalamus and are pharmacologically specific, occurring only in response to specific monoamines and not to GPP(NH)P. These changes may reflect postsynaptic events that are either primary or secondary to alterations in presynaptic activity.

1074 EFFECT OF ANTERO-VENTRAL THIRD VENTRICLE LESIONS ON ANTIDIURETIC RESPONSES TO CENTRAL ANGIOTENSIN II. Steven L. Bealer, M. Ian Phillips and Phillip Schmid*. Depts. Psychology, Physiology and Internal Med., Univ. Iowa, Iowa City, IA 52242.

Electrolytic lesions of periventricular tissue of the antero-ventral third ventricle (AV3V) typically render rats adipsic for a period of one to 10 days following surgery, with no apparent primary aphagia, hyperemotionality, or other behavioral disturbances. In addition, during the period of adipsia, animals continue to excrete dilute urine, indicating a failure to initiate an appropriate antidiuresis which would be expected in view of their accumulating fluid deficit. Consequently, AV3V lesioned animals rapidly become hypernatremic and hyperosmotic (Johnson & Buggy, Am. J. Physiol., 1978, 234, R122-R129). The continued diuresis during lesion-induced adipsia indicates that antidiuretic hormone (ADH) mechanisms of fluid conservation have been compromised by AV3V ablation. The present experiment was designed to determine if AV3V lesions attenuate ADH release in response to intraventricular (IVT) injections of angiotensin II (AII), hypertonic NaCl, and phenylephrine during the adipsic period.

Following electrolytic ablation of the AV3V region or sham lesioning in 20 rats, each animal was implanted with a cannula in the lateral cerebral ventricle. On the day following surgery, all animals were prepared with arterial, venous and bladder catheters. Blood pressure, urine conductance, and urine flow rate were monitored in awake, unrestrained animals during a continuous intravenous infusion of a hydrating solution administered to produce a diuresis. Changes in these blood and urine parameters were recorded following IVT injections of 100 ng and 500 ng AII, 1 ul 3% NaCl, and 50 ug phenylephrine.

In the AV3V lesioned rats increases in blood pressure and urine conductance, as well as the decreased urine flow rate normally evoked by AII and hypertonic NaCl were significantly attenuated relative to the responses of sham operated controls. However, there was no difference in the pressor and antidiuretic responses evoked by IVT infusion of phenylephrine between lesioned and sham lesioned animals. In addition, a water deprived control group was tested to determine the effect of adipsia on ADH release in intact animals. This group had responses similar to water replete shams for all stimuli tested.

These data suggest that the integrity of the AV3V region is essential for the ADH release response to AII and osmotic stimuli IVT. Whether this is due to impaired synthesis or release of ADH remains to be shown. Finally, the lower blood pressure response in the presence of an attenuated ADH release is consistent with a role for ADH in the pressor response to AII.

1075 CORTICOSTERONE INDUCED PROTEINS IN THE PITUITARY OF ADRENALECTOMIZED MALE RATS. Margery C. Beinfeld* and Paul M. Packman* (SPON: R. A. Cohen). Dept. Psychiatry, Washington U. Med. Sch., St. Louis, MO 63110.

Corticosterone is known to be taken up and retained in the liver, pituitary, hippocampus and hypothalamus. The possibility that the synthesis of specific soluble proteins follows this uptake has been investigated using mature and immature Sprague-Dawley rats. The rats were given either steroid or the same volume solvent and sacrificed after one or three hours. Tissues from steroid treated animals were incubated with ^{14}C labeled leucine while controls were incubated with ^{3}H labeled leucine at 37°C for one hour. The steroid treated and control tissues were pooled separately, homogenized, and spun at 105,000 x g for one hour. The pellets from the high speed centrifugation were extracted with high salt and spun to clarify. The soluble protein extracts were analyzed on SDS-polyacrylamide gels.

Using this technique we have confirmed the result of Shelton and Alfrey (Nature 228:132, 1970) that corticosterone induces the synthesis of a protein in the liver with a subunit molecular weight of about 42,000 daltons.

We find no corticosterone-induced protein in the hippocampus, hypothalamus, cortex, or cerebellum in either the immature or adult rats at either one or three hours after steroid injection. Also, there is no induced protein in the high salt extracts of the pellets from these tissues.

However, in immature rats we do find that corticosterone induces the synthesis of two proteins with molecular weights of about 17,000 and 19,500 daltons. In mature rats corticosterone induces the synthesis of a single protein with a molecular weight of 17,000. There have been several reports recently that corticosterone causes growth hormone to increase in rat pituitary tumor cells (J. Martial, et al., PNAS 74:4295, 1977). Since the larger protein, 19,500 daltons, is sufficiently close in size and mobility to rat growth hormone, it is possible that one of the induced proteins is growth hormone. The experimental identification of the induced proteins will be described.

1076 ALTERED NEUROANATOMICAL ORGANIZATION IN THE CENTRAL NERVOUS SYSTEM OF THE GENETICALLY OBESE (ob/ob) MOUSE. David A. Bereiter and Bernard Jeanrenaud*. Univ. of Geneva, Laboratoires de Recherches Medicales, Geneva, SWITZERLAND.

The genetically obese (ob/ob) mouse is characterized by excessive body weight gain, hyperphagia and hyperinsulinemia. These and other endocrine-related abnormalities have suggested a generalized central nervous system (CNS) disorder, possibly hypothalamic. The following results have been obtained from nine week old male genetically obese (C57BL/6J ob/ob) mice and lean (C57BL/6J ++) control mice: (1) Ob/ob mice have greatly reduced total brain wet weight (-14.6%) that is not due to altered water retention. (2) Using a planimetric technique, ob/ob neurons demonstrate significantly reduced soma cross-sectional areas in eight of nine brain regions sampled, including the ventromedial hypothalamic nucleus. (3) Only lateral hypothalamic area neurons in ob/ob mice have soma cross-sectional areas as large as those of control mice. (4) A Golgi-Cox study of ventromedial and lateral hypothalamic neurons reveal no dramatic difference in dendritic organization between these two mouse strains.

Conclusion. The reduced total brain weight coupled with the morphometric data suggest that the ob/ob mouse brain differs significantly from that of lean controls. These differences may underlie the abnormal adult endocrine status of this genetic obesity model. (Supported by Swiss National Science Foundation, Berne.)

1077 RATE OF SYNTHESIS OF NEUROSECRETORY PROTEINS IS NOT INFLUENCED BY SOMATIC POOL SIZE. Robert W. Berry. Dept. Anat., Northwestern Univ. Med. Sch., Chicago, IL 60611.

Feedback inhibition is one conceivable method by which neurosecretory cells could adjust their production of secretory proteins in accordance with physiological demand. Under this hypothesis, the size of the somatic storage pool of proteins destined for axonal transport would influence the rate of synthesis of such proteins. I have tested this hypothesis in cells L11 and R15 of Aplysia. Each of these cells produces a group of low molecular weight proteins which leave the soma by axonal transport, and in each cell these peptides account for 40-50% of the total incorporation of ^{3}H-leucine into protein in a two-hour period. These peptides leave the soma with a half life of approximately 4 hours at 20-25°C, and this decay can be completely abolished by exposure to 0.1 mg/ml vinblastine. Exposure to vinblastine for 4 hours at this temperature does not inhibit incorporation of ^{3}H-leucine into total protein, and can thus induce a doubling of the somatic content of these peptides. However, the extent of incorporation of ^{3}H-leucine into these species during a 2 hour labeling period following 4 hours in vinblastine is identical to that of controls kept in seawater. Furthermore, somatic accumulation of these peptides can also be induced in L11 by crushing its axon close to the soma, and again, this treatment does not affect the relative rate at which it synthesizes the transported proteins. These data indicate that feedback inhibition is not an important mechanism in the short-term regulation of the synthesis of neurosecretory proteins. (Supported by NIH grant NS-11519).

1078 PROGESTIN RECEPTORS IN GUINEA PIG BRAIN: CHARACTERIZATION AND RELATIONSHIP TO LORDOSIS. Jeffrey D. Blaustein, Institute of Animal Behavior, Rutgers University, Newark, NJ 07102.

The synthetic progestin, 17α, 21-dimethyl-19-nor-pregna-4,9-diene-3,20-dione (R 5020), which binds with higher affinity and dissociates less rapidly than progesterone from the progestin receptor, was used to measure progestin receptors in the high speed supernatant of guinea pig central nervous system and pituitary gland. The receptor has an apparent dissociation constant of .2 nM as measured by LH-20 gel filtration. It is progestin-specific; 100x excess of radioinert progesterone, 5α-dihydro-progesterone, or d-norgestrel inhibits ^{3}H-R 5020 binding by more than 50%, whereas corticosterone, cortisol, testosterone, estradiol, dexamethasone and several other steroids do not. The receptor is partially protein in nature; the binding is destroyed by pronase, not DNase or RNase. Although the progestin receptor is detectable in the hypothalamus, preoptic area-septum, cortex, midbrain, amygdala and pituitary gland of ovariectomized guinea pigs, estradiol pretreatment increases the concentration only in the hypothalamus (150%), preoptic area-septum (57%), midbrain (28%) and pituitary gland (144%). The increase in a pooled sample of hypothalamus-preoptic area-septum (HPS) is dependent on the dose of estradiol benzoate injected.

Sequential administration of estradiol benzoate and progesterone results in sexual receptivity in ovariectomized guinea pigs. Following subcutaneous injection of 1.6 µg of estradiol benzoate (slightly above the threshold dose for inducing lordosis when followed by progesterone in our guinea pigs) the HPS progestin receptor content increases between 14-24 hr, peaks by 40-64 hr and decreases by 88 hr. This time course correlates well with the previously reported time course for the induction of sexual receptivity by estradiol benzoate and progesterone. The concentration of cytosol receptor in HPS and midbrain, measured by this assay, is decreased in vivo by behaviorally effective doses of progesterone. Following termination of heat, a refractory period is seen during which time an additional injection of progesterone does not facilitate sexual receptivity. The failure of progesterone to facilitate lordosis correlates with an absence of the progestin receptor in HPS and midbrain. The lack of cytosol receptor may prevent progesterone from exerting its facilitatory effect on sexual receptivity. These experiments are consistent with the notion that brain progestin receptors may mediate at least some of the behavioral effects of progesterone.

1079 INCREASED SERUM GROWTH HORMONE (GH) AND SOMATIC GROWTH IN ADULT HAMSTERS WITH HIPPOCAMPAL TRANSECTIONS. K.T. Borer, R.P. Kelch*, and M.E. Trulson, Departments of Phys. Educ. and Pediat., Univ. Michigan, Ann Arbor, MI 48109 and Dept. Psych., Princeton Univ., Princeton, N.J. 08540.

Lesions of rostral septum lead to increased serum GH and somatic growth and to decreased pituitary GH content and concentration in adult hamsters (Borer et al., Neuroendo., 1977, 23, 133). We examined the hypothesis that this effect was due to damage to fibers of passage by producing bilateral transections of dorsal hippocampus in 30 adult female hamsters (HIPPO) and of overlying cerebral cortex in 30 control animals (CON) with a retractable wire knife. Ponderal and skeletal growth and percentage of body fat were determined in 10 HIPPO and 10 CON hamsters allowed to survive 90 days after surgery. Endocrine changes associated with somatic growth were examined by measuring the concentration of serum GH and insulin with heterologous radioimmunoassays for hamster GH and rat insulin, respectively, and changes in brain neurotransmitter pathways were determined in four brain regions: hippocampus (HIP), cerebral cortex (CC), corpus striatum ST) and diencephalon (D) by the spectrofluorometric method in 20 HIPPO and 20 CON animals killed on 12th postoperative day.

HIPPO hamsters gained weight 10.7 times faster ($p < .001$) between days 3 and 35 and had a 2 to 7% greater ($p < .01$) skeletal growth than CON hamsters. In HIPPO hamsters serum GH was increased regardless of the prandial state (9.6 ± 1.9 vs 2.1 ± 0.2 ug SHAP/ml, $p < .01$) and serum insulin was increased in animals killed ad libitum (16.4 ± 4.2 vs 5.2 ± 1.3 ng/ml, $p < .01$). HIPPO hamsters were significantly fatter than CON (17.9 vs 11.0%, $p < .01$) with obesity accounting for 25% of weight differences between the groups. HIPPO hamsters had significant depletions of 5-HT in HIP (-50%, $p < .001$) and CC (-12.4%, $p < .02$) and of NE in HIP (-37.9%, $p < .001$) and in CC (-16.6%, $p < .01$)

We conclude that 5-HT, NE and/or other nerve fibers travelling through rostral septum to HIP inhibit GH secretion and somatic growth in adult hamsters.

1080 INVOLVEMENT OF ADENOHYPOPHYSIAL DOPAMINE IN THE REGULATION OF PROLACTIN RELEASE. Sara R. Chiocchio*, Miguel A. Cannata*, Jorge R. Cordero Funes* and Juan H. Tramezzani* (SPON: D.A. Pasquier). Instituto de Neurobiología, Serrano 665, 1414 Buenos Aires, Argentina.

Dopamine (DA) was measured in the pituitary anterior lobe and median eminence from lactating rats using a modification of Coyle and Henry's method which increases its sensitivity. The effect of pup separation and suckling was studied in order to correlate changes in DA levels with changes in serum prolactin.

In lactating rats that were separated from their pups low levels of circulating prolactin were found at 2, 4 and 8 hours. DA levels in the median eminence showed a decline at 2 hours; at 4 and 8 hours of separation a significant increase was observed. In the pars distalis the concentration of DA increased with the length of non-suckling interval. Suckling induced a rapid rise in serum prolactin levels in rats that were separated from their pups 4 hours earlier. Under these conditions a significant decrease on DA levels in the median eminence and pars distalis was observed as early as 5 min after the onset of suckling; at 30 min the DA levels were still low. In the situations studied, suckling and pup separation, a negative correlation between serum prolactin and DA levels both in the median eminence and pars distalis was always found. These data suggest a role for adenohypophysial DA in the regulation of prolactin release.

1081 CHARACTERISTICS OF THE ARCUATE NEURONS IN RESPONSE TO MEDIAL PREOPTIC STIMULATION. Carlos M. Contreras* and Ei Terasawa (SPON: R. W. Goy). Wis. Regional Primate Res. Center, Madison, WI 53706.

The medial preoptic nucleus (MPN) is necessary for the release of LH-RH in rats. However, the mode of innervation from this structure to the basal hypothalamus (MBH) remains unknown. A neurophysiological attempt was made to clarify this relation in ovariectomized (OvX) or ovariectomized estrogen primed rats (EB - 5 µg, 2 days prior to recording). A concentric electrode for stimulation was stereotaxically implanted in the MPN under urethane anesthesia. Glass pipette microelectrodes for single unit recording were inserted into the MBH by a parapharyngeal approach. A side-by-side electrode for stimulation was visually placed on the surface of the stalk median eminence (ME) for identification of the recording neurons.

A total of 68 neurons from the OvX rats and 59 neurons from the EB rats were recorded. In both groups about 52-60% of the neurons were recorded from 0.5-1.5 mm depth of the ventral surface (where the arcuate nucleus is located), 32-42% of the neurons were from 1.6-2.5 mm depth and 6-8% of the neurons were from the superficial layer (0-0.5 mm depth). Distribution of neurons responding to ME stimulation in OvX and EB rats was similar: 1) neurons of 19.1% (13/68, mean latency 8.9 msec) in OvX and 18.6% (11/59, mean latency 8.3 msec) in EB were antidromically identified; 2) the remaining 80.9% (55/68) in OvX and 81.4% (48/59) in EB were not antidromically identified, but they were classified as paucisynaptic neurons (latency 15-30 msec, 47.1% in OvX and 35.6% in EB) and as polysynaptic neurons (latency over 30 msec; 33.8% in OvX and 45.8% in EB); 3) the majority of antidromically activated neurons and paucisynaptic neurons were recorded from the arcuate nucleus and a higher percent of polysynaptic neurons with long latency were recorded at 1.6-2.5 mm from the ventral surface. 4) MPO stimulation induced more activation in the antidromically identified neurons than polysynaptic neurons, and MPO stimulation induced more depression in the polysynaptic neurons than antidromically identified neurons in both OvX and EB groups. 5) During MPO stimulation slightly higher percentages of activated neurons and lower percentages of depressed neurons were recorded in the EB group. 6) EB treatment induced prolonged MPO activation and shortened MPO depression in the antidromically identified and the paucisynaptic neurons, while EB treatment produced shortened MPO activation in the polysynaptic neurons.

It is concluded that 1) a major portion of antidromically identified and paucisynaptic neurons originate from the arcuate nucleus, 2) those neurons were activated rather than depressed by MPO stimulation, and 3) this activation is facilitated with EB treatment. (Supported by NIH Grant RR-00167.)

1082 EFFECTS OF BODY WEIGHT VARIATION ON ESTRADIOL INDUCED ACTIVITY. Verne C. Cox and James M. King.[1] Dept. Psychol., Univ. Texas, Arlington, TX 76019.

Previous work (Neurosci. Abs., 1978, 3, abs. no. 1111) has shown that estradiol benzoate (EB) acts on the medial preoptic - anterior hypothalamic area in the female rat to produce increments in wheel running activity. In female rats which have not sustained brain lesions, the increments in activity produced by EB are accompanied by substantial changes in body weight (BW). If EB induced activity is BW regulatory, like estrogenic suppression of food intake, then the EB induction of activity should be modulated by BW level. The present study explored the effects of BW variation on EB induced wheel running activity in female rats. Twenty-four female Holtzman albino rats were maintained in activity wheels for the duration of the study. After a 21 day baseline period, the subjects were ovariectomized, and allowed to recover for 19 days. During this recovery period, 1/2 of the subjects were maintained at their preoperative BW level by restricting their food intake while the rest of the subjects were given unrestricted access to food. At the end of the recovery period, 1/2 of the subjects in each BW condition were given daily subcutaneous injections of 3.0 µg/day of EB for 14 additional days. The postsurgical activity decrement was greatest in those animals given unrestricted access to food. However, EB treatment significantly enhanced activity in both hormone treated groups, and this effect was independent of BW level. When animals in the EB unrestricted group are matched for BW level, before and during EB treatment, it was found that activity levels were higher during hormone treatment. Thus, the activity increments induced by EB are independent of BW level.

[1](Present Address: Neuropsych. Br., BML, DRDAR-CLL-MN, APG, MD 21010).

1083 NORADRENERGIC CONTROL OF PITUITARY OXYTOCIN (OXT) AND ARGININE VASOPRESSIN (AVP): EFFECTS OF ESTROUS CYCLE, OVARIAN HORMONE TREATMENT AND VENTRAL NORADRENERGIC BUNDLE LESIONS. W. R. Crowley, T. L. O'Donohue*, J. M. George* and D. M. Jacobowitz (SPON: M. B. Carpenter). Lab. Clin. Sci., NIMH, Bethesda, Md. 20014 and Dept. Med., Ohio State Univ., Columbus, Ohio 43210.

Several lines of evidence suggest a role for posterior pituitary hormones in reproductive neuroendocrine processes. The present studies employed radioimmunoassays to measure pituitary OXT and AVP over the course of the four day estrous cycle and after ovariectomy and subsequent ovarian hormone treatment in female rats. Because norepinephrine (NE) has been implicated in feedback actions of gonadal steroids, changes in OXT and AVP were correlated with NE levels and turnover in the paraventricular and supraoptic nuclei. Maximal levels of OXT and AVP in the pituitary were attained on proestrus and lowest levels on metestrus. NE levels in the paraventricular nucleus were high during metestrus and diestrus and low during proestrus and estrus. NE in the supraoptic nucleus did not vary during the cycle.

Pituitary OXT levels were elevated 54 hr. after a single injection of estradiol benzoate (5 µg) in ovariectomized rats. Subsequent administration of progesterone (1.5 mg) or a second estradiol injection 48 hr. later did not further increase or decrease OXT levels. A single estrogen injection did not affect AVP levels but subsequent treatment at 48 hr. with progesterone or estrogen significantly elevated pituitary AVP levels when measured 6 hr. later. AVP was significantly decreased 30 hr. after a second estrogen injection. Steroid effects on AVP could be related to NE changes in the paraventricular nucleus because NE levels and turnover were decreased by the treatments that elevated pituitary AVP content. The ovarian steroids did not affect NE in the supraoptic nucleus.

Bilateral transection of the caudal ventral noradrenergic bundle reduced NE in the paraventricular (-30%) and supraoptic (-50%) nuclei, decreased pituitary AVP (-70%) and markedly elevated pituitary OXT (+ 710%).

These studies suggest that pituitary content of OXT and AVP is modulated by central noradrenergic neurons and that this control may mediate the effects of ovarian steroids on posterior lobe hormones.

1084 UPTAKE OF IODOTHYRONINES INTO SYNAPTOSOMES: EVIDENCE FOR A HIGH-AFFINITY TRANSPORT MECHANISM. F. L. Crutchfield*, M. B. Dratman, Veterans Administration Hospital and Medical College of Pennsylvania, Phila., Pa.

Intravenously administered ^{125}I-labeled iodothyronines (T_3*, T_4*) reaching the rat brain become highly localized in synaptosomes (SYN). Although both hormones are taken up to the same degree in brain cytosol, T_3* is approximately 2-fold more concentrated than T_4* within nerve terminals. Measurement of endogenous hormone concentrations in SYN (isotope equilibrium studies) confirm significant enrichment in T_3 relative to T_4. To determine whether different rates of SYN membrane transport of the two hormones might account for the observations, and to gain information regarding mechanisms of iodothyronine transport into SYN, enriched nerve ending preparations, separated from other particulate fractions (on discontinuous sucrose density gradients), were incubated under 95% O_2:5% CO_2 in bicarbonate buffered salt solution (artificial CSF, Glowinski) containing $1x10^{-9}$M T_3* or T_4*. To verify uptake into, as distinguished from binding to, SYN vesicles, portions of prelabeled SYN were treated with either CSF or H_2O; intact and osmotically shocked particles were recovered by centrifugation and identity of iodocompounds* in each pellet determined by means of paper chromatography (2 systems). Results: Uptake rates were highly temperature-dependent, were maximum during the first 3 min (0.2-0.3 pmol/min/mg SYN), reached a plateau in 10 min and were similar for both T_3* and T_4* throughout the 30 min period of observation. At 30 min, iodothyronine* was 40-50 fold more concentrated in SYN than in medium. Addition of increasing concentrations of unlabeled hormone, over a range of $1x10^{-7}$ to $5x10^{-6}$M, progressively decreased labeled hormone uptake. Hypoosmolar conditions produced approximately 40 % loss of iodothyronines* from SYN; most individual metabolites were lost to an equal or greater degree. Conclusions: No differences in rates of T_3* and T_4* transport into SYN were observed in these experiments. Therefore differences in concentrations of the two hormones may be due to differences in their disposal rates. Features of iodothyronine uptake thus far measured: high initial velocity at low amino acid concentrations, saturability, and marked temperature dependence, resemble the high-affinity SYN membrane transport characteristics described for other aromatic amino acids. Supported by funds from the Medical Research Service, Veterans Administration Hospital, Philadelphia, Pa.

1085 PITUITARY-DEPENDENT CHROMATOPHORE CHANGES FOLLOWING FROG DIENCEPHALIC ROOF ELECTRICAL STIMULATION. M. Duff Davis* and Mac E. Hadley* (SPON: P. E. Pickens). University of Arizona, Tucson, Arizona 85721.

Melanophore stimulating hormone (MSH) is known to effect melanin dispersion within pigment cells for adaptive color change in most lower vertebrate species. In higher mammals, including humans, MSH is a modulator of selective attention and other behavioral parameters. This hormone is secreted from the pars intermedia lobe of the pituitary gland. Severing the hypothalamic connections leading into the pituitary releases neuronal inhibition of the pars intermedia with a resulting spontaneous secretion of MSH.

It has long been reported that the sensory input controlling MSH secretion is from photic cues processed through the lateral eyes. However, Oshima and Gorbman (Gen. Comp. Encocrinol. 13: 98-107, 1969) propose that the pineal complex is the light transducer which regulates MSH release via neural tracts through the hypothalamus which then innervate pars intermedia secretory cells.

We have been able to induce darkening of Rana pipiens melanophores in vivo by electrically stimulating the surface of the diencephalon on and immediately surrounding the pineal gland. The latency between onset of stimulation and skin darkening, as measured by a photoelectric reflectometer, is between one and three minutes. Stimulation after hypophysectomy did not lead to melanin dispersion. Continuous stimulus pulses were 1 milliamp in current, 0.5 msec duration and 100 Hz through bipolar stainless-steel electrodes (50 mic.) separated by 0.2 mm.

It is concluded that stimulation of the pineal region influences hypothalamic neurons either through a humoral step via the cerebrospinal fluid in the third ventricle or possibly by direct neuronal connections to the pars intermedia.

(USPHS Grant AM-16282)

1086 LOCALIZED BEHAVIORAL EFFECTS OF TRITIATED ESTRADIOL IMPLANTS IN THE VENTROMEDIAL HYPOTHALAMUS OF FEMALE RATS. P. G. DAVIS*, B. S. McEwen, D. W. Pfaff, Rockefeller Univ., New York, NY 10021.

The ventromedial nucleus (VMN) of the hypothalamus has been implicated consistently in the control of feminine sexual behavior. The broad objective of the present experiments was to determine if estrogenic stimulation of the VMN of ovariectomized (OVX) rats is sufficient to activate lordotic behavior. For this purpose, it was important to determine first the amount of hormone contained within a cannula, the amount delivered to the brain, and the degree of spread from the site of implantation. Thirty gauge implants of undiluted estradiol contain ≃ 10 μg of steroid, which appears to be a considerable excess. Therefore, we chose to use a refined implant technique in which crystalline ^{3}H estradiol (^{3}H-E$_2$) was diluted with cholesterol in a ratio of ≃ one to 300. Such cannulae contain 9-15 ng of ^{3}H-E$_2$. Similar cannulae were implanted unilaterally into the VMN of OVX rats (n=12). Progesterone was administered to the animals on days 3 and 6 post-implantation and tests for feminine sexual behavior were conducted. Seven of the 12 females exhibited lordotic behavior on at least one of the tests ($\bar{X}$ LQs: Test I=38; Test II= 68). Following the last test, animals were decapitated, their brains removed and dissected and whole tissue radioactivity determined by scintillation counting. High levels of radioactivity were recovered from the half of the hypothalamus containing the cannula (350 pg/gm tissue); whereas virtually no radioactivity was recovered from the contralateral side of the hypothalamus, or the preoptic area, amygdala, cortex, pituitary, or uterus (≤ 3% of hypothalamic levels). Determinations of the radioactivity remaining in the cannulae indicated that ≃ 30% of the total was delivered in a 7-day period. Subsequently we showed that similarly prepared bilateral implants produced a reliable degree of lordotic responding without increasing the spread of hormone to regions outside the hypothalamus (whole tissue homogenates: hypothalamus, 990 pg/gm tissue; all other regions, 0.6-3.2% of hypothalamic levels). Determinations of nuclear bound radioactivity in animals with either unilateral or bilateral implants in the VMN revealed a pattern of distribution of radioactivity essentially identical to that shown in whole tissue (individual hypothalami: 17-25 fmoles/mg DNA; other regions: ≤ 6% of hypothalamic levels). These results suggest that behaviorally effective, dilute implants of estradiol exert their actions primarily within the region of implantation. 1087 PROGESTERONE INHIBITION OF ANDROGEN- OR ESTROGEN-INDUCED SEXUAL DIFFERENTIATION IN THE FEMALE HAMSTER. Joseph F. DeBold and Lynwood G. Clemens*. Dept. Psych., Carnegie-Mellon Univ., Pittsburgh, PA 15213 and Dept. Zool., Michigan State Univ., East Lansing, MI 48824.

Progesterone can inhibit a number of central effects of estrogen and androgen in adult rodents. This inhibitory action may be an important component in the ability of progesterone to coordinate sexual receptivity and ovulation and reduce the probability of receptivity in the absence of ovulation. Another possible role of progesterone could be to protect the female fetus or neonate from androgenic or estrogenic stimulation during sexual differentiation. The present study examined the effect of progesterone (P) on sexual differentiation and its protective ability against the action of testosterone propionate (TP) and estradiol benzoate (EB) in developing hamsters.

Entire litters were treated 24hr after birth with either 10ug TP, 2ug EB, 500ug P, 2mg P, 10ug TP + 500ug P, 10ug TP + 2mg P, 2ug EB + 500ug P, 2ug EB + 2mg P or the oil vehicle. In another set of litters the pups were treated with 500ug P, 10ug TP + 500ug P, or 2ug EB + 500ug P 24hr after birth and then also given 500ug P 48 and 72hr after birth. High or repeated dosages of P with or without TP or EB resulted later in some acyclicity and gonadal abnormalities. TP or EB alone did not have either effect. After gonadectomy at 70 days of age the animals were tested for female and male patterns of sexual behavior with appropriate hormone replacement. Neonatal treatment with either EB or TP decreased adult sexual receptivity (defeminization) and induced the capacity for masculine sexual behavior (masculinization) in female hamsters. Neonatal treatment with 2mg P or 500ug P/d x3 (but not a single injection of 500ug P) reduced the defeminizing effect of early EB or TP. None of the P treatments reduced the masculinizing action of EB or TP. Neonatal treatment with P alone had no effect on the adult sexual behavior of either female or male hamsters.

Although P was found to be capable of inhibiting defeminization induced by either EB or TP, this required large dosages of P. Even these large amounts of P failed to reduce the masculinizing influence of EB or TP. However, the effective P treatments did result in higher pup mortality and adult gonadal abnormalities. This weak behavioral action of P coupled with its side effects does not support an important protective role of endogenous P during sexual differentiation in hamsters. In addition, a comparison of the dose-effectiveness of P inhibition of EB induced neonatal sexual differentiation and of EB and P induced adult sexual receptivity seen in earlier studies suggests that these two inhibitory effects of P are subserved by different mechanisms of action.

1088 DOPAMINE LEVELS IN HYPOPHYSEAL STALK BLOOD OF THE RAT DURING SURGES OF PROLACTIN SECRETION INDUCED BY CERVICAL STIMULATION. W.J. de Greef* and J.D. Neill*. (SPON: K.V. Anderson). Physiol. Dept., Emory Univ., Atlanta, GA. 30322.

Stimulation of the rat's uterine cervix establishes a pseudopregnancy and the secretion of two daily prolactin (PRL) surges. One PRL surge is called nocturnal and is secreted from 0100-0700 hr and the other is diurnal and is secreted from 1600-2000 hr (lights on 0600-1800 hr). These surges also can be induced in long-term ovariectomized rats and last for 6 days. We found in the present study that urethane anesthesia (1.1 g/kg BW) did not abolish the PRL surges induced by electrical stimulation of the uterine cervix 16-24 hr before treatment with urethane. Under urethane anesthesia, PRL levels during the nocturnal surge (0130-0430 hr) were 11.8±3.0 ng/ml vs 2.9±0.5 ng/ml in unstimulated rats (mean ± SE, n=6). During the diurnal surge (1530-1830 hr), PRL concentrations were 7.4±1.2 ng/ml vs 2.0±0.6 ng/ml in unstimulated rats (n=6).

There is now strong evidence that dopamine (DA) is a physiological prolactin inhibiting factor. The purpose of this study was to measure DA levels in hypophyseal stalk blood during the PRL surges in urethane-anesthetized, ovariectomized rats. Blood from the hypophyseal stalk was collected for 3-one hr periods during both the nocturnal and diurnal surges. During the nocturnal PRL surge, stalk plasma DA levels were 7.5±2.6 (0230 hr), 6.1±1.3 (0330 hr) and 5.7±0.5 (0430 hr) ng/ml (n=10) whereas in unstimulated rats DA levels at the same time intervals were 10.3±4.0, 12.5 ±4.8 and 8.8±2.6 ng/ml (n=10). During the diurnal PRL surge, stalk plasma DA concentrations were 4.1±0.9 (1630 hr), 3.7±0.7 (1730 hr) and 4.3±0.8 (1830 hr) ng/ml (n=10), whereas in unstimulated rats DA levels at the same time intervals were 7.7±1.9, 6.0 ±1.2 and 6.7±1.3 ng/ml (n=10).

Statistical analysis revealed that DA levels were not significantly different between stimulated and unstimulated rats at any of the individual time intervals. However, when the data from the 3 individual hourly collections during the diurnal surge were pooled, DA levels were significantly lower in stimulated than in unstimulated rats ($P < 0.05$). The correlation coefficient (-0.41) between mean DA levels in hypophyseal stalk blood and PRL levels in peripheral blood at the individual time intervals, was not significant ($P > 0.05$).

Thus, although hypothalamic DA secretion is important for the tonic inhibition of PRL secretion (Gibbs and Neill, ENDOCRINOLOGY 102:1895, 1978) it seems unlikely that changes in DA secretion alone can account for the changes in PRL secretion observed during pseudopregnancy. (Supported by grants from the NIH, HD 04312, and from ZWO, The Netherlands).

1089 EFFECT OF MONOSODIUM GLUTAMATE ADMINISTRATION ON THE TANYCYTES OF THE ARCUATE NUCLEUS. Manuel del Cerro, Edith Hurst (1)*, Kirk I. Moldoff* and Karl M. Knigge. Dept. Anat. and Brain Res. U. of Rochester, Rochester, N.Y. and Dept. Biology, Eastern Mich. U., Ypsilanti, MI (1).

It is well known that the administration of high doses of monosodium glutamate (MSG) to perinatal animals induces widespread neuronal death within the hypothalamic arcuate nucleus. Recently we have shown (del Cerro and Knigge, 77,78) the existence of intimate contacts between the tails of the tanycytes of the third ventricle and the somas of arcuate neurons (Fig. I). Thus we decided to investigate what cytological alterations occur in the tanycytes when the adjacent neurons are destroyed by MSG.

Newborn rats and mice were injected with MSG, at a dose of 4 MG/KG of body weight. The animals were allowed to survive from 6 hrs to 18 months, and studied by optical and electron microscopy. Controls included littermates injected with NaCl and non-injected animals. 24 hrs after injection most of the arcuate neurons show signs of advanced degeneration. By 48 hrs the neurons undergo lysis, but the adjacent tanycytes do not show any obvious damage. Their tails extend unaltered across pools of liquified material resulting from the dissolution of the neuronal elements (Fig. II). However, in animals sacrificed months after the injection, the tanycytic somas appear distorted and their nuclei abnormally orientated in relation to the ventricular surface. The more striking finding, however, is that the tanycytic tails have disappeared. This causes a profound change in the geometry of the tanycyte, which loses its contact with pial and neural elements and adopts the configuration of a low cuboidal epithelium (Fig. III).

These experiments show that if the neural-glial associations in the arcuate nucleus are disrupted, by destruction of the neural elements, the glial component undergoes a slow but extensive morphological regression. This result is consistent with the idea, postulated by this and other laboratories, that the tanycytes may functionally link hypothalamic neurons with the CSF of the III ventricle.

1090 HETEROGENEOUS AXOPLASMIC RETICULUM (AR) IN PEPTIDERGIC NEUROSECRETROY (NS) NEURONS: POSSIBLE ROLE IN HORMONE TRANSPORT AND VESICLE FORMATION. H. Dieter Dellmann*, Mona Castel* and John G. Linner* (SPON: D. G. Emery). Department of Veterinary Anatomy, Pharmacology and Physiology, Iowa State University, Ames, IA 50011 and Zoology Department, Hebrew University of Jerusalem, Israel.

Ultrastructural studies of the hypothalamo-neurohypophysial system (HNS) in several rodent species and in the frog reveal extensive AR extending from the NS perikarya into the axon terminals. This reticulum consists of anastomozing tubes often containing electron-dense material similar to that in the neurosecretory granulated vesicles (NGV). Constrictions and dilatations are seen along the tubes from which NGV may bud. NGV bearing protrusions, like vestiges of reticulum, are apparent and reticular connections may exist between NGV (Castel, M.: Gen. Comp. Endocr. 31: 63, 1978).

AR is scarce in the HNS of normal adult animals, but increases after water deprivation,hypertonic saline administration, excessive doses of HRP, stalk transection or compression and after adrenalectomy. The HNS of fetal and neonatal rats is particularly well endowed with AR. We suggest that this electron-dense AR may transport hormone and carrier or precursor, representing an extension of the Golgi complex into the axon. The NGV may be formed not only in the perikaryon but also along the axon and even in the axon terminal.

The AR of the HNS is heterogeneous. In addition to that described above, electron-lucent tubules of AR are seen, often fragmenting into vesicles. Furthermore, a type of narrow and extensively anastomozing AR is present under some experimental conditions, but is usually not associated with NGV or vesicles. These other types of AR in NS axons are possibly concerned with anterograde and retrograde axonal transport of substances, other than hormones.

The electron dense AR with which the NGV are associated may represent the avenue of fast axonal transport postulated by Droz (In: The Nervous System, D. B. Tower, ed., Vol. 1, pp. 111-127, Raven Press, New York, 1975). In the stressed HNS and in the fetal and neonatal HNS it becomes abundant, demonstrating a remarkable adaptation of the neuron to the organism's increased hormone demand.

1091 SEROTONERGIC MODULATION OF THE EFFECT OF STRESS ON THE PLASMA ACTH AND CORTICOSTERONE RESPONSES TO SUBSEQUENT STRESS. Errol B. De Souza* and Glen R. Van Loon* (SPON: **D.R.Crapper**). Depts. of Medicine and Physiology, University of Toronto, Toronto, Canada.

The possibility that plasma ACTH and corticosterone responses to stress may be modified by prior exposure to stress was examined in male Sprague-Dawley rats using a 2 min. immobilization stress. The discrete 2 min. immobilization stress is a low to medium intensity stimulus to the adrenocortical system which produces a submaximal plasma corticosterone response that peaks at 15 min. (35.8±3.6 ug/dl; mean ± S.E.M.) and returns to the control range by 90 min. (12.5±3.4 ug/dl). The peak ACTH response to a single stress occurs at 5 min. (117.0±11.0 pg/ml) and returns to basal levels by 30 min. (62.0±13.5 pg/ml). A second stress was then applied at varying intervals (30, 60 and 90 min.) after the initial stress in an attempt to study the effect of stress-induced ACTH and corticosterone secretion on subsequent stress responses. Peak ACTH and corticosterone responses always occurred at 5 and 15 min. respectively following the second stress. The level of the peak responses were similar in magnitude to the corresponding levels following a single stress, but the duration of elevation was less in the 30 and 60 min. stress groups. The plasma corticosterone time course of the second stress applied at 90 min. was almost identical to that following a single stress. The time courses of plasma ACTH and corticosterone following four repeated stresses at 90 min. intervals (stress at 0, 90, 180 and 270 min.) reflect those to a single stress. Incremental (base to peak differences) plasma ACTH and corticosterone responses were similar in rats that received 1 to 7 repeated stresses at 90 min. intervals. These data suggest that prior exposure to discrete stresses does not modify ACTH and corticosterone responses to subsequent stresses, provided that the stresses are separated by an interval (90 min.) allowing plasma corticosterone to return to control levels. A second stress applied during the recovery period (refractory period) results in inhibition of the total corticosterone response (integrated area). Correlation was demonstrated between plasma ACTH and corticosterone responses to stress in refractory versus responsive periods with changes in concentrations of serotonin and 5-hydroxyindoleacetic acid in discrete brain regions. These data suggested that during the refractory period hypothalamic and cerebral cortical serotonin turnover and release were increased, and suggested further that brain serotonin may play an inhibitory role in modulating the ACTH and corticosterone responses to a subsequent stress applied during the refractory period.

1092 FEMALE FROG REPRODUCTIVE BEHAVIOR ELICITED IN THE ABSENCE OF THE OVARIES. Carol Diakow, Josiah N. Wilcox*and Richard Woltmann*. Biology Department, Adelphi University, Garden City, N.Y. 11530.

A release call is emitted by unreceptive female frogs when they are clasped around the trunk; this call is inhibited in receptive females. A recent study indicates that water accumulation induced by arginine-8 vasotocin causes a mechanical distension that inhibits the call (Diakow, Sci. 199: 1456, 1978). This finding, that a posterior pituitary hormone is important for mating behavior, leads to the question of the role of ovarian steroids in the reproductive behavior of the female frog, and the experiments reported here address this question.

In one experiment, ovariectomized female Rana pipiens given subcutaneous estradiol and/or progesterone continued to call at a rate equivalent to that of unreceptive females. These results fail to provide evidence that ovarian steroids inhibit the release call.

In another experiment, the release call was inhibited in the absence of the ovaries by distension of ovariectomized Rana pipiens with intraperitoneal fluid. These results are consistent with the interpretation that the release call is inhibited by a mechanism that involves water accumulation, but not ovarian participation.

1093 CONTROL OF RELEASE OF ACTH AND VASOPRESSIN BY SUPRAOPTIC AND PARAVENTRICULAR NUCLEI. Anne Dornhorst*, Drew E. Carlson*, Said M. Seif*, Alan G. Robinson*, Earl A. Zimmerman and Donald S. Gann. The Johns Hopkins Univ. Sch. Med., Baltimore, MD 21205, Univ. Pittsburgh Sch. Med., Pittsburgh, PA 15261 and the College of Physicians and Surgeons, Columbia Univ., New York, NY 10032.

To determine the relative roles of the supraoptic (SON) and of the hypothalamic paraventricular (PVN) nuclei in the control of release of vasopressin and of ACTH, we have examined the hormonal responses to electrical stimulation of these regions. Cats (38) were anesthetized with chloralose-urethane, artificially respired, and immoblized with gallamine. Electrical stimulations (200μA, 0.2msec, 100 HZ, 20sec) were delivered with bipolar coaxial electrodes, positioned stereotaxically. Blood samples were taken 30 seconds prior to stimulation and 1.5 minutes poststimulation. Hypovolemia was prevented by simultaneous infusion of equal volumes of warmed isoncotic dextran. ACTH and vasopressin were measured in plasma by radioimmunoassay. Stimulation sites were determined histologically. Eleven brains were immunostained for vasopressin using the triple-layer peroxidase-antiperoxidase method of Sternberger. The relative vasopressin content of neurons was measured as the mean optical density of stained cells by means of a microdensitometer. Stimulation of the lateral portion of the supraoptic nucleus (SON) increased vasopressin (2.1±0.5μU/ml, N=14, $p<0.01$) and decreased ACTH (-26±4 pg/ml, N=13, $p<0.01$). In contrast, stimulation of the hypothalamic paraventricular nucleus (PVN) increased vasopressin (2.2±0.7μU/ml, N=7, $p<0.02$) and increased ACTH (107±20 pg/ml, N=32, $p<0.01$). Stimulation of either nucleus decreased the vasopressin content of neurons adjacent to the electrode (-30.5±3.5%, N=8, $p<0.001$). In addition, the immunostaining of the descending projections from these nuclei became more prominent. Stimulations in regions which led to no hormonal changes yielded no cytochemical differences. Previous work has shown that vasopressin neurons of PVN, but not of SON, project to the zona externa of the median eminence. Others have suggested that retrograde flow of blood from the neural lobe to the median eminence and thence to the anterior lobe would allow vasopressin to influence the release of ACTH. The present results indicate that both SON and PVN control the release of vasopressin. However, PVN facilitates, but SON inhibits, release of ACTH. These findings suggest that a projection from PVN to the median eminence mediates release of ACTH, and that retrograde flow from the neural lobe is not important in the short-term control of ACTH.

1094 EFFECT OF OVARIAN HORMONES ON NEURONAL MEMBRANE SENSITIVITY TO HYPOTHALAMIC-RELEASING HORMONES. Carol A. Dudley* and Robert L. Moss. Dept. of Physiology, Univ. of Texas Health Science Center at Dallas, Dallas, Texas 75235

The ability of ovarian hormones to affect neuronal membrane responsiveness to iontophoretically applied luteinizing hormone-releasing hormone (LRH) and LRH analogs was evaluated in ovariectomized (OVX) non-primed and OVX, estrone (E)-progesterone (P) primed female rats. Extracellular action potentials were recorded from 274 medial preoptic (MPO) neurons. The spontaneous activity of these neurons was monitored to detect changes resulting from microelectrophoretic deposition of 1mM solutions of LRH, LRH agonist analog (D-Trp^6, Pro^9 NHEt[LRH+]), and/or LRH inactive analog (des-Pro^9-Gly^{10}[LRH^o]). One hundred and seventy MPO units (n=170) were recorded in OVX rats while the remaining units (n=104) were found in OVX, E-P primed females. A summary of the results is presented in the table below.

Agents Microelectrophoresed	N	Response In Untreated Ovariectomized Female Rats			N	Response In Estrogen-Progesterone Treated Ovariectomized Female Rats		
		↑	↓	→		↑	↓	→
LRH	170	52 (31%)	22 (13%)	96 (56%)	104	51 (49%)	3 (3%)	50 (48%
LRH$^+$	135	49 (36%)	15 (11%)	71 (53%)	103	57 (55%)	2 (2%)	44 (43%
LRH^o	98	30 (31%)	14 (15%)	52 (54%)	87	43 (50%)	3 (3%)	41 (47%

In the OVX rat, the majority of cells recorded were found to be unresponsive to the microelectrophoresis of the releasing hormones. Of the responsive neurons, more displayed excitation than inhibition. In contrast to the relative inability of these hormones to effectuate changes in spontaneous activity in non-primed females, the predominant response to LRH and its analogs in E-P primed females was excitation. A 2 x 3 x 3 chi square analysis conducted on responsiveness to LRH and its analogs in primed and non-primed rats yielded a significant association between hormonal status and response. Primed animals were more likely to respond to a given LRH drug with excitation, regardless of the LRH drug tested. Although the excitatory effects produced by LRH^o are perplexing, preliminary experiments with an LRH antagonist analog in OVX rats have resulted in more inhibition than excitation. The observation that neuronal responsiveness to LRH is dependent on the hormonal status of the animal is consistent with LRH's postulated role in mediating gonadotropin secretion and mating behavior.

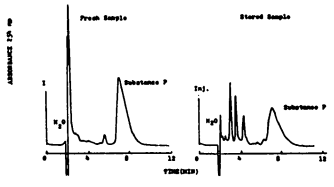
1095 POSTNATAL DEVELOPMENT OF THE LUTEINIZING HORMONE-RELEASING HORMONE (LHRH) SYSTEM IN NORMAL AND NEONATALLY ESTROGENIZED RATS. Karen E. Elkind*, Joan C. King, and Arnold A. Gerall. Dept. Psychol., Tulane University, New Orleans, LA., 70118.

The postnatal development of the luteinizing hormone-releasing hormone (LHRH) system was studied in normal and neonatally estrogenized rats using the peroxidase-antiperoxidase immunocytochemical technique of Sternberger et al (J. Histochem. Cytochem. 18: 315, 1970). Thirty-three male and 33 female albino rat pups were randomly assigned to one of 4 experimental treatments on day 2 (day 1= day of birth): the high dosage group was injected with 1000µg of estradiol benzoate (EB) dissolved in 0.05 cc sesame oil, the low dosage group with 1 µg EB in 0.05 cc sesame oil, the control group with an equivalent amount of the oil vehicle and a handled control group which received no injection. Two to 3 animals from each group were perfused on days 6, 9, and 11 after birth and the brain prepared for immunohistochemical study. The distribution of LHRH processes in the neonatal animal resemble that described for the adult; a rostral pathway is located close to the organum vasculosa of the lamina terminalis (OVLT) in the vicinity of the rostral preoptic area (POA) and another caudal one extended throughout the arcuate-median eminence (ARC-ME) region. LHRH immunopositive cell bodies were found in the rostral POA but not in the ARC-ME region. The pattern of development of LHRH positive perikarya is to be described for the first time in the neonatal rat.

The present study provides immunocytochemical evidence for salient maturational differences between males and females in the distribution of LHRH perikarya. Both the intensity of positive stained processes and the number of LHRH cell bodies localized are greater in the normal male than in the female neonatal rat at all ages. The high dosage of neonatal estrogen reduced the number of immunoreactive perikarya visualized and the intensity of stained processes in the male while estrogen enhanced the staining of LHRH elements in the female. The results also indicate that early estrogen treatment alters the LHRH system in a dose dependent manner. The data are consistent with the hypothesis that the hypothalmic-pituitary-gonadal inhibitory feedback system is functional earlier in the male than in the female rat. It is concluded that the administration of exogenous estrogen neonatally modifies the organization of the hypothalamic LHRH system as well as the mediation of reproductive function in adulthood.

1096 HYPOTHALAMIC PEPTIDES - PURITY, STABILITY AND MEASUREMENT BY HIGH PERFORMANCE LIQUID CHROMATOGRAPHY (HPLC). Joseph A. Feldman*, Major L. Cohn and Dorothea Blair* (SPON: Richard W. Keller, Jr.) Duquesne Univ. and Dept. Anes. Magee-Womens Hosp., Univ. Pgh. Sch. Med., Pittsburgh, PA 15123.

Although radioimmunoassay has permitted detection of the neuropeptides in brain structures, the technique is associated with serious shortcomings. Until recently, available methodology was not sensitive enough to efficiently determine purity and stability of synthetic neuropeptides. We are now reporting our new HPLC method which separates, identifies, quantifies and purifies the tripeptide thyrotropin releasing hormone (TRH), the pentapeptides met and leu enkephalin, the decapeptide luteinizing hormone releasing hormone (LHRH), the eleven amino acid peptide substance P and the tetradecapeptide somatostatin. Our equipment consists of a Waters Associate HPLC System with a M-6000 A pump, a U6K septumless injector, a reversed phase analytic column and a model 450 variable wavelength U.V. detector. The reversed phase solvent system varied according to specific peptide tested. The eluting system was run isocratically at room temperature at a flow rate of 1.5 ml/min. With detector set at 254 nm and the eluting solvent system 50% MeOH/50% HAc (8%) pH 2.9, K' values for LHRH, substance P and somatostatin were recorded respectively at 2.10, 6.08 and 10.19. Under identical conditions, met and leu enkephalin were separated; K' values for the peptides were recorded at 1.17 and 1.67 respectively. For TRH, which does not absorb at 254 nm, with the detector set at 215 nm and an eluting system of 50% MeOH/50% HAc (0.1%), a K' value of 1.23 was obtained. Our HPLC technique demonstrates that 1) several peptides lack chromatographic homogeneity; 2) dissolved in water several peptides are not stable; new absorbance peaks appear while the peak representing the parent compound disappears. For example LHRH in aqueous solution is stable if kept for 3 months at 8°C while TRH, substance P (Fig) and somatostatin show significant structural alterations in a short period of time.



1097 CORRELATION OF HYPOPHYSIAL PORTAL PLASMA DOPAMINE AND PERIPHERAL PLASMA PROLACTIN: EFFECTS OF INTRAVENTRICULAR HISTAMINE AND ACETYLCHOLINE. D.M. Gibbs*, P.M. Plotsky, and J.D. Neill*, (SPON: J. W. Manning). Dept. Physiol., Sch. Med., Emory U., Atlanta GA 30322

Dopamine secreted by the hypothalamus into the hypophysial stalk vessels has a physiologic role, at least tonically, in the inhibition of pituitary prolactin secretion (ENDOCRINOLOGY 102:1895 1978). The role of dopamine in the dynamic regulation of prolactin is still unknown. Histamine is one of many putative hypothalamic transmitters which stimulate prolactin secretion when injected into the cerebral ventricles. Histamine antagonists interfere with a number of physiologic and pharmacologic stimuli of prolactin secretion suggesting that the functional site of histamine action is relatively close to the final hypothalamic output to the pituitary. We studied the effect of 10µg histamine injected into the lateral ventricle of urethane anesthetized, diestrous rats. Prolactin levels in 5 control rats injected with acidified saline increased only to 111% ± 5 (mean ± SE) of baseline values while prolactin levels in 6 rats injected with histamine increased to 692% ± 134 of baseline ($P < 0.005$). Stalk plasma dopamine levels in 7 control rats injected with acidified saline increased to 117% ± 16 of baseline values while dopamine levels in 8 rats injected with histamine decreased to 74% ± 6 ($P < 0.025$). While it appears that the effect of histamine to increase prolactin secretion may be mediated by a decrease in hypothalamic dopamine secretion, it remains to be determined if the observed 35% decrease in stalk plasma dopamine concentration can account for a 7 fold increase in prolactin release.

ACh is another putative hypothalamic transmitter that may be involved in the regulation of prolactin secretion. In most previous studies, ACh caused a decrease in prolactin secretion in unanesthetized rats. We were surprised to find that in 5 urethane anesthetized diestrous rats, 50µg ACh injected into the lateral ventricle caused prolactin to increase to 2580% ± 410 of baseline values. This stimulation of prolactin by ACh was seen over a wide range of ACh doses under urethane and pentobarbital anesthesia, and in urethane anesthetized, ovariectomized estrogen-progesterone treated rats. However, stalk plasma dopamine levels in 8 diestrous rats injected with ACh were 93% ± 17 of baseline. This response was not significantly different from the response in rats injected with saline.

These data suggest that the effects of histamine on prolactin secretion may be mediated by dopamine, but that the effects of ACh probably involve some other hypothalamic factor(s).

1098 IMMUNOCYTOCHEMICAL STAINING OF DOPAMINE RECEPTORS ON MAMMOTROPHS. Paul C. Goldsmith*, Michael J. Cronin*, Robert J. Rubin* and Richard I. Weiner. Dept. of Ob., Gyn. and Reprod. Sci., U.C. Sch. Med., San Francisco, CA. 94143, and Dept. Psych., U.C.L.A. Sch. Med., Harbor Gen. Hosp., Torrance, CA. 90509.

Dopamine in physiological concentrations inhibits prolactin secretion. A high affinity, saturable dopamine receptor has been characterized in crude homogenates of the anterior pituitary with various radioligands including haloperidol (Hal). In the present study we have demonstrated immunocytochemically that the majority of these receptors are located on mammotrophs.

Anterior pituitaries from mature female rats were dispersed using the technique of Hopkins and Farquhar. Intact cells were separated from debris by centrifugation through 4% BSA. The cells were incubated overnight at 37°C in Medium 199 containing Earle's salts, glucose, HEPES buffer, BSA and antibiotics (CM199) with 14% fetal calf serum added. Ninety percent of these cells appeared viable by the exclusion of trypan blue. The presence of functional dopamine receptors was verified by the ability of 10^{-5}M dopamine to inhibit 50% of the prolactin released.

Aliquots of unfixed or lightly fixed cells were washed in CM199 and incubated in $2x10^{-7}$M Hal in CM199. Following intervening washes and centrifugation in CM199, cells were suspended in 1:20 to 1:100 rabbit antiserum to Hal-BSA conjugate (R-a-Hal), 1:100 goat antirabbit IgG, and finally 1:100 rabbit PAP. After reaction with substrate, cells were fixed with dilute Karnovsky mixture and post-fixed in osmium. Pellets were embedded in agar, dehydrated, stained with uranyl acetate, embedded in Araldite, and thin sectioned for electron microscopy. Two or more PAP complexes at membrane sites were interpreted as positive binding. Cell types were identified on a basis of established ultrastructural criteria for the rat anterior pituitary.

Patches of characteristic PAP complexes appeared on the plasmalemma of the vast majority of mammotrophs. PAP complexes were preferentially observed on microvilli and in plasmalemmal invaginations. Immunostaining was also observed on the inner face of apparent endocytotic vesicular membrane. Staining was infrequently observed on somatotrophs, to a lesser degree on gonadotrophs, and was not seen on other pituitary cell types. Controls included elimination of Hal, co-incubation of cells with Hal and 100-fold excess of d-Butaclamol, substitution of CM199 for one of the three antisera, or use of R-a-BSA in place of R-a-Hal or R-a-Hal absorbed with excess Hal. These controls had reduced or absent staining on mammotrophs and other cell types. Dopamine receptors on mammotrophs support the function of dopamine as prolactin inhibitory hormone. 1099 EFFECTS OF ESTROGEN ON BRAIN AND PITUITARY POLYAMINES IN THE OVARIECTOMIZED RAT. H.E. Gray, T.W. Jasper*, W.G. Luttge, J.B. Shukla* and O.M. Rennert*. Dept. Neuroscience, Univ. Fla. Coll. Med., Gainesville, FL 32610 and Dept. Pediatrics, Univ. Oklahoma Health Sci. Center, Oklahoma City, OK 73190.

The natural polyamines, especially putrescine (PUT), spermidine (SPD) and spermine (SPM) have been implicated in a variety of essential cell functions in several tissues including the mammalian central nervous system. For example, recent studies using peripheral steroid target tissues have suggested that polyamines are involved in the mediation of steroid-induced alterations in RNA and protein synthesis. Since many estrogenic effects within the central nervous system also appear to require ongoing RNA and protein synthesis, we have thus initiated an investigation of the effects of estradiol on the levels of endogenous polyamines in several brain regions of adult female rats.

Two weeks following ovariectomy rats were injected with 20 µg estradiol benzoate (EB) or the oil vehicle and killed by perfusion 12, 24, or 36 hrs later after the removal of a blood sample. PUT, SPD and SPM are now being determined by high-pressure liquid chromatography (Durrum D-500) in extracts of plasma, pituitary, cerebral cortex, whole hypothalamus and amygdala. Preliminary results from the group receiving EB or oil 24 hrs prior to killing reveal significant estrogen-induced alterations in polyamine metabolism in both brain and pituitary. In the pituitary, concentrations of all three polyamines were elevated by EB priming. However, in the hypothalamus only SPD and SPM were elevated, while PUT showed a significant decrease in endogenous concentration. Amygdala and cortex showed small, marginally significant changes in SPM and SPD, respectively. Polyamine concentrations in plasma were unaltered by EB treatment.

Thus, although polyamine metabolism in the hypothalamus and pituitary are both responsive to EB priming, the patterns of the responses, at least in the 24 hr group, may be fundamentally different and may reflect the different functional roles of estrogen in these very dissimilar tissues. When completed, the analysis of samples from the rats receiving 12 and 36 hrs of EB priming will provide a time course for the hormone-induced changes.

1100 CELLULAR ANALYSIS OF A SEXUALLY DIMORPHIC REGION OF THE PREOPTIC RAT BRAIN. R.E. Harlan*, C.D. Jacobson*, J.E. Shryne* and R.A. Gorski. Dept. Anat., Sch. Med., UCLA, Los Angeles, CA 90024.

In the preoptic area (POA) of the rat brain, a distinct area of increased nissl staining is found, the volume of which is sexually dimorphic (larger in males). To examine the cellular characteristics of this area and to determine possible bases of this sex difference, cresyl-echt violet stained 10µ sections were projected through a closed circuit television camera and monitor so that three investigators could view and characterize the same cells simultaneously. A fourth person measured the longest diameter of each cell. Nearly 5000 cells were evaluated. An area encompassing the sexually dimorphic region and regions adjacent to it was systematically analyzed. One coronal section was viewed in each of 4 male and 4 female gonadectomized rats, without the investigators' knowledge of the sex of the subjects. Each cell was rated by each investigator according to the following parameters: intensity of staining (light, medium or dark), shape (round, medium or angular), the presence of processes extending from the soma, and the presence of a nucleolus. The rating score for each cell was defined as that score agreed upon (in subsequent data analysis) by at least two investigators. After completion of the cell characterization, outlines of the sexually dimorphic area were drawn for each animal. Comparison between the drawings and the area viewed through the TV monitor allowed the assignment of each cell to a position outside or inside the sexually dimorphic area. Since the mean density ($\bar{x}$ number of cells per 37.5µ grid) of cells inside the drawn borders was significantly greater than the density outside, in both sexes, the sexually dimorphic region can be described as a nucleus, here called the Sexually Dimorphic Nucleus of the POA (SDN-POA). The density of cells either outside or inside the nucleus was not sexually dimorphic. The area of the SDN-POA was about 60% larger in males than in females. Inside the nucleus, the mean cell size of males (10.1µ) was significantly ($p < 0.01$) larger than that of females (9.2µ; Mann-Whitney U test). After dividing the cells into three size groups, we found that, of those cells inside the SDN-POA, there was a significantly greater proportion of relatively large cells (>12.5µ) in males than in females; 22.6% were large in males compared to 13.6% in females. Although no significant sex differences were found in any other cellular characteristic, in males a larger proportion of cells were angular inside than outside the nucleus. In summary, 1) the sexually dimorphic region of the POA is indeed a nucleus, 2) within this nucleus the mean cell size is larger in males than in females, apparently due to an increase in the proportion of large cells, and 3) in males, the frequency of angular cells is greater inside than outside the nucleus. (Supported by HD 01182.)

1101 INTRACELLULAR RESPONSES FROM THE PARAVENTRICULAR NUCLEUS IN SLICES OF RAT HYPOTHALAMUS. G.I. Hatton, B.A. MacVicar and F.E. Dudek. Depts. of Psych. and Zool., Mich. State Univ., E. Lansing, MI 48824, and Dept. of Zool. and Erindale Coll., Univ. of Toronto, Mississauga, Ont.

Little is known about the physiology of intrahypothalamic cellular interactions, in part because of the difficulty of obtaining intracellular recordings from hypothalamus. Recent work (Hatton et al., Neurosci. Abstr. 3:345, 1977) demonstrating the viability of hypothalamic slices and the physiological nature of the spontaneous unit activity in such preparations suggested the feasibility of studies of cellular physiology and synaptic relationships (or lack thereof) within relatively circumscribed hypothalamic regions. The paraventricular nucleus (PVN), due to recent anatomical findings of far-reaching and varied connections, is among the more interesting of hypothalamic nuclei, especially since no intracellular data have been reported for this nucleus and only two reports have been made of intracellular recording in mammalian magnocellular neurosecretory neurons of which PVN, in large part, consists.

Intracellular recordings were obtained from the PVN in 400 µm thick slices of rat hypothalamus. Activity patterns observed included cells that were either silent, slow-irregular or bursting. The action potentials of some of these cells were characterized by long durations (2.5 msec at ½ amplitude or 4-5 msec at threshold) and followed by afterhyperpolarization. Other cells in the PVN displayed short-duration action potentials (1-1.5 msec at ½ amplitude). Small depolarizing potentials with a fast rising phase, slow decay, and graded in amplitude up to 11 mV also occurred spontaneously. Since weak hyperpolarizing current injection could increase the amplitudes of these depolarizations, they probably arise from chemical synaptic inputs within the slice. Extracellular stimulation lateral to the PVN appeared to evoke excitatory postsynaptic potentials, which also increased in amplitude during small hyperpolarizing currents. These results suggest the presence of local circuits at the level of PVN. The long- and short-duration action potentials probably represent magnocellular neurosecretory and parvocellular non-neurosecretory cells, respectively. The electrophysiological characteristics of these intracellular responses in vitro are consistent with earlier in vivo and in vitro studies.

1102 MAGNITUDE OF THE RESPONSE OF THE PITUITARY-ADRENAL SYSTEM IS A FUNCTION OF THE DEGREE OF STIMULUS UNFAMILIARITY. J. P. Heybach*†, M. B. Hennessy*‡, J. Vernikos-Danellis*† and S. Levine‡ (SPON: W. R. Mehler). †NASA/Ames Res. Ctr., Moffett Field, CA 94035; ‡Dept. of Psychiatry & Behav. Sci., Stanford Univ., School of Med., Stanford, CA 94305.

Measurement of fluctuations in adrenal corticoid levels has been widely used as an index of emotional state. Yet it has been recently argued that the adrenal response is insensitive (i.e., cannot distinguish various levels of emotional state) and therefore is an ineffective measure of emotionality. This conclusion was based on studies in which rats exposed to a range of intensities of stimulation never showed more than two levels of corticoid elevation. However we have recently shown that the corticoid response of mice can accurately reflect various intensities of psychological stimulation, i.e., degrees of unfamiliarity. The present study extends these findings to the rat and examines concomitant changes in ACTH.

Rats were exposed for 15 min to three apparatus which differed in their degree of unfamiliarity. A linear increase in plasma corticosterone concentrations over the resting level was found as a function of the degree of unfamiliarity. A control group which received the same handling as did the experimental animals showed corticosterone concentrations which were significantly greater than the basal control group, and significantly less than any of the experimental groups. Plasma ACTH concentrations displayed a pattern similar to that found for plasma corticosterone. Although ACTH concentrations obtained here are probably not maximal, the values are interpreted as reflective of group differences at the time of peak circulating levels. Thus overall, four distinct levels of pituitary-adrenal activity were observed in the present study. These data confirm the capacity of the pituitary-adrenal system to differentiate various levels of stimulus intensity under appropriate conditions.

1103 DIURNAL CHANGES OF MELATONIN IN RETINA, PINEAL GLAND, SUPRACHIASMATIC NUCLEUS, COLON, AND DUODENUM OF THE RAT. W. R. Holloway*, L. J. Grota, and G. M. Brown. Dept. Psych., Sch. Med., U. Roch., Roch., N. Y. 14642, and Dept. Neurosci., McMaster U., Hamilton, Ontario, Canada.

Melatonin(M) has been localized immunohistologically in a number of extrapineal areas (Br. Res. 118:417, 1976; Exp. 33: 662, 1977). Although known to exhibit a diurnal fluctuation in the pineal, daily rhythms of M in other organs have not been established. Because of its potential role in physiological functioning, relative M levels were determined using quantitative immunohistology in several tissues of the rat during the 24 hour day. Adult male Charles River rats, kept on a 12:12 light:dark cycle, were decapitated at 3 hr intervals beginning 1.5 hr after light onset. Unless noted, n = 4 per time period. Trunk blood was collected and the pineal gland(P), eyes(R), suprachiasmatic area of the hypothalamus(SCN), duodenum(D), and descending colon (C) were removed and frozen on dry ice. Tissues were sectioned in a cryostat at 10um. The presence of M was determined with a modified Coons double antibody technique, using a highly specific anti-M antibody (sheep) and FITC labeled anti-sheep IgG (Miles). Fluorescence intensity was measured with a CdS photocell having its maximum spectral sensitivity (515nm) close to the emmission peak of FITC (520nm). The photometer reading differences between sections stained with anti-M serum and adjacent sections stained with normal sheep serum were used in all statistical analyses.

Plasma corticosterone exhibited a normal rhythm with peak and trough 1.5 hr after lights-off(L-off) and 4.5 hr after lights-on (L-on), respectively. M content of the P had a single broad peak, beginning late in the light period and falling sharply to background 7.5 hr after L-off. The SCN showed a similar pattern, although only 2 animals were observed at each point. Three tissues exhibited double peaks, or troughs. The C, with intense fluorescence in the epithelial layer, had a major peak 7.5 hr after L-on, with a smaller increase 4.5 hr after L-off. The R, with fluorescence in both the inner and outer nuclear layers, mirrored the C pattern. There was a large drop in intensity 7.5 hr after L-on, with a smaller decrease 4.5 hr after L-off. The D, with specific fluorescence in the lamina propria of the villi, had 2 minima; the first 7.5 hr after L-on, the second 4.5 hr after L-off.

These results indicate the usefulness of this method for measuring M. Possible influences of M from these areas on rhythmic processes and functions in the specific tissues studied will be discussed.

Supported in part by NIMH grant MH-14650.

1104 PERSISTANCE OF A CIRCADIAN RHYTHM OF N-ACETYLTRANSFERASE IN THE CHICK PINEAL IN VITRO. C.A.Kasal*, M.Menaker, and J.R. Perez-Polo. Dept. Zool., Univ. Texas, Austin, TX 78712 and Dept. of Human Biol. Chem. and Gen.,Univ. of TEX Med Branch,Galveston, Tx 77550.

A circadian rhythm in melatonin production has been demonstrated in the pineal gland of birds and mammals. Examination of levels of N-acetyltransferase (NAT), the enzyme involved in melatonin production, also reveals a circadian rhythm. The location of the oscillator (clock) driving these rhythms appears to differ between birds and mammals. In rats, the oscillator is located somewhere outside the pineal gland and controls the levels of NAT via adrenergic innervation. In contrast, experiments in sparrows have produced evidence supporting the hypothesis that the oscillator controlling melatonin production resides within the pineal gland.

The present study was carried out to determine whether the rhythm of NAT activity will persist under constant conditions in vitro. White Leghorn chicks were raised from one day of age under the same lighting regime (12 hours light-12 hours dark). At three weeks of age animals were sacrificed, pineals removed and placed into culture. Examination of days one and two in culture entailed placing cultured glands directly into constant darkness(DD) and sampling glands every four hours. A significant rise and fall in NAT activity occured during the projected night of day one, remained low during the projected day period of day two and rose again on the night of day two. Experiments on days three and four entailed placing glands into culture for two days under the continued lighting regime of the intact animal. Media was changed on day three and then the glands were placed into DD at which time sampling began at four hour intervals. Again levels of NAT increased during the projected night period of day three, fell and remained low during the projected day period of day four, rose again in the projected night period of day four and fell again during the day period of day five.

These findings of a perisitant rhythm of NAT in vitro support the propostion that the avian pineal gland is a source of endogenous oscillation in the bird.

1105 QUANTITATIVE AUTORADIOGRAPHIC ANALYSIS OF ESTROGEN CONCENTRATING CELLS IN HYPOTHALAMUS, PREOPTIC AREA AND AMYGDALA. M.S. Krieger*, J.I. Morrell, and D.W. Pfaff. (SPON: R. Norgren). Rockefeller University, New York, NY 10021.

The anatomical locations of estrogen-concentrating cells have been described for the major classes of vertebrates (for review, see Morrell and Pfaff, Am. Zool., 1978). In this study quantitative analyses of the peak areas of hormone concentration were done to determine whether there are different modes of hormone concentration and to investigate possible area-to-area differences in hormone concentration.

The basic methods used in this study were those previously used in this laboratory (Pfaff and Keiner, 1973) with modifications to facilitate the interpretation of apparently unlabelled cells. The dose of ^{3}H-estradiol administered was increased to the nuclear saturating level of 2.7 μg/kg and was administered by an intravenous route. This hormone infusion maintained blood levels at or above proestrus levels for 3 1/2 to 4 hours. Tissue was sectioned at 2 μ.

A cell-by-cell analysis of 32 sections through the preoptic area (POA), the ventromedial nucleus (VMN), arcuate (ARC), or medial nucleus of the amygdala (AMYG) was performed. Each cell was designated as either labelled or unlabelled. The percentages of labelled cells were calculated, and a representative section was chosen of each area for each animal. In these sections the number of silver grains per cell was counted. The total number of cells in which grains were counted was 314 in POA, 453 in VMN, 485 in ARC and 654 in AMYG.

Frequency distribution histograms of the number of silver grains per cell were analyzed. The shape of the frequency distribution curve was similar for all four areas. Even under these conditions of high, maintained blood levels, there were still unlabelled cells visible. The large number of unlabelled cells and the wide range in the number of silver grains per cell resulted in curves which differed significantly from the Poisson distribution. In addition, these frequency distribution curves were smooth; modes in the curve, as might reflect quantal uptake processes, were not seen.

1106 MATURATION OF CNS CONTROL OF GROWTH HORMONE SECRETION IN RATS. Cynthia M. Kuhn* and Saul M. Schanberg. Department of Pharmacology, Duke University Medical Center, Durham, N. C. 27710.

The concentration of growth hormone (GH) in serum of neonatal rats was determined after administration of various drugs that are known to alter serum GH in adult rats. Administration of the serotonin precursor 5-hydroxytryptophan, morphine or TRH increased while treatment with the serotonergic antagonist cyproheptadine decreased serum GH in pups 15, 20 or 35 days old but had no effect on serum GH in younger animals. Clonidine decreased serum GH in pups 10, 14 or 20 days old and increased GH in older animals. Urethane produced its characteristic decrease in serum GH in 20 day old pups but had no consistent effect on GH in younger animals. These results suggest that the serotonergic system involved in regulation of GH secretion in rats and the midbrain and/or pituitary mechanism through which morphine affects GH secretion are functional within the first postnatal week. In contrast, the extrahypothalamic mechanisms through which pentobarbital and urethane exert their effects do not mature until 2-3 weeks after birth. Finally, the inability of clonidine to stimulate GH secretion before day 35 suggests that the noradrenergic mechanism which generates the characteristic "surges" of GH secretion observed in adult rats does not mature until after puberty. (Supported by NIMH grants MH-13688 and MH-06489 and NIH Fellowship NS0-5152.)

1107 STEROID HORMONES AND DOPAMINERGIC ACTIVITY IN THE STRIATUM. P. Langelier, J. Dankova, R. Boucher and P. Bédard, SPONS. by L.J. Poirier, Lab. Neurobiologie, Univ. Laval, Québec, G1K 7P4,Canada.

Estrogens inhibit dopaminergic transmission at the level of the hypothalamus and hypophysis resulting in an increased secretion of prolactin (Raymond, V., Labrie, F. and others, Science, in press). We have recently reported a beneficial effect of estrogens in patients suffering from L-DOPA-induced-dyskinesias and neuroleptic-induced tardive dyskinesias, two conditions which appear to result from overstimulation of certain dopaminergic receptors in the striatum (Bédard et al., 1977, Lancet 2 (8052): 1367-1368). In a group of 25 female rats a radiofrequency lesion of the left entopeduncular nucleus was performed stereotaxically and the animals were tested several times for circling after apomorphine 0.5 µg s.c. General motility was also tested with a motility box after saline and apomorphine 0.5 µg s.c.

The animals were then divided into four groups, kept in constant lighting conditions and treated twice a day with one of the following: 1) 17-β-estradiol 2 µg s.c.; 2) R-5020 (a progestative coumpound) 200 µg s.c.; 3) a combination of 1) and 2); 4) vehicle.

During treatment, the animals were tested three times for circling and motility. The animals were then castrated and after a period of recovery the same procedure was applied. Our results show a clear effect of the hormone treatment on both apomorphine induced circling and motility, which are decreased by 40% with respect to the control group. The three hormone treated groups behaved in the same fashion. Our results suggest that both estrogens and progesterone exert an inhibitory action on dopaminergic receptors in the striopallidal system. This hormonal influence on the motor system contributes to our understanding of the mechanisms which modulate the sensitivity of dopaminergic receptors in the striatum. This may have very interesting clinical applications.

1108 MELATONIN INTERACTIONS WITH THE CENTRAL NERVOUS SYSTEM. Robert M. Levy*, Huda Akil, Stanley J. Watson, Pamela Angwin*, Laughton Miles*, and Jack D. Barchas.

Melatonin, N-acetyl-5-methoxytryptamine, a product of the pineal gland, has been shown to have a number of significant endocrine and behavioral effects. Our laboratory has recently developed a highly sensitive radioimmunoassay (RIA) which when coupled with various other indicators of melatonin action provides new information on the interaction of this indoleamine with the central nervous system.

One RIA, developed by our laboratory utilizes tritium-labeled melatonin and has a sensitivity of 25-50 pg per assay tube. Antibodies have been raised to both BSA- and thyroglobulin-coupled melatonin, although the thyroglobulin-coupled antibody is slightly more potent. A second RIA, using an ^{125}I-labeled trace and an antibody from Rollag and Niswender (Endocrinology 98:482-489, 1976), has a sensitivity of 2.5 pg per assay tube, an effective range into nanogram levels, and has also been used in these studies.

Bovine and rat tissue studies investigating both the effects of various pharmacological treatments on melatonin levels and activity, and the effects of melatonin, by pinealectomy and administration via various routes of infusion, on the neuroendocrine axis are currently underway. Human clinical studies involving medicated psychiatric and medical patients are also being performed. These studies include patients receiving monoamine-altering agents, as well as one group receiving mega-propranolol therapy (increasing doses up to 3 g/day). Further studies of melatonin interaction with the CNS are in progress.

1109 EFFECTS OF SEPTAL LESIONS ON LORDOSIS BEHAVIOR AND MALE SEX BEHAVIOR IN FEMALE AND MALE RATS. M.Y. McGinnis*& R.A. Gorski (SPONS A.M. Adinolfi). Dept. Anat., Sch. Med. UCLA, Los Angeles, CA. 90024.

Septal lesions have been shown to facilitate lordosis behavior in ovariectomized rats when primed with estradiol benzoate(EB) only. The first study was designed to test whether this increase in hormone sensitivity would also manifest itself in a facilitation of male sex behavior. Ovariectomized rats were given septal lesions (SL) or sham surgery(no current passed) and 3 weeks later tested for lordosis behavior following 2ug EB/day for 3 days and tested on day 4. Three weeks later they were given a pretest for male sex behavior and tested on days 4,7,11 & 15 of 150ug daily testosterone propionate(TP) treatment. Mount latency and mount and intromission frequencies were measured. Mean lordosis quotients(LQ) were higher in SL(74±7) than in sham operated(12±4) rats($p<.05$). However there was no difference between SL and sham groups on any test for male sex behavior. Thus the septal lesion effect in females appears to be specific for female sex behavior.

Unless SL male rats are chronically exposed to EB for 2-4 weeks during the immediate post-lesion period, septal lesions do not facilitate lordosis behavior in males. The purpose of the second study was to determine whether adult males given SL would show enhanced male sex behavior. Rats were castrated on day 60 and at the same time given SL, sham surgery(sham) or were unoperated(unop;anesthesia + incision). One month later they were tested for lordosis behavior with EB only(2ug x 3 days;test on day 4) and again 3 weeks later under the same hormonal regime except that .5mg Progesterone(P) was given 4-6 h prior to the test. Since these animals were not exposed to chronic EB, no facilitation of lordosis behavior occurred after either EB or EB + P($\bar{X}$ LQ<5 on all tests). Furthermore, SL rats did not show enhanced male sex behavior relative to that of sham or unop groups. This is in contrast to our recent report of enhanced male sex behavior in male rats given SL neonatally. We suggest that the SL itself does not induce neural plasticity with regard to male sex behavior except at a time when neural connections are still in an immature state. Once the connections for male sex behavior are established, they are apparently not altered by SL.
(Supported by HD 01182)

1110 REVERSIBLE DISRUPTION OF CENTRAL SEROTONERGIC SYSTEM POTENTIATES THE STIMULATION OF PROLACTIN SECRETION BY SEROTONIN AGONISTS IN MALE RATS. H.Y. Meltzer, M. Simonovic* and V.S. Fang*, Depts. of Psychiatry and Medicine, University of Chicago Pritzker School of Medicine, Chicago, Illinois, 60637.

Serotonin (5HT) neurons originating from raphe nuclei of the midbrain participate in the regulation of prolactin (PRL) secretion in the rat. We have previously reported that depletion of brain 5HT potentiates the stimulation of PRL release by 5HT agonists. In order to determine whether this phenomenon is due to supersensitivity of 5HT receptors we have measured dose-related increases in plasma PRL levels produced, under different conditions, by the following 5HT agonists: 5HT, 5HTP, quipazine, 5-methoxytryptamine (5MT), bufotenin (B), 5-methoxy-N,N-dimethyltryptamine (5DMT) and N,N-Dimethyltryptamine (DMT). The dose-response (D-R) curves for each compound were determined by measuring plasma PRL concentration in blood samples obtained from male rats 15 min after the intraperitoneal (ip) injection of an agonist. Our results indicate that 5HT, B and 5MT are more potent in stimulating PRL secretion than 5DMT and DMT. In order to test for a possible increase in sensitivity of 5HT receptors caused by relative absence of 5HT from the synapse, we have selected two pretreatment (PT) conditions aimed at producing reversible disruption of 5HT transmission. PT-I consisted of a single administration of a large dose of parachlorophenylalanine methylester (PCPA) (300 mg/kg, ip), which depletes brain 5HT by inhibiting its synthesis. PT-II consisted of 4 injections of 5DMT (5 mg/kg, ip, every 3 hr). Frequent administration of 5DMT, which inhibits firing of raphe neurons and decreases 5HT turnover should produce prolonged inhibition of 5HT neuronal activity. The D-R curves for each compound were redetermined in these animals 24 hr after the beginning of each PT. Both PTs shifted the D-R curves to the left. The two PTs produced shifts of comparable magnitudes for any one agonist. The period required for the appearance of greater PRL response was also similar for both PTs and no further potentiation was noted when the two PTs were combined. In view of these similarities, we believe that the development of supersensitivity of post-synaptic 5HT receptors is a common mechanism underlying the effects of these two PTs. Studies are in progress to determine the effect of these PTs on 5HT turnover and on receptor sensitivity in vitro, as well as the effects of either lesions of central 5HT system or spaced injections of other drugs known to inhibit firing of 5HT neurons, such as tricyclic antidepressants, on the 5HT agonist stimulated PRL secretion. (Supported in part by ADAMHA grants MH 30938 and 29206, RCSA MH 47808 to HYM and USPHS MH 07083 to MS.

1111 THE EFFECTS OF LOCOMOTOR ACTIVITY ON CEREBELLAR cGMP. James L. Meyerhoff, R.H. Lenox, G. Jean Kant, Edward H. Mougey*, Lee L. Pennington*, and G. Rufus Sessions, Depts. of Medical Neurosciences and Microwave Research, Walter Reed Army Inst. Rsch. Washington, DC 20012.

Stress is reported to elevate cyclic 3'5' guanosine monophosphate (cGMP) in cerebellum in the rat. Because we found that the stress of forced immobilization failed to produce this elevation (Lenox et al., Neurosci. Abstr., 1977), we decided to study the effect of locomotor activity on cerebellar cGMP.

Male albino rats were initially allowed access to activity wheels for 3 periods, each of 24 hr duration. The access was subsequently reduced over the course of a week to 120 minute, 60 minute, 30 minute and finally, to ten minute periods on each of two consecutive days. After the second day of 10-minute access to the wheel, the animals were divided into experimental and control groups. The two groups were balanced with respect to tendency to run in the wheel, based on averages of the preceding 2 day's running scores. The experimental group was allowed to enter the activity wheel for 5 minutes a day for 3 consecutive days. The control rats were also allowed to enter the activity wheel on these 3 days, but the wheel was not permitted to turn; with the access door shut they merely explored the immobile wheel for 5 minutes. On the fourth day, the animals were treated in a manner identical to the preceding 3 days except that immediately following 5 minutes in the moving or fixed wheel, the animals were placed in a lucite holder, and rapidly sacrificed by exposure to microwave irradiation. We used a 2.5 kilowatt, 2450 megahertz, microwave inactivation system, as modified in our laboratory. Following sacrifice and decapitation, trunk blood was collected for radioimmunoassay for corticosterone (CS) and prolactin (Prl), and brain tissue samples were obtained for radioimmunoassay for cGMP.

During five minutes in the activity wheel, the experimental group averaged 52 revolutions (range 30-76). This group had cerebellar cGMP levels more than twice as high as levels in control rats which merely explored the wheel while it was prevented from revolving (1.999 ± 0.103 vs 0.919 ± 0.095 picomoles per mg wet wt.). Both groups had relatively elevated plasma CS and Prl. These levels, however, were not statistically different between groups suggesting that locomotor activity, not environmental stress, was associated with the elevations in cerebellar cGMP. These data suggest that locomotor activity may be a major contributor to the elevation of cerebellar cGMP in rats exposed to environmental stress.

1112 SECONDARY SYNCHRONIZING STIMULI, THE SUPRACHIASMATIC NUCLEUS (SCN) AND THE ENTRAINMENT OF CIRCADIAN RHYTHMS IN THE RAT. R. Y. Moore and B. Ziegler*, U. Calif. at San Diego, La Jolla, CA. 92093

The purpose of this study was to determine the effectiveness of secondary synchronizing stimuli in entrainment of endogenous circadian oscillating mechanisms. Albino rats (n=12) were placed in individual cages illuminated on an LD, 12:12 schedule throughout the study. Activity was continuously monitored; drinking behavior was assessed by the interruption of a light beam each time the rat placed its head in a plastic cylinder surrounding the drinking tube attached to the water bottle. After a control period in which all animals showed normal rhythmicity in activity and drinking, half of the animals were subjected to a deprivation schedule, water available 0900-1000 hrs each day. These exhibited bursts of activity and drinking during the morning period but had normal activity rhythms and continued to place their heads in the plastic cylinder during the dark period even though no drinking tube was present. After two weeks, the animals again had free access to food and water and showed normal activity and drinking rhythms. All animals were then blinded and exhibited free-running rhythms. Introduction of a deprivation schedule as before again produced a burst of activity between 0900 and 1000 hrs but free-running activity and drinking behavior rhythms persisted with an unchanged τ. SCN lesions abolished the free-running rhythms but reintroduction of a deprivation schedule again produced the morning burst of activity and drinking which again disappeared when the deprivation schedule was stopped. These observations indicate that a deprivation schedule will result in a diurnal change in activity and drinking but does not affect any central circadian oscillating system in the presence or absence of the SCN. Supported by USPHS Grant NS-12267.

1113 EFFECT OF OVARIAN HORMONES ON SYNCHRONY OF HAMSTER CIRCADIAN RHYTHMS. Lawrence P. Morin. Dept. Psychol., Dartmouth College, Hanover, N.H. 03755.

Adult female hamsters were continuously housed under constant fluorescent light (LL) in translucent plastic cages each containing a 17 cm diameter running wheel. Light energy levels measured inside the cage end facing the light source were about 12.2 uwatts/cm^2 (also measured as a mean 48.3 lux). Freerunning locomotor rhythms were recorded on an event recorder. Splitting of the rhythm occurred during 108 days of LL in 7/12 intact control female hamsters within a range of 27-86 days. The phase relationship between the two oscillator peaks in intact animals was $157.5 \pm 4.0°$. Among animals which were ovariectomized after about 50 days of freerunning in LL 8/13 split into two peaks with a phase relation of $166.5 \pm 2.5°$. Ovariectomized animals entrained to LD 14:10 were given subcutaneous silastic capsules containing estradiol benzoate, progesterone or blanks and significant treatment differences appeared when the animals were given access to wheels in LL. Splitting occurred in only 1/7 animals given estradiol benzoate. In contrast, progesterone (4/7) or blank (9/11) capsules were associated with splitting and other rhythm anomalies such as desynchrony of endogenous oscillations. The results suggest a role for estradiol as a mediator of synchronous internal rhythmicity.

1114 NEONATAL SCN ABLATION: EFFECTS ON THE DEVELOPMENT OF THE PITUITARY-GONADAL AXIS IN THE FEMALE RAT. Sarah S. Mosko and Robert Y. Moore. Dept. Neurosciences, U. Calif., San Diego, La Jolla, Calif. 92093.

Lesions of the suprachiasmatic nuclei (SCN) in adult rodents are known to abolish a variety of behavioral and physiological circadian rhythms. Previously we reported that, like lesions performed in adulthood, ablation of the SCN in neonatal rats prior to the formation of the retinohypothalamic projection results in persistent vaginal cornification (PVC) in the postpubertal female. Long-term assessment indicates that this effect is permanent. In the present study, we have further characterized the nature of this neuroendocrine alteration resulting from destruction of the SCN in 2 day old female rats.

Extensive lesions of the SCN do not alter the onset of puberty, as indexed by the age of vaginal opening, in either sighted or neonatally blinded animals. Daily examination of vaginal smears over the first 3 weeks of puberty reveals a higher cornification index (proportion of days in vaginal estrus) in SCN rats, irrespective of whether or not they are also blinded, than observed in littermate controls. PVC, however, does not necessarily appear in SCN rats until after puberty: during puberty, irregular sequencing of smears or constant diestrus are also frequently observed; normal cycling is seen in only a few cases where damage to the SCN is only moderate. In addition, PVC in adulthood is accompanied invariably by abnormally small, polyfollicular ovaries and large pituitaries in both blinded and sighted rats with lesions. Furthermore, while sighted control females display a surge of circulating luteinizing hormone on the afternoon of proestrus, sampling of plasma in the morning and afternoon for 9 consecutive days in SCN rats reveals continuously low hormone levels. This constellation of endocrine alterations is absent in rats with lesions in nearby hypothalamic sites which spare the SCN. Since the organization of the rodent estrous cycle is circadian, these results emphasize further the central importance of the SCN in circadian rhythm generation and demonstrate the necessity of an intact SCN for the development of normal, cyclic reproductive function.

1115 EFFECTS OF SUCKLING ON SERUM PROLACTIN LEVELS AND CATECHOLAMINE CONCENTRATIONS AND TURNOVER IN DISCRETE BRAIN REGIONS OF LACTATING RATS. John A. Moyer, Thomas L. O'Donohue*, Lorraine R.•Herrenkohl, Richard R. Gala*, and David M. Jacobowitz. Laboratory of Clinical Science, NIMH, Bethesda, MD. 20014

The effects of suckling on serum prolactin (PRL) levels and catecholamine concentrations and turnover were examined in eight discrete brain regions associated with norepinephrine (NE) and dopamine (DA) containing pathways and with brain regions associated with the regulation of PRL secretion. Turnover rates were assessed by using the synthesis inhibitor alpha-methyltyrosine (aMT) in combination with microdissection techniques for the removal of individual brain regions and sensitive radioenzymatic assays for NE and DA. PRL secretion was induced by mothers experiencing 6 hours of pup removal with subsequent pup replacement.

Suckling or the administration of aMT to mothers resulted in a marked increase in circulating titers of PRL in these mothers compared to saline treated mothers who were not allowed to suckle. A decrease in steady-state NE concentrations in the anterior hypothalamus and a decrease in steady-state DA concentrations in the ventromedial nucleus were noted in the suckling mothers. The comparison of relative rates of NE depletion after aMT treatment revealed a suckling-induced decrease in turnover in the anterior hypothalamus and a suckling-induced increase in turnover in the ventromedial nucleus.

These findings suggest that suckling-induced activation of PRL results in a stimulatory action on noradrenergic processes in the ventromedial nucleus. In addition, a decrease in NE turnover in the anterior hypothalamus of suckling mothers suggests the involvement of noradrenergic systems in suckling-induced PRL release.

The changes in turnover rates of NE in the ventromedial and anterior hypothalamic nuclei suggest that noradrenergic processes in these regions may participate in the suckling-induced alterations of endocrine processes. The determination of individual suckling related neuroendocrine and behavioral relationships requires further investigation.

1116 ACTH Release by Human Pituitary Cells in a Superfusion System G.H. Mulder*and D.T. Krieger. Mt. Sinai Sch. Med., Dept. of Med. Div. of Endocrinology, New York, New York 10029

In vivo studies on the regulation of ACTH release in man are difficult to perform. The present studies utilize an *in vitro* approach, using superfused columns of normal pituitary or tumor cells (Mulder et al. Endocrinology 100: 1143, 1977).

Cells were prepared by collagenase dissociation of tissue. Cell viability (trypan blue exclusion) was 80-90%; the degree of viability bore no relation to the postmortem time span (7-24 hours). Tissue obtained at surgery yielded cells with ≈ 95% viability. The number of cells obtained varied from 1.3 to 2.5 x 10^4 per mg tissue. From 0.5 to 2 x 10^6 freshly prepared cells were placed in a flow-through chamber and were superfused with M-199 at 0.5 ml/min. and 37°. 1 ml fraction of eluate were immediately acidified (IN HCl) and frozen for later ACTH determination by RIA (West antibody) or bioassay (dispersed adrenal cortex cells). 30-60 minutes after the start of a superfusion the cells had reached a stable level of basal ACTH release. By using four-way valves, the cell columns were exposed to discrete pulses of a crude NIH rat hypothalamus extract (NIH-HME). The response of the cells was immediate and transient. Linear log. dose response curves were constructed following 1 minute pulses of NIH-HME (doses: 0.1 to 0.8 rat hypothalamus). Up to 466 pg ACTH/10^5 cells was released, which is about 0.1% of the cellular content. Slopes obtained with different normal pituitary preparations were identical, but different cell preparations showed different sensitivities and released different amounts of ACTH. Repeated pulses (once every 30 min.) gave repeated peaks -- sustained perfusion with extract caused sustained periods of ACTH release. 0.5 µg/ml cortisol resulted in an inhibition of up to 80% after 1 minute pulses containing the extract of 0.5 hypothalamus and 20-30% with 1 hypothalamus. The inhibition is slow in developing (≈ 20 min) and disappearing, and is often followed by a rebound phenomenon. Dexamethasone at 0.2 µg/ml was also effective in inhibiting the cells' ACTH release. These results are very similar to what has been observed with rat cells. The 1 pituitary tumor (chromophobe) cell preparation assayed thus far showed a greatly exaggerated response to NIH-HME. In pilot experiments, MIF (10^{-6}M) and isoproterenol (5 x 10^{-6}M) had no effect on basal ACTH release. This system appears to be well-suited for analysing many aspects of ACTH synthesis and release in various human cells.

1117 THE EFFECT OF GONADAL STEROIDS ON ACTIVITY OF CHOLINE ACETYLTRANSFERASE IN DISCRETE BRAIN REGIONS OF GONADECTOMIZED RATS. E. A. Muth*, W. R. Crowley, and D. M. Jacobowitz. Dept. Pharmacol. George Washington Univ. and Lab. Clin. Sci., NIMH, Bethesda, Maryland 20014.

In order to assess the possible involvement of cholinergic mechanisms in the feedback actions of gonadal hormones, the activity of choline acetyltransferase (ChAT), the enzyme catalyzing acetylcholine synthesis, was measured in 25 microdissected brain nuclei of male and female rats after gonadectomy and subsequent treatment with gonadal steroids. Male rats were castrated or sham-operated at 60 days of age. One group of castrated rats received testosterone propionate (TP, 100 µg/day, s.c.) and another group sesame oil vehicle daily for 14 days. Sham controls also received oil. Castration significantly elevated ChAT activity in the medial preoptic nucleus and in the posterior medial amygdala, while TP lowered ChAT activity to sham levels in these areas. The TP treatment also significantly decreased ChAT activity in the nucleus tractus diagonalis.

Female rats, ovariectomized four weeks previously, received either estradiol benzoate (EB, 5 µg, s.c.) or oil at 0 hr, followed 48 hr later by either progesterone (P, 1.5 mg, s.c.) or oil, and were killed at 54 hr. EB + P reduced ChAT activity in the caudal nucleus tractus diagonalis and in the periventricular nucleus and increased ChAT activity in the supraoptic nucleus. P alone also reduced ChAT activity in the caudal nucleus tractus diagonalis. The present results demonstrate that cholinergic activity in certain discrete brain regions known to be targets for testicular and ovarian hormones is altered by gonadectomy and gonadal hormone treatment and suggest involvement of cholinergic systems in the central effects of gonadal hormones on gonadotropin secretion and mating behavior.

1118 OXYTOCIN-NEUROPHYSIN PATHWAYS TO THE LOWER BRAINSTEM AND SPINAL CORD OF THE RAT. Gajanan Nilaver*, Julie Wilkins*, Jennifer Michaels*, Donald L. Hoffman*, Ann-Judith Silverman, and Earl A. Zimmerman. Departments of Neurology and Anatomy, College of Physicians and Surgeons, Columbia University, New York City, N.Y. 10032.

In recent years projections from magnocellular paraventricular nucleus of the hypothalamus have been traced to a number of extrahypothalamic sites including lower brainstem and spinal cord. Several laboratories have reported that this pathway contains neurophysins (NPS) and may be oxytocin (OT)- and or vasopressin (VP)-ergic. Swanson showed that fibers to the nucleus solitarius in the ox contain OT-NP (Brain Res. 128:346, 1977). Studies of the relative contributions of fibers containing OT-NP and VP-NP in the rat have been obviated by lack of specific antisera to each rat NP. This problem was circumvented in two ways: (1) by studying homozygous Brattleboro rats with diabetes insipidus (DI) rats which have OT, OT-NP and lack VP, VP-NP; (2) by preabsorption of antiserum to rat NPS with DI rat NP (OT-NP) extracted from hypothalami and pituitaries of DI rats. Sections of hypothalamus, medulla and spinal cord of normal and DI rats were reacted by immuno-peroxidase technique using these antisera to NP and antisera to OT and VP. Use of unabsorbed antiserum to NPS revealed similar numbers of reactive fibers in both rat types which appeared to terminate in the solitary and dorsal motor vagal nuclei of the medulla. Positive fibers throughout the cord were found in the intermediate grey and the substania gelatinosa including sacral segments; they appeared to descend in the dorsolateral funiculus adjacent to the substania gelatinosa. Lesser numbers of OT, and only a few VP fibers were seen in medulla and cord. No reactive cell bodies were seen caudal to the hypothalamus. Absorption of antiserum to NPS with DI extract totally removed staining in DI rat and severely, but not totally, reduced it in normal rat medulla and cord; in normal rat hypothalamus it selectively abolished NP in OT but not VP cells. These findings indicate that hypothalamic projections to the medulla and spinal cord are predominately OT, OT-NP pathways. Like substance P and enkephalin, OT is found in the substania gelatinosa of the spinal cord where it may have a role in pain regulation.

1119 INVOLVEMENT OF THE ADRENAL MEDULLA IN THE MATURATION PROCESS OF THE ADRENAL CORTEX. Anthony D. Okonmah* and Karam F. A. Soliman. School of Pharmacy, FAMU, Tallahassee, Florida 32307.

The establishent of corticosterone circadian rhythm was studied and related to the response to some cholinergic and anticholinergic drugs in the immature rat. Three different age groups of Sprague-Dawley rats were placed on 14:10 light dark cycle at a controlled temperature of 23±1°C. Litter size was limited to 10 animals per litter. Animals were sacrificed by decapitation at the ages of 12-13, 18-19 and 21-22 days old. Plasma was obtained for corticosterone determination every 4 hours along the 24 hrs. period. The results from the different age groups indicate the absence of diurnal rhythm in this adrenocortical hormone. Following the absences of nycthothermal variation in glucocorticoid secretion, cholinergic study was designed. Different sets of rats in the age range of 12-14 and 29-30 days old rats were utilized. One group was subjected to cholinergic drug treatment while the other group also recieved the same treatment but was later exposed to ether stress. Physostigmine (0.20 mg/kg) and neostigmine (0.1 mg/kg) administered did not produce any significant changes in corticosterone level. Neither did 0.1 mg/kg of teteraethylammonium, hexamethonium nor atropine caused any change in the level of corticosterone. Since epinephrine was found to prolong the plasma half-life of corticosterone in this group of immature animals, it may be suggested that the cortex maturation is probably related and regulated by the adrenal medulla.

1120 EFFECTS OF ESTROGEN PRIMING ON SEXUAL BEHAVIOR AND ON STEROID RECEPTORS IN THE FEMALE RAT BRAIN. B. Parsons*, N.J. MacLusky*, M.S. Krieger*, B.S. McEwen and D.W. Pfaff. (SPON: C. Pfaffmann) Rockefeller University, New York, NY 10021.

Ovariectomized rats pretreated with estradiol benzoate (EB) display greater behavioral sensitivity to a subsequent dose of EB than do animals which did not receive pretreatment. This study investigated the effects of 17-β-estradiol (E_2) pretreatment on sexual behavior and steroid receptors in the rat brain.

Female rats ovariectomized for 21 days received a 5 mm silastic implant of E_2 or of cholesterol (C) for one week. Some animals were sacrificed for chemical analyses; the remainder had their implants removed. Five days later, the remaining animals were either sacrificed for chemical analyses, or were reimplanted with 5 mm E_2 for behavioral testing. Females were tested with an experienced male 44-46 hr after reimplantation. Then, females received 500 µg progesterone (P), and were retested 4 hr later. Animals pretreated with E_2 showed significantly higher lordosis quotients than animals pretreated with C, both when tested with E_2 alone and when tested with E_2 + P.

Cytosol estrogen receptors were measured by incubating pituitary (PIT) and hypothalamus, preoptic area and septal region (HPS) extracts pooled from 2 animals with 1 X 10^{-9}M ^{3}H-E_2 for 2.5 hr at 4°C. Bound ^{3}H-E_2 was measured by gel filtration on Sephadex LH-20. Corrections for non-specific ^{3}H-E_2 binding were made using parallel incubations containing 1 X 10^{-6}M unlabeled R2858 (17-α-ethynyl-11-β-methoxy E_2) in addition to 1 X 10^{-9}M ^{3}H-E_2. For progestin receptors measurements, cytosols were incubated with a synthetic progestin, ^{3}H-R5020 (17,21-dimethyl-19-nor-pregna-4,9-diene-3,20-dione) for 4 hr at 4°C. Bound ^{3}H-R5020 was measured by Sephadex LH-20 gel filtration. Corrections for non-specific binding were made using parallel incubations containing 2 X 10^{-8}M unlabeled R5020, in addition to 0.4 X 10^{-9}M ^{3}H-R5020.

Seven days after E_2 implantation, PIT and HPS cytosol estrogen receptor levels were significantly reduced, while progestin receptor levels were significantly increased, as compared to C controls. Five days after E_2 implant removal, PIT and HPS E_2 receptor levels, and HPS progestin receptor levels were indistinguishable from those seen five days after C removal. PIT progestin receptor levels also fell after E_2 implant removal, but remained slightly higher than in C pretreated animals.

Therefore, the 'long term' potentiation of lordosis by estradiol does not appear to be the result of a change in either estrogen or progestin receptor levels in the HPS of the female rat brain.

1121 DAILY RHYTHMS IN CSF MELATONIN AND BRAIN TEMPERATURE IN PRIMATES. Mark J. Perlow, Steven M. Reppert*, Lawrence Tamarkin*, Richard J. Wyatt and David C. Klein*, NIMH, St. Elizabeth's Hospital, Washington, DC 20032 and NICHD, Bethesda, MD 20014.

CSF melatonin and brain temperature have been studied using chronically restrained monkeys (Macaca mulatta; 5.5 to 6.5 kg). These animals were adpated to chronic restraint for 3 weeks and housed in sound-attenuated chambers. Lighting was automatically regulated (LD 12:12) so that the lights were on from 0600 to 1800 hrs EST. CSF was removed via an indwelling polyethylene catheter which terminated in the cisternal subarachnoid space; the rate of removal was 1 ml/hr. Melatonin in the CSF was measured by a RIA procedure which was validated for monkey CSF by GCMS. Brain temperature was measured continuously; the sensor was a YSI thermistor probe (No 44018) implanted on the dural surface overlying the frontal cortex.

Under these conditions daily rhythms in both CSF melatonin and brain temperature are apparent. The melatonin rhythm has a 3- to 15-fold amplitude with high values (12 to 40 pg/ml) occurring only at night. The daily changes in CSF melatonin closely reflect daily changes in plasma melatonin; plasma melatonin values are higher than CSF values. There is rapid transfer of melatonin from blood to CSF as indicated using tracer amounts of [^{3}H]melatonin; the discrepancy between the total amount of melatonin in CSF and plasma appears to reflect differences in binding proteins.

A rhythm in brain temperature also occurs in the restrained monkey, with high values of about 37.6°C occurring during the day; night values are about 36°C. Both the CSF melatonin rhythm and the brain temperature rhythm persist in constant darkness, suggesting that one or more endogenous oscillators drive these rhythms, and that they are truly circadian in nature. A difference, however, exists between the CSF melatonin and brain temperature rhythms as regards the effects of constant light. A 36-hr exposure to light blocks the melatonin rhythm resulting in continuously low daytime values. On the other hand, the rhythm in brain temperature persists in constant light in only a slightly attenuated manner.

1122 EFFECT OF KNIFE CUTS BETWEEN THE SUBFORNICAL ORGAN (SFO) AND ORGANUM VASCULOSUM LAMINAE TERMINALIS (OVLT) ON THE CENTRAL ACTIONS OF ANGIOTENSIN II (AII). M. Ian Phillips, J. Phipps and Steven Bealer, Department of Physiology and Biophysics, University of Iowa, Iowa City, IA 52242.

The SFO and the OVLT have both been proposed as receptor areas for the effects of AII. These effects include drinking behavior and blood pressure increases. Independent claims have been made that lesioning the SFO or the OVLT area abolishes or impairs the responsiveness of a rat to AII injected intraventricularly (IVT) or intravenously (iv). Since connections have been demonstrated between the SFO and the OVLT it is possible that OVLT lesions have destroyed the output pathway of the SFO. If the SFO is the only AII receptor area, cutting these tracts should abolish responsiveness to AII iv or IVT, but if the OVLT area is also a receptor, cutting the connections would not impair the action of AII.

To cut the SFO efferents a Halasz knife guide was lowered at +1mm/0/4.5mm stereotaxic coordinates, the knife protruded 2mm and turned 90° left and 90° right. Such a cut is shown in figure 1, which is redrawn from a histological section.

Twelve rats were prepared with implanted catheters and brain cannulas. In seven rats with a cut, drinking to 100ng AII IVT was 8.0 ± 3.0 ml and in uncut controls drinking was 7.2 ± 1.2 ml. There was no significant difference between the blood pressure response to AII IVT in controls and experimentals. AII iv given by infusion over 30 minutes also produced drinking in experimental subjects.

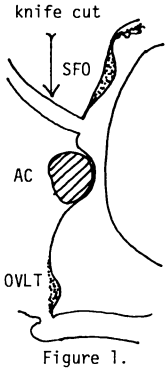

Figure 1.

These results indicate that descending fibers from the SFO are not necessary for the responses to central or peripheral AII. There may be dorsal efferents from the SFO. The results prove that the effects of lesions in the OVLT area ("AV3V") are not the result of interrupting efferents from the SFO. This adds to the evidence of low dose responses, ventricular plugging, lesioning and binding studies, that the OVLT is an independent receptor area for AII. (Supported by grants from NIMH and NSF.)

1123 SERUM LH AND PROLACTIN CONCENTRATIONS IN INTACT AND CASTRATED RATS TREATED WITH 5-HYDROXYTRYPTAMINE Nancy S. Pilotte and John C. Porter. Dept. OB-GYN and Physiology, Southwestern Med. Sch., Dallas, TX.

The effects of 5-hydroxytryptamine (5HT) on serum prolactin and LH levels in rats of both sexes has been investigated. The group of male rats included orchiectomized as well as intact animals. The group of female rats included acutely and chronically ovariectomized animals as well as ovariectomized rats bearing Silastic implants containing 17β-estradiol. All female rats were castrated on the morning of proestrus. All animals were given 5HT (20 mg/kg BW, sc) or 0.5 ml phosphate-buffered saline (PBS) (0.5 ml, sc) daily for 3 days. Thirty min after the last injection, each rat was decapitated and exsanguinated. The acutely castrated animals received the first injection immediately after castration, whereas the chronically castrated animals received the first injection 28 days after castration. 5HT treatment decreased serum LH levels in acutely-castrated males but increased serum LH concentrations in castrated females bearing estradiol implants (Table 1). Serum prolactin levels of all animals were elevated after 5HT administration.

Table 1. Mean Serum LH and Prolactin Levels

Group		LH (ng/ml)	p	Prolactin (ng/ml)	p
Male					
Intact:	PBS	43 ± 5.9*	NS	39 ± 6.4	<.001
	5HT	39 ± 5.8		278 ± 54.0	
Acutely castrated:	PBS	395 ± 38.9	<.01	41 ± 8.9	<.001
	5HT	230 ± 21.4		260 ± 31.8	
Chronically castrated	PBS	492 ± 36.0	NS	24 ± 5.7	<.05
	5HT	399 ±120.7		123 ± 37.1	
Female					
Acutely castrated + E_2	PBS	<30	<.01	76 ± 14.9	<.01
	5HT	65 ± 9.7		332 ± 84.3	
Acutely castrated	PBS	62 ± 10.9	NS	36 ± 9.2	<.05
	5HT	79 ± 20.0		77 ± 13.9	
Chronically castrated:	PBS	364 ± 30.9	NS	18 ± 1.8	<.01
	5HT	307 ± 46.0		53 ± 11.7	

*Mean and SE; N = 10

The results suggest that serum prolactin concentration can be increased by the systemic administration of 5HT.

1124 AFFERENT AND EFFERENT CONNECTIONS OF PUTATIVE PEPTIDERGIC NEURONS OF THE PARAVENTRICULAR NUCLEUS (PVN). Q.J.Pittman, H.W.Blume and L.P.Renaud. Div. of Neurology, Montreal General Hospital and McGill University, Montreal, Canada, H3G 1A4

Peptidergic neurons of the PVN project to the posterior pituitary (PP) where they release oxytocin, vasopressin and their neurophysins. There is now anatomical evidence for neurophysin-containing pathways to other sites, including median eminence (ME), brainstem and amygdala. We have carried out an electrophysiological study of PVN cells in order to further define their afferent and efferent connections.

Experiments were conducted on pentobarbital anaesthetized Sprague-Dawley rats implanted with bipolar stimulating electrodes in the amygdala and midbrain central gray. Bipolar electrodes were also placed on the surface of the ME and/or across the PP stalk. Micropipettes inserted by a ventral approach were used to record extracellular unit activity. A PDP 11/40 computer was utilized for analysis of spike discharge patterns.

Antidromic invasion techniques were used to identify efferent pathways from PVN. Antidromic invasion was recorded in 6 PVN cells after amygdala stimulation and in 2 PVN cells after midbrain stimulation, thus providing support for the existence of pathways to these two areas. The PVN-PP projection was evident in the observation of antidromic invasion from the PP in 93 PVN cells. A further 68 PVN cells, including 5 having phasic activity, displayed antidromic invasion from the ME, thus supporting the existence of a PVN-ME pathway. For the most part, this population of cells appeared to be separate from that which projected to the PP. However, 13 of 138 PVN cells tested with both PP and ME stimulation displayed antidromic invasion from both sites. This would indicate the presence of simultaneous axon projections to both areas.

Afferent influences from the amygdala were evident in neurons with projections to the PP and in those projecting to the ME. 32% (n=90) of PP projecting neurons and 19% (n=48) of ME projecting neurons responded in an orthodromic manner after amygdala stimulation; the predominant initial effect was a decrease in excitability. In contrast, none of the PVN cells with projections to either the PP (n=54) or the ME (n=29) showed orthodromic responses to midbrain stimulation. Thus the amygdala, but not the midbrain central gray can be shown to influence the excitability of these putative peptidergic neurons.

These observations provide electrophysiological evidence for the existence of projections from the PVN to not only the PP,but also to ME, amygdala and midbrain, and provide evidence for simultaneous projections of some PVN neurons to both ME and PP. (Supported by MRC)

1125 RELEASE OF LUTEINIZING HORMONE INDUCED BY N-METHYL ASPARTATE IS BLOCKED BY GABA OR TAURINE BUT NOT BY DOPAMINE ANTAGONISTS. M.T. Price, J.W. Olney and T.J. Cicero. Washington University School of Medicine, St. Louis, MO 63110

Glutamate (Glu) and certain acidic analogs excite central neurons when applied iontophoretically or destroy neurons of the arcuate nucleus of the hypothalamus (AH) when administered systemically. Since AH is an important neuroendocrine regulatory center, the selective action of these agents on AH neurons makes them potentially valuable systemic neuroendocrine probes. Their bimodal action (neuroexcitatory or neurotoxic) permits their use for either provocative or ablative experimental purposes - e.g., removal of AH neurons by neonatal treatment with high doses of Glu (ablative approach) results in markedly reduced AH concentrations of dopamine (DA) and choline acetyltransferase, which suggests there may be at least two subpopulations of AH neurons - dopaminergic and cholinergic. In provocative experiments, subtoxic doses of Glu, i.e., doses that do not destroy AH neurons, cause an acute elevation of serum luteinizing hormone (LH) in adult rats and subtoxic doses of the more potent excitotoxic analogs of Glu powerfully mimic this effect. One such analog, N-methyl aspartate(NMA), has proven particularly useful in studies of LH release.

In the present experiments we examined the ability of the neuroinhibitory amino acids, GABA and taurine, or the DA receptor blocking agents, pimozide and chlorpromazine, to influence NMA-induced LH release. All compounds were administered subcutaneously to 25 day old male rats. The four potential blocking agents were given either by themselves or in combination with a dose of NMA (25 mg/kg) which had previously been found highly reliable in inducing 5 to 10-fold elevations of LH within 7½ min. In drug combination experiments, GABA and taurine were injected immediately before NMA while pimozide and chlorpromazine were given 24, 14 and 2 hrs prior to NMA injection. We found: (1) Pimozide (0.6 mg/kg) and chlorpromazine (25 mg/kg) had no significant effect either on basal LH levels or on NMA-induced LH release. (2) Neither GABA nor taurine (up to 1000 mg/kg) had any effect on basal LH levels. (3) Both GABA and taurine (300-1000 mg/kg) completely blocked NMA-induced LH release.

It is known from microelectrophoretic experiments that GABA and taurine block excitation of central neurons by Glu and its analogs. The observation that GABA and taurine block the LH releasing action of NMA strengthens the hypothesis that NMA-induced LH release is triggered by depolarization of AH neurons. The failure of DA receptor blocking agents to block NMA-stimulated release of LH suggests that the subpopulation of AH neurons responsible for this effect is not dopaminergic. NIH grants NS-09156, DA-00259, MH-14677 and RSD Awards MH-38894 and MH-70180.

1126 VASOPRESSIN, CARDIOVASCULAR AND BEHAVIORAL RESPONSES TO NICOTINE IN THE CAT. T.A. Reaves, Jr., H-M. Liu*, M. Qasim* and J.N. Hayward. Dept. Neurology & Neurobiology Program, University of North Carolina, Chapel Hill, North Carolina, 27514.

The antidiuretic and cardiovascular effects of nicotine have been attributed to its action at several central neural sites such as the hypothalamus, the limbic system (Milton & Paterson, J. Physiol. 241: 607, 1974) and the brainstem (Porsius & Van Zwieten, Prog. Brain Res. 47: 131, 1977) as well as at peripheral neural sites in the cervical parasympathetic baroreceptors (Cadnapaphornchai et al., Am. J. Physiol. 227: 1216, 1974). Our studies in the unanesthetized monkey suggested a linkage between vasopressin (VP) release and nicotine-induced behavioral events (Hayward & Pavasuthipaisit, Neuroendocrin. 21: 120, 1976). The objective of this study was to examine the relationships between VP-release and nicotine-induced behavioral, cardiovascular and autonomic responses in the acute and chronic cat.

In the chronically prepared, chamber-isolated, adult cat we observed behavior and obtained blood samples from an indwelling cardiac cannula for measurement of plasma VP by RIA (Hayward et al., Endocrinol. 98: 965, 1976). During a 10-minute intravenous (i.v.) infusion of nicotine (25-50 ug/kg/min), plasma VP rises rapidly to 20-60 fold above control values in association with the behavioral responses of restlessness, ear twitching, salivation, chewing, retching and vomiting.

In the acutely prepared chloralose-anesthetized, paralyzed and artificially respired cat, we recorded mean femoral arterial blood pressure (MABP), heart rate (HR), pupil size, salivation and cortical EEG and obtained blood samples from a femoral venous cannula for plasma VP. During a 10-minute i.v. infusion of nicotine (25-50 ug/kg/min), plasma VP rose rapidly to 5-15 fold above basal values in association with an immediate and transient MABP rise of 50-100%, a biphasic HR response, pupillary dilatation, an increase in salivation and an unchanged EEG. Bilateral cervical vagotomy did not change these responses to nicotine. Hypophysectomy abolished the nicotine-induced rise in plasma VP but did not alter the cardiovascular and autonomic responses.

We conclude that nicotine releases VP from the neural lobe in the cat in association with behavioral, cardiovascular and autonomic responses. Nicotine-induced cardiovascular events are linked in some way with VP-release while behavioral responses and the cervical vagus are not essential.

1127 SIMILAR AND DIFFERENTIAL ROLES FOR THE SEPTUM AND MEDIAL PREOPTIC AREA ON ESTROGEN-DEPENDENT NEUROENDOCRINE PROCESSES. Jorge F. Rodriguez-Sierra and Ei Terasawa. Wisconsin Regional Primate Research Center, Madison, WI 53715. Lesion of either the septum (SEP) or the medial preoptic area (MPOA) in female rats enhances their sensitivity to estrogen which is responsible for the induction of sexual receptivity. It is also well demonstrated that lesion of the MPOA advances the onset of puberty. The present experiment was designed to test whether those estrogen-dependent phenomena are regulated by the same neural elements or not. Radiofrequency lesions were placed stereotaxically in the SEP of MPOA of prepubertal (25 days of age) rats. The condition of the vagina was inspected daily and vaginal smears were taken after its opening until the day of ovariectomy. The first and subsequent ovulations were determined by laparatomy. All animals were ovariectomized around day 50 of age. Three weeks after ovariectomy, animals were injected with estradiol benzoate (EB, 5 ug/Kg), followed by progesterone (0.5 mg/rat) 44 hours later. Animals were tested for lordosis responding with a male 4 hours after progesterone. The sham-operated (n=6) and control (n=6) animals showed comparable days of vaginal opening (39.7 $\pm$ 0.8 and 38.3 $\pm$ 0.8 days, respectively), which were followed by the first ovulation one day later. Animals bearing SEP lesions (n=8) exhibited a significant delay in vaginal opening (33.6 $\pm$ 1.3 days) and first ovulation. Half of the SEP-lesioned animals did not ovulate on the day following vaginal opening, although they showed normal estrous cycles subsequently. In contrast, most of the MPOA-lesioned animals ovulated after vaginal opening, but displayed continuous vaginal cornification thereafter. Both SEP- and MPOA-lesioned rats displayed significantly higher LQ scores than control animals (SEP = 76.3; MPOA = 60; Control = 10). Thus, it was suggested that the neural mechanisms involved in estrus behavior are different from those involved in the onset of puberty in the female rat, although both phenomena are estrogen dependent. The SEP and the MPOA exert a similar inhibitory effect on sexual receptivity in the adult, while these brain structures exert opposite effects (SEP-facilitatory; MPOA-inhibitory) on the onset of puberty. (Supported by NIH Grant RR00167)

1128 BRAINSTEM AND DIENCEPHALIC SINGLE-UNIT ACTIVITY CORRELATES OF SEXUAL BEHAVIOR RECORDED IN UNRESTRAINED FEMALE CATS. James D. Rose. Dept. Psychol., Univ. Wyoming, Laramie, WY 82071.

Sexual behavior in the cat entails a sequence of events in which the male initiates contact by grasping a fold of skin on the dorsum of the female's neck in his mouth, then mounts and begins pelvic thrusting, which continues until intromission occurs. After a few seconds of intromission, the female becomes hostile and the male releases her. The female then exhibits the afterreaction, a period of vigorous licking, rubbing, and rolling which was triggered by intromission. Genital stimulation does not elicit the afterreaction in anestrous cats. The present work was aimed at identifying the patterns of single-unit activity which accompany the display of the cat's estrogen-dependent behavioral responses to manually-applied genital and somatosensory stimulation. Single unit activity was recorded in 16 cats by means of a skull-mounted microdrive or with permanently-implanted fine wire microelectrodes. The majority of the midbrain and diencephalic units sampled displayed a characteristic pattern of unit activity in response to the test stimuli. Application of the neck grip induced a slowing of unit activity which was correlated with the inhibitory effect of this stimulus on the cat's locomotor behavior. Unit resposes to genital stimulation were typically accelerations of firing at the onset and offset of the stimulus. Upon release of the neck grip there was a surge of firing which preceded and continued into the onset phase of the afterreaction. Genital licking, usually the first event in the afterreaction, was associated with a decline in unit activity. The transition from licking to rolling was immediately preceded by accelerated unit firing which occurred before any change in behavior or neck electromyographic activity was apparent. Activity in anterior brainstem units was related to the overall level or general class of behavioral activity (licking, rolling) being displayed by the cat, but caudal brainstem cells showed firing patterns more closely associated with specific fragments of a motor pattern. On stimulation trials when genital stimulation did not elicit an afterreaction, as in anestrous cats or estrous cats which were sedated with ketamine HCl, there was no surge of midbrain activity following vaginal probing and release of the neck grip. Because the somatosensory responsiveness of the units varied greatly between cells, it is unlikely that sensory feedback from movements could account entirely for the consistent patterns of unit activity seen during the elicitation and display of the estrous behavioral responses.

1129 ESTRADIOL-CONCENTRATING STRUCTURES AND AFFERENT CONNECTIONS TO ESTROGEN TARGET AREAS IN THE CAT BRAIN. Mark J. Rowinski, Howard D. Rees, and Richard P. Michael*. Dept. of Psychiat., Emory Univ. Sch. of Med. and Ga. Ment. Health Inst., Atlanta, GA 30322.

The distribution of estradiol-concentrating cells in the cat brain was determined by autoradiography in two ovariectomized adult females 1 hr after iv injection of 3 µg of ^{3}H-estradiol (NEN, 92 Ci/mmol). Heavily labelled cells were found in the bed nucleus (n.) of the stria terminalis, lateral septal n., periventricular and medial preoptic nuclei, anterior hypothalamic area, periventricular n., ventromedial n., tuberoinfundibular area, the cortical and basomedial nuclei of the amygdala, amygdalo-hippocampal area, periamygdaloid cortex, and ventral dentate gyrus. Less heavily labelled structures included the islands of Calleja, n. of the diagonal band, medial septal n., the lateral, paraventricular, dorsomedial, and posterior hypothalamic nuclei, periaqueductal gray, interpeduncular n., medial n. of the solitary tract, and spinal n. of V. Estrogen accumulation by many neurons in the interpeduncular n., which has not been observed in any other species to date, raises the question of the possible neuroendocrine significance of this structure in the cat.

To determine the sources of neuronal input to one of the most heavily estradiol-concentrating regions, namely, the medial preoptic-anterior hypothalamic area, horseradish peroxidase (HRP) studies were conducted in 3 adult male and 6 adult female cats. At 48-78 hours after the injection of 0.05-0.15 µl of 30% HRP in saline, neurons containing the granular reaction product were consistently found in subiculum, entorhinal cortex, retrosplenial gyrus, septum, and amygdala. Ventromedial, dorsomedial, tubero-infundibular, perimammillary and lateral regions of the hypothalamus were also found to contain neurons labelled by retrograde transport of the enzyme. Many of these were relatively close (<15µm) to blood vessels and had processes directed toward the vessels. HRP labelled neurons were also found in most cases in anterior thalamic nuclei, periaqueductal brain stem structures, and some cortical areas. Taken together, these results indicate that estradiol-concentrating cells in the cat are widely distributed with concentrations in the basal forebrain and hypothalamus and that these cells are likely to be influenced by non-estrogen sensitive limbic structures involved in the mediation of affective states.

1130 FACTORS CONTROLLING PROGESTERONE-STIMULATED GONADOTROPIN RELEASE. K.B. Ruf, Dept. Ob/Gyn, Royal Victoria Hospital, McGill University, Montreal, Canada H3A 1A1.

Estrogen-primed ovariectomized rats exposed to standard lighting conditions and given progesterone (P) release large amounts of LH in the afternoon and evening, but not in the morning (Caligaris et al., Endocrinology 89: 331, 1971). The following hypotheses could explain the absence of the morning response: a) inactivity of central monoaminergic pathways mediating the P-effect, b) reduced pituitary sensitivity to LHRH, c) diurnal variation in the formation of obligatory P-metabolites. Adult ovariectomized rats were maintained under 14 h light/10 h dark for 1 month. They were primed with estradiol benzoate at either 0700 h or 1200 h colony time and challenged with P or P-metabolites (5α-dihydro-P, 20α-dihydro-P, 3α-hydroxy-5α-pregnan-20-one) or with D-Ala^6-des-Gly-NH$_2^{10}$)-LHRH-ethylamide exactly 72 h later. The monoamine precursors DL-threo-dihydroxyphenylserine or 5-hydroxy-L-tryptophan(5-HTP) were administered in conjunction with P in the morning. 5-HTP given at 0630 h significantly increased P-induced LH and FSH release in the morning ($p < 0.005$). LH and FSH release induced by the LHRH analog and monitored over 4 h was significantly greater in the afternoon (LH: $p = 0.028$; FSH: $p = 0.009$). All P-metabolites tested (as well as ACTH) led to significant LH surges in the afternoon, but not in the morning. The absence of the P-response in the morning may thus be caused, at least in part, by reduced activity of central serotoninergic neurons and reduced pituitary responsiveness to LHRH. In contrast, the formation of P-metabolites does not appear rate-limiting.

1131 FACILITATION OF LORDOSIS BEHAVIOR FROM HYPOTHALAMIC AND MESENCEPHALIC ELECTRICAL STIMULATION. Yasuo Sakuma* and D.W. Pfaff. The Rockefeller University, New York, NY 10021.

Estradiol-concentrating neurones are found in several cell groups thought to be involved in the regulation of female copulatory behavior. We now report that electrical stimulation of some of these cell groups can cause changes in the lordosis reflex. Monopolar electrical stimulation was applied through chronically implanted platinum-iridium electrodes to the ventromedial nucleus of the hypothalamus (VMN) (n=48); medial preoptic area (POA) (n=9), or mesencephalic central gray (CG) (n=49) of ovariectomized, estrogen-treated female rats. Lordosis reflex occurrence and strength were tested using cutaneous manual stimulation or male rat mounting.

Electrical stimulation of the VMN facilitated lordosis in response to manual stimulation ($P < .001$) and in response to male mounting ($P < .01$). Percent increases ranged between 53 and 150% of the prestimulation control. A gradual increase followed a relatively long period of stimulation of about 1 hr, and required low frequency, 10-30 Hz. Threshold for effective stimulation was, on the average, 12.5 μA. Adrenal progesterone release was not required for the VMN facilitation of lordosis, since stimulation was effective in adrenalectomized rats, in dexamethasone-primed animals, and in animals preloaded with exogenous progesterone. In contrast, POA stimulation suppressed lordosis performance both in response to manual stimulation ($P < .01$) and male mounting ($P < .01$). The time course of the inhibition was slow, similar to that seen in the facilitation by VMN stimulation. Electrical stimulation of the CG induced immediate and large increases in the lordosis reflex, both in response to manual stimulation ($P < .001$) and male mounting ($P < .001$). What distinguished the facilitatory response to CG stimulation from the effect of VMN stimulation was its fast time course. The increase was often obvious within 2 min from the start of CG stimulation. This facilitation from CG, which does not depend on the integrity of the hypothalamus, increases in a graded manner to increased stimulus intensity with average threshold of 10 μA, and is optimally induced by stimuli delivered at 50-150 Hz.

These results suggest that different cell groups with estradiol-concentrating neurones are not functionally uniform in their influence on a reflex such as lordosis. For instance, the difference in the time course of facilitation in response to VMN and CG stimulation indicates that CG could be in the direct reflex arc for lordosis, while the VMN is not. Instead, the VMN may exert a tonic hormone-sensitive bias on reflex arcs completed in the brainstem.

1132 EFFECTS OF AGENTS WHICH DEPLETE SEROTONIN ON ULTRASTRUCTURE OF THE MEDIAN EMINENCE AND PITUITARY PARS INTERMEDIA. Linda C. Saland* and William G. Dail, Jr. Department of Anatomy, University of New Mexico, School of Medicine, Albuquerque, New Mexico 87131.

The pituitary pars intermedia contains catecholamine nerve fibers which are believed to participate in inhibition of hormone release. Recently, Kraicer and Morris (1976, Neuroendocrinol., 21:275) showed serotonin-stimulated adrenocorticotropin (ACTH) release from intermedia cells in vitro. They suggested that serotonin-containing fibers may be present in the pars intermedia. To investigate this hypothesis, we have studied the effects of antiserotonergic drugs on the morphology of nerve fibers in the pars intermedia and in the median eminence. 5,7-dihydroxytryptamine (5,7 DHT) and p-chloroamphetamine (PCA) significantly lower brain serotonin levels, and produce morphologic evidence of toxic effects and/or degeneration of nerve fibers. Administration of a single 150 μg dose of 5,7 DHT to the lateral cerebral ventricle of adult male rats leads to the appearance of some degenerative changes in fibers of the median eminence, a brain area known to contain serotonin terminals. Similar changes are observed with one 10 mg/kg intraperitoneal dose of PCA. Three sequential injections of PCA (5 mg/kg or 10 mg/kg) result in clearcut areas of degenerating fibers in the median eminence, particularly in the zone near the portal vessels. In contrast, nerve terminals on pars intermedia cells appear normal after all drug treatments. After PCA injection, some secretory cells of the intermediate lobe contain numerous, tightly packed granules. We interpret the results to suggest that antiserotonergic agents affect nerve fibers in the median eminence, and that the morphologic effects are greater with multiple doses of PCA. Lack of morphologic alterations in intermediate lobe nerve fibers suggests that those fibers are not serotonergic. Alternatively, the purported serotonergic fibers of the pars intermedia may be unresponsive to drug treatment, as has been shown for pituitary catecholamine fibers after administration of 6-hydroxydopamine (Shoemaker et al., 1977, Soc. for Neurosci. Abstracts, #1149). Positive effects on secretory cells of the pars intermedia may reflect drug inhibition of granule release.

1133 RADIOIMMUNOLOGIC LOCALIZATION OF VASOACTIVE INTESTINAL POLYPEPTIDE (VIP) IN INTRA- AND EXTRA-HYPOTHALAMIC SITES OF THE RAT BRAIN. W. K. Samson*, S. I. Said* and S. M. McCann (SPON: A. Giachetti), Depts. of Physiology and Pharmacology, University of Texas Health Science Center at Dallas, Dallas, Texas 75235.

The presence of significant quantities of VIP in whole hypothalamus and the demonstration that VIP can act at the level of the hypothalamus to modulate anterior pituitary hormone release led us to reinvestigate the exact localization of the peptide in structures which might be related to anterior pituitary function. Blood was taken from the external jugular vein of lightly etherized adult male Sprague-Dawley rats. They were subsequently decapitated and anterior and posterior lobes of the pituitary were removed. Brains were frozen on dry ice prior to sectioning in the frontal plane on a cryostat. Sections 100 μm in thickness were taken through the plane of the desired nuclei or areas and tissue was removed with flattened 15 gauge needles. Tissues from two rats were pooled, homogenized in 1 ml 0.2N acetic acid, and centrifuged. Supernatants were assayed for extracted protein and radioimmunoassayable VIP content at two dilutions. The following areas were found to contain VIP in quantities sufficient to be detected by RIA (expressed here as pg VIP/μg extracted protein): Suprachiasmatic Nucleus 262.3±35.3, Medial Amygdaloid Nucleus 106.7±9.5, Amygdaloid Cortex and Central Amygdaloid Nucleus 28.1±7.6, Medial Preoptic Area 16.9±5.9, Anterior Hypothalamic Area 20.7±1.5, Organum Vasculosum Lamina Terminalis 17.0±3.1, Median Eminence 8.5±1.7, Anterior Pituitary 5.6±1.2, Posterior Pituitary 6.1±0.7, Cerebellar Cortex 23.0±3.0. Plasma was found to contain 42.6±2.0 pg VIP/ml. Both Median Eminence and Cerebellar Cortex contained VIP levels that were near the lower limit of radioimmunoassay sensitivity (20 pg). Our present data using RIA agrees with immunohistochemical localization of VIP-positive staining elements in the rat brain. Thus, VIP appears to be localized in discrete hypothalamic and extra-hypothalamic sites which have been shown previously by lesion and stimulation studies to exert control over the release of anterior pituitary hormones. The lower levels of VIP found in anterior pituitaries and median eminence fragments, together with our earlier in vivo and in vitro studies, suggest that VIP acts at the level of the cell bodies of neurons which produce or modulate the production of hypothalamic releasing or release-inhibiting factors.

1134 SUPRASELLAR CONTROL OF LUTEINIZING HORMONE (LH) SECRETION BY N-METHYL ASPARTIC ACID (NMA). Bruce A. Schainker* and Theodore J. Cicero, (SPON: James S. Nelson) Depts. of Psychiatry and Anatomy & Neurobiology, Wash. U. Sch. Med., St. Louis, MO 63110.

Parenterally administered NMA, an acidic "excitotoxic" amino acid, acutely elevates serum LH levels in immature (25 day) male rats at subtoxic doses (Price et al., N.S. Abst. 3:335, 1977). Other analogues, such as glutamic acid and kainic acid, act similarly but their relative impotence and extreme neurotoxicity, respectively, limit their usefulness as neuroendocrine probes.

In order to confirm NMA's provocative effects upon serum LH levels we administered NMA s.c. to young adult (54 d, 177 g avg) male Sprague Dawley derived rats 7.5 min prior to sacrifice. Serum LH values (mean ± S.E.M., n=6), determined by radioimmunoassay after H_2O, 16.5 mg/kg, 33 mg/kg or 66 mg/kg BW were 113±54, 446±116, 609±108 and 461±96 ng/ml, respectively.

A suprasellar locus is the presumed site of action of subtoxic doses of NMA since circumventricular organs of the brain, especially the arcuate nucleus of the hypothalamus, are vulnerable to toxic doses. However, to demonstrate whether NMA acts at the level of the pituitary to induce LH secretion we incubated 16 vials, each containing 4 hemipituitaries from 61 day male Sprague Dawley rats, for 3 hrs. in Medium-199 in the presence of LH releasing hormone (LHRH), NMA, both or neither. Radioimmunoassayable LH levels secreted into the media are tabulated:

Compound in Medium	LH in Medium/2ml flask/3 hr S.E.M.	
Control	35 ± 6	
LHRH 10^{-8}M	150 ± 10*	*p < 0.001 vs cont.
NMA 10^{-5}M	19 ± 7†	†p > 0.10 vs cont.
LHRH 10^{-8}M + NMA 10^{-5}M	140 ± 8*	

These results demonstrate that NMA does not induce LH secretion by a direct action upon the pituitary, but rather presumably acts at a suprasellar locus.

Accordingly, NMA will undoubtedly provide a useful tool to the neuroendocrinologist in elucidating the central control over pituitary LH secretion since it: 1) acutely (within minutes) elevates serum LH in the young adult (54 days) as well as immature (25 day) male rat of different strains; 2) does not act at the level of the pituitary; 3) is easily administered to produce its effects - viz., parenterally; and 4) is the only known agent that acutely provokes marked LH secretion in the male rat when given parenterally at subtoxic doses. This research was supported in part by USPHS grants DA-01407 and DA-00259. T.J. Cicero is a recipient of Research Scientist Development Award AA-70180.

1135 THE DISTRIBUTION OF LUTEINIZING HORMONE-RELEASING HORMONE (LHRH) IN THE FETAL GUINEA PIG BRAIN. M. Schwanzel-Fukuda* and A.J. Silverman. Dept. Anat., Columbia Univ., New York, NY 10032.

Brains from littermate male and female fetal guinea pigs were studied using an antiserum to LHRH ("F" rabbit, supplied by S. Sorrentino) and the unlabeled antibody enzyme technique. Time-mated guinea pigs (Hartley albino) were decapitated, the fetuses removed and their brains fixed by immersion in Bouin's solution. Tissue was embedded in paraffin and 6 µm sections cut and processed for immunocytochemistry. Immunoreactive LHRH neurons and processes were present on the 35th day of a 68-72 day gestation period. In the females, LHRH cells were found predominately in the arcuate nucleus (AN) but were also numerous in the suprachiasmatic nucleus (SCN), preoptic area (POA), olfactory tubercle (OT), septal region (S), and nucleus and tract of the diagonal band (DB). Fibers were observed in these regions and in both oral and caudal portions of the tuber cinereum. In the males, LHRH neurons were clustered in AN with a few scattered neurons in SCN, DB and S. LHRH fibers were observed in AN and in the caudal portion of the tuber cinereum, but not in the rostral regions of the brain. At 40 days of gestation, the total number of LHRH neurons in the female brain was twice that in the male brain. In both sexes cells were now present in AN, SCN, POA, OT, S, DB. LHRH positive fibers were found in all of these regions and in the median eminence. At 45 days of gestation the situation vis-à-vis the LHRH neurons was reversed; there were now twice as many positive cells in the male as compared to the female. The same regions contained positive cells and fibers as was noted for day 40. At 50 and 60 days of gestation, there was a decrease in the total number of LHRH neurons detected in both sexes. The frequency of occurance of immunoreactive neurons was approximately equal in both sexes by this period in development. These cells and their fibers were now found predominately in the rostral regions (SCN, POA, DB, OT, S); very few were noted in AN. Positive axons were first noted caudally at 50 days in the capsule of the mammillary body, fasciculus retroflexus, interpeduncular nucleus and midbrain tegmentum. From 35 days onward there was a continuous increase in the numbers of LHRH axons to the median eminence.

This study represents a description of a transitory sexual dimorphism in the LHRH neurosecretory system of a developing mammal. Supported by HD10665 and HD10533.

1136 LACK OF PARALLELISM BETWEEN EFFECT OF LESIONS OF THE CORTICO-MEDIAL AND BASO-LATERAL AMYGDALA ON PLASMA PROLACTIN AND CORTICOSTERONE RESPONSES TO STRESS. Jo. A. Seggie, Departments of Neurosciences and Psychiatry, McMaster University, 1200 Main St. Hamilton, Ontario L8S 4J9.

In 1977 it was reported at the Society for Neurosciences (abs #642) that cortico-medial amygdala lesions had no effect on the pattern of plasma corticosterone response to the stress of handling or exposure to a novel environment. However, lesions of the baso-lateral amygdala resulted in a corticosterone response to these stresses that was of shorter latency and greater magnitude in comparison with non-lesioned controls. The present study was undertaken to determine the effect of lesions of the cortico-medial or baso-lateral amygdala on plasma prolactin responses to the stress of 5 seconds of handling and three minutes exposure to a novel environment in comparison with corticosterone stress responses in the same experimental preparations.

Adult male rats were housed in individual cages under a light cycle of 12 hours light/12 hours dark. Separate groups of normal, sham-operated or amygdala-lesioned rats were subjected to one of two stressors at the same time of day and sacrificed by decapitation 0, 5, 10 or 15 minutes after the end of stress. Trunk blood was collected for hormone assay. A low level of stress was imposed by picking the animal up for 5 seconds while a higher level of stress was imposed by placing the animal into a novel environment for 3 minutes. In the first study, lesions were placed bilaterally in the baso-lateral amygdala while in the second study the lesion group sustained cortico-medial amygdala lesions.

Baso-lateral amygdala lesions had no effect on the pattern of plasma prolactin responses to either of the stressors. The cortico-medial amygdala lesion however, resulted in a prolactin response following exposure to a novel environment that was of shorter latency and greater magnitude than that seen in non-lesioned controls. The prolactin response to handling was unaffected by this lesion.

Thus the two types of amygdala lesions have different effects on the corticosterone and prolactin responses to stress in this study. Furthermore, success in visualizing this differential influence may well depend on the nature of the stress stimulus used to challenge the system under observation.

Supported by project grants from the Ontario Mental Health Foundation (O.M.H.F.). Dr. Jo Seggie is an O.M.H.F. Scholar.

1137 EFFECTS OF RESERPINE ON VASOPRESSIN AND NEUROPHYSINS IN THE EXTERNAL LAYER OF THE MEDIAN EMINENCE IN THE RAT. V. Seybold*, R. Elde and T. Hokfelt*. Dept. of Anatomy, Univ. of Minnesota Medical School, Minneapolis, MN 55455.

The indirect immunofluorescence technique was used to qualitatively assess the effect of reserpine on peptides in the median eminence (ME) of the rat. Changes in the distribution of neurophysins (NP) and vasopressin (VP) were of particular interest. These secretory products could be localized in both the internal layer of the ME in cross-sections of axons en route to the posterior pituitary, and in the external layer in nerve terminals adjacent to portal capillaries.

Acute reserpine treatment (10 mg/kg i.p. 24 hr prior to sacrifice) specifically depleted NP and VP in the external layer of the ME. Depletion was observable at 8 hr post-injection, but the effect was maximal at 24 hr. No qualitative changes in internal layer NP, VP or oxytocin were observed. Levels of other peptides (somatostatin, TRH, LHRH) localized by immunofluorescence in the external layer did not appear to be altered by 24 hr reserpine treatment. Chronic reserpine treatment (2 mg/kg/24 hr i.p. for 5 days, animals sacrificed 24 hr after the last injection) resulted in an apparent increase in external layer NP and VP.

The acute effect of reserpine is believed to be unrelated to the monoamine depleting effect of the drug. The disappearance of NP and VP from the external layer of the ME could not be duplicated with other depletors of monoamines. Treatment with α-methyl-p-tyrosine (250 mg/kg/8 hr i.p. for 24 hr) and p-chlorophenylalanine (300 mg/kg i.p. for 24 hr) did not produce observable decreases in NP and VP in the external layer by immunofluorescence. Furthermore, the monoamine oxidase inhibitor, phenipra-zine (10 mg/kg i.p. 14 hr prior to sacrifice) did not reverse the acute effect of reserpine on NP and VP.

The paraventricular nucleus (PVN) was determined as the source of NP and VP in the external layer. Bilateral lesion of the PVN eliminated all of the external layer of NP and VP. Bilateral lesion of the suprachiasmatic nucleus has no qualitative effect on NP and VP in either layer of the ME.

Therefore, the NP and VP fibers in the external layer of the ME can be distinguished from NP and VP fibers terminating in the posterior pituitary on an anatomical basis, as well as by a differential response to acute reserpine treatment. Furthermore, the effect of acute reserpine treatment on NP and VP in the external layer may be due to a direct effect of the drug on neurosecretory neurons and not reflect reserpine's action on the storage of monoamines.

Supported in part by a grant from the Graduate School of the University of Minnesota and a PMA Fellowship to V. Seybold.

1138 COMPARISON OF ANGIOTENSIN ACTIONS AT TWO SITES IN RAT BRAIN. John B. Simpson and Michael L. Mangiapane, Depts. of Psychol. and Physiol.-Biophysics, Univ. Washington, Seattle, WA 98195

There are at least two significant central sites of action of angiotensin II (A II) in rats for provoking water intake and hypertension. These loci are the subfornical organ (SFO; Mangiapane and Simpson, Neurosc. Abstr., 1977) and the tissue proximal to the optic recess of the third cerebral ventricle (OR), including the organum vasculosum (Hoffman and Phillips, Brain Res., 1976). These two loci were compared. One group of rats each received an intracranial cannula (26 ga) terminating in the SFO, in tissue proximal to SFO, or in the dorsal third ventricle (III V). SFO cannulae did not perforate ventricular ependyma. A second group each received a cannula terminating within the OR. For ventricular loci (OR or III V), ependyma was ruptured only at the classified site of injection. Measures of water intake and mean aortic pressure were made following intracranial injections of various doses of A II.

Injection of 10 ng or less of A II at the SFO provoked highly correlated dipsogenic and pressor effects. The pressor effect in every case preceded the onset of drinking and was found in rats not ingesting water. The pressor effect was not secondary to the elicited behavior since it occurred in anesthetized animals. Maximal efficacy for both A II effects was observed when the cannula terminated in the SFO and not in adjacent tissue or III V. Application to OR of those doses of A II also provoked dipsogenic and pressor effects. The sensitivity of this region to dipsogenic and pressor effects was less than the SFO and approximately equal to III V. Further, OR injection of these doses of A II provoked a pressor response which frequently commenced only after drinking began. The pressor effect of OR injections of A II may be secondary to the elicited behavior. This is suggested by the striking similarity of the time course and magnitude of the OR pressor effect to that seen in animals spontaneously ingesting water. In contrast, SFO-injected animals are unlike spontaneously drinking animals because the pressor response typically is near-maximal by the onset of elicited drinking.

Thus, SFO injections of low doses of A II cause a pressor effect which is not secondary to the elicited drinking, whereas OR injections of the same doses of A II can cause a pressor effect which is secondary to the elicited drinking. These data, then, suggest at least two different modes of and neural sites of dipsogenic action of A II.

1139 ROLE OF ACETYLCHOLINE AND ANGIOTENSIN IN THE OSMOTIC CONTROL OF VASOPRESSIN RELEASE BY THE ORGAN CULTURED RAT HYPOTHALAMO-NEUROHYPOPHYSEAL SYSTEM. Celia D. Sladek and Robert J. Joynt*. Depts. Neurology and Anatomy, Univ. Rochester School of Medicine, Rochester, N.Y. 14642

The organ cultured hypothalamo-neurohypophyseal system (HNS) has been used as an in vitro system for studying control of vasopressin (VP) release. Each of these organotypic explants includes the supraoptic nucleus, median eminence, and neural lobe. The HNS releases VP at a constant rate in vitro and releases VP in response to acetylcholine (ACH), angiotensin II (AII), and osmotic stimulation. VP release in response to ACH and osmotic stimulation is blocked by the addition of hexamethonium (10^{-5}M, Sladek and Joynt, Neurology 28:366, 1978), but not by atropine ($5x10^{-5}$M). Thus, a nicotinic cholinergic synapse appears to mediate osmotic stimulation of VP release. Furthermore, saralasin, an AII antagonist, blocks osmotically stimulated VP release by the HNS (Sladek and Joynt, Neurosci. Absts. 3:357, 1977). These data suggest that AII also modulates osmotic control of VP release. The relationship between AII and cholinergic modulation of VP release was examined by assessing the effect of hexamethonium on AII stimulation of VP release, and the effect of saralasin on cholinergic stimulation of VP release. Hexamethonium (10^{-5}, 10^{-4}, 10^{-3}M) was ineffective in blocking VP release by AII (10^{-5}M). Saralasin (10^{-4}M) did not block stimulation of VP release by either ACH (10^{-5}M) or nicotine (10^{-5}M). These findings suggest independent AII and cholinergic mechanisms controlling VP release, however the effectiveness of both saralasin and hexamethonium in blocking osmotically stimulated VP release indicates some interaction between these regulators of VP release. A hypothetical model which would fit these data consists of a VP producing cell possessing nicotinic-cholinergic receptors and a separate osmoreceptive cell which communicates with the VP cell by way of a cholinergic synapse which does not impinge directly on the VP cell. Information from the osmoreceptor is modulated by AII possibly by modulating release of or acting as a neurotransmitter from an interneuron.

1140 A ROLE OF THE SUPRACHIASMATIC PART OF THE MEDIAL PREOPTIC NUCLEUS ON THE AFTERNOON OF PROESTRUS IN FEMALE RATS. Ei Terasawa and Stanley J. Wiegand. Wis. Primate Res. Center, Madison, WI 53706.

Previously we have reported (Neuroscience Abstract 3: 1161, 1977) that the medial preoptic nucleus (MPN), a small periventricular nucleus caudal to the organum vasculosum of the lamina terminalis, is necessary for estrous cyclicity in rats. In the present experiment, function of the MPN, as well as adjacent structures, for the release of gonadotropins during the critical period on the day of proestrus was examined. In regular 4 or 5 day cyclic rats brain lesions and stimulations were performed on proestrous day, and ovulation was determined by direct observation of the ampulla on estrous morning. If the ampulla was dilated, it was dissected out and the number of ova counted under a microscope. If the ampulla was not dilated, the ovary was not removed and vaginal cyclicity was followed postoperatively.

Experiment I: Bilateral electrolytic lesions with a platinum electrode were made in the MPN, the periventricular part of the medial preoptic area (PMPO, just dorsal to the MPN), or the suprachiasmatic nucleus (SCN) under ether anesthesia on proestrous morning (900-1000). Lesions of either the MPN or the PMPO blocked ovulation (0 of 12, 0 of 11 rats ovulated, respectively), while lesions of the SCN failed to block (4 of 4 rats ovulated). However, in the animals with PMPO lesions, subsequent cyclic ovulation was indicated by resumption of vaginal cycles, while most of the animals with MPN lesions showed persistent vaginal estrus.

Experiment II: In order to overcome the ovulation blockade with MPN- or PMPO-lesions, electrochemical stimulation (ECS) was applied to the medial preoptic area (MPOA) under ether anesthesia on proestrous afternoon (1400-1500). Anodal DC of 75 μA to the MPOA through stainless steel electrodes for 60 sec consistently induced ovulation in the pentobarbital blocked proestrus rats (all 8 ovulated). ECS to the MPOA with the same current resulted in ovulation in only 1 of 10 MPN-lesioned rats. With higher current (200 μA for 30 sec), ECS of the MPOA induced ovulation in 3 of 11 MPN-lesioned animals and 6 of 7 PMPO-lesioned animals. Sham ECS in the MPN- or PMPO-lesioned animals were without effects.

It is concluded that 1) the major portion of the neurons necessary for the release of LH-RH on the afternoon of proestrus originate in the vicinity of the MPN, but not the SCN; 2) most, but not all, of the neurons in the MPOA responding to ECS may exert their influence indirectly via neural cells located in the MPN; and 3) neural fibers originating in the MPN may be distributed diffusely through the dorsal periventricular region as they pass caudally to the medial basal hypothalamus. 1141 BINDING OF CORTICOSTERONE TO SYNAPTIC PLASMA MEMBRANE FROM RAT BRAIN. A.C. Towle* and P.Y. Sze (SPON: B.E. Ginsburg). Dept. of Biobehavioral Sci., Univ. of Connecticut, Storrs, Ct. 06268

To investigate the possibility that glucocorticoids may act directly on nerve terminals in the brain, the binding of corticosterone to synaptic plasma membrane (SPM) was examined. Male rats were adrenalectomized for 3 days and perfused with saline prior to brain dissection. SPM and other subcellular fractions were prepared from the hippocampus, hypothalamus and cerebral cortex by a centrifugation procedure using discontinuous sucrose density gradients. After equilibration with 3H-corticosterone at 4° C, SPM was applied to DEAE-cellulose filters and washed free of unbound 3H-steroid. The binding of 3H-corticosterone to cell cytosol (105,000 g supernatant after 17,000 g) and to soluble content of synaptosomes (soluble fraction after osmotic shock) was determined by Sephadex G-25 gel filtration. In all cases, specific binding was distinguished from non-specific binding by competing the 3H-corticosterone with 1,000-fold unlabeled steroid.

From ligand bound/mg protein vs. log [ligand concentration] plots, specific binding of 3H-corticosterone to SPM obtained from all 3 brain regions shows a similar sigmoidal curve, reaching saturation of dissociable binding sites at 3×10^{-7}M steroid. Compared with 3H-corticosterone binding to cell cytosol (saturation at $2\text{-}6x10^{-8}$M), the affinity of the steroid binding sites in SPM appears to be lower than those in cytosol. From the 3 brain regions, SPM isolated from hypothalamus shows the highest binding capacity. This is in contrast to cytosol binding which is highest in hippocampus. Thus, SPM binding may represent a different case from the soluble corticoid binding protein(s) known in brain cytosol. The nature of this SPM binding with regard to kinetic characteristics, differential affinity for various glucocorticoids, and the physical properties of the binding sites will be discussed. It should be noted that synaptosomal soluble content shows only minimally detectable binding capacity, indicating that in brain neurons the cytosol binding protein(s) may be confined to the perikarya.

Specific binding of glucocorticoids to cell plasma membrane has been described in liver by other investigators. The demonstration here of glucocorticoid binding to brain SPM suggests that the steroid hormone may act on nerve terminals by possibly regulating membrane properties.

1142 REGIONAL PATTERNS OF ENDOGENOUS CORTICOSTERONE BINDING IN RAT BRAIN: BASAL VS. STRESSED STATES. Barbara B. Turner, Elaine Smith* and Bernard J. Carroll*. Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109.

We wished to determine the physiological distribution of corticosterone binding (cytosol) in brains of resting, unstressed rats. The regional pattern of binding in basal animals could then be compared with that following acute stress. The observation of area differences would suggest specific anatomical sites as having significant roles in the stress response. The following parameters were measured in each of 8 regional cytosols: total corticosterone, bound steroid, and the number of unoccupied binding sites. Eighty adult male rats were killed between 0900-1000h. "Basal" animals were perfused within 3 min. of cage approach; "stressed" rats were subjected to 30 min prior shaker stress. Tissue from 4-5 rats was pooled for each region and homogenized (20 ml/g) in Tris-EDTA buffer, pH 7.4. Free steroid was removed by dextran-charcoal. All samples were extracted into CH_2Cl_2, chromatographed on LH-20, and corticosterone levels measured by radioimmunoassay. Unoccupied sites were estimated by the addition of 3H-corticosterone (3.5×10^{-8}M) to aliquots of the homogenate.

In the unstressed rat the highest levels of cytosol binding were observed in the preoptic and septal regions (POS), followed by the pituitary and hypothalamus. In general, only 50% of cytosol binding sites were occupied in the basal animal except for the POS which had 80% occupation. Total sites were also higher in the POS than in other brain regions with the exception of the pituitary. Stress produced an increase in endogenous binding only in the pituitary. Four regions including the HC showed virtually no change; however, a substantial decrease (40-50%) in binding was observed in the POS. All brain regions, but not the pituitary, showed a decrease in total cytosol sites following stress. An increase in the percentage occupancy of the remaining sites was observed in all regions with the exception of the POS.

These results suggest unique roles not only for the pituitary but also for the preoptic and septal regions in the mediation of the stress response. (Supported in part by NIMH training grant 07417 to BBT.)

1143 A STIMULATORY ROLE OF THE SEROTONERGIC DORSAL RAPHE-HYPOTHALAMIC PROJECTION IN LH SECRETION. L. van de Kar*, S.A. Lorens+, A. Vodraska*, G. Allers* and L.S. Van Orden III. Depts. Pharmacol. and Psychiatry, U. of Iowa, Iowa City, IA 52242 and +Loyola Univ., Stritch Sch. Med., Maywood, IL 60153.

Various studies have indicated that 5-hydroxytryptamine (5HT) is regulating both luteinizing hormone (LH) secretion as well as sexual behavior. The site of 5HT action was assumed to be in the hypothalamus but it is not known which of the hypothalamic nuclei are involved in these regulatory systems. Studies using autoradiographic as well as lesion techniques have shown that both the midbrain dorsal (DR) and the median (MR) raphe nuclei project to the hypothalamus. Since it was demonstrated that the MR and DR have differential projections to telencephalic regions, projections of the MR and DR to hypothalamic nuclei were investigated.

Descrete MR and DR lesions were produced electrolytically in adult male rats. The rats were decapitated 17-20 days after surgery and 5HT content in various hypothalamic nuclei was determined by an enzymatic radioisotopic method (Saavedra et al., JPET, 1973). MR lesions produced a significant decrease in 5HT content of the medial preoptic area (49%), suprachiasmatic (70%) and anterior hypothalamic (60%) nuclei, the anterolateral hypothalamus (46%), arcuate nucleus (58%) and the hippocampus (61%). In contrast DR lesions produced a significant decrease in 5HT content only in the anterolateral hypothalamus (45%), arcuate nucleus (48%) and caudate-putamen (66%). In a second experiment 5,7-dihydroxytryptamine (5,7-DHT 5 µg in 1 µl) was injected into either the MR or DR 45-60 min following desipramine administration (10 mg/kg i.p.). The rats were decapitated 20-27 days after surgery and serum LH was measured by a double antibody radioimmunoassay, using a kit provided by NIAMDD. DR lesions produced a 37% decrease in serum LH levels and a 46% reduction in the 5HT content of the caudate-putamen. No change was observed in the 5HT content of the hippocampus. In contrast MR lesions did not affect serum LH levels or the 5HT content of the caudate-putamen but produced a decrease in the 5HT content of the hippocampus (52%). These results suggest that, although the MR projects both to the medial preoptic area and arcuate nucleus, these projections are not involved in LH secretion. In contrast, the projection from the DR to the arcuate nucleus may have a stimulatory influence on LH secretion.

1144 A GOLGI AND EM STUDY OF THE RAT HYPOTHALAMIC MAGNOCELLULAR PARAVENTRICULAR NUCLEUS. Anthony N. van den Pol. Sect. Neurosurgery, Yale Univ. Sch. Med., New Haven, Conn. 06510.

Neurons of the paraventricular nucleus, pars magnocellularis, (PVN) synthesize and secrete oxytocin and antidiuretic hormone. Although numerous reports (e.g., Szentágothai et al., Hypoth. Cont. Ant. Pit., Akadémiai Kiadó, '72) have suggested that the neurosecretory cells of the PVN are relatively resistant to impregnation by Golgi methods, by systematically varying block size, animal age, chemical concentration, and times in solutions in 207 rats, a Golgi method was found which yielded excellent results with magnocellular PVN neurons of 29 rats. To verify the identity of Golgi impregnated PVN neurons, soma size, 1 µ plastic sections counterstained with osmium/toluidine blue, amount of vasculature, and local topography were examined. Cells containing silver chromate were compared with horseradish peroxidase filled neurons and with ultrathin sections investigated with EM.

Two or three primary dendrites issue from PVN somata. Some dendrites have no branches; others bifurcate once or twice. Spine-like protrusions, 2 µ long, either straight or with a bulbous ending, emerge from dendrites and less frequently from perikarya. While Golgi impregnated dendrites of identified PVN cells sometimes have smooth contours, dendrites were also seen with very irregular outer membranes, with dilations interspersed with narrow constrictions; since these were also visible with EM, it is unlikely these are Golgi artifact. Although exceptions were noted, dendrites tend to stay within PVN borders, commonly entering into the medial and ventromedial parvicellular region. Abundant Golgi apparatus was found not only in somata, but also in large proximal dendrites. Soma-soma appositions exceeding 15 μ^2 are common; sometimes, a single thin glial projection separates neighboring cell bodies. Of 54 cells in which axon origin was determined, the axons of 21 cells came off proximal dendrites; the remaining cells had axons leaving perikarya. The majority of axons leave PVN in a lateral or ventrolateral direction; rarely an axon was seen which left PVN, but after proceeding 50 to 80 µ turned around and headed towards PVN. Although magnocellular axons establish contact in passing PVN dendrites or somata, whether these are functional or chance contacts is unknown. No unambiguous collaterals were found arising from PVN axons within the nucleus. Profiles containing large dense core vesicles are situated near blood vessels; whether these represent areas of local release of nonapeptides within PVN or axons passing by has not yet been determined. Quantitative analysis of 1 µ Nissl sections revealed that 3 times the area is taken up by vasculature in PVN as compared to the hypothalamus immediately lateral to PVN.

1145 SEX DIFFERENCES IN THE RESPONSE OF HIPPOCAMPAL CA1 PYRAMIDS TO GONADAL STEROIDS: EFFECTS OF TESTOSTERONE AND ESTRADIOL ON THE IN VITRO SLICE PREPARATION. Richard M. Vardaris and Timothy J. Teyler. Kent State University, Kent, Ohio 44242 and Northeastern Ohio Universities College of Medicine, Rootstown, Ohio 44266.

Monosynaptic extracellular EPSPs and population spikes were recorded from hippocampal CA1 pyramidal cells following stimulation of the Schaffer collaterals in explants from rat hippocampus. The major criteria used to establish appropriate physiological status of the preparations were: (a) EPSP and spike thresholds equal to or less than 3 or 5 volts respectively; (b) waveforms similar to those observed in intact preparations; (c) presence of paired-pulse facilitation.

Testosterone (T) and 17-beta-estradiol (E_2) were added to the Ringer's solution bathing hippocampal slices from normal adult male and female rats. The steroids were administered at a 100pM concentration, in the sequences E_2-T-E_2 or T-E_2-T. Slices were obtained from estrous and diestrous females. Electrophysiological measures were taken pre-drug, and at 10 and 20 min intervals post-drug using a conditioning-test stimulation procedure.

In males, E_2 enhanced the amplitudes of CA1 field potentials, whereas T depressed these responses. The same pattern of effects was seen with estrous females. In diestrous females, however, the pattern was reversed, with E_2 depressing responses and T enhancing responses. There were indications that the two steroids were interacting with different receptors, as has been reported for other tissues.

1146 EFFECTS OF AMYGDALA LESIONS OR OLFACTORY BULBECTOMY ON LUTEINIZING HORMONE (LH) RESPONSE TO OVARIAN STEROIDS IN RATS. J. Vitale and R. A. Gorski. Depts.Psychol. and Anat., UCLA, Los Angeles,CA 90024

Amygdala lesions and olfactory bulbectomy have divergent effects on behavioral indices of estradiol benzoate (EB) sensitivity.Since neural mechanisms subserving behavioral and hormonal responses to steroids may differ, this study was conducted to determine the effects of these lesions on plasma LH levels in response to EB and progesterone (P). 63 rats were divided into 3 groups: those receiving sham operations (SHAM), bilateral bulbectomy by a cut & suction technique (BULBX),or small bilateral lesions of the corticomedial amygdala using a platinum electrode (AMYG). Vaginal cycles were unaffected. 1 to 2 mos. post-lesion rats were ovariectomized. Tests for LH response began 3 weeks later. Each rat received in ascending order each dose of EB: 7,35, & 70 ug/kg, at 4 week intervals. Plasma samples were drawn via jugular puncture at 1700-1745 hrs (lights on 0500-1900) at these times: 44 hrs prior to EB (Pre-EB), and 5,29,53, & 77 hrs after each dose of EB. Half of each group was always injected with 2mg P 5hrs before the 77hr sample and half received oil. Plasma LH levels were assayed by RIA and evaluated with ANOVA and Duncan's Range Tests. Comparisons presented were significant at $p < 0.05$ or less. All 3 doses of EB suppressed LH relative to Pre-EB levels to an equivalent degree (26-52%) at 5hrs post-EB, redardless of lesion. At 29 hrs, higher doses of EB were more effective than 7ug/kg in suppressing LH (58-61% vs 22-34%,respectively). At 53 hrs, LH levels following 7 or 35ug/kg were not different from Pre-EB levels. However, after 70ug/kg, LH values of both SHAM and BULBX were elevated: SHAM, 123% of Pre-EB, at 695ng/ml; BULBX, 144% of Pre-EB, at 806ng/ml. Values for AMYG were 95% of Pre-EB, at 515 ng/ml, significantly different from SHAM and BULBX. P after 35 or 70ug/ml was equally effective in elevating LH above Pre-EB and oil-treated control values at 77 hrs, regardless of lesion group.

Thus, BULBX do not deviate from the SHAM pattern of LH responses to EB, although in behavioral studies they show increased sensitivity to EB as measured by the lordosis quotient. AMYG, typically normal in behavioral responsiveness, do not show facilitated LH response to 70 ug/kg before P. While all doses of EB exerted negative feedback on LH, the higher doses were more effective, and were necessary to prime the system for a significant LH response to P. Only the 70ug/kg dose increased LH above Pre-EB values directly. These results suggest that the effects of EB on LH depression, priming, and facilitation are differentially dose-dependent and that AMYG lesions differentially affect these functions. (Supported by HD-01182.)

1147 EVIDENCE FOR A HYPOTHALAMIC SITE OF ACTION OF VASOACTIVE INTESTINAL PEPTIDE (VIP) TO MODULATE PITUITARY HORMONE RELEASE IN CONSCIOUS FEMALE RATS. E. Vijayan*, W. K. Samson*, S. I. Said* and S. M. McCann, Depts. of Physiology, Internal Medicine and Pharmacology, University of Texas Health Science Center at Dallas and V.A. Hospital, Dallas, Texas 75235.

Vasoactive intestinal peptide (VIP) has been recently shown to be present in the hypothalamus and other areas of rat brain. To evaluate the possible role of VIP in influencing pituitary hormone release, ovariectomized (OVX) conscious rats bearing chronically implanted 3rd ventricular cannula were injected with 2 µl saline containing varying doses of VIP and plasma LH, Prl, GH, TSH and FSH levels were measured by RIA in jugular blood samples drawn through an indwelling silastic cannula. Control injections of saline iv or into the 3rd ventricle did not modify plasma hormone levels. Third ventricular injection of 4, 40 and 100 ng VIP produced a significant elevation within 5 min in plasma LH, while Prl levels were elevated by 40 and 100 ng doses; however, the highest dose of 500 ng had no effect on plasma LH or Prl levels. Plasma GH titers increased significantly after 3rd ventricular injection of each dose of VIP at 15 min and remained elevated for the duration of the experiment. Intravenous injection of VIP at doses of 40 and 1000 ng had no effect on plasma LH, but Prl levels were significantly elevated by the 1000 ng dose. Plasma GH was not modified by iv injection of 40 ng, while the 1000 ng dose induced a significant reduction. No significant changes in FSH or TSH levels were induced by 3rd ventricular or iv injection of VIP. In vitro incubation of hemipituitaries in 2 ml of TC medium 199 (Difco Labs.) at 37°C under 95% O_2 and 5% CO_2 with doses of VIP ranging from 10 ng to 10 µg had no effect on pituitary hormone release into the medium. Third ventricular injection of 100 ng VIP had no effect on mean arterial blood pressure, while iv injection of 1000 ng significantly lowered blood pressure within 5-10 sec of injection. The results indicate that 3rd ventricular injection of VIP in unanesthetized OVX rats can alter pituitary hormone release presumably by a hypothalamic site of action and are consistent with the concept that the peptide may act as a transmitter or modulator of neuronal activity controlling pituitary hormone release. (Supported by Grants from NIH #AM10073, #HD09988 and from the Ford Foundation to SMM and #HL14187 and #CA21570 to SIS)

1148 CENTRAL EFFECTS OF ENDORPHIN ON THE HYPOTHALAMUS AND ANTERIOR PITUITARY OF THE RAT: IN VITRO STUDIES IN HYPOTHALAMIC ORGAN CULTURE AND DISPERSED ANTERIOR PITUITARY CELLS. K. Yamauchi*, C.S. Hollander*, Y. Hirooka*, S. Richardson*, P. Ferdinand*, and J. Prasad* (SPON: J. Ransohoff). Endocrine Division, Dept. of Med. NYU School of Medicine, N.Y., N.Y.

In the course of in vitro studies undertaken to elucidate the in vivo endocrine effects of βendorphin we examined its actions (a) on thyrotropin releasing factor (TRF) and somatostatin (SRIF) release in organ culture of a hypothalamic fragment essentially encompassing the medial basal hypothalamus and (b) upon basal release of thyrotropin (TSH) in primary culture of dispersed anterior pituitary cells. TRF, SRIF, and TSH were measured by radioimmunoassays which were specifically validated for the in vitro systems we employed. In hypothalamic organ culture, βendorphin at 10^{-7}M, 10^{-6}M and 10^{-5}M increased TRF release in a dose responsive fashion to 200 ± 12.4% ($p<0.001$), 247 ± 32% ($p<0.001$) and 430 ± 79% ($p<0.005$) of control. The effects of βendorphin at 10^{-6}M and 10^{-5}M were significantly inhibited by naloxone at 5 x 10^{-7}M. SRIF demonstrated a complex biphasic response to βendorphin with significant release at 10^{-9}M but inhibition at 10^{-8}M. Surprisingly we also noted a small but highly significant and consistent increment in basal TSH release with 10^{-10}M to 10^{-6}M βendorphin from 305 ± 6ng/dish (control) to 467 ± 29, 482 ± 30, 428 ± 28, 496 ± 47 and 568 ± 28 ng/dish. All of these observations were significant at the 0.001 level. In conclusion βendorphin has complex actions with discrete effects on the release of TRF and SRIF by the hypothalamus and upon the release of TSH by the anterior pituitary. The physiological relevance of these observations to the in vivo situation remains to be established. However the complexity and biphasic nature of our findings suggest that a definitive assessment of the in vivo effects of βendorphin on TRF, SRIF and TSH,and probably the other hypothalamic and pituitary hormones as well,will require multiple acute and chronic measurements in conjunction with a careful dose response curve in a variety of pathophysiological circumstances.

NEUROETHOLOGY

1149 AERIAL MANEUVERING IN ORTHOPTERAN JUMPING AND FLIGHT: SENSORY BASIS OF HINDLIMB MOVEMENTS. Edmund A. Arbas, Dept. of Biology, Univ. of Oregon, Eugene, OR 97403.

Flying locusts employ several mechanisms for stabilizing flight and initiating turns, including: 1) changes in timing of motor output to bilateral sets of wing muscles; 2) curling of the abdomen in a rudder-like fashion; 3) lateral excursions of meso- and metathoracic limbs. These are but a few elements of a system of complex exteroreceptive reflexes which serve to assure smooth, coordinated, oriented flight.

A similar set of reflexes exists in certain flightless grasshoppers. Barytettix sp., a brachypterous, subtropical grasshopper, possesses no hindwings, and only vestiges of forewings. Tethered individuals respond to initiation of a windstream over their bodies by throwing their legs up into a stereotypic flight-like posture, and under simulated yaw conditions, perform asymmetrical orientation movements of their hind limbs. Barytettix never fly, but they are powerful jumpers, able to traverse up to about 40 body lengths (1.2 M) in a single leap. These movements may be used to stabilize the aerial phase of the jump.

Sensory ablation experiments were performed on the powerful flyer, Schistocerca gregaria, and on the flightless Barytettix, to examine the roles of particular sensory structures, including cephalic mechanosensory hairplates, antennae and cerci, in generation of the hindlimb movements. Those animals whose receptors had been removed or reversibly occluded by painting, were tethered in front of a moveable wind tunnel and subjected to simulated yaw conditions by changing the angle of airflow over their bodies. Presence or absence of limb movement was monitored visually for some experiments, while in others, a continuous record of limb position was obtained using a movement transducer (Sandeman, 1968 Comp. Biochem. Phys., 119: 267-283).

Symmetrical flight posture and aerial posturing of the limbs in the jump is initiated by a generalized "wind sense" mediated by a distributed system of receptors including hairplates, antennae and the cerci, as well as general body hairs, and perhaps the tympani. Asymmetrical maneuvers, on the other hand are specifically mediated by the hairplates and the antennae.

Both sets of reflexes are strictly coupled to the condition of being airborne, and are inhibited by tarsal contact with any firm substrate.

Supported by P.H.S. 5-T-32 GM07257.

1150 THE JAMMING AVOIDANCE RESPONSE IN AN ELECTRIC FISH PULSE SPECIES: BEHAVIOR AND SENSORY PHYSIOLOGY. Curtis L. Baker, Walter F. Heiligenberg and Joseph Bastian. Dept. Neurosci.,UCSD,La Jolla, CA 92093.

Weakly electric fish produce an electric field in their near vicinity; objects in the water cause distortions of this field which are monitored by electroreceptors on the body surface. This electrolocation ability is jammed by signals, normally from another fish, which are nearly coincident with the animal's own electric organ discharges (EODs). To prevent such jamming,gymnotoid electric fish with pulsatile EODs shorten their EOD intervals in response to pulses that scan their EOD from negative to positive latencies; they lengthen intervals, or only slightly shorten them, in response to pulses that scan from pos. to neg. latencies. Thus this Jamming Avoidance Response (JAR) minimizes the chances of long series of pulse coincidences, which are most detrimental to electrolocation. The JAR in pulse species strongly resembles the JAR in wave species (Bullock et al,J.Comp.Physiol.77:1,1972).

Based on behavioral data, a theory is proposed to account for the JAR in pulse species. Pulse stimuli at negative latencies with respect to the EOD trigger an excitatory process, which accelerates the EOD, while stimuli at small positive latencies activate an inhibitory process. The process which is triggered first dominates the over-all response.

Studies in curarized preparations demonstrate that the JAR is controlled by electroreceptive input alone, without reference to an internal electric organ pacemaker-related signal. A sufficient stimulus input consists of a train of strong, EOD-like stimulus pulses (S_1), which mimic the animal's experience of its own EOD, and a train of small pulses (S_2) of a slightly different repetition rate, which mimic EODs of a neighbor. Correct behavioral responses require S_1 repetition rates comparable to normal EOD frequencies; also spatial and temporal patterns of the S_1 must closely resemble those of the animal's EOD. These features are of little significance for S_2 pulses which, while scanning S_1 pulses, only provide a small perturbation of electroreceptive feedback from S_1 pulses.

S_1 pulses must also be of sufficient intensity to recruit electroreceptors, of which there are two types. Pulse markers fire one spike at a constant latency after the S_1, and do not respond to scanning by S_2s. Burst duration coders fire a burst of spikes following each S_1; the burst pattern changes during S_2 scans.

The electric fish JAR provides an ideal preparation for the study of neural correlates of behavior in a vertebrate, since it is possible to monitor the on-going behavior while simultaneously recording from single units in the nervous system.

1151 ROLE OF THE ANTERIOR HYPOTHALAMUS-PREOPTIC AREA IN THE REGULATION OF MALE REPRODUCTIVE BEHAVIOR IN THE LIZARD, Anolis carolinensis. David Crews, James Wheeler*, and Abraham Morgentaler*. Museum of Comparative Zoology, Harvard University, Cambridge, MA 02138.

Bilateral radiofrequency lesions ($\bar{x}$ current=6.5mA; $\bar{x}$ duration 75 sec using glass insulated platinum-iridium microelectrodes with exposed tips of 100 or 250μm courtesy of F. Haer Co.) of the anterior hypothalamus-preoptic area (AH-POA) abolish male courtship and agonistic behaviors in both intact and castrated/androgen treated Anolis carolinensis. Lesions caudal and dorsal to the AH-POA also cause no significant decline in the behavior of intact animals. Histological examination of testes showed that lesions including and rostral to the AH-POA cause testicular collapse and regression to initial stages of spermatogenesis, indicating interruption of gonadotropin secreiton. Castration and subcutaneous testosterone implants restores courtship and agonistic behaviors in rostral and caudal lesion groups to prelesion levels, while AH-POA lesioned animals remain at their low behavioral levels. Neither AH-POA or control lesions cause significant changes in animals' body weight.

Free testosterone (T) or testosterone propionate (TP) implants (ejected pellet technique using 33g hypodermic tubing) placed unilaterally in the AH-POA restores sexual behavior in castrated, behavioral inactive lizards. Cholesterol implants had no effect on behavior nor did T implants located dorsal and lateral to the AH-POA. The mean response latency differed for the two hormones used: T averaged 2.6 days (range 1-4 days) while TP imlants averaged 5.4 days (range 3-8 days). Examination of secondary sex structures (renal sex segments) gave no indication of steroid leakage into peripheral plasma.

1152 THE MAUTHNER SYSTEM MEDIATES DIRECTIONAL RESPONSES TO LOCAL VIBRATIONAL STIMULI. Robert C. Eaton, Dept. E.P.O. Biology, Univ. Colorado, Boulder, CO, 80309, Charles B. Kimmel & Stanley K. Sessions, Dept. Biology, Univ. Oregon, Eugene, OR, 97403.

Electrophysiological experiments show that the Mauthner (M-) cells of zebrafish larvae initiate startle responses to local vibrational stimulation produced by low-frequency, axial excursions of a microcapillary positioned against the body (Eaton et al., 1977, J. Neurobiol. 8:151). In free swimming animals this stimulation results in startle behavior involving a contraction of the contralateral body musculature, such that the animal gives a directional avoidance response. Can the M-system initiate directional responses to local vibrational stimulation? Previous technology did not readily permit determination of which of the two M-cells fired in response to a stimulus. To solve this problem we analyzed larvae with radiation-induced M-cell deletions (Kimmel et al., 1978, Develop. Biol. 62:526) to determine the probability at which a single M-cell will fire in response to bilateral stimulation. In 10 larvae with only one M-cell, the probability of eliciting an M-spike by suprathreshold stimulation on the M-cell side was 0.58 in 86 attempts whereas there was a significantly lower probability (0.11) for firing to the non-M-cell side in 94 attempts. In 17 irradiated and non-irradiated control fish with two M-cells, M-spikes were elicited with a probability of 0.53 to 0.60 in 250 attempts when stimulating either side. Thus, the irradiation treatment does not affect the probability of obtaining an M-spike to ipsilateral stimulation and the results suggest that the M-system is capable of distinguishing the directionality such that the ipsilateral M-cell is normally activated to a local stimulus. What sensory systems mediate this directionality? To test whether the auditory system is necessary, we inactivated the auditory input by surgically removing the otoliths from 5 embryos, 30-50 hr after fertilization and found that absence of the otoliths made no difference in the threshold for activation of the M-system when these fish were compared with normal control fish of the same age (5-9 days). Although, as previously shown, the auditory system functions in normal larvae, the present results suggest that audition is not necessary for activation of the M-cell to such local stimuli. Other systems possibly important are the Rohon-Beard cell system and the lateral line. In contrast to control animals with otoliths, animals without otoliths failed to give a startle response to water-conducted vibrational stimulation, thus illustrating the importance of audition for some types of startle behavior.

1153 NEUROPHYSIOLOGICAL BASIS OF CONFIGURATIONAL PREY-SELECTION IN THE COMMON TOAD. Jörg-Peter Ewert, Neuro-ethology and Biocybernetic Laboratories, University of Kassel, FRG.

From quantitative dummy experiments with rectangular moving stripes we know that toads Bufo bufo prefer "worm-like" prey objects (stripe axis oriented parallel to the movement direction) and avoid "antiworm-like" objects (stripe axis oriented perpendicular to the movement direction). The ability of toads to distinguish worms from antiworms is invariant to (i) the stimulus movement direction in the x,y,z-coordinates, (ii) the direction of the stimulus background contrast, (iii) the velocity of motion (within visible ranges), (iv) the stimulus distance (within behaviorally relevant limits). Extracellular recordings from single axons of the three retinal ganglion cell classes demonstrate that the configurational area effects on prey-catching are not simply derived from the output of one of these neurons. Extracellular recordings from single visual "small-field" neurons of retinal central projection areas in the thalamic pretectal (TP) region and the optic tectum in response to configurational parameters of moving contrast stimuli indicate for possible neuronal "gestalt filters". The TP small-field neurons are sensitive to the whole stimulus area, mainly its expansion perpendicular to the direction of stimulus movement. Tectum neurons of type 1 are sensitive to the whole stimulus area but mainly to its expansion in the direction of movement. There is a statistically distinct second neuronal population, tectum type 2 neurons, with response characteristics to configurational parameters, which reflects to a good approximation the probability that the stimulus fits the category prey. Presumably, tectum 2 neurons receive excitatory inputs from tectum 1 neurons, and there is evidence that they receive inhibitory inputs from TP-neurons. It is thought that tectum 2 neurons are involved in a system which triggers the prey-catching orienting movement, once a particular level of neuronal activity has been reached. This is supported by the results from electrical point stimulation of the optic tectum in freely moving animals.

1154 CENTRAL GREY LESIONS DEPRESS ULTRASOUND PRODUCTION AND LORDOSIS BY FEMALE HAMSTERS. Owen R. Floody and Thomas L. O'Donohue. Bucknell Univ., Lewisburg, PA 17837.

Female hamsters produce 35kHz vocalizations (ultrasounds) as courtship behaviors in reproduction. Since the mesencephalic central grey (MCG) has been implicated in the control of both vocalization (e.g., Brown, Science, 149, 1002, 1965) and reproductive behaviors (e.g., Pfaff et al., Progr. Physiol. Psychol. 5, 253, 1973), we studied the effects of MCG lesions on hamster ultrasounds and lordosis.

Ultrasound rates by ovariectomized, hormone-primed, females were observed in tests with stimulus ultrasounds or males. The postoperative ultrasound rates of females receiving MCG lesions were compared with preop rates for the same females, and with call rates of sham controls. MCG lesions consistently caused decreases in rates of ultrasound production. These decrements were most pronounced in tests with stimulus males, and in females with maximal damage to the caudal MCG.

Lordosis responses were observed in tests with manual stimulation or stud males. The incidence of lordosis decreased significantly following MCG lesions. This change tended to be all-or-none in character, so that lesioned females showed either no lordosis or lordosis of normal latency and duration. However, this dichotomy in behavior did not correspond to clear differences in lesion placement.

These findings support earlier descriptions of MCG mediation in vocal and sexual behaviors. In species for which these classes of behavior overlap, the MCG may function to coordinate different components of reproductive behavior with each other, or with other internal or external events.

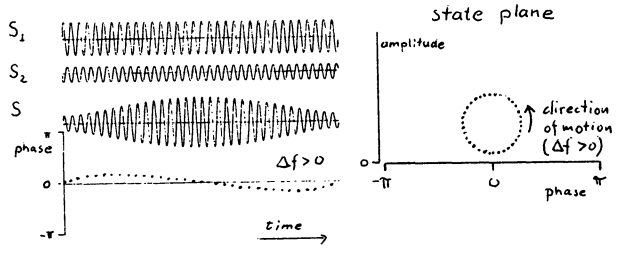
1155 THE JAMMING AVOIDANCE RESPONSE (JAR) IN EIGENMANNIA: MOTION DETECTION IN A TWO-DIMENSIONAL STATE PLANE.
Walter Heiligenberg, Curtis L.Baker and Joanne Matsubara. Scripps Institution of Oceanography, UCSD, La Jolla, Cal. 92093

The JAR in the electric fish Eigenmannia is an attempt to move the electric organ pacemaker frequency away from similar frequencies of a jamming stimulus, normally the electric organ discharge (EOD) of a conspecific. The JAR requires simultaneous electroreception of the animal's own EOD and the jamming stimulus (Bullock et al. 1972, J.comp.Physiol. 77, 1-48). Correct JARs can be elicited if the EOD, silenced by curarization, is replaced by a sinewave stimulus, S_1, which sufficiently mimics the natural EOD field geometry. The EOD substitute, S_1, need not be locked to any particular phase of the pacemaker cycle and may freely run at frequencies tens of Hz different from that of the pacemaker. The JAR therefore appears to be driven by electroreceptive afferences alone, i.e. without an internal reference to the pacemaker cycle.

The addition of the EOD or its substitute, S_1, and a jamming sinewave stimulus, S_2, results in a sinusoidal signal, S, whose amplitude and phase with regard to that of S_1 are modulated at the beat frequency, Δf, the difference between the frequencies of S_2 and S_1. Whereas beat amplitude modulation is identical for positive and negative Δfs, phase modulations are opposites of one another. Amplitude and phase are coded by different types of electroreceptors, P- and T-units resp. (Scheich et al. 1973, J.Neurophysiol.36, 39-60), and simultaneous evaluation of their time courses of activity should yield the magnitude and the sign of the Δf. By plotting amplitude and phase as parameters in a two-dimensional state plane, closed graphs are obtained which are reproduced Δf times per second. The direction of motion of a point in this graph is determined by the sign of the Δf. Evidence is given that the animal detects motion in this state plane by a mechanism comparable to motion detection in the realm of vision.



1156 DOES THE MAUTHNER NEURON MEDIATE UNIQUE BEHAVIOR?
Charles B. Kimmel, Susan L. Powell*, Dept. Biology, Univ. Oregon, Eugene, OR 97403, & Robert C. Eaton, Dept. E.P.O. Biology, Univ. Colorado, Boulder, CO 80309.

On the basis of both electrophysiological and behavioral evidence we proposed that the Mauthner (M-) cells of larval zebra fish initiate fast start behavior in which the first movement is a short-latency (<10 msec) stereotyped contraction that causes the body to form the shape of a "C" (Eaton et al., J. Neurobiol. 8: 151, 1977). This initial phase is believed to represent the direct output of an M-cell and its motoneuron pool. We have studied larvae with deletions of the M-cells induced by irradiation at the gastrula stage (Kimmel et al., Develop. Biol. 62: 526, 1978) to learn whether presence of the M-cell is uniquely correlated with presence of this behavior.

High speed (400 f/sec) cine records of startle responses of 3 larvae missing both M-cells revealed starts to either side, with different combinations of latencies and strengths. The fastest starts were similar in these parameters, and in the detailed pattern of movement, to responses previously proposed as being M-initiated. To examine this critically we recorded 67 responses from 14 larvae (day 7-10), each possessing only 1 M-cell. Again, responses to either side were observed. There was a strong correlation, however, between the presence of short-latency C-type fast starts and presence of the M-cells.

A higher proportion of short-latency (<10 msec) responses were observed to the side possessing the M-axon than to the opposite side (18 of 37 vs. 4 of 30). All of the short-latency responses to the M-axon side were C-type fast starts (mean displacement: 0.61 body lengths in 10 msec), whereas those to the opposite side were heterogeneous and significantly less in mean strength (0.32 body lengths in 10 msec). Only 1 of these starts to the side missing the M-axon was as strong as the weakest short-latency response observed to the side where it was present.

We conclude that the presence of the M-cell greatly increases the probability that the short-latency C-type fast start will occur. On the other hand, other neural circuits are sometimes capable of producing apparently identical responses. It is not known whether these other circuits arise as a result of loss of the M-cells. However, even though such compensation may have happened, it was insufficient to match the performance advantage which occurred when the M-cell was present. (Supported by NSF, BNS 77-08685, and an Intramural Grant from Univ. Colorado)

1157 HOW WELL DO ELECTRIC FISH ELECTROLOCATE UNDER JAMMING? Joanne A. Matsubara* and Walter F. Heiligenberg (SPON: J. Bastian). Scripps Institution of Oceanography, UCSD, La Jolla, CA 92093.

Weakly electric fish can be classified on the basis of their electric organ discharges (EODs) into pulse and wave species. When certain wave species are submitted to electric stimuli, normally EODs of conspecifics, with frequencies sufficiently near their own EOD freq. they will shift their EOD freq. in order to maximize the freq. difference, ΔF. The significance of this jamming avoidance response (JAR) is one of maintaining a private freq. channel for unambiguous object detection. With the exception of Sternopygus, JARs have been observed in all South American wave species tested and even in the non-related African species Gymnarchus. The observation that Sternopygus does not exhibit a JAR suggests that it has an alternative mode of electric image processing which is less vulnerable to jamming. To test this hypothesis, comparative studies on the effects of jamming on the electrolocation performance (ELP) of three species were undertaken, providing the following results.

1) Sternopygus' lack of a JAR is adaptively correlated with an unusual immunity of its ELP to jamming signals. It is only with unnaturally strong sinusoidal stimuli, as great as 50 times stronger than the fish's own near field EOD intensity, that impairment of ELP begins in Sternopygus. In contrast, ELP in all other wave-emitting genera tested is greatly impaired by stimuli as weak as the animal's own near field EOD intensity. Hence, Sternopygus evidently possesses an alternative protection mechanism, other than a JAR, for electrolocation under natural jamming situations. It is suggested that a neuronal mechanism such as lateral inhibition between higher order representatives of neighboring electroreceptors could account for Sternopygus' exceptional immunity to electrical noise.

2) Under jamming regimes, Sternopygus (given stimuli of sufficient intensity), Adontosternarchus and Eigenmannia are most vulnerable to stimulus freqs. which differ slightly from their own EOD freqs.; i.e., when ΔF = 1 to 4 Hz. However, in all cases ELP improves for ΔFs sufficiently close to zero.

These behavioral data coincide with the prediction, based on theoretical considerations (Heiligenberg, 1977 Studies of Brain Function, Vol. 1, 1-85) and neurophysiological evidence (Behrend, 1977 J comp physiol 118, 357-371), that ELP improves as the ΔF either approaches zero or increases beyond critical values. As an alternative to the basic JAR, a fish could just as well phase lock its EODs to those of a conspecific (ΔF = 0) in order to protect its ELP.

1158 NEURONAL ACTIVITY AND AVOIDANCE BEHAVIOR IN GREEN LACEWINGS. Lee A. Miller and Jens Olesen*. Inst. of Biology, Odense Univ., Odense, Denmark, DK-5230.

Green lacewings are nocturnal insects that can evade bats primarily by folding the wings and passively falling to low cry repetition rates. Should a bat attempt to catch a falling green lacewing, the insect can momentarily extend the wings in a last chance maneuver. This switch in behavior from a passive fall to a momentary wing extension is provoked by an increase in cry repetition rate during an attempted catch. We mapped the dorsal longitudinal flight motor neurons (DL-MN) in the prothoracic ganglion with cobalt chloride applied to cut motor nerves. Up to 7 DL-MN's have been filled with positions similar to homologous neurons in locusts (M.Burrows,J.exp.Biol.62: 189,1975). We recorded intracellularly from neurons in the prothoracic ganglion using pulsed ultrasound as stimuli. Repeater neurons fire from 2 to 5 spikes for each 10 msec sound pulse. They have tuning and sensitivity characteristics similar to the sensory units. The activity of other neurons may be correlated with avoidance behavior. For example, DL-MN's, which were identified by simultaneous myographic recordings in the DL muscles, are often silent. Such DL-MN's can receive excitatory inputs and spike when stimulated. This activity may be correlated with wing extension during a fall. Some neurons have endogenous spike rhythms, which occur at rates slightly lower than the wing beat frequency and can be interrupted by a pulse train. The flight motor is quiescent during a fall (L.Miller,J.Insect Physiol.21:205, 1975). Other neurons show no activity until about 600 to 2000 msec after the pulse train ceases. Insects resume flight after a fall. We have not yet found neuronal correlates of switching as implied in the last chance behavioral response. Many epsp, ipsp and spike patterns show variability and are less obviously correlated with behavior. But, essentially all patterns of avoidance behavior in free flying green lacewings show some sort of variability, which may be neurally programed. Such variability could be of selective advantage by making the insect's behavior less predictable (K.D. Roeder,J.exp.Zool.194:75,1975).

These studies were initiated in the laboratory of Dr. Malcolm Burrows, Univ. of Cambridge. We acknowledge support by the Danish Research Council.

1159 FACTORS MODULATING THE OCCURENCE AND DIRECTION OF THE STARTLE RESPONSE IN GOLDFISH. Thomas J. Mueller. Dept. Biol. Sci., USC, Los Angeles, CA 90007.

The startle response was elicited in goldfish swimming freely in the center section of a large tank. The stimulus was an impact at a point on the surface of the water. The size of the tank was such that free field conditions existed for one to two milliseconds after stimulation. The resulting startle response was recorded using infrared serial repetitive photography.

Under these conditions the response was much more variable than previously reported. However, in a statistically significant number of trials the startle response, initiated within fifteen milliseconds or less of stimulation, resulted in the fish turning away from the sound source.

Circumstances prior to the moment of stimulation were found to affect the response. For example, fish given a flash of light one half second prior to stimulation habituated much more rapidly than control fish.

Work by others has shown that this startle response is initiated by the Mauthner cells in the hindbrain; presumably via the posterior branch of the VIIIth nerve which originates in the auditory portion of the labyrinth and synapses on the distal part of the Mauthner cell's lateral dendrite. It is generally accepted that with this apparatus, a loud noise will initiate a startle response. Based on the above data, I propose that the response is significantly modulated by a "set" imposed on the Mauthner cells by other sensory and CNS inputs prior to "release" of the response by auditory (or perhaps other) stimulation.

1160 SPECIES-TYPICAL BEHAVIOR OF HAMSTERS DEPRIVED FROM BIRTH OF NEOCORTEX. Michael R. Murphy, Paul D. MacLean, and Sue C. Hamilton*, Laboratory of Brain Evolution and Behavior, NIMH, Bethesda, MD 20014.

The purpose of this study is to test the hypothesis that the two older evolutionary formations of the forebrain--the striatal complex and the limbic system--are sufficient, along with the remaining neuraxis, for the expression of most forms of species-typical behavior.

Hamsters were used for this work because they have a short gestation period and display many natural forms of behavior in a laboratory setting. Experimental subjects were deprived of virtually all neocortex from the time of birth by thermal destruction of the developing layers on the first or second postnatal days. Supplemental observations were made on animals in which the neocortex was surgically removed by suction, or in which cortical neuroblasts were destroyed by prenatal administration of methylazoxymethanol acetate. Quantitative measures of mating and other behavior were made with the use of a computer-assisted event recorder and time-lapse television. Behavioral development was followed and recorded on a checklist derived from an extensive ethogram.

Hamsters deprived of neocortex grew and developed like normal animals. They showed the usual hamster-typical behaviors including nest and hoard building, tunnel blocking, use of a urination post, daily activity rhythm, play-fighting, territorial aggression, scent-marking, species preference and identification, and reproductive behavior. The experimental males had some motor difficulties during mating and required twice the normal number of intromissions to achieve ejaculation, but successfully impregnated females. A female with bilateral absence of neocortex mated, became pregnant and reared her young. Experimental animals displayed more stereotyped activity than the normal controls.

Some animals had varying amounts of damage to the midline limbic cortex. In those devoid of neocortex, there was corresponding reduction of the neothalamic nuclei.

The results of this study reveal that animals with intact striatal and limbic structures, but lacking neocortex, are capable of giving expression to a wide range of species-typical behavior.

1161 AFFERENT PROJECTIONS ASSOCIATED WITH ATTACK SITES IN THE VENTRAL TEGMENTAL AREA OF THE CAT. C. A. Opsahl* and W. M. Schoel* (SPON: J. P. Flynn). Dept. Psychiatry, Yale Med. Sch. New Haven, Ct. 06508.

Quiet biting attack on a deeply anesthetized rat was elicited by electrical stimulation of the ventral tegmental area in six cats. These sites were located in the region lateral and ventral to the red nucleus, from which quiet biting attack has previously been elicited (Chi, Bandler, and Flynn, Brain Behav. and Evol., 1976, 13, 91-110). The elicited behavior included pupillary dilation, approach from a distance, contralateral paw placing (in some cats), and a directed bite to the head and neck region of the rat. Hissing, paw striking, escape, back arching, and eating were never observed. After an attack site was located, the moveable, bipolar concentric electrode was cemented into place; and a number of trials were performed in order to obtain a complete description of the behavior and to ensure stability of the response. The cat was then anesthetized (Ketamine, 33 mg/Kg), and the inner shaft of the electrode was removed. A glass micropipette filled with a 30% solution of horseradish peroxidase (Sigma Type VI) was lowered to the attack site through the outer cannula of the electrode, and the HRP was iontophoresed into the tegmental site (4μA for 4 min). Between 24 and 30 hours later the cats were anesthetized and perfused with a solution containing 1% paraformaldehyde and 1% gluteraldehyde in 0.1M phosphate buffer (pH=7.4). The tissue was then processed according to a variant of the procedure first described by Graham and Karnovsky (J. Histochem. Cytochem., 1966, 14, 291-302).

Cells sending projections to the attack sites were frequently located in gyrus proreus, gyrus rectus, bed nucleus of stria terminalis, bed nucleus of anterior commissure, hypothalamus (anterior, lateral, perifornical, dorsal), zona incerta, amygdala (N. centralis, N. basalis), thalamus (N. reticularis, N. anteromedialis, N. centromedialis), substantia nigra, mesencephalic reticular formation, parabrachial nucleus, nucleus of the lateral lemniscus, superior colliculus, locus coeruleus, mesencephalic trigeminal nucleus, N. reticularis pontis oralis, and central grey. Additional sites of origin appeared with less regularity.

These results agree with previous findings of similar afferent projections associated with quiet attack sites in the lateral hypothalamus and pontine tegmentum (Smith and Flynn, submitted for publication). The projections to attack sites in the ventral tegmental area correspond in many cases with anatomical loci from which attack can be elicited or modulated. (Supported by NIMH grants MH-05507 and MH-08936).

1162 RHYTHMIC CUES FOR SONG RECOGNITION IN CRICKETS. Gerald S. Pollack and Ronald R. Hoy* Section of Neurobiology and Behavior, Cornell University, Ithaca, New York 14853.

Female crickets respond to the calling song of a conspecific male by locomoting toward its source. Females offered a choice between conspecific and heterospecific songs locomote preferentially toward conspecific song. The present study centers on the role played by rhythmic song parameters in permitting female Teleogryllus oceanicus to recognize conspecific calling song.

Freely walking females were presented simultaneously with two electronically synthesized song models which differed only in the arrangement of sound pulses in time, played from two hidden speakers. The percentage of females that approached each speaker indicated the relative attractivenesses of the two songs.

T. oceanicus females preferred a model of T. oceanicus song to a model of the song of a related species, T. commodus. Thus, crickets can identify conspecific song using only rhythmic cues.

T. oceanicus song consists of sound pulses separated by three classes of intervals, arranged in a stereotyped sequence. A song in which the durations and relative proportions of these intervals were identical to T. oceanicus song, but in which the sequence of these intervals was random, was not distinguished from T. oceanicus song. This finding argues against a hypothesis for song recognition which asserts that females possess a copy of the central neuronal pattern generator used by males to produce calling song, and that females use this pattern generator as a template against which to compare auditory input.

Of the three intervals comprising T. oceanicus song only one is necessary and sufficient for song to be interpreted as conspecific. A song consisting only of this interval is not distinguished from T. oceanicus song, and is preferred to T. commodus song. A song containing only the other two intervals is treated as heterospecific, i.e., T. oceanicus song is preferred to such a song.

We have confirmed many of these findings using a different behavioral assay for song preference, in which tethered flying females were presented with two songs from speakers located to their right and left. In response to sound flying crickets perform rudder-like movements with their abdomens and hind legs in an attempt to turn. The direction of these movements indicates the relative attractivenesses of the two songs. This flight assay has so far yielded results similar to those obtained with walking crickets. Furthermore, the flight assay appears to be more sensitive and more reliable, and has the additional advantage of providing a simple, well-defined motor output which reflects song preference. This should facilitate physiological analyses of song recognition mechanisms.

1163 SEPTAL STIMULATION INHIBITS INTRASPECIFIC AGGRESSION IN HAMSTERS. Michael Potegal, Alan Blau*, and Murray Glusman. N.Y. State Psychiatric Institute, New York, NY 10032.

We have recently observed an apparently specific form of intraspecific aggression inhibition following septal stimulation in hamsters. Our subjects were 3-4 month old individually-housed male golden Syrian hamsters, selected for aggressiveness and implanted with a chronic, movable monopolar electrode. During testing sessions these subjects readily attacked non-aggressive target hamsters which were pretreated with the analgesic methotrimeprazine (2 mg/kg) and muzzled to prevent retaliatory biting. In between sessions the electrode was lowered in 300μ steps, one step at a time, along a 2-3 mm descending track. The subject's baseline attack latencies were reevaluated at every step of electrode descent and the effects of stimulating the septal region with 0.1 msec 100 pps biphasic pulses in the presence of a target were studied.

At current levels which did not produce any motor automatisms or stereotyped competing responses, septal stimulation prevented the initiation, and suppressed the ongoing performance, of subjects' attacks on the targets. At some sites in some animals we have also been able to inhibit mouse killing. At the completion of the track the electrode was raised to the site at which current levels for inhibition were at their minimum and a marking lesion was made. All the low threshold sites so marked lie within the septum. Stimulation at minimum current levels necessary for aggression inhibition (35-150μ amp) has had no effect on sunflower seed acceptance (a highly preferred food for hamsters) in any animals tested to date. In half the animals tested, this stimulation also has had no effect on copulatory behavior with a receptive female. Recordings from the stimulating electrode before and after stimulation have not yielded any indication of seizure activity. Preliminary tests of the reinforcing value of the stimulation in an operant chamber indicated that the stimulation may be moderately aversive. There is also some indication that this aversiveness may be minimized when aggression-suppression occurs at lower current levels. These results extend previous reports of septal inhibition of predatory (Siegel & Skog, Brain Res., 1970), and defensive (Brayley & Albert, J.C.P.P., 1977) aggression to include effects on intraspecific aggression. (Supported by N.I.M.H. Grant #R03 MH28836.)

1164 THE ROLE OF ENVIRONMENTAL CONCENTRATIONS OF MINERALS AND PITUITARY HORMONES IN REGULATING REPRODUCTION OF THE PARADISE FISH, MACROPODUS OPERCULARIS. Trudy Villars, Joseph Morris* and David Sever*. Saint Mary's College, Notre Dame, IND 46556.

Environmental cues such as temperature and photoperiod play a major role in teleost reproductive behavior. Changes in mineral content ('hardness') of the water following rainfall or drought might also be expected to affect reproductive readiness in some freshwater species. The present study examined 1) the effects of water 'hardness' on nestbuilding and spawning of the paradise fish and 2) the role of pituitary hormones in mediating such an effect.

The paradise fish is a fairly specialized species which has an elaborate reproductive sequence including a courtship of 1 to 4 days in which the male builds and defends a bubble-nest at the water surface. In the laboratory, pairs will spawn repeatedly and show no seasonal variation in reproductive readiness. Thus it is likely that environmental factors rather than internal rhythms determine spawning readiness in the natural environment.

Subjects were held and tested in 'hard', medium or 'soft' water. Local tap water with approximately 280 ppm calcium and magnesium was directly used in the 'hard' water condition and diluted with distilled water to 33 or 10 percent for the medium and 'soft' water conditions. Fish were paired and observed for their latency to nestbuild and spawn. A normal male introduced to a tank with a lone female will invariably build a nest by the second day after its introduction and three fourths of normal pairs will spawn by the fifth day (Villars and Davis, Phys. Beh. 19: 371, 1977). In the present experiment male nestbuilding was blocked 'hard' water and impaired in the intermediate concentration. Spawning was blocked in both 'hard' and medium conditions.

N	WATER CONDITION	PERCENT NESTING BY DAY 5	PERCENT SPAWNING BY DAY 5
10	'hard'	10%	0%
11	medium	90%	0%
15	'soft'	100%	66%

Preliminary histological analysis of the pituitary indicates a reduction of activity in the acidophilic cells of the pars distalis which are probably prolactin secreting. In other species such cells are inhibited by environmental salinity and play a role in osmoregulation (Schreibman et al. Am. Zool. 13: 719, 1973). In the male paradise fish prolactin is believed to stimulate nestbuilding behavior (Machemer, Z. Tierpsy. 28: 33, 1971). In the course of evolution pituitary hormones serving a role in osmoregulation could have acquired a secondary function in the induction of reproductive behavior in the paradise fish and related species.

NEUROMUSCULAR JUNCTION

1165 MODULATED RECEPTOR HYPOTHESIS FOR THE INCREASE IN DESENSITIZATION OF THE ACETYLCHOLINE RECEPTOR BY ANESTHETIC TYPE AGENTS. Roger Anwyl* and Toshio Narahashi. Dept. Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611.

The ability of a variety of agents to increase desensitization and to cause antagonism of extrajunctional acetylcholine (ACh) receptors of denervated rat muscle has been investigated. Desensitization was produced by evoking iontophoretic ACh potentials at a frequency of 10 Hz. Half-maximal increase in desensitization rate and half-maximal reduction in the amplitude of the ACh potential were caused respectively by: 1×10^{-7}M and 1×10^{-6}M histrionicotoxin; 1×10^{-6}M and 6×10^{-6}M chlorpromazine; 5×10^{-5}M cytochalasin B; 6×10^{-6}M and 6×10^{-5}M Triton X-100; 5×10^{-5}M and 5×10^{-5}M lidocaine and QX 314; 2×10^{-4}M and 1×10^{-4}M sodium pentobarbital; 8×10^{-4}M and 5×10^{-4}M heptanol; no effect and 5×10^{-4}M benzocaine; no effect and 5×10^{-4}M methylguanidine. Thus desensitizing agents are characterized by very hydrophobic groups and also by a charged atom (preferably nitrogen).

It is proposed that there are different binding sites on the ACh receptor or channel for the desensitizing and antagonistic action of these agents, although binding to both sites occurs only after the receptor has been activated by ACh. After binding of an agent to the desensitization site, the receptor channel closes at its normal rate but the receptor is converted to an inactive or desensitized state. Supported by NIH grant NS 14145.

1166 PRE- AND POSTJUNCTIONAL ACTIONS OF ERYTHROSIN B. George J. Augustine, Jr. and Herbert Levitan. Dept. of Zoology, University of Maryland, College Park, MD 20742.

The anionic dye Erythrosin B has both pre- and postsynaptic effects when applied to isolated frog neuromuscular junctions. Using standard electrophysiological techniques, we have attempted to quantify these effects in an effort to determine their cause. After exposure to Erythrosin B in concentrations ranging from 10 μM to 1 mM, the frequency of spontaneous miniature end-plate potentials (mepps) increases exponentially with time from control rates of less than 1/sec to greater than 100/sec. The period of elevated frequency is followed by an abrupt decline to a level below that of control. The time of onset of this decline is variable, but it occurs more rapidly with higher dye concentrations. 'Giant' mepps, with amplitudes as large as 25 mV, are observed in this period of depressed frequency. The rate of the dye-induced exponential increase in mepp frequency (α), determined from the slope of semi-logarithmic plots of mepp frequency vs. time, varies with the concentration of dye applied. Mean values of α range from .023 (± .004 S.E.M.)/min for 10 μM (corresponding to a 10-fold increase in mepp frequency every 43 minutes) to 0.44 (± .029)/min for 1 mM. These values are all significantly greater than the α of .004 (± .003)/min found for junctions which were not treated with dye. The mean α values are related to dye concentration by a power function, with an apparent K_m of approximately 0.5 mM determined from a double reciprocal plot. The increase in mepp frequency is apparently independent of external divalent cations, since it occurs in Ringer's free of Ca^{+2} and Mg^{+2}, with EDTA present (1 mM). Erythrosin B must therefore alter presynaptic function in some other manner. This dye also rapidly and reversibly increases the membrane potential and input resistance of muscle fibres. These postsynaptic effects are apparent at dye concentrations exceeding 0.2 mM and increase with concentration. An increase in the variation of muscle membrane potential with external K^+ concentration in the presence of the dye suggests an increase in K^+ permeability relative to other ions. This may be the result of both an increase in K^+ permeability and a decrease in membrane permeability to Cl^-. These postsynaptic alterations could account for the increase in mean mepp amplitude which accompanies dye-induced increases in mepp frequency.

1167 SUPPRESSION OF ORIGINAL NERVE INPUTS TO A MAMMALIAN SKELETAL MUSCLE BY A FOREIGN MOTOR NERVE. J. L. Bixby* and D. C. Van Essen* (SPON: J.-P. Revel). Division of Biology, California Institute of Technology, Pasadena CA 91125.

A foreign motor nerve placed over an extrasynaptic region of a mammalian skeletal muscle does not form synapses unless transmission from the original nerve is interrupted or the muscle is directly injured. We have found, however, that foreign synapses can be established in the presence of intact original innervation if care is taken to implant the foreign nerve directly over the original endplate region. A motor branch of the superficial peroneal nerve was placed over the soleus muscle near the site of original nerve entry in adult Sprague-Dawley rats. The foreign nerve remained in place and grew over the original endplate region in half (9 of 18) of the muscles examined 4-10 weeks after the operation. In most of these cases (7 of 9), stimulation of the foreign nerve elicited contractions in soleus muscle fibers directly under the nerve implant. The degree of cross-innervation ranged from only a few muscle fibers to several percent of the whole muscle, and was not obviously correlated with the time after the initial operation. Foreign and original nerve inputs co-existed on the same muscle fiber in many of the fibers examined at both short and long survival times. In substantial numbers of other fibers, however, the foreign nerve had completely suppressed transmission by the original nerve. Stimulation sometimes elicited sub-threshold responses via one or both nerves, suggesting that the suppression of original synapses and the establishment of foreign ones is a graded phenomenon. We believe, on the basis of cholinesterase staining and rise times of endplate potentials, that foreign synapses are established specifically at the original endplate sites in the great majority of cases. Control experiments suggest that the establishment of foreign synapses was not a result of temporary interruption or traumatization of original nerve inputs following the initial operation. These results indicate that an endplate in an adult muscle fiber can accept innervation from more than one source. At what we presume is a later stage, interactions can take place leading to the loss of one of these inputs, just as occurs during the maturation of neonatal muscles. The determination of which synapses are to be eliminated may be linked to a competitive advantage of terminals belonging to motor neurons having relatively few peripheral connections. Supported by NIH grant RR 07003

1168 NEWLY-FORMED NEUROMUSCULAR JUNCTIONS IN XENOPUS TISSUE CULTURE: FREEZE-FRACTURE AND THIN-SECTION ELECTRON MICROSCOPY. Paul C. Bridgman*, H. Benjamin Peng* and Yasuko Nakajima. Dept. of Biol. Sci., Purdue Univ., W. Lafayette, IN 47907.

Neuromuscular contacts were formed in vitro by adding dissociated neurotube cells to one-day-old myotome-cell cultures prepared from stage 20-21 Xenopus laevis embryos. Following one to three days of co-culture, preparations were processed either for freeze fracturing or for thin sectioning.

Previously we reported in our freeze-fracture work the existence of membrane particle clusters which are putative acetylcholine receptors (AChRs). In innervated cultures, these clusters were found in the muscle membrane along the nerve contact (PNAS 75: 500, 1978). In the present developmental study, most nerve-muscle contacts in one-day co-culture were marked by only sparsely populated small clusters. In two-day co-culture, however, very tight aggregations of particle clusters were observed along many nerve-muscle contacts. Most of these clusters were located within 1 μm from the nerve terminal. Each cluster was separated from its neighbor by a shallow groove free of membrane particles. During early stages of innervation, many caveolae (ranging from 50-100 nm in diameter) were observed in the muscle membrane along the path of the neurite. On the P-face replica, particles of the same size as that of putative AChR particles were often observed at the bottom of these caveolae. Thus, these caveolae might have a role in the incorporation of AChRs into the sarcolemma.

In thin sections, after one to two day co-culture, most muscle cells were well developed, showing regular arrays of myofibrils. At the junctional area nerve endings contained many synaptic vesicles, mitochondria and microtubules. The postjunctional membrane sometimes formed caveolae. Beneath the membrane there were occasional accumulations of dense material in small patches. The junctional cleft was narrow, about 10 ~ 20 nm wide. In several instances there were very close junctions between the pre- and post-junctional membranes. In addition, in one case, the presence of a small aggregate of gap junction-like particles was found in the post-junctional membrane in freeze-fractured material (1 1/2 day co-culture). We are now conducting a study in the same system, using α-bungarotoxin conjugated to horseradish peroxidase, to detect the localization of AChRs in thin-section electron microscopy.

1169 DISTRIBUTION OF ACETYLCHOLINE RECEPTORS IN THE MYOTOMES OF XENOPUS LAEVIS DURING NORMAL DEVELOPMENT. I. Chow* and M.W. Cohen. Dept. of Physiology, McGill University, Montreal, Canada.

Previous studies have indicated that innervation of the myotomes in Xenopus laevis begins at stage 21, when the embryo is 22-23 hr old, and that sensitivity to acetylcholine can be detected 1-2 hr earlier, at stage 19-20 (Blackshaw and Warner, Nature 262 217, 1976; Kullberg et al., Devel. Biol. 60 101, 1977). In the present study we have investigated how the number and distribution of acetylcholine receptors in the myotomes change during the course of development by using α-bungarotoxin, labelled with radioactive iodine or with fluorescent dye (tetramethylrhodamine). Specific uptake of radioactive toxin was demonstrated as early as stage 19. The number of toxin binding sites per myotome increased progressively with age throughout the period of development studied (up to 1 month). The distribution of these sites was examined in radioautographs of the same preparations embedded in Epon and cut longitudinally. At all stages of development grains were observed throughout the entire length of the myotomes. Away from the ends of the myotomes, the main site of innervation, the grains appeared to be randomly distributed and their density increased up to stage 36 (50 hr), when the embryo hatches and becomes a free-swimming tadpole. Subsequently the grain density along the myotomes declined but was still significant in 1-month-old animals. The density of grains at the ends of the myotomes was clearly greater than along the rest of their length at stage 24 (26 hr) and became more pronounced with age. Some examples of such a differential distribution were also seen at stage 22 but not at earlier stages. Fluorescent staining with rhodamine-toxin revealed the presence of discrete patches of high receptor density at the cell ends as early as stage 22. At this stage the patches were less than 1 μm in length and their occurrence was rare. Subsequently their size and number increased. Similar patches of stain were also observed randomly distributed along the myotomes but at much lower frequency. Experiments on 2-4 day old animals revealed that many of the fluorescent patches, at the cell ends as well as along the myotomes, are associated with cholinesterase activity, and therefore likely reflect sites of synaptic contact. Taken together these results indicate that the development of patches of high receptor density begins within about 1 hr after the onset of innervation. Such a temporal sequence is consistant with the notion that a local interaction between the axon and muscle cell induces the accumulation of acetylcholine receptors at developing synaptic sites in vivo. 1170 PHARMACOLOGICAL EXPERIMENTS ON FROG MUSCLE USING AN ELECTROPHORETIC VOLTAGE CLAMP TECHNIQUE.* J. del Castillo and P. Specht. Lab. of Neurobiol. and Dept. of Pharmacol., Med. Sci. Campus, University of Puerto Rico, San Juan, P.R. 00936.

The conventional technique of electrophoretic drug application (Nastuk, Fed. Proc. 12: 102, 1953; del Castillo and Katz, J. physiol. 128: 157-181, 1955) has been employed successfully to map receptor distribution and to determine, both qualitatively and quantitatively, the chemical sensitivity of cell membranes. However, it has failed to generate significant information on the characteristics of drug-receptor reactions. Indeed, the electrophoretic "potentials" elicited by brief pulses of agonists can be made very similar in amplitude and time course by manipulating the position of the pipette and the braking and pulse currents. The actual drug concentration transients produced by those pulses are not known and therefore the different reaction kinetics cannot be analyzed.

To use the electrophoretic technique in the study of drug-receptor interactions at steady state, we have been experimenting with a system in which the agonist current is controlled, through a feed-back loop, by the membrane potential (del Castillo and Specht, Proc. Physiol. Soc., 1978). In this manner, the depolarization induced by the agonist can be fixed at any desired level for periods of up to several minutes while measuring the required drug current. The most obvious application of this technique is the measurement of the time course of desensitization, a phenomenon which is revealed as a steady increase in the drug current. For example, when acetylcholine is applied to maintain a depolarization of 5 mV, the current increases linearly with a slope of about 1 nA sec^{-1}. With some other drugs, such as tetramethylammonium and ethyltrimethylammonium, the current needed to maintain a steady depolarization decreases slowly. This technique has also been employed to study the interactions between agonists and antagonists.

1171 DELAY OF DENERVATION-DEGENERATIVE CHANGES IN RAT MOTOR NERVE TERMINALS FOLLOWING GLUCOCORTICOID TREATMENT. Anna B. Drakontides. Dept. of Anat., New York Medical College, Valhalla, NY 10595.

Glucocorticoids have been shown to directly affect mammalian motor nerve function and neuromuscular transmission. It has been demonstrated that these agents increase the excitability of mammalian motor nerves and the spontaneous release of transmitter. In view of these findings, studies were undertaken to determine whether these agents are effective in altering the time sequence of progressive degenerative changes or the characteristics of morphological alterations evident in motor nerve terminals following denervation. As these events have been well documented in the rat phrenic-nerve diaphragm, this preparation was chosen for study.

Triamcinolone 8mg/kg was injected intramuscularly in the thigh muscles of rats for 3-5 days. Either on the last day of drug treatment or 3-5 days following the last drug administration, under Nembutal anesthesia the left phrenic nerve was transected in the neck. At time intervals of 16, 18, 20 and 24 hrs after phrenicotomy the rats were sacrificed and segments of muscle containing intramuscular nerves were prepared for electron microscopy. In non-drug treated rats there is evidence of degenerative changes at the neuromuscular junction by 14-16 hrs after denervation. By contrast the majority of nerve terminals sampled from rats treated with triamcinolone 16 hrs after phrenicotomy appeared normal. In the non-treated rat 18-20 hrs after denervation there is unequivocal evidence of degeneration. Mitochondria are disrupted, synaptic vesicles are markedly reduced in numbers, lysosomal-like complexes are present, the nerve terminal becomes fragmented and Schwann cell processes invade the site of the terminal. In triamcinolone-treated rats, 18-20 hrs after phrenicotomy approximately 35% of terminals sampled were normal in appearance. The degenerative changes evident in other end-plates were primarily of the axonal terminal organelles; the terminal was not fragmented. Fragmentation of the nerve terminal was evident 24 hrs after denervation in triamcinolone-treated rats. At this time in non-treated rats, all end-plate sites are replaced by the Schwann cell.

Hall et al. (Ann. Neurol. 1; 263, 1977) have demonstrated in the 48 hr subacutely denervated cat soleus preparation that a short-term triamcinolone regimen significantly reduced the excitability loss that would normally appear in axons and nerve terminals. The present preliminary studies suggest that this glucocorticoid may delay the onset of degenerative changes associated with denervation. Supported in part by NIH Grant # RR5398.

1172 CELLULAR DISTRIBUTION OF 16S ACETYLCHOLINESTERASE IN MAMMALIAN TISSUES. Myron J. Duell*, Hugo L. Fernandez and Barry W. Festoff (SPON: P.A. Singer). Neurobiology Research Lab, VA Hospital, Kansas City, MO 64128 and Dept. of Neurology, Univ. of Kansas Med. Ctr.

Several molecular forms of acetylcholinesterase (AChE) distinguished by their sedimentation coefficients (16,10, and 4S) are present in endplate, but only two (10,4S) in non-endplate regions of skeletal muscle (Hall, J. Neurobiol. 4:343, 1973). The 16S form has been claimed to be endplate specific which decreases with denervation and may be produced by muscle cell cultures "induced" by neuronal elements. Several reports have indicated its absence from smooth muscle, brain, spinal cord and peripheral nerve (Vigny et al, J. Neurochem. 27:1347, 1976). Recently, however, small amounts of 16S AChE have been detected in peripheral nerve. Since cellular localization of 16S AChE may be important in understanding nerve-muscle trophic interactions, we re-evaluated the enzyme's cellular distribution and assessed its possible selectivity for a particular class of neural cell.

Tissue samples obtained from male Sprague-Dawley rats were processed for separation of AChE molecular forms (BW284C51 sensitive) on linear sucrose gradients (5-20%) containing 1% Lubrol-WX. All tissues examined, including whole blood, contained 4 and 10S AChE. The 16S form was detected in: diaphragm and anterior gracilis muscle endplate regions, spinal cord (L1-L6), phrenic, obturator, and sciatic nerves (peripheral, mixed motor-sensory), hypoglossal (predominantly motor, cranial XII), vagus (sympathetic efferent), and spinal ventral roots (L5-S1). 16S AChE was not detected in: diaphragm and anterior gracilis muscle non-endplate regions, smooth muscle (large intestine) and spinal dorsal roots (L5-S1). A 6.5S molecular form was found only in spinal cord and peripheral nerve. This may be a reflection of 6.5S AChE specificity for nervous tissue. Alternatively, this form could represent a state of aggregation or transformation of the other AChE species.

Results indicate that 16S AChE is not only present in muscle endplates, but is also found in spinal cord and peripheral nerve. In sciatic nerve, the 16S AChE activity may be totally attributed to motor neurons and not to sensory neurons or Schwann cells found in this peripheral nerve. This might be related to neurotrophic regulation of neuromuscular junction AChE, since neural 16S AChE might provide a source for the endplate enzyme. Current experiments are concerned with this possibility.

1173 DIFFERENT COMPONENTS OF BLACK WIDOW SPIDER VENOM MEDIATE TRANSMITTER RELEASE AT VERTEBRATE AND CRUSTACEAN NEUROMUSCULAR JUNCTIONS. Lawrence C. Fritz*, Mu-Chin Tzeng* and Alexander Mauro* (SPON: C. M. Connelly). Rockefeller Univ., New York, NY 10021

Crude black widow spider venom (BWSV) causes a massive increase in mepp frequency at vertebrate neuromuscular junctions, a similar increase in mepsp frequency at crustacean neuromuscular junctions, and can release a number of transmitters from mouse cerebral cortex slices. Using purified fractions of BWSV, it has previously been determined that (1) a 130,000 MW component, α-latrotoxin (formerly called B_5), accounts for all the known physiological effects at the vertebrate junctions and in mouse brain slices; and (2) the partially purified fraction E, whose major component has MW 65,000, depolarizes the crayfish stretch receptor.

The present study demonstrates that α-latrotoxin has no effect on the lobster neuromuscular junction, while fraction E can account for all of the physiological effects of the crude venom in that preparation. Application of 9-18 μg of fraction E to a small (~0.2 ml) vaseline enclosed pool surrounding exposed muscle fibers causes an increase in mepsp frequency, eventual block of epsp's and ipsp's, and the characteristic "giant mini" response, all of which are seen in response to crude venom. Application of α-latrotoxin (10 μg) however produces no effect. In contrast, at the frog neuromuscular junction, where 1-4 μg of α-latrotoxin in a 3 ml bath causes a rapid increase in mepp frequency, fraction E has no effect.

These results demonstrate that the effects of BWSV at vertebrate synapses and lobster neuromuscular junctions are mediated by different components. This suggests that the mechanism of BWSV action at vertebrate and at crustacean synapses may be different.

1174 SEROTONIN (5HT) MODULATORY ACTION AT THE LOBSTER NEUROMUSCULAR JUNCTION. MECHANISM OF FACILITATION OF TRANSMITTER RELEASE. Silvio Glusman and Edward A. Kravitz. Dept. Neurobiol., Harvard Med. Sch., Boston, MA 02115.

5HT facilitates synaptic transmission at the crustacean neuromuscular junction by increasing the probability that quanta of neurotransmitter will be released with nerve stimulation. We have examined this phenomenon in greater detail using the opener muscle of the dactyl of the lobster walking leg. The threshold for 5HT action in this preparation is approximately 5 x 10^{-9}M and a marked increase in excitatory junctional potential (ejp) size (2-3x) is seen at 10^{-7}M. In a typical experiment, the preparation was superfused for ten minutes with lobster saline containing 5-8 x 10^{-7}M 5HT. The amine was then washed out by continuous perfusion. Facilitation of the ejp can be seen for sixty min. after washout of 5HT from the bathing medium. The prolonged duration of 5HT action allows experimental manipulation to be performed during the period of amine treatment, followed by testing for facilitation after a return to control conditions. Using this approach we have observed that nerve activity during the amine treatment itself is not necessary to obtain facilitation; the time course of decline of facilitation, tested after removal of 5HT, is identical whether or not the excitatory axon is stimulated during exposure to 5HT. To examine whether facilitation results from movements of ions across the nerve terminal membrane during 5HT treatment, 5HT was superfused onto preparations in lobster saline of different ionic compositions: 1) calcium-free (calcium replaced by magnesium plus 1mM EGTA); 2) sodium free-calcium free (sodium replaced by Tris); 3) solutions with added $MnCl_2$ or Verapamil to block calcium channels. After return of the preparation to normal saline the degree of facilitation was examined; the extent and time course of facilitation after 5HT treatment in all of the test solutions was the same as in normal saline. To examine whether 5HT might cause a direct change in free calcium concentration within the nerve terminals, we analyzed the frequency and size of spontaneous miniature excitatory junctional potentials (smejps). In normal lobster saline 5HT increased the frequency of smejps with a time course similar to the increase in nerve-evoked release. There was no effect on smejp size. A similar increase in smejp frequency was seen in calcium free solution (high magnesium - 1mM EGTA), sodium free solution (replaced by lithium) with or without calcium, or in saline in which potassium conductance was blocked by TEA. Our results suggest that the long lasting facilitation produced by 5HT at lobster neuromuscular junctions is due to an increase in free calcium concentration within the nerve terminals, possibly caused by release of calcium from some intracellular storage sites. (Supported by NIH).

1175 SYNAPTIC EFFECTIVENESS IN FROG CUTANEOUS PECTORIS AND SARTORIUS MUSCLES: EVIDENCE FOR COMPETITIVE INTERACTION IN MULTIPLY INNERVATED FIBERS. Albert A. Herrera* and Alan D. Grinnell. Dept. Biol., UCLA, Los Angeles, CA 90024

Many neuromuscular junctions in the normal sartorius (sart.) muscle of Rana pipiens and R. catesbeiana are subthreshold to single stimulation in normal frog ringer (1.8 mM Ca^{++}). If the [Ca^{++}] is increased to 3 mM, twitch tension increases by 20% or more. If [Ca^{++}] is decreased to 1 mM, twitch tension falls by 50% or more. This is not true of the cutaneous pectoris (c.p.) muscle, which shows no change in tension in the same range of Ca^{++} concentrations. This difference has been verified by intracellular recording. In ringer containing 0.3 mM Ca^{++} and 1 mM Mg^{++}, the quantal content of c.p. neuromuscular junctions was an average 4 times greater than those in sart. fibers. Synaptic efficacy is known to depend on area of synaptic contact (Kuno et al. J. Physiol., 1971, 213:545-556) and on postsynaptic input resistance. In an attempt to explain the difference in safety factor of junctions in the two muscles, these variables have been examined in marked fibers where the morphology and physiology of identified junctions can be correlated. For a given fiber diameter, c.p. terminals are longer, but the difference is not adequate to explain the 4-fold difference in quantal content. Moreover, the terminal width and area of contact/unit length are significantly greater in sartorius fibers. Input resistance of c.p. fibers is, on the average, 1.5 to 2 times greater than sart. fibers, which could help explain the greater c.p. safety factor, but not the greater quantal content. Thus there remains a difference in synaptic effectiveness that cannot be explained simply in terms of terminal morphology. Sartorius fibers differ from c.p. fibers in that the former are multiply innervated. The functional ineffectiveness of the sart. junctions may be due to competitive interaction between these multiple junctions. We are examining the quantal content and morphology of junctions remaining at different times after partial denervation of sart. muscles, or after multiple innervation of c.p. muscles. The functional importance of low safety factor in sartorius junctions is unknown, but this property might constitute an independent mechanism for increasing the tension exerted by each motor unit as the repetition rate of nerve firing is increased, thereby increasing the smoothness with which contraction could be graded.

1176 SPINAL CORD AND BRAIN EXTRACTS INCREASE ACETYLCHOLINE RECEPTOR NUMBER ON CULTURED CHICK MYOTUBES. T.M. Jessell*, R.E. Siegel*, and G.D. Fischbach. Dept. Pharmacology, Harvard Medical School, Boston, MA 02115.

Motoneuron axons that extend from spinal cord explants form synapses with chick myotubes in culture. The synaptic region of the myotube is characterized by the presence of discrete clusters of acetylcholine receptors (AChR). In addition, extrasynaptic regions of myotubes located in the immediate vicinity of the explant exhibit an increased ACh sensitivity when compared to myotubes located far from the explant (Cohen and Fischbach, Dev. Biol. 59, 24, 1977). This general increase in ACh sensitivity may be mediated by a soluble factor released from spinal cord tissue. To investigate this possibility, membrane-free extracts were prepared from 14 day embryonic chick spinal cords and added, in buffered salt solution, to primary cultures of chick myotubes in 18mm wells (plating density: $6x10^4$ cells/well). Specific binding of ^{125}I-α bungarotoxin (^{125}I-αBTX) was used to quantify AChR number. In control cultures, grown for 8 days, ^{125}I-αBTX binding was 4.7±0.3 fmol/culture (mean±s.e.m.; 7 experiments). In 4 of these experiments, addition of spinal cord extracts to fused myotubes (75μg protein/day from days 4-7) resulted in an increase in ^{125}I-αBTX binding to 12.9±1.4 fmol/culture. The protein content of control and treated cultures differed by less than 20%.

Similar extracts prepared from the brains (with cerebellar cortex removed) of 14 day embryonic chicks produced a 1.9 fold increase in ^{125}I-αBTX binding. The effect of brain extract was dose-dependent over the range 15-300μg protein/day; at the highest concentration of brain extract added, a 4.5 fold increase in AChR was observed. In cultures treated with brain extract, increases in receptor density estimated by autoradiography and by electrophysiological determination of ACh sensitivity corresponded with increases determined by ^{125}I-αBTX binding. From autoradiographic studies, brain extract increased the total receptor density and the number of receptor clusters. Extracts prepared from the retina and cerebellar cortex produced smaller increases in ^{125}I-αBTX binding. Liver and heart extracts did not alter AChR number.

We are now examining whether this factor is located exclusively in cholinergic neurons. A reasonable correlation exists between receptor induction and the distribution of choline acetyl transferase activity in tissues examined. Furthermore a pure population of cholinergic nerves dissociated from chick ciliary ganglia increased AChR number 2-3 fold when cultured with chick myotubes, while chick dorsal root ganglia neurons did not alter AChR number. (Supported by NS11160; TMJ is a Harkness Fellow.)

1177 EFFECTS OF Δ^9-TETRAHYDROCANNABINOL ON EXCITABLE MEMBRANES AND NEUROMUSCULAR TRANSMISSION Nuran M. Kumbaraci*, W. L. Nastuk, Dept. of Physiology, Columbia Univ., N. Y., N. Y. 10032

Electrophysiological studies were conducted on the isolated sciatic nerve-sartorius muscle preparation of the frog Rana pipiens treated with the principal component of cannabis, Δ^9-tetrahydrocannabinol (THC). Bath application of 30 X 10^{-6} M THC for 3 hrs produced changes in the electrophysiological properties of muscle fibers and in neuromuscular transmission (NMT). Resting potentials of THC treated fibers did not differ from controls. Records taken at non-junctional regions showed that single supramaximal nerve stimulation failed to evoke a propagated action potential (AP) in 7 out of 16 fibers. In 60% of these non-neurally excitable fibers direct electrical stimulation initiated an AP. The critical membrane potential was in the control range. Analysis of the neurally initiated propagated APs recorded at non-junctional regions showed on the average a 17% decrease in rate of rise, a 20% decrease in rate of fall and a 12% decrease in overshoot. Thus THC 30 X 10^{-6} M depresses the ionic conductance mechanisms which underly propagation of APs in muscle fibers.

Recordings taken at surface neuromuscular junctions of THC treated muscle showed, in 87% of the fibers tested, only subliminal endplate potentials (EPPs) with amplitudes ranging from 5-30 mV. Occasionally a propagated AP was found superimposed on the falling phase of these subliminal EPPs. Apparently these APs were initiated from a second neuromuscular junction of the muscle fiber at which NMT had not been blocked. At those junctions where the EPPs were subliminal, the MEPP frequency was found to be reduced, but MEPP amplitude was either unchanged or greater than the control value. Occasionally, MEPPs 2-3 mV in amplitude were recorded. Thus it was concluded that THC at 30 X 10^{-6} M can block NMT.

To determine the manner by which THC blocks NMT, postjunctional membrane (PJM) sensitivity was tested by microperfusing carbamylcholine (CARB) onto the junctions of THC treated muscle. Application of 20 X 10^{-6} M CARB depolarized the PJM by 23.9 ± 3.7 mV in the THC treated preparations compared with 19.5 ± 2.2 mV in controls. Thus apparently THC does not block NMT by decreasing the sensitivity of the membrane to cholinergic agonists.

The effect of THC on quantal content was tested on the nerve-muscle preparation equilibrated in Ringer solution containing 0.9 mM Ca^{++} and 4.0 mM Mg^{++}. The failure rate in quantal release was determined using a low frequency train of nerve stimuli ("method of failures"). Perfusion of junctions of these preparations for 15 min with 30 X 10^{-6} M THC caused complete blockade of quantal release with 100% failure rate. Thus THC has a substantial effect in reducing the AP evoked release of acetylcholine.

1178 EFFECT OF α-BUNGAROTOXIN ON THE RISING PHASE OF THE MINIATURE ENDPLATE CURRENT. B. R. Land*, M. M. Salpeter, and E. E. Salpeter*. Section of Neurobiology & Behavior and Dept. of Physics, Cornell Univ., Ithaca, NY 14853.

Recent studies at various vertebrate neuromuscular junctions suggest that each quantal packet of nerve released acetylcholine (ACh) interacts with ACh receptors (AChR) over a small distinct post junctional area at very high ACh concentrations (Hartzell, Kuffler and Yoshikami, J. Physiol. 251: 427, 1975; Fertuck and Salpeter, J. Cell Biol. 69: 144, 1976; Matthews-Bellinger and Salpeter, J. Physiol., in press, 1978). According to such a model, the rise time of the miniature endplate current (mepc) reflects: a) the spreading rate of ACh in the cleft, b) the binding rate of ACh to receptor and esterase, and c) some constant time delays such as the conformational change to open the ion gate. Both (a) and (b) above are dependent on AChR and AChE site density. Furthermore, if (a) is a significant factor, then the time to peak of a mepc and its amplitude should be positvely correlated. To determine the relative importance of these parameters, we studied the rise time of the mepc in the lizard (Anolis Carolinensis) intercostal muscle, for normal AChR and AChE site densities and when these sites were reduced by α-Bungarotoxin (α-BTX) and diisopropyfluorophosphate (DFP) respectively.

Mepcs were acquired under voltage clamp (-100 mV at 23°C). Individual mepcs were then averaged into amplitude bins, 1 nA wide, after bringing them into register in time. Mean mepc rise time (from 10% to 90% of full amplitude) was 100±30 μsec in normal muscle, 220±40 μsec after incubation with BTX ($4x10^{-8}$M for 40 min) and 280±60 μsec with BTX plus DFP (10^{-3}M for 20 min). The mean mepc amplitude was 8±1 nA in normal muscle, 2±1 nA after BTX and 3±1 nA with BTX plus DFP. The mepc amplitude and rise time were positively correlated after BTX plus DFP, but not in normal muscle. From these results we conclude that a) a large fraction of the 100 μsec rise time of the unpoisoned endplate consists of a constant time delay, probably the conformational change of the receptor, and b) diffusion of ACh in the cleft becomes an appreciable factor in determining the mepc rise time of the BTX plus DFP poisoned preparation.

A determination of AChR site density by E-M autoradiography combined with mepc time-course data should therefore allow us to determine the actual ACh diffusion and binding rate constants in the cleft. (Supported by grant NS09315).

1179 ACh RECEPTOR-CHANNELS BEGIN TO OPEN WITHIN 30 μSEC AFTER AGONIST IS APPLIED. Henry A. Lester, Menasche M. Nass*, Mauri E. Krouse*, Norbert H. Wasserman* and Bernard F. Erlanger*. Division of Biology, California Institute of Technology, Pasadena, CA 91125, and College of Physicians and Surgeons, Columbia University, New York, New York 10032.

These experiments measure how soon ACh receptor-channels begin to open after agonist appears near receptors. Isolated Electrophorus electroplaques are arranged for transcellular recording. The innervated face is bathed in a 1 μM solution of cis-Bis-Q (3,3'-Bis-[α(trimethylammonium) methyl] azobenzene). This solution contains less than 1% trans isomer and has no effect on ACh receptors. Trans-Bis-Q, on the other hand, is a potent agonist; a concentration of 400 nM produces half-maximal receptor activation at the resting potential. A light flash increases the concentration of trans-Bis-Q in the solution to about 200 nM within 40 μsec (individual molecules of cis-Bis-Q are presumably photoisomerized to trans in less than 1 μsec after absorbing a photon). At 34°C the cell begins to depolarize detectably less than 30 μsec after the start of the light flash. More intense light flashes, we presume, will reduce the latency further. The minimum measurable latency increases at lower temperature ($Q_{10} \geq 2$), probably because the channel opening rate decreases. On the other hand, the growth phase of the miniature postsynaptic current (MPSC) has a much lower temperature dependence (Q_{10} of 1.2, Gage and McBurney, J. Physiol. 244, 385-407, 1975). Therefore the growth phase of the MPSC is probably not shaped primarily by the growth of ACh concentration; it may be limited by lateral diffusion of transmitter within the cleft. Our results indicate that channels begin to open rapidly when agonist is suddenly applied, and that only a small part of the synaptic delay is due to interaction of agonist and receptor. This work was supported by the NIH (grant NS-11756 and RCDA NS-242) and by the Muscular Dystrophy Association (grant and postdoctoral fellowship), and by NSF (grant PCM 74-02140).

1180 STRUCTURAL ORGANIZATION OF THE DEVELOPING AMPHIBIAN NEUROMUSCULAR JUNCTION. Michael S. Letinsky and Paige A. DeCino*. Dept. of Physiol. and Ahmanson Laboratory of BRI, Sch. Med., UCLA, Los Angeles, CA 90024.

The structural organization of the neuromuscular junction was analyzed at different stages of development. To accomplish this, we have developed a new, combined staining technique whereby pre- and postsynaptic endplate structures can be visualized simultaneously at the same junctional site. The basic procedure consists of first staining the presynaptic nerve using nitroblue tetrazolium (NBT), which upon reduction to its diformazan state colors the entire presynaptic terminal arborization intensely blue. The NBT nerve stain is compatible with common endplate acetylcholinesterase (AChE) stains such as the Karnovsky procedure (J. Cell Biol. 23:217-232, 1964). This staining combination vividly displays the blue colored nerve terminal processes outlined by the Hatchett's brown colored AChE reaction product. The technique independently stains pre- and postsynaptic elements of endplates successfully on developing, mature, and reinnervated frog muscle as well as on avian and mammalian skeletal muscle.

By using such a procedure, we have been able to characterize the developmental pattern of the growing nerve terminal processes relative to the distribution of the endplate AChE, a marker for postsynaptic specialization. The neuromuscular junctions in the cutaneous pectoris muscle from different stages of tadpoles and frogs (R. pipiens and R. catesbeiana) were examined. The earliest endplate specializations were observed on immature myotubes where NBT-stained unmyelinated axons formed small, unbranched contact points with weak subneural AChE activity. The initial contacts were formed by single axons, but with further development the endplates became multiply innervated. As tadpoles mature and go through metamorphosis, the multiply innervated terminals increase in size and become more complexly branched. Multiple innervation decreases with further development, but is still present in some terminals even in mature frogs. At all stages there were nerve terminal processes which appeared to be growing out of the established, AChE stained postsynaptic junctional arborization (escaped nerve fibers). The incidence of escaped fibers decreases with development, but is still present even at adult nerve muscle junctions. During the protracted course of development in frogs we have also observed endplates with portions of the AChE stained postsynaptic membrane devoid of any overlying nerve terminal processes. The decrease in multiple innervation coupled with the presence of escaped nerve terminal processes and AChE stained postsynaptic membrane without any overlying neural processes may reflect ongoing growth and reorganization of the neuromuscular junction.

1181 NEUROMUSCULAR TWITCH-TENSION STUDIES WITH C. SCULPTURATUS VENOM (CSV) AND PURIFIED FRACTIONS. Gesina L. Longenecker, Herbert E. Longenecker, Jr. and Barbara Beyers*. Depts. of Pharmacology and Physiology, Univ. of S. Ala. Coll. of Med., Mobile AL 36688.

Ours and other studies on neurotoxic scorpion venom have used electrophysiological techniques including voltage clamp and intracellular recording. These methods are adequate for examining mechanisms and are ultimately required, but they preclude simple statistical evaluation of vast numbers of fibers under many conditions and doses of reagents. Thus, using supermaximal indirectly evoked twitch-tension measurements of frog sciatic/sartorious preparations, we have conducted 40 experiments to restudy CSV and fractions (CSVF); both were furnished by D. Watt of Creighton University. Preparations were dissected and mounted in Ringer's containing 2.0 mM Ca++, 1.5 mM K+ and 114.5 mM Na+. Muscle length was adjusted for max twitch tension. Stimuli were presented at 0.1 per second. The preparations stabilized during 1-2 hours, during which tension decreased by about 50%. CSV and CSVF (0.5 to 10 ug/ml in Ringer's) were added for study after stabilization.

In standard Ringer's twitch tension was facilitated (2.36±.36) with max responses within 4 minutes. Indirectly increased twitch tension gradually subsided, reaching control levels in 14 minutes, with total and irreversible block by 140 minutes (control preparations with no venom were viable for at least 600 minutes). If the muscle chamber was flushed with Ringer's as venom response peaked, there was some reversibility of venom action, but twitch block still occurred. Duration of the facilitation period, time to peak facilitation and time to final block of twitch tension were increased with increased Ca++ concentration. Peak facilitation decreased with increased Ca++. These effects are consistent with repetitive neural firing caused by venom effects on the Ca++ dependent Na conductance system as described by others. Final twitch block and our inability to inhibit the occurrence of block with high Ca++ is not explained by this mechanism.

Preliminary studies with three highly purified CSVF (Toxins I, IV, and B140-1) showed that all toxins facilitated twitch; however, kinetics and appearance of records are different with each toxin. Toxin IV facilitates immediately and is a rapid and potent blocker of twitch tension. Toxin I shows delayed facilitation but eventually blocks twitch. B140-1 causes initial depression, then gradual increase in tension, then eventually blocks.

1182 ELECTROPHYSIOLOGICAL COMPARISON OF THREE PURIFIED NEUROTOXINS FROM C. SCULPTURATUS VENOM ON ISOLATED FROG NEUROMUSCULAR PREPARATIONS. Herbert E. Longenecker, Jr., Gesina L. Longenecker, Barbara Carter*, Depts. Physiology & Pharmacology, Univ. of S. Ala. College of Medicine, Mobile, AL 36688.

We, as well as other investigators, have demonstrated effects of crude Scorpion venom (CSV) on isolated frog sciatic nerve/sartorious muscle preparations. Following venom addition, repetitive firing of nerves is induced; also, prolonged nerve action potentials are elicited. These neural effects cause respectively repetitive stimulus-evoked endplate potentials (EPP) and prolonged EPPs. In this study we report results from 40 preparations using standard intracellular recording techniques on three highly purified venom fractions, Toxin I, Toxin IV and Toxin B-140-1. (Toxins were furnished by D. Watt of Creighton University.) All preparations were pretreated with glycerol to prevent muscle twitching. The Ringers' contained 1mM Ca++, 1mM Mg++, 2.5mM K+, 114.5 mM Na+ (pH 6.8).

Toxin I (.05-.8 ug/ml) caused facilitation (2.7±2.6) of the EPP, a prolonged period (82±24 mins.) of repetitive(R) EPPs (peaks 90±26) and eventual EPP block at 146±23 minutes. Miniature(M) EPP frequency(F) rose slightly from 0.6 to ~44/second. MEPP amplitude(A) was unaffected.

Toxin IV (.05-.8ug/ml) caused slight facilitation (.7±.21) of the EPP, then total EPP block at 64±20 minutes. REPPs (peak # 56±14) continued for 46±21 minutes. Before EPP block MEPPF rose from 0.8 to 24±15/sec, then decreased. Occasional MEPP (10-15/sec) bursts occurred following EPP block.

Toxin B-140-1 (.2-4.0ug/ml) caused prolonged EPPs (normal=2 msec, peak=204 ±105 msec). REPPs occurred (duration 140±24), but to a lesser degree (peak=5±1). The EPP was blocked (225 mins.) in 2 of 11 experiments. MEPPA was unchanged.

Each purified venom fraction effects prejunctional transmitter release phenomena distinctly, yet there are many similarities differing only perhaps by relative kinetic parameters. It seems reasonable to assume that facilitation of the EPP, the amount of REPPs, and increases in MEPPF relate directly to altered Na permeability of the nerve terminal. The aggregate effects can account for our prior observations with crude CSV. A new finding is that Toxins I and IV cause block of the EPP without apparent nerve terminal depletion. No obvious mechanism is apparent, although the response seems similar to that induced by Botulinum toxin. The EPP did not recover with increased Calcium (up to 2mM).

1183 THE AVIAN SYRINX: AN ANDROGEN SENSITIVE MOTOR ORGAN? V. Luine, I. Lieberburg*, F. Nottebohm, C. Harding*, and B. McEwen. Rockefeller University, New York, N.Y. 10021.

Song in male zebra finches is part of courtship and agonistic displays. The amount of singing is influenced by testosterone (T): castrate males sing little and T therapy reinstates normal amounts of singing. Castration (GDX) and T therapy also influence the volume of the syringeal muscle mass. The syrinx is the vocal organ of birds, innervated by hypoglossal motoneurons. Injections of ^{3}H-T lead to heavy concentrations of label over the nucleus of these motoneurons. The preceding observations, from the work of Arnold, Exp. Zool. 191 309 '75 and Arnold et al., J. Comp. Neurol. 165 487 '76, suggest that T may have an effect on the peripheral organs of song control. As a first step toward describing mechanisms responsible for these effects, we hypothesized that T affects neuromuscular transmission or even possibly syringeal muscle itself.

Adult, male zebra finches were Gdx and at various times after surgery were replaced with T or cholesterol. Levels of circulating androgens were verified by RIA. Two weeks following Gdx, syrinx wt.decreased by 24% (intact = 21.4mg). Replacement for 1 week returned weights to intact levels. Similar changes in larynx weight were not found. Activity of acetylcholinesterase (AChE) was measured in Gdx, intact and Gdx+T birds. Expressed as specific activity (nM/mg protein/hr) or as total activity (nM/muscle/hr), AChE activity decreased approximately 40% 2 weeks following Gdx. T replacement for 1 week restored AChE. AChE activity in hyoid or pectoralis muscle was not affected.

The possibility of T acting directly in the syrinx as in classic androgen target tissues was examined by measuring for high affinity T binding. Using standard cell fractionation techniques, ^{3}H-T binding was measured in cytosol prepared from syrinx, larynx, hyoid and pectoralis muscle and in serum and trachea. In the syrinx, high affinity T binding was detected (K_d=0.62nM) with a capacity of 14.8 fmoles/mg cytosol protein, values comparable to those in androgen sensitive tissues of the rooster. 83% of bound radioactivity recovered from syringeal cytosol was still in the form of ^{3}H-T. No high affinity binding was detected in the other tissues. The specificity of syringeal receptor binding is T = RU1881 = 5αDHT>estradiol>5 βDHT>progesterone.

The presence of high affinity T receptors and changes in AChE activity in syrinx after Gdx and concentration of label in hypoglossal motoneurons following ^{3}H-T systemic injections suggest T action via classic genomic mechanisms. However, the changes reported in syringeal muscle cannot at this time be attributed to direct neuronal or muscular effects. 1184 SYNAPTIC TRANSMISSION IN THE RABBIT SUPERIOR CERVICAL SYMPATHETIC GANGLION: COMPARISON TO THE FROG NEUROMUSCULAR JUNCTION. K.L. Magleby,[1] J.E. Zengel*[1] J.P. Horn,[2] D.A. McAfee,[2] & P.J. Yarowsky.[2] [1]Dept. Physiol., Univ. Mia. Sch. Med., Miami, FL 33152 and [2]City of Hope Med. Center, Duarte, CA 91010

At least four processes can act to increase transmitter release during and following repetitive stimulation at the frog neuromuscular junction. These processes and their time constants of decay (20°C) are: 1st and 2nd components of facilitation, 50 and 300 msec; augumentation, 7 sec; and potentiation (PTP), 30 sec to min. In this study we investigated whether similar processes are present in the sympathetic ganglion.

Excitatory post-synaptic potentials (fast EPSPs) were recorded from rabbit sympathetic ganglia using the sucrose gap technique. The preparation was perfused with oxygenated Locke solution (25-27°C) with reduced Ca^{++} and elevated Mg^{++} to reduce quantal content.

The preganglionic nerve trunk was conditioned with 1-600 impulses at 5/sec. The EPSP amplitude typically increased during the conditioning trains. Testing impulses applied after the conditioning trains established that the EPSP amplitudes then returned to the control level with at least three apparent time constants of decay: 460±80 msec, 17±4 sec, and 140±40 sec (±S.D.). The addition of Ba^{++} (0.1-0.2 mM) to the Locke solution led to a greater increase in the magnitude of the EPSPs during and following the conditioning train. This increase was associated with an increase in the magnitude but not the time constant of the 17 sec process. This effect of Ba^{++} on the 17 sec process in the sympathetic ganglion is similar to the effect of Ba^{++} on augumentation at the frog neuromuscular junction. The addition of Sr^{++} (0.2-0.8 mM) to the Locke solution also led to a greater increase in the magnitude of the EPSPs during the conditioning train. Sr^{++} had little effect on the 17 or 140 sec processes, suggesting that it is acting on a shorter time course process, perhaps the 460 msec process. This effect of Sr^{++} is similar to the effect of Sr^{++} on facilitation in the frog.

If Ba^{++} and Sr^{++} act the same in the rabbit sympathetic ganglion as the frog neuromuscular junction and if the observed changes in EPSP amplitude reflect changes in transmitter release, then the results of this preliminary study suggest that in the sympathetic ganglion (25-27°C) the 460 msec process is facilitation, the 17 sec process is augmentation, and the 140 sec process is potentiation (PTP). Thus, at least three of the processes that act to increase transmitter release at the frog neuromuscular junction also appear to be present in the rabbit sympathetic ganglion. It is interesting to note that even though the data from the sympathetic ganglion were collected at a higher temperature than in the frog (25-27°C vs 20°C), the decays of the identified processes were slower. It is necessary, therefore, to identify the processes in different preparations by their pharmacological and kinetic properties in addition to their time constants of decay. Supported by NIH grants NS10277, NS07044, NS05820, NS05363, and a Scottish Rite Fellowship.

1185 A STATISTICAL MODEL INDICATES THAT MULTIPLE PEAKS IN MEPP AMPLITUDE HISTOGRAMS ARE SIGNIFICANT. D. R. Matteson* and M. E. Kriebel* (SPON: J. B. Preston). Dept. Physiol., Upstate Medical Center, Syracuse, NY 13210.

A statistical model describing the probability density function of MEPP amplitudes was derived from the following three assumptions. (1) Small mode MEPPs (Kriebel & Gross, 1974, J. Gen. Physiol.) result from the release of a subunit of transmitter. (2) Larger MEPPs result from the synchronous release of several subunits. The release of T subunits would produce a subpopulation of MEPP amplitudes with a mean equal to T times the mean of the small mode MEPPs. (3) The overall MEPP amplitude distribution is thus composed of the sum of several subpopulations, each subpopulation being capable of generating a peak in the distribution, with a mean amplitude at some integral multiple of the small mode mean.

In a qualitative way, MEPP amplitude distributions fit this model since they appear multimodal (Kriebel, Llados & Matteson, 1976, J. Physiol.). In order to obtain a quantitative estimate of the fit we tested the significance of the multiple peaks by testing the above multimodal model against a reduced bimodal model. The reduced model should give a significantly better fit if the larger MEPPs result from the release of a single quantum of transmitter and the small mode MEPPs result from the release of a constant fraction of a quantum (or a smaller quantum). The test of significance we utilized was the generalized likelihood ratio test.

Amplitude histograms obtained under a variety of experimental conditions are shown to be fit significantly better by the multimodal model. Furthermore, when mean MEPP amplitude is decreased by increasing temperature, extracellular Ca^{++}, or addition of colchicine, the small mode mean (and therefore the interval between successive peaks) does not change significantly. The model indicates that the decrease in MEPP amplitude occurs as a result of a decrease in the conditional probability associated with larger amplitude subpopulations and an increase in the conditional probability of intermediate amplitude subpopulations. This analysis provides further evidence for the hypothesis that MEPPs result from the synchronous release of transmitter subunits.

1186 INTERACTIONS BETWEEN STRONTIUM AND CALCIUM IN THE PROCESS OF EVOKED TRANSMITTER RELEASE AT THE FROG NEUROMUSCULAR JUNCTION. A.M. Mellow and E.M. Silinsky. Dept. Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611.

The evoked release of transmitter at the neuromuscular junction is manifested in two ways: (1) synchronous release, recorded postsynaptically as the end-plate potential (e.p.p.) and (2) asynchronous release, recorded as a delayed increase in miniature end-plate potential (m.e.p.p.) frequency following nerve stimulation. Both of these processes are dependent upon extracellular calcium ion (Ca^{2+}) and both can occur when Ca^{2+} has been substituted by strontium ion (Sr^{2+}). The orders of effectiveness, however, are $Ca^{2+} > Sr^{2+}$ for synchronous release and $Sr^{2+} > Ca^{2+}$ for asynchronous release. This study was undertaken to investigate the interactions between these ions in both forms of release in the isolated nerve - cutaneous pectoris preparation of the frog.

It has been shown previously that, under certain conditions, Sr^{2+} can antagonize Ca^{2+} - mediated synchronous release. Using the dose-ratio method from basic drug-receptor theory, we estimated the equilibrium dissociation constant (K_d) for Sr^{2+} to be 4 mM. This value indicates that Sr^{2+} has an affinity for the nerve terminal membrane that is one order of magnitude lower than has been calculated for Ca^{2+} by the same method. Under conditions in which Sr^{2+} antagonized Ca^{2+} - mediated synchronous release, it actually enhanced Ca^{2+} - mediated asynchronous release. Further, Ca^{2+} was able to effectively antagonize Sr^{2+} - mediated asynchronous release, in an apparently competitive fashion. These observations suggest that the two forms of evoked transmitter release are activated by different intraterminal mechanisms with separate divalent cation sensitivities. The interactions between Sr^{2+} and Ca^{2+} may provide a tool for further understanding the basic mechanisms of depolarization-secretion coupling at presynaptic nerve terminals. (Supported by NIH grant NS 12782 and NIH training grant GM 07263. AMM is a NIH Predoctoral Fellow.)

1187 CALCIUM-LIKE ACTION OF COLCHICINE ON FROG SKELETAL MUSCLE MEMBRANE. Terry M. Mikiten and Nikki Martin*, Dept. Physiology, The Univ. of Texas Health Science Center, San Antonio, TX 78284.

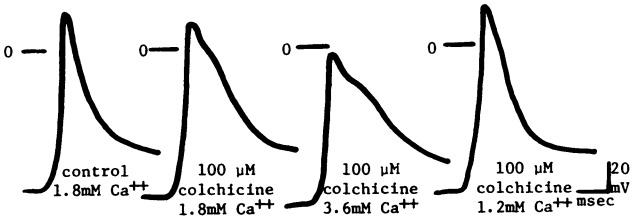
Because microtubules and tubulin have been implicated in the functioning of the postsynaptic membrane, we investigated the action of colchicine at the frog nerve-muscle junction. In these experiments, membrane potential is measured using conventional microelectrode technique. When applied in vitro in concentrations from 10-100 μM, colchicine increases the rate of desensitization of the postjunctional membrane (pjm) in the presence of 100 μM carbamylcholine (carb).

To test whether this is due to some action at the ACh receptor, colchicine was added to preparations bathed in 2-4 μM d-tubocurarine. No change ($p > 0.1$) in endplate potential amplitude is observed 30-60 min. after addition of the alkaloid.

Further, the final steady-state membrane potential during desensitization (control = 75.5 ± 1.4 S.E. mV) is shifted by colchicine in the direction of E_k (88.2 ± 1.7 S.E. mV; $p < .001$). This effect, as well as the increase in the rate of desensitization, can be duplicated by simply raising the extracellular calcium concentration.

Since calcium also alters some action potential parameters in frog skeletal muscle fibers, we measured these in the presence of 100 μM colchicine in different calcium concentrations. In these experiments, 100 μM colchicine increases (by 50%; $p < .001$) the duration of action potentials recorded at the pjm, and this is reflected by a decrease (by approx. 50%; $p < .005$) in the rate of membrane repolarization. Although it has no effect on resting membrane potential or rate of rise of the action potential, colchicine decreases the amplitude of the overshoot. Doubling the extracellular calcium alone has similar effects.

Because increasing or decreasing extracellular calcium alters the effects of colchicine, we propose that colchicine acts on both junctional and nonjunctional membrane by some mechanism which is calcium-like or calcium dependent (tracings below).



CALCIUM EFFECTS ON ACTION POTENTIALS IN COLCHICINE

1188 EFFECTS OF HISTRIONICOTOXIN ANALOGS ON THE IONIC CHANNEL OF THE CHOLINERGIC RECEPTOR. A.C. Oliveira*[1], E.X. Albuquerque[1], J.W. Daly[2], M.E. Eldefrawi*[1] and Amira T. Eldefrawi*[1]. Dept.Pharm. Exp. Ther., Sch. Med., Univ. MD., Baltimore, MD. 21201 and Lab. Chemistry,[2] NIH, Bethesda, MD. 20014.

Histrionicotoxin (HTX), a neurotoxin isolated from the skin secretion of the frog Dendrobates histrionicus, has been shown to block neuromuscular transmission by reacting rather specifically with the ionic channel of the cholinergic receptor. At present we report on some electrophysiological and biochemical studies performed with 3 HTX analogs: perhydrohistrionicotoxin (H_{12}-HTX), octahydrohistrionicotoxin (H_8-HTX) and isotetrahydrohistrionicotoxin (Iso-H_4-HTX). The effects of these analogs on endplate currents (EPCs) were studied in frog sartorius muscle under voltage clamp. All compounds (4-25 μM) decreased the EPCs peak amplitudes (70-85%) and half-decay times (25-30%) significantly. The decay of EPCs remained a single exponential function of time but its voltage dependence was decreased by the analogs. In presence of those neurotoxins, the current voltage relationship of the EPCs became highly nonlinear and very frequently showed hysteresis in the region of hyperpolarized potentials (-100 to -180 mV). Equilibrium potentials were unaffected. Effects of the analogs on ionic channel conductance and lifetime were studied by acetylcholine (ACh) noise analysis. They mainly decreased single channel conductance, but at hyperpolarized potentials (-120 mV) there was, in addition, shortening of channel lifetime. The effects of these analogs were also studied on the binding of [^{3}H] acetylcholine and [^{3}H] H_{12}-HTX to the ACh receptor and its ionic channel, respectively, in Torpedo ocellata electroplax membranes, using a centrifugal assay. At concentrations ranging from 0.1 to 30 μM, none of the HTX analogs displaced [^{3}H] ACh from its receptor sites. On the other hand, all three analogs were very effective in displacing [^{3}H] H_{12}-HTX from its binding sites in Torpedo membranes with I_{50} values ranging from 0.2 to 0.6 μM. There was good correlation between the electrophysiological and biochemical data. It is concluded that these analogs and the parent compound HTX, react mainly with the ionic channel of the ACh-receptor, but not with the ACh recognition site. (Supported by NIH grant NS-12063, NSF grant BNS 76-21683 and FAPESP, Sao Paulo, Brazil.)

1189 NEWLY FORMED NEUROMUSCULAR JUNCTION IN TISSUE CULTURE HAS A LOW SENSITIVITY TO LANTHANUM. H. Benjamin Peng*, Shigehiro Nakajima Allan Greenberg*. Dept. of Biol. Sci., Purdue Univ., W. Lafayette IN 47907

Lanthanum (La^{3+}) is one of the most potent agents in enhancing the spontaneous transmitter discharge at the adult amphibian neuromuscular junction. At millimolar concentration it increases MEPP frequency more than 10,000 fold (Heuser et al., Proc. R. Soc. Lond. B. 179: 247, 1971). However, in certain developing junctions, lanthanum has been shown to have little or no effect in transmission (Harris et al., Nature 268: 265, 1977; Kidokoro et al., C.S.H.S. 40: 373, 1976).

We have investigated the effects of lanthanum on newly formed neuromuscular junctions (NMJ's) in tissue culture. Neurons and muscle cells from Xenopus embryos were isolated and put into culture. One day after nerve-muscle co-culture, MEPPS could be recorded from muscle cells contacted by neurites. The MEPP amplitude showed a skewed distribution, ranging from a few millivolts to more than 25 millivolts. The input impedance of these cells was on the average 109 MΩ.

Since we were unable to maintain the co-cultures for more than a week, we used the tail muscle from mature tadpoles as a control in our studies. The tail muscle is the in-vivo counterpart of our cultured muscle cells. The MEPP amplitude in the mature tadpole muscle showed a normal distribution. Lanthanum, 100 μM in unbuffered Ringer solution, caused roughly a 16-fold increase in MEPP frequency over the Ringer control.

To study the effects of lanthanum on newly formed junctions, we recorded MEPPs from junctions 1 to 6 day after nerve-muscle co-culture. MEPPs were continuously recorded in unbuffered Ringer solution, followed by solution containing La^{3+}. Of the 14 junctions examined, only one showed a sensitivity to lanthanum approaching that of the mature junction, viz., it showed a 16-fold increase in MEPP frequency in solution containing 100 μM lanthanum. The majority of junctions (11) showed either no increase or less than 5-fold increase in MEPP frequency in 100 μM lanthanum solution. The remaining junctions showed an intermediate increase, between 6 to 10-fold. This indicates that the newly formed junction has a low sensitivity to lanthanum relative to the mature junction.

Our result suggests that the sensitivity to La^{3+} develops quickly in Xenopus NMJ cultures compared with rat (Kidokoro et al., op cit). However, the developing junction still has a low sensitivity to La^{3+} compared with the mature junction. Assuming that La^{3+} interferes with the Ca^{2+}-transmitter secretion coupling, our finding suggests that the maturation of NMJ involves a development of Ca^{2+}-dependent transmitter release mechanism. (Supported by USPHS grants NS-10457, NS-08601, F32-NS05631, T32-GM07211).

1190 DIVERSE MECHANISMS OF POSTSYNAPTIC RECEPTOR BLOCKADE AT THE MOUSE NEUROMUSCULAR JUNCTION. P. Pennefather* and D. M. J. Quastel. Dept. of Pharmacology, Faculty of Medicine, The Univ. of British Columbia, Vancouver, B. C., V6T 1W5, Canada.

A variety of drugs act to depress the amplitude of end-plate potentials by interference with receptor function. Examination of amplitude and time course of miniature end-plate currents (m.e.p.c.s) and of response to locally applied cholinergic agonists permits identification of at least three different kinds of inhibitory postsynaptic action. In the case of bungarotoxin and curare, m.e.p.c.s are reduced in amplitude and decay somewhat faster than normal. The time course of m.e.p.c.s becomes much closer to a pure exponential decay, as would be expected from reduction of the probability of "reverberatory" ACh action. In the presence of curare, or other agents that act similarly, the response of the end-plate to exogenously applied ACh or carbachol is depressed much more than the m.e.p.c.; this can be expected from simple models of ACh interaction with receptor, when binding of ACh to receptor is inhibited.

Local anaesthetics and some other agents (e.g., pentobarbital, diphenylhydantoin) characteristically cause the m.e.p.c. decay phase to be "split" into two or more components; there is little change of peak amplitude and the early (fast) phase of decay is little affected by ethanol or inhibition of AChE.

A third mode of postsynaptic "blockade" is exhibited by a variety of agents with general anaesthetic properties, including at least paraldehyde, pentane and some alcohols (e.g., butanol, pentanol). The action resembles that of curare in that (a) m.e.p.c.s are reduced in amplitude; (b) the time course of m.e.p.c.s becomes somewhat briefer than normal (with the exception of the alcohols, which also have an ethanol-like action to prolong m.e.p.c.s); (c) ethanol and AChE inhibition continue to prolong m.e.p.c.s and (d) there is no "split" such as is produced by local anaesthetics. However, these agents contrast with curare in that they inhibit the response of end-plates to exogenously applied cholinergic agonists much less than they depress me.p.c.s. Moreover, the time course of m.e.p.c. decay is not affected in the same way as with curare or bungarotoxin. The effects of these agents are difficult to explain, except in terms of modification of rate constants in rather complicated schemes of interaction of ACh with receptor.

Supported by grants from the Medical Research Council of Canada and the Muscular Dystrophy Association of Canada.

1191 RUETHENIUM RED BLOCKS SPONTANEOUS, EVOKED, AND IONOPHORE-INDUCED RELEASE OF TRANSMITTER AT THE NEUROMUSCULAR JUNCTION. R.J. Person and G.A. McLean, Dept. of Physiology and Biophysics, O.U. Health Sciences Center, Oklahoma City, OK 73190

Ruthenium Red (RuR), a heavy metal, histochemical stain for mucopolysaccharides, also blocks calcium (Ca) binding sites thereby inhibiting the translocation of Ca across membranes and probably also inhibiting Ca-dependent processes such as excitation-secretion coupling. We observed changes in evoked and spontaneous transmitter release, measured as endplate (EPPs) and miniature endplate potentials (MEPPs), at the frog neuromuscular junction using standard intracellular recording techniques while junctions were exposed to 1-5 μM concentrations of crude RuR (Sigma). Junctions were additionally exposed at various times to 100 μM concentrations of the cation ionophore X537A.

RuR at 5 μM blocked both evoked and spontaneous transmitter release within 2 min of initial exposure. At 1 μM, the dye produced a similar blockade with a monotonic decline in MEPP frequency, or, with an early acceleration of MEPP frequency. Evoked transmitter release was blocked by a reduction in quantal content. Although there was a 50% reduction in MEPP amplitude at 1 μM RuR, this reduction was not sufficient to cause the disappearance of recordable MEPPs. Simultaneous exposure of junctions to 1 μM RuR and 100 μM X537A resulted in the typical ionophore-induced catastrophic reaction: acceleration of MEPP frequency and subsequent block of MEPPs within 1-2 min of ionophore exposure with simultaneous muscle fibrillation and a decline of membrane potential in the region of the endplate. If X537A exposure was delayed until the RuR-induced blockade of MEPPswas nearly complete no response to the ionophore is observed except for resting potential decline.

These results demonstrate that RuR acts to block both extra- and intracellular Ca-binding sites. Intracellular blockade of Ca transport sites on organelles which modulate terminal [Ca] would explain an increase in MEPP frequency as suggested by Alnaes and Rahamimoff (J. Physiol., 248:265) but it does not explain the subsequent block of spontaneous release unless RuR also blocks an intracellular Ca-binding site required for transmitter release. Extracellular blockade of voltage dependent Ca channels is expected from the reported specific actions of the dye with a consequent reduction in evoked release. However, blockade of the effects of X537A action by RuR suggests that either the extracelluar membrane site of action of the dye is sufficiently nonspecific to prevent interaction of the Ca-ionophore complex with the membrane or, that one or more of the sites to which RuR binds are required for Ca translocation across the membrane via the ionophore. 1192 δ-AMINOLEVULINIC ACID INHIBITS EVOKED RELEASE BY A PRESYNAPTIC MECHANISM IN RAT NEUROMUSCULAR JUNCTIONS. Jackson B. Pickett, Joel C. Bornstein* and Ivan Diamond Dept. Neurology, Sch. Med., U.C.S.F., San Francisco, CA 94143.

Acute attacks of weakness are a prominent feature of the hepatic porphyrias. The hepatic porphyrias are caused by a defect in heme synthesis leading to increased excretion of δ-aminolevulinic acid (ALA) and porphobilinogen. During acute attacks, serum levels of ALA may rise to 10^{-6} -- 10^{-5} M. It has been suggested that the symptoms of porphyria result from elevated serum levels of ALA. We investigated this possibility using conventional microelectrode techniques in a rat phrenic nerve-hemidiaphragm preparation.

End-plate potential (EPP) amplitude in curare-treated preparations was reduced 90% by 12 mM ALA. 0.2 mM ALA did not change EPP amplitude. EPP amplitude could be reduced by reducing the number of quanta released by a nerve stimulus, or by reducing the postsynaptic response to a single quanta. To distinguish between these two possibilities we increased the magnesium/calcium ratio in the bathing solution and found that the number of quanta released by 0.5 Hz stimulation was reduced by ALA without changing quantal size as determined by measuring miniature end-plate potential amplitude. The mechanism of this presynaptic inhibition of evoked release is unknown. ALA mimics the action of γ-aminobutyric acid (GABA) in frog spinal cord and at crayfish stretch receptors. However, picrotoxin (0.1 mM), a GABA antagonist, did not prevent the usual decline in EPP amplitude seen with ALA.

The concentration of ALA required to reduce EPP amplitude in rat neuromuscular junctions is more than that seen in the serum of patients with acute porphyria. This suggests that circulating ALA is not the sole cause of weakness seen in patients with acute porphyria.

1193 THE APPEARANCE OF ACETYLCHOLINESTERASE AT NEWLY FORMED NEUROMUSCULAR JUNCTIONS IS REGULATED BY NERVE-MUSCLE ACTIVITY. L.L. Rubin, S.M. Schuetze*, C.L. Weill and G.D. Fischbach. Dept. Pharmacol., Harvard Med. Sch., Boston, MA 02115.

Acetylcholinesterase (AChE) accumulates at 70% of nerve-muscle synapses that form in spinal cord explant-muscle cocultures. Enzyme activity was detected histochemically and also by measuring the rate of decay (τ) of extracellularly recorded synaptic potentials (ExSPs). The two measures were closely correlated: 76% of synapses with τ<1.8msec (30°C) stained for AChE, whereas none with τ>2.6msec stained. In addition, the end-plate specific (19S) form of the enzyme was found by sucrose gradient centrifugation of extracts of dissociated spinal cord cell-muscle cocultures.

The appearance of synaptic AChE, in contrast to synapse formation itself and to the clustering of acetylcholine receptors (AChR), is dependent upon some aspect of nerve-muscle activity. When cultures were grown in tetrodotoxin ($3x10^{-7}$M), or the AChR antagonists curare (50-250μM) or α-bungarotoxin ($2x10^{-8}$M), the mean rates of ExSP decay were prolonged--the percentage of synapses with τ<1.8msec decreased by a factor of 5. Only 2% of the synapses in these cultures stained for AChE. Further, although total AChE activity did not decrease, the 19S form of the enzyme was not detected in cocultures grown in curare. Thus, nerve-muscle activity is apparently required for the assembly, as well as for the accumulation at synapses, of this unique form of AChE. Activity of muscle cells seems to be a crucial factor. Synaptic AChE did not appear when cultures were grown in 3μm curare, which reduced synaptic potential size by only 50%, but which nearly abolished muscle twitching. Moreover, muscle activity alone was sufficient for the appearance of AChE at synapses. Myotubes in cocultures grown in 50μm curare were stimulated directly (in the presence of curare) through an extracellular electrode at a rate of 2-3/sec for 8-12 hours. ExSPs at 5 of 5 previously identified synapses decayed more rapidly (mean τ at 30°C decreased, from 2.76msec to 1.74msec). This change, in which each synapse served as its own control, was quite significant.

We are now investigating factors which can replace synaptic transmission and/or muscle activity in inducing synaptic AChE. In cultures grown in 50μm curare and 10-100μm dibutyryl cyclic GMP, the majority of synapses exhibited rapidly decaying ExSPs, and 70% stained for AChE. Other factors tested thus far--including dibutyryl cyclic AMP (100μm), the calcium ionophore A23187 (0.5μm) and veratridine (1.5μm)-were ineffective.

1194 MATHEMATICAL MODEL OF THE DYNAMICS OF SYNAPTIC TRANSMISSION AT THE NEUROMUSCULAR JUNCTION. Claude Sarrazin* and Patrick Cavanagh* (SPON: Franco Lepore). Dept. Psychol., Univ. de Montréal, Montréal, Québec, Canada H3C 3J7.

Two different hypotheses are normally suggested to explain the phenomena of facilitation (F), depression (D) and post-tetanic potentiation (PTP) which characterize synaptic transmission (ST): the first attributes these phenomena to variations in release probability resulting from the action of calcium at the presynaptic level; the second attributes the phenomena to variations in the immediately available transmitter store. Our approach has been 1) to simulate with first degree linear equations the possible interactions of different physiological mechanisms (transmitter synthesis and vesicle recharging movement and mobilisation of vesicles within the synapse, exocytosis at release sites vesicle membrane recycling) that may influence ST during and following stimulation and 2) to correlate the postsynaptic potentials (PSPs) predicted by these mechanisms with the experimental PSPs obtained with different frequencies and durations of stimulation in a variety of studies of the neuromuscular junction. Using a modified Marquardt minimum sum of squares procedure for adjusting the values of the model's parameters, it was possible to account for all the observed phenomena (F, D and PTP; minimum correlation obtained was $r = 0.92$, $p < 0.01$) in the six groups of data analysed.

The values of model's parameters and their variations as a function of the components of synaptic preparations (Ca and Mg concentrations, temperature) revealed that the two hypotheses given above to explain F, D and PTP are not necessarily mutually exclusive but rather complementary. The main conclusions of the study are 1) that F and D are mainly imputable to the variations of the immediately available transmitter store and its blockage by "empty" vesicles rather than the modification of release probability, 2) that vesicular movement under the control of intracellular calcium is largely responsible for the variations of the available store during stimulation, and 3) that, following a long stimulation, the production of the PTP results from a residue of active calcium that acts both on the amount of available transmitters and on the probability of release.

1195 CHANNEL OPEN TIME DECREASES POSTNATALLY IN RAT SYNAPTIC ACETYLCHOLINE RECEPTORS. S.M. Schuetze* and G.D. Fischbach. (SPON: S.W. Kuffler). Dept. Pharm., Harvard Med. Sch., Boston, MA 02115.

The mean channel open time (τ) of acetylcholine receptors (AChR's) was studied in skeletal muscle fibers of the chick and rat at different stages of development. The average τ of AChR's in small (ca. 15μm^2) discrete membrane patches was estimated by spectral analysis of ACh-induced membrane current fluctuations recorded with an extracellular pipette filled with 40μM ACh. Previously (Schuetze et al., PNAS 75:520, 1978) no difference in τ was detected between receptors clustered at synapses and more diffusely distributed AChR's on cultured embryonic chick myotubes innervated by spinal cord explants. For both receptor populations, τ was rather long (4 ms at 23°) with a Q_{10} of 3.1. Apparently, τ is independent of innervation and receptor density. We now report that synaptic AChR's in anterior latissimus dorsi and intercostal muscle fibers of 4- to 18-week posthatched chicks have the same, relatively long open times as found in embryonic muscle grown in vitro. The decay of extracellularly-recorded synaptic currents, an independent estimate of τ, was prolonged in junctions of both muscles and was in good quantitative agreement with the results of fluctuation analysis. Thus the mean channel open time of AChR's clustered in adult chick junctions is longer than that recorded in other species at the same temperature. The metabolic half-life of chick synaptic AChR's increases from 30 hr to more than 5 d during the third week after hatching (S. Burden, Devel. Biol. 61:79, 1977). We conclude that τ is independent of metabolic stability as well as receptor clustering.

We have confirmed earlier reports that synaptic AChR's in adult rat diaphragm fibers have short τ's (1.4 ms at 21°). However, the open time of AChR's in junctions of neonatal (0-4 d post-partum) rat diaphragm fibers was much longer (4.5 ms at 21°) than in adult junctions. Synaptic current decay constants were 3 times longer in neonatal than adult fibers. The slow decay in neonates was not due to lack of acetylcholinesterase: the enzyme was demonstrated histochemically and methane sulfonyl fluoride (an AChE inhibitor) prolonged the decay two-fold. Studies of 1-15 d rats have shown that fibers with short τ's first appear 6 d after birth and are predominant by 13 d. Between 6-11 d, some junctions exhibited complex ACh power spectra and biphasic synaptic currents. These junctions may contain a mixture of AChR's with fast and slow channels. Experiments are in progress to determine what (if any) other changes in synaptic structure and function occur during this interval. In any case, it is clear that a change in AChR channel open time occurs long after functional transmission is established.

1196 MOLECULAR FORMS OF CHOLINESTERASES IN CHICKEN MUSCLES. Janez Sketelj*, Mark G. McNamee* and Barry W. Wilson. Depts. of Avian Sci. and Biochem., UCD, Davis, CA 95616

AChE activity varies during development, behaves differently in fast and slow chicken muscles and is defective in its regulation in dystrophic and denervated muscles. The relationship between the molecular species of AChE and BChE in these muscles and in plasma was studied by velocity sedimentation in 5-20% linear sucrose density gradients.

A 7s form of AChE predominated and 11s and 20s forms were found in normal and dystrophic embryo pectoral muscle. Muscle cultures did not contain the 20s form present in their tissue-of-origin.

A 20s AChE form predominated in normal fast PLD muscle of 10-13 week old chickens. 7s and 11s forms were especially reduced. Total AChE activity was much lower than in embryo muscle. The high AChE activity of dystrophic muscle was accompanied by increases in 7s, 11s, and to a lesser extent in 20s AChE forms.

AChE activity increased after denervation of normal and dystrophic muscles. In both cases activity of the 20s form disappeared and the 7s form increased. Twelve days after denervation AChE patterns were the same in normal and dystrophic muscle. Patterns from dystrophic muscle resembled those of embryo more than those of denervated muscle.

The AChE pattern of slow ALD muscle (a muscle little affected by dystrophy) was the same in both lines of chickens and differed from that of the fast PLD. Activity of the 7s form was high and 20s form low.

BChE activity was high in dystrophic PLD muscles. Most sedimented as a 5s form; 3 other forms (7s, 11s, 20s) sedimented with the corresponding AChE forms. The 20s form disappeared and 7s and 11s forms increased following denervation of dystrophic muscles. The final pattern was the same as that found in denervated normal muscle.

The relationships between these sedimentable forms and those revealed by acrylamide gels and the AChE forms in plasma of embryo and dystrophic muscle will be shown.

The results reconfirm that AChE rises after denervation of the chicken; they add to the evidence that AChE and BChE are regulated by neural activity, and that this regulation is interrupted with denervation and defective in dystrophy.

1197 QUINACRINE ON NEUROMUSCULAR TRANSMISSION. M-C. Tsai*, A.C. Oliveira*, A.T. Eldefrawi*, M.E. Eldefrawi* and E.X. Albuquerque. (SPON: J.E. Warnick). Dept. Pharmacol. & Exp. Ther., Univ. Maryland, Sch. Med., Baltimore, MD 21201.

The effect of quinacrine on neuromuscular transmission was studied on the rat soleus and frog sartorius muscles. At 10 μM and 30 μM quinacrine blocked the indirect stimulated muscle twitch by 40% and 80%, respectively. At 200 μM, neuromuscular transmission was completely blocked in 10 min and membrane depolarization induced by carbamylcholine (0.7 mM) was simultaneously reduced. At 50 μM, the drug reduced the carbamylcholine-induced membrane depolarization by 80%. However, it had no significant effects on either resting membrane potential or quantal size. Quinacrine (30 μM) markedly decreased the amplitude and time constant of the decay phase of the endplate current (EPC) recorded at -90 mV in glycerol-treated frog sartorius muscles by 78 and 62%, respectively. The voltage-current relationship of the EPC became nonlinear in the presence of quinacrine and the time constant of decay was less dependent on membrane potential. There was no effect on either the EPC reversal potential or the single exponential function of the falling phase. Quinacrine inhibited acetylcholinesterase (K_i=0.3 μM) and the binding of ^{3}H-perhydrohistrionicotoxin and ^{3}H-acetylcholine to acetylcholine receptor of the electric organ of Torpedo ocellata (K_i=17 μM and 60 μM respectively). Since the blockade of acetylcholinesterase occurs simultaneously with the partial block of the acetylcholine receptor-ionic channel complex, it was difficult to record a typical prolongation of the EPC as seen with other anticholinesterase compounds such as neostigmine. The data suggest that quinacrine alters neuromuscular transmission in a rather complex manner, that is, by altering the kinetics and voltage sensitivity of the ionic channel, partially blocking the receptor recognition sites for acetylcholine, and blocking acetylcholinesterase. (Supported, in part, by USPHS Grant NS-12063, NSF Grant BNS 76-21683 and FAPESP, Sao Paulo, Brazil.)

1198 END-PLATE BLOCK BY GUANIDINE DERIVATIVES. Shigenori Watanabe*, Jerry Farley* and Toshio Narahashi (SPON: S.C. Cheng). Dept. Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611.

The effects of methylguanidine (MG), 1,1-dimethylguanidine (DMG) and amylguanidine (AG) on the neuromuscular transmission in the frog were studied. MG, DMG and AG reduced iontophoretically induced ACh potentials with ED_{50} of approximately 0.5 mM, 5 mM and 0.2 mM, respectively. They had little effect on the input resistance of the muscle in these doses. The end-plate potential was reduced, but the end-plate blocking actions of low doses of MG and DMG was obscured by the stimulation of transmitter release in these doses. The I-V relation of the peak amplitude of end-plate current (EPC) and membrane potential (E_m) as determined by voltage clamp is normally linear. However, in the presence of DMG, MG or AG there was a dramatic rectification of the currents at E_m more negative than the reversal potential (E_r). E_r was unaffected by these compounds. At E_m more negative than E_r the EPCs were greatly reduced. At E_m more positive than E_r the I-V relation showed no rectification. Shifting E_r by approximately 20 mV to E_r' by replacing Na^+ with sucrose did not alter this pattern of rectification, that is rectification occurred only at E_m more negative than E_r'. The suppression of the outward EPC was removed by repetitive stimuli. We conclude that these guanidine derivatives block the end-plate channels. This block seems to be current dependent and reversed by outward current flow through the channels. Supported by NIH grant NS 14145.

1199 NERVE MUSCLE SYNAPSE FORMATION: FIRST ATTEMPTS TO BLOCK WITH EMBRYONIC MUSCLE MEMBRANES AND ANTI-MEMBRANE ANTIBODIES. C.L. Weill, C.J. Loria*, G.D. Fischbach. Dept. of Pharmacology, Harvard Medical School, Boston, MA 02115.

Membranes were partially purified from homogenates of cultured chick myotubes and from freshly dissected 14 day embryonic muscles by differential centrifugation followed by separation on a discontinuous sucrose density gradient. Five fractions were collected at the following sucrose interfaces: I=8-20%, II=20-27%, III=27-32%, IV=32-40%, and V=40-55%. As previously reported (Schimmel et al. PNAS 70, 3195, 1973), the highest specific activity of ^{125}I-α bungarotoxin binding sites (ACh receptors) were found in fractions I and II. Typically, these fractions contained 9-18 times as many toxin sites/mg protein as the homogenate. Acetylcholinesterase activity was more uniformly distributed over the gradient but the specific activity of the relatively large (19S), end plate form was highest in fraction III. The 19S form was found in innervated (14-day) embryonic muscle but not in uninnervated cultured myotubes. Antisera were raised in rabbits and guinea pigs against the crude (40,000g) membrane pellet and also against each of the first three fractions. Anti-muscle antibodies were detected on uninnervated and innervated myotubes in vitro by indirect immunofluorescence. In all cases the fluorescence was apparently distributed uniformly over the myotube surface.

Muscle membranes (pooled fractions I-III) (but not anti-membrane antibodies) bind to nerve processes that grow out of cultured spinal cord explants. This was detected by indirect immunofluorescence and by scintillation counting after chemically iodinating the membranes. Preliminary experiments indicate that muscle membranes bind more avidly to a monolayer of spinal cord cells than to a monolayer of fibroblasts.

Our first attempts to block nerve-muscle synapse formation in spinal cord explant-muscle cocultures, with material from fractions I-III, have been negative, even when 100μg of protein (>1000 x the estimated amount of membrane in the target muscle cells) was added. Attempts to block synapse formation with anti-muscle antibodies have been complicated by the fact that at high concentrations the immune sera and purified IgG were invariably cytotoxic in the long run. Although no acute effects have been observed on membrane potential, ACh sensitivity, or synaptic transmission, most of the myotubes were lysed after 12-18 hours in the presence of 1:10 dilutions of the sera or 100μg/ml of IgG. The toxicity was selective in that nerve processes and mononucleated cells in the same cultures and liver cells, heart cells, and fibroblasts in other cultures were spared.

Supported by grants from the NIH (NS11160) and MDAA. C.L.W. is a MDAA postdoctoral fellow.

1200 NEUROMUSCULAR FUNCTION RELATED TO HISTOCHEMICALLY DETECTABLE ACETYLCHOLINESTERASE ACTIVITY AT THE ENDPLATE. Otto L. Wolthuis and Larry A. Kepner. Med. Biol. Lab. TNO, P.O. Box 45, 2280 AA Rijswijk Z.H., The Netherlands.

During studies of oxime therapy following intoxication with organophosphorous cholinesterase inhibitors (OP's), the question arose as to what relationship exists between histochemically detectable acetylcholinesterase activity at the endplate and the degree of neuromuscular function (NMF).

NMF of isolated phrenic nerve diaphragm preparations from rats was determined from recordings of tetanic contractions following indirect stimulation with four 3 sec trains of 25, 50, 100 and 200 stim/sec, respectively. Each curve was graded on a scale from 0 (full block), 1/3, 2/3 to 1 (fully sustained tetanus). After full blockage by the OP tabun, the reactivator obidoxime was administered in varying doses and recovery of NMF was determined. Immediately thereafter the diaphragms were stained histochemically for AChE-activity and the staining intensities were graded on a scale from 0 to 4. All gradings were done 'blind', by two investigators and the results were averaged.

A good correlation was found between AChE-activity and NMF (r=0.93; conf. limits 0.97-0.87). Furthermore, 1) AChE-activity fell below detection level and must be very low when considerable NMF still existed and 2) at approximately grade 3 of the AChE staining levels all tetanic contractions were fully sustained. The former finding is in accordance with earlier results obtained with other methods but the latter finding seems not to be. The degree of staining found seems to indicate a higher amount of endplate AChE-activity than the 50% required for normal neuromuscular function suggested by earlier studies. Possible explanations for this discrepancy are discussed.

It is concluded that a clearcut relation exists between endplate AChE-activity and NMF. The results suggest that the use of histochemical staining may provide more valid results than does measurement of hydrolysis of exogenous acetylcholine.

NEURONAL CIRCUITS AND PATTERN GENERATION

1201 SYNAPTIC PERTURBATION AND ENTRAINMENT OF THE GASTRIC MILL RHYTHM OF THE SPINY LOBSTER. Joseph Ayers, Dept. of Biology, B-022, U.C.S.D., La Jolla, CA. 92093.

The control of the gastric mill network of the spiny lobster by the IVN through fibers has been studied as a model system for the control of neuronal oscillators by synaptic input. The gastric mill rhythm is generated by a network of ten motor neurons and four interneurons resident in both the stomatogastric and commissural ganglia (Prog. Neurobiol. 7:215-290). The gastric rhythm basically consists of synergistic bursts in the E, LG and MG neurons which alternate with the discharge of Int 1. The effect of IVN input trains (500 msec duration, 20/sec), depends on where they occur in the ongoing gastric cycle. Inputs which occur during or near the end of the LG-MG burst delay subsequent bursts by prolonging the duration of the E-LG-MG burst and delaying the subsequent LG-MG burst by a proportional amount. Inputs which occur at the termination of an ongoing LG-MG burst may have one of two effects. If they occur before the end of the E neuron burst, they prolong the E cell burst and may trigger a short LG-MG burst. If the E neuron burst has terminated, they may trigger a longer burst which is of the same duration as a normal LG-MG burst, but intercalcated between the two ongoing LG-MG bursts. One may conclude therefore that the characteristics of the responses depend on the detailed activity status of several elements of the network. This complexity of organization contrasts with the response of the pyloric network to similar input, where the responses depend only on the activity state of one set of elements.

Repetitive IVN trains which occur at frequencies near that of the free run gastric rhythm can entrain the rhythm. If the repetitive stimulus is slightly faster than the free run gastric rhythm, it tends to occur after the termination of the ongoing LG-MG burst in the interburst interval. In such situations all entrained bursts have the characteristics of intercalcated bursts. If the entraining cycle is slightly slower than the free run gastric rhythm, the stimulus tends to occur near the end of the LG-MG burst where they cause a prolongation of the E neuron burst. Thus the phase relationships which obtain during entrainment of the gastric oscillator depend on the ratio of frequencies of the cyclic stimulus and the free run gastric rhythm.

1202 CROSS-CORRELATION OF EEG SIGNALS FROM OLFACTORY BULB AND CORTEX. Steven L. Bressler. Dept. Physio-Anat. UCB, Berkeley, CA 94720.

Incoming bursts of impulses along primary olfactory nerve fibers set the cellular circuitry in the olfactory bulb into oscillation at a characteristic frequency of 40 to 80 c/s. Bulbar activation is manifested by oscillation of the bulbar EEG (generated by the granule cell population) at this frequency. Mitral cells form the excitatory limb of the feedback circuit which generates the oscillation, so volleys of spikes propagate on mitral axons in the lateral olfactory tract at a density that oscillates with bulbar EEG activity. These spikes activate the prepyriform cortex to produce EEG activity at the same frequency as that of the bulb.

The hypothesis was proposed that during normal physiological activity the prepyriform cortex may be treated as a linear oscillator being driven by the oscillatory input from the bulb. This was tested by measuring the frequency of oscillation and the phase difference between bulbar and cortical signals.

Records were taken from alert, responsive rabbits in which indwelling electrodes had been implanted in the olfactory bulb and an array of electrodes had been placed on the cortical surface. The signals from these electrodes were amplified, digitized at 1 msec intervals, and stored on magnetic tape in 4 sec blocks, ten channels maximum. For a selected bulbar and cortical pair, segments containing bursts of oscillation in both were edited from the 4 sec block. These burst segments typically ranged from 100 to 300 msec in duration. A cross-correlation function was formed between bulbar and cortical signals for each segment after appropriate normalization. The function gave a value for the cross-correlation coefficient each time the signals were shifted with respect to one another by one digitizing interval(1 msec). The maximum coefficient value occurred at a shift which brought the signals into phase. This shift to "in phase" was that fraction of a cycle which supplied the phase angle between bulbar and cortical signals. Since the cross-correlation function of two sinusoids was sinusoidal at the same frequency, its zero-crossings provided a measure of frequency. When phase was plotted as a function of frequency and a linear regression was performed on the data, it was found that the cortex typically lagged the bulb and that the phase lag increased as the frequency increased. The slope and abscissa intercept of the experimental curve were found to conform well to those predicted on the basis of theoretical considerations.

The prepyriform cortex thus can be described by a linear oscillator that is driven by oscillatory input from the bulb. Variations in this mechanism that occur during olfactory information processing will be discussed. Supported by MH 06686.

1203 PREMOTOR NEURONS OF A GASTROPOD BUCCAL GANGLION. Andrew G. M. Bulloch* and Derek A. Dorsett* (SPON: R. M. Pinter). Dept. of Mar. Biol., Mar. Sci. Labs, U.C.N.W., Menai Bridge, N. Wales.

Studies of feeding behaviour in the Atlantic nudibranch mollusc Tritonia hombergi have shown the cycle of intrinsic buccal mass movements to be divided into three phases: Phase I ("Protraction"), Phase II ("Retraction") and Phase III ("Flattening"). Populations of motoneurons which control these phases of movements have been identified and designated as P, R and F cells respectively.

Correctly patterned motor output is determined by a number of common synaptic inputs of different sign to the three motoneuron populations. Three inputs have been specified: Input 1 (active before and during Phase I), Input 1a (active during Phase I) and Input 2 (active during Phase II). These inputs are thought to be derived from buccal interneurons called 1, 1a and 2 respectively.

Searches for the buccal interneurons have revealed several types of premotor neurons: (a) A multiaction neuron which synapses on motoneurons in a manner consistent with Interneuron 1. (b) A group of three or four cells which generate synaptic potentials on motoneurons resembling Input 1, but via polysynaptic pathways. (c) A dorsal white cell which can generate feeding output in a quiescent ganglion and is often active during Phase II. Although the neuron synapses directly on some motoneurons, the synaptic potentials are usually very small (<1mV) and are apparently superimposed upon Input 2. (d) Another neuron capable of initiating motor output, but not exhibiting spontaneous activity. In common with the cells described in (b) and (c), this cell receives inhibitory input from Interneuron 1a.

It is thought that some of these premotor neurons are part of a network which can initiate and sustain feeding, but their functional roles are not yet fully understood. The existence of interactions not predicted by motoneuron recordings indicates the complexity of the neural circuit which underlies feeding.

1204 THE NEURONAL BASIS OF THE HEARTBEAT RHYTHM IN THE LEECH, HIRUDO MEDICINALIS. Ronald L. Calabrese. Dept. of Biology, UCSD, La Jolla, CA 92093

The paired heart tubes of the leech, Hirudo medicinalis are controlled, via excitatory synapses, by a set of bilaterally paired segmental motor neurons, the HE cells. In turn, the HE cells are controlled, via inhibitory synapses, by a set of bilaterally paired segmental interneurons, the HN cells. The HN cells interact with one another both by inhibitory synapses and electrical coupling. In a totally isolated ventral nerve cord preparation, the HE and HN cells display a coordinated activity pattern, during which they produce rhythmic impulse bursts separated by IPSP's from HN cells. This coordinated activity pattern constitutes the central motor pattern for heartbeat in the leech.

To determine whether the heartbeat rhythm results from the synaptic interactions among the HE and HN cells or whether endogenous membrane properties cause certain elements to produce rhythmic impulse bursts, isolated nerve cord preparations were bathed in "low Cl^-" physiological saline. This saline reversibly blocks IPSP's from HN cells onto both HE cells and other HN cells but leaves electrical transmission among HN cells unaffected.

1)The HE cells normally produce rhythmic impulse bursts because their inherent steady discharge is periodically inhibited by the HN cells; in low Cl^- saline the HE cells produce tonic impulse trains.

2)The HN cells (except for the HN(5) cell pair) produce rhythmic impulse bursts endogeneously: (a)low Cl^- saline does not interrupt the impulse burst rhythm of HN cells (except the HN(5) cell pair); (b)in low Cl^- saline brief intracellularly injected hyperpolarizing current pulses can prematurely terminate an HN cell's impulse burst, resetting its impulse burst rhythm; and (c) in low Cl^- saline brief intracellularly injected depolarizing current pulses can prematurely initiate an impulse burst in an HN cell which outlasts the current pulse and resets the cell's impulse burst rhythm.

3)The inhibitory synaptic interactions among the HN cells serve to coordinate their independent activity cycles into their defined pattern; in low Cl^- saline the HN cells loose their fixed activity phase relations to one another.

These results indicate that the HN cells produce rhythmic impulse bursts endogeneously, that their inhibitory synaptic interactions serve to coordinate their independent activity cycles into a functional pattern and that this pattern is imposed the HE cells via inhibitory synapses.

1205 PATTERN DETECTION IN SPIKE TRAINS. Judith Dayhoff*and George Gerstein. Dept. Physiology, University of Pennsylvania, Philadelphia, Pa. 19104

Traditional spike train analysis methods measure time relations among only a few spikes or between a stimulus and spikes. Such methods cannot be used to identify patterns of firing which occur frequently but at arbitrary times. It is appropriate to search for repeating patterns because such patterns could be used for information transfer. We have developed a new method for identifying repeating temporal patterns in a single spike train.

The pattern detection method consists of a statistical test of whether a given temporal pattern occurs more frequently than expected on a random model. In the random model, each interspike interval is independent of all previous intervals. The patterns detected consist of an arbitrary number of sequential interspike intervals, forming a specific "word." The patterns can occur at arbitrary times in the spike train. The calculation does not require a priori specification of a template word. The pattern does not have to be exactly the same each time it occurs. A pattern which varies within certain limits can still be detectable if it occurs sufficiently often. The sensitivity for pattern detection of the new method has been measured by detecting known patterns which were inserted into random spike trains.

The method described here identifies patterns that recur excessively in the data. Once the patterns are identified, one can explore the relation of pattern occurrences to stimulus presentation or to motor function. If each occurrence of the pattern is treated as a point event, the resulting point process can be studied by traditional spike train analysis methods such as poststimulus time histograms, autocorrelograms, or cross-correlograms.

We have analyzed spike trains from experiments with crayfish claw motor and proprioceptive neurons. Certain patterns occur excessively in these data.

1206 A NEURAL CIRCUIT INVOLVED IN THE CONTROL OF LOCOMOTION IN APLYSIA. Steven M. Fredman and Behrus Jahan-Parwar. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545

Aplysia californica is capable of two mutually exclusive forms of pedal locomotion. During normal locomotion (crawling) the foot is extended and attached to the substrate both anteriorly and posteriorly. A posterior moving wave of contraction pulls the animal forward. In rapid locomotion (galloping) the anterior part of the foot is extended and attached, but the tail is released and the entire body contracts off the substrate moving the body forward in a large step. Except for its greater magnitude, it resembles the final stage of crawling when the pedal wave reaches the tail. Crawling can be elicited by such stimuli as food at a distance and can be maintained for long periods. Galloping is elicited by noxious stimuli and is of short duration, lasting only a few cycles. It requires intact cerebro-pleural (C-PL) connectives. We have examined synaptic connections between neurons in the cerebral and pleural ganglia which appear to be involved in mediating part of galloping.

The initiation of crawling requires input from the cerebral ganglion descending to the pedal ganglia. The cerebral B cluster neurons which appear to be pedal and parapodial motoneurons (J. Neurophysiol., 1978) may be involved in the initiation process. They are tonicly excited by food chemicals. The pleural ganglia contain a group of neurons which appear to be involved in the tail retraction phase of galloping. When stimulated intracellularly they evoke a tail contraction which is followed by a contraction of the middle of the foot. These neurons are strongly excited by noxious stimuli, particularly to the tail and indirectly inhibited by stimuli which excite the B neurons. The pleural neurons in turn monosynapticly inhibit the B neurons. These connections, along with those made by other pleural neurons may serve as part of the control system for galloping. Each part inhibits the conflicting behavior. Stimuli which excite the B neurons and elicit crawling which requires both head and tail attachment, inhibit the pleural neurons which contribute to tail retraction. Noxious stimuli to the tail excite the pleural neurons, inhibiting the B neurons and crawling. The effect of removing this mutual inhibition can be seen when a noxious stimulus is presented during ongoing crawling to animals with C-PL lesions. The resulting tail and posterior body contractions totally disrupt crawling for up to several minutes. This can be interpreted as the result of a conflict between commands for mutually exclusive behaviors. Since crawling and galloping have common elements the neurons in this circuit may contribute to specific phases of crawling as well. This work was supported by PHS grant NS 12483 to BJP.

1207 DETECTION OF LOW-AMPLITUDE WATER MOVEMENTS: A NEW SENSORY MODALITY IN THE MEDICINAL LEECH. W. Otto Friesen and Rosier D. Dedwylder II*, Department of Biology, University of Virginia, Charlottesville, VA 22901.

The ability of the leech Hirudo medicinalis to detect water movements associated with water waves was investigated by observing the effects of waves on the behavior of intact leeches and on the activity of identified neurons in segmental ganglia of the leech nerve cord. For behavioral experiments, leeches were placed lengthwise at the bottom of a narrow trough, 10 cm wide and 80 cm long, which was filled to a depth of 2 cm with pond water. Drops of pond water were then released from a pipette, held at a height of about 6 cm, either 10 cm in front of or 10 cm behind the leech to produce a series of small water waves. Previously quiescent leeches responded to these waves by initiating directed swimming movements; namely, they swam straight ahead if the waves were initiated from in front or they turned and swam towards the rear if the waves were initiated from behind. These experiments demonstrate that water waves can provide leeches with directional cues as well as provide a stimulus to initiate swimming movements.

That the cells tranducing the stimulus provided by the water waves are not the previously identified mechanoreceptor neurons, T, P and N (Nicholls and Baylor. J. Neurophysiol. 31: 740-756, 1968; D. Mistick. Thesis. University of California, Berkeley, 1975), was demonstrated by the following experiments. A nearly isolated preparation, consisting of the leech ventral nerve cord attached to a small flap of body wall by the nerve roots of one ganglion, was placed in a dish and covered to a depth of 0.5 cm with saline. Waves were created by saline drops falling into the dish from height of about 6 cm. Intracellular recordings from identified mechanoreceptor neurons (including all of the touch cells) in the ganglion innervating the body wall flap failed to detect any wave-evoked impulse activity, even though simultaneous extracellular recordings from connectives and segmental nerves showed bursts of activity associated with the waves. In addition, intracellular recordings from AE cells under similar conditions showed that waves evoked 5 mv hyperpolarizations in these cells, whereas previous researchers (Jansen et al. J. Physiol. 242: 289-305, 1974) have shown that stimulation of T, P and N cells evokes excitatory potentials in AE cells. Thus leeches have sensory receptors, not previously identified, which are sensitive to low-amplitude water movement and whose activity can initiate swimming behavior. (Supported by a subgrant from the UVA-NIH Biomedical Sciences Support Program.)

1208 AUTORADIOGRAPHIC PROJECTIONS OF THE ANTERIOR MEDIAL CORTEX OF THE RAT. D.C. German, M. Dalsass*, M. Mendershausen* and R.S. Kiser. Depts. of Physiol. and Psychiat., U. of Texas Health Sci. Ctr., Dallas, TX 75235.

The anterior medial cortex of the rat is an area which supports intracranial self-stimulation behavior, and this behavior is thought to be related to its midbrain dopaminergic input (Myers & Mora, 1977). The connections of the anterior medial cortex, in the region of the anterior cingulate-prefrontal cortex, have been studied with silver degeneration (Leonard, 1969; Domesick, 1969), and horseradish peroxidase (Beckstead, 1976) methods. In order to further map the projections of this area, iontophoretic ejections of S^{35}-methionine or H^3-adenosine were made and the tissue was prepared for autoradiography. The rats treated with S^{35}-methionine (567-1065 Ci/mmole) survived from 1 to 4 days, and the rats treated with H^3-adenosine (35 Ci/mmole) survived 3 days. Following a 7-day (methionine) or 21-day (adenosine) exposure period, the tissue was developed, stained for Nissl, and examined microscopically. In agreement with previous silver degeneration studies, S^{35}-methionine-labelled fibers were observed running caudally in the cingulum and in the internal capsule through and in the dorsomedial caudate nucleus. Fibers left the internal capsule to end in several thalamic nuclei (e.g., dorsal medial, central medial, ventral medial, parataenial). Further caudally, labelled fibers were found in the medial forebrain bundle, the medial tip of the internal capsule, the central gray area, the pretectal area, and the ventral superior colliculus. Labelled fibers also ended in the region of the medial substantia nigra and nucleus A10 dopamine-containing neurons. Unlike the previous work, we also found label in the brainstem raphé nuclei, in a region medial to the locus coeruleus, and further caudally in the brainstem pyramidal tract. Also, we found bilateral projections to the claustrum, lateral amygdaloid nucleus, and extensive contralateral projections often similar to the above-mentioned ipsilateral projections. In the H^3-adenosine tissue, besides many of the above projections, heavily-labelled clusters of cell bodies were found in the anterior medial cortex contralateral to the injection site. Labelled cell bodies were also found in the dorsal medial thalamus. Adenosine has been reported to travel both retrograde and orthograde-transynaptic, and the present results may represent either transport method. These autoradiographic data further our knowledge on the interconnections of the anterior medial cortex in the rat. (Supported by USPHS grant MH-27574.)

1209 CYCLIC AMP MAY MODULATE PROLONGED ENDOGENOUS BURSTING AND SPIKE BROADENING IN THE VENTRAL WHITE CELL OF Pleurobranchaea californica. Martha U. Gillette*, Rhanor Gillette and William J. Davis. Thimann Labs, UCSC, Santa Cruz, CA 95064.

Intracellular injection of cyclic AMP as well as bath application of cyclic AMP analogues or isobutylmethylxanthine (IBMX, which augments native cyclic AMP) alter the parameters of the prolonged endogenous bursts of the Ventral White Cell (VWC), a neuron which can drive the neural output of feeding behavior of Pleurobranchaea. Such treatments increase burst duration and decrease interburst interval. They also accelerate the progressive broadening of the action potential waveform during the prolonged burst. The effects of these treatments may last until drug washout at 4 hr.

In the accompanying paper we present evidence that altering a Ca^{++}-activated K^+ conductance has similar modulatory effects to those reported here for cyclic AMP. Therefore, the relationship of cyclic AMP to this conductance was investigated. The waveforms of undershoots (after-hyperpolarizations) of action potentials in VWC's treated with intracellular cyclic AMP injections, IBMX or cyclic AMP analogues were found to be attenuated in identical fashion to those of VWC's treated with blockers of Ca^{++}-activated K^+ conductance (0-Ca^{++}, 30 mM Co^{++}, substitution of Ba^{++} for Ca^{++} or intracellular injection of EGTA.) Intracellular injection of high Ca^{++} buffer (5×10^{-7} M free Ca^{++}) reverses the effects of cyclic AMP on spike undershoot, as well as on spike broadening and bursting.

These findings suggest that cyclic AMP is altering either the ability or the availability of Ca^{++} to activate the Ca^{++}-activated K^+ conductance and that this is the action by which cyclic AMP modulates bursting and spike broadening. We speculate that cyclic AMP increases burst duration and frequency by enhancing the rate of removal of free cytoplasmic Ca^{++}. Since the VWC is still responsive to added IBMX after a 3 hr incubation in 2 mM CN^-, a potent blocker of mitochondrial Ca^{++} sequestration, the ultimate site of action of cyclic AMP in the control of intracellular Ca^{++} levels may be at a membrane Ca^{++} pump.

1210 PROLONGED ENDOGENOUS BURSTING AND SPIKE BROADENING ARE SUBSTRATES OF COMMAND FUNCTION IN THE FEEDING NETWORK OF Pleurobranchaea californica. Rhanor Gillette, Martha U. Gillette* and William J. Davis. Thimann Labs, UCSC, Santa Cruz, CA 95064.

A symmetrical pair of neurons in the buccal ganglion of Pleurobranchaea, the Ventral White Cells (VWC's), drives the cyclic neural output of feeding behavior when tonically stimulated with depolarizing currents. The VWC's are endogenously bursting neurons which display unusually long burst durations (1-4 minutes) and long interburst intervals (3-15 minutes). The long enduring bursts of a VWC may be triggered by short depolarizing current pulses or by excitatory synaptic inputs, which thus initiate vigorous feeding output. During repetitive activity, VWC spike duration progressively increases by 6-10 X. Inhibition of spike broadening by hyperpolarization during antidromically-driven trains shows that broadened VWC action potentials are much more effective than unbroadened spikes in driving motor output. This provides functional significance for a commonly observed property of neuronal plasticity, spike broadening during repetitive activity, in commanding motor network output.

Ion substitutions and the use of blocking agents show that Ca^{++} is the major charge carrier in the late phase of the broadened spike. The temporal, ionic and voltage parameters governing the VWC spike broadening fit a model for progressive spike broadening based on progressive depolarization-induced inactivation of a voltage-dependent K^+ conductance, which was proposed by Thompson and Getting (Neurosci. Abs. 3: 594, 1977.)

Further experiments indicate that a distinct Ca^{++}-activated K^+ conductance, while not causal, is a powerful modulator of spike broadening which determines rate and extent of broadening. Treatments which reduce Ca^{++}-activated K^+ conductance by lowering $(Ca^{++})_i$ enhance rate and extent of spike broadening; conversely, increasing $(Ca^{++})_i$ suppresses broadening. Since broadened spikes are more effective at driving network output than unbroadened spikes, $(Ca^{++})_i$ may determine the ability of the VWC's to drive the feeding rhythm.

1211 CRAYFISH MOTORNEURONES ARE AN INTEGRAL PART OF THE SWIMMERET CENTRAL OSCILLATOR. W.J. Heitler and B. Mulloney. Dept. of Zoology, University of California at Davis, Davis, CA 95616.

Experiments performed on the isolated abdominal nerve cord of Pacifastacus leniusculus indicate that the swimmeret motorneurones are not simply output elements which passively integrate and relay the activity of pre-motor interneurones and sensory neurones. Recordings from the integrative segments of swimmeret motorneurones show that individual motorneurones are coupled to populations of other motorneurones. The coupling typically takes a form such that depolarising current injected into one motorneurone excites its synergists and inhibits its antagonists, while hyperpolarising current excites its antagonists and inhibits its synergists. Reciprocal interactions occur between power- and return-stroke motorneurones. The interactions can result from subthreshold changes in membrane potential; they could be mediated either by electrical or graded chemical synapses. Subthreshold interactions have been demonstrated between motorneurones in adjacent ganglia, and it is likely that these at least are mediated by a polysynaptic pathway involving spiking interneurones.

When the C.N.S. is producing the rhythmic motor output associated with swimmeret beating in the intact animal, motorneurone membrane potentials undergo rhythmic oscillations of about 10 mV amplitude, which, in the isolated preparation, can be subthreshold in some motorneurones. Under these circumstances injection of current into a single motorneurone can affect the intensity, period, and phasing of the oscillator. Thus, continuous hyperpolarising current (1-2 nA) injected into a power-stroke excitor motorneurone (which was not itself spiking) increased the period of the rhythm, decreased the intensity of the power stroke activity, and increased the intensity of the return-stroke activity. Continuous depolarising current (1-2 nA) had the opposite effect on the relative intensity of the antagonist motor output, but had no effect on period. Evidently, it is easier for motorneurones to slow the oscillator down than for them to speed it up. However, short pulses of depolarising current dramatically reset the oscillator. Thus both depolarising and hyperpolarising current injected into a single motorneurone can directly alter the fundamental oscillator properties of period and phase.

The levels of current required to demonstrate these effects are low (< 2 nA), and thus it is likely that the changes in motorneurone membrane potential occurring in the absence of experimental interference are effective in producing these central interactions. The parameters of the motor pattern produced within the C.N.S. which controls swimmeret beating in crayfish must thus be an emergent property of a system of neurones which includes the motorneurones. Supported by U.S. P.H.S. Grant NS 12295.

1212 MEMBRANE PROPERTIES SHAPE SYNAPTICALLY DRIVEN BURSTS IN TRITONIA FLEXION NEURONS. Richard I. Hume and Peter A. Getting. Dept. of Biological Sciences, Stanford University, Stanford, CA 94305

The neuronal correlate of swimming recorded from the isolated brain of Tritonia diomedea is a series of alternating bursts in two relatively large pools of pedal ganglion neurons, the dorsal flexion neurons (DFN) and the ventral flexion neurons (VFN). We have examined how the pools of flexion neurons (FN) are organized, and some of the mechanisms that may be responsible for that organization.

Flexion neurons were sampled in a large number of preparations to assess the variability within the entire pool of flexion neuons. Studies of the organization of spikes within single bursts revealed that bursts can be classified into one of five general burst structures. To test the constancy of burst structure, five DFNs that could be identified by criteria other than their activity during swimming were studied in a number of preparations. Each identified cell had its own characteristic burst structure which was consistent from swim to swim and from animal to animal.

Variations in burst structure between neurons may have two sources: 1) intrinsic membrane properties and/or 2) synaptic drive. To test the contribution of intrinsic membrane properties, identified cells were driven with similar current stimulus waveforms and their resultant activity compared. The pattern of spikes generated was distinct for each cell, and the response correlated well with the structure of that cell's bursts during swimming. Cells may have dramatically different burst structures and response patterns even when they are closely matched in input resistance. Other experiments also support the idea that intrinsic cell properties contribute to burst structure.

We have also found that not all DFNs receive the same synaptic input and that synaptic interactions also contribute to burst structure. Our results suggest that the burst structure of a given neuron arises from the filtering of specific synaptic drive through the intrinsic properties of that cell's membrane.

1213 NEURAL CONTROL OF LOCOMOTION IN APLYSIA. Behrus Jahan-Parwar and Steven M. Fredman. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

Cinematographic analysis of pedal locomotion in Aplysia revealed four major phases in each locomotor step: 1) detachment and lifting the anterior foot from the substrate; 2) extension of the detached body region; 3) attachment of the anterior edge of the foot to the substrate; 4) generation of a series of bilaterally coordinated waves of contraction in the resulting arch which pull the animal forward. The arch moves backward until the tail is released and retracted behind the rest of the body, completing the step. In recent work we have demonstrated that the neural program for pedal locomotion resides in the central ganglia and that the peripheral nervous system is not necessary for the spread of pedal waves (J. Neurophysiol. 1978a,b; Comp. Biochem. Physiol. 1978). In the present study we have investigated the role of the individual central ganglia in pedal locomotion using a series of connective lesions.

Coordination of both halves of the foot is maintained by the pedal commissure. When it was sectioned, contractile waves generated in each half of the foot became desynchronized. Subjects with bilateral sections of both cerebro-pedal (C-P) and cerebropleural (C-PL) connectives were unable to locomote normally. Although slow continuously running ripples were present in the foot, head extension and normal waves were absent. The same lesion performed unilaterally resulted in diagonal waves in the foot, with the lesioned side always trailing the intact side. Bilateral sections of the C-P also abolished normal locomotion. These animals were no longer capable of extending and attaching the anterior foot. When the C-PL were cut bilaterally goal directed locomotion remained essentially normal. However, noxious stimuli to the tail were no longer capable of eliciting rapid aversive locomotion (galloping) and disrupted any ongoing locomotion. Bilateral sections of the pleuropedal connectives impaired normal locomotion and eliminated rapid locomotion. Although capable of generating waves in the foot, the rate of these waves and locomotion remained very slow. A unilaterally isolated pedal ganglion failed to generate normal pedal waves on that side.

From these experiments we have drawn the following conclusions: The motor program for locomotion appears to reside in the pedal ganglia but requires the cerebral and pleural ganglia for full expression. The cerebral ganglion via the C-P is necessary for the initiation of normal locomotion. The pleural ganglia appear necessary for controlling the rate of locomotion. They also appear to provide a relay for ascending input needed for rapid locomotion. We are in the process of investigating the neuronal substrates of these relationships. This work was supported by a PHS grant NS 12483 to BJP.

1214 RECIPROCAL CONNECTION BETWEEN DOPAMINE CONTAINING PREFRONTAL CORTEX AND DEEP MESENCEPHALIC REGION. H. Kimura* and T. Maeda* (SPON: W.K. Ovalle). Dept. Anatomy, Shiga Univ. Med. Sci., Shiga, Japan.

Reciprocal neuronal connection between dopamine containing prefrontal cortex and deep mesencephalic region has been studied by means of glyoxylic acid fluorescence histochemistry after the destruction of the dopaminergic ascending pathway in combination with light and electron-microscopic examination of anterograde and retrograde transport of horseradish peroxidase. The dopaminergic cortical innervation is restricted mostly to the frontal region which corresponds to the prefrontal cortex receiving direct projection from the mediodorsal nucleus of the thalamus. Dopaminergic terminals are localized in two main areas. The area of the highest density is the pregenual field of the anteromedial cortex and the axons are distributed mainly in the intermediate cortical layers (III-V) except in the frontal pole where the laminer pattern of the cerebral cortex is not clear. A moderate fiber density is found in the sulcal field, forming the dorsal part of the rhinal sulcus, in which the dopaminergic fibers are also scattered in the molecular layer as well as in the intermediate cortical layers. No dopaminergic innervation is observed in the dorsolateral part of the frontal cortex. Two mesencephalic cell groups, which project fibers to the frontal cortex, were demonstrated by retrograde as well as anterograde transport of horseradish peroxidase. The dopaminergic fibers of the anteromedial cortex originate from the cell group situated in the field between the lateral part of the ventral tegmental area and the mediodorsal part of the pars compacta of the SN. On the other hand, the anterolateral cortex comprised of the dopamine containing dorsal bank of the rhinal sulcus and the adjacent area devoid of dopamine, namely the dorsolateral cortex, receives projection not only from a dopamine cell group in the lateral part of the pars compacta of the SN, but also from a nonaminergic cell group in the pars reticulata. These mesencephalic dopamine neurons receive direct afferents ipsilaterally from the pyramidal cells of layer V in the anteromedial cortex. Cortico-nigral fibers form axodendritic synapses, while reciprocal mesocortical dopaminergic projections form axosomatic synapses.

1215 EFFECTS OF LINGUAL NERVE SECTION OR NEOCORTICAL ABLATIONS ON RAT'S LICKING RESPONSE. Jon D. Kirwin*, Sarah P. Parkerson*, and David W. Watkins*. (SPON: J. A. Jane). Departments of Neurosurgery and Anatomy, University of Virginia School of Medicine, Charlottesville, VA 22901

Long-Evans hooded rats were deprived of water and then given access to a recessed drinking spout daily for 8 minutes. Their licking responses were recorded electronically during bouts of uninterrupted licking. Preoperatively, all rats licked the spout rhythmically at mean rates of 5.2-5.9 licks per second. There were differences among individual rats' mean lick rates, but for any individual, these rates were affected little by deprivation state. After bilateral lingual/chorda tympani nerve sectioning, we found: 1) initially, the rats failed to lick continuously, 2) within 2 day post-op, they licked rhythmically, but at less than normal rates (77-89% of pre-op rate), and 3) at one month post-op, their lick rates evidenced partial recovery (89-96% of pre-op rate). Following large, bilateral cerebral neocortical ablations, including all of the tongue motor and sensory cortex and parts of the prefrontal cortex rostral to the tongue motor cortex and situated just dorsal to the rhinal sulcus, we found: 1) the rats were motivated to drink, 2) their tongues were not paralysed, 3) they chewed on food pellets with repetitive jaw and tongue movements, 4) they swallowed food or water put in their mouths, but 5) they did not lick in our experimental situation which requires tongue protusion to contact the spout. With partial lesions of the face motor cortex, the rats licked rhythmically, but at significantly slower rates (90-97% of pre-op rate). With the spout positioned to require less tongue protusion, these rats' lick rates were normal. The neocortex plays a role in the rat's licking response, and appears to be related to tongue protusion and/or the initiation of licking. The sensory inflow from the anterior two-thirds of the tongue (i.e. lingual/chorda input) is not essential to rhythmic licking, but appears to exert a facilitatory influence on lick rate.

1216 THE NEURONAL BASIS OF THE SHORTENING RESPONSE IN LEECHES. William B. Kristan, Jr., Dept. Biology, University of California, San Diego, La Jolla, CA 92093.

Mild tactile stimulation of a leech produces a localized shortening response which consists of longitudinal muscle contractions limited to a single segment. At more intense levels of stimulation, the shortening response spreads to the entire body. The localized shortening response results entirely from the activation of previously identified tactile sensory neurons (Nicholls & Baylor, J. Neurophysiol. 31:740-756, 1968), particularly the cell responsive to pressure, i.e., the P cell. The evidence for this conclusion is threefold: 1. The stimulus threshold for activation of these tactile sensory neurons is indistinguishable from the threshold for the shortening response. 2. Hyperpolarization of these cells suppresses the shortening response. 3. Stimulation of these cells by passing intracellular current produces a normal shortening response. The motor neurons involved have also been identified previously (Stuart, J. Physiol. 209:627-646, 1970; Ort, Kristan & Stent, J. Comp. Physiol. 94:121-154, 1974). The motor neuron innervating all longitudinal muscles on one side of each segment (the L cell) produces a brief burst of impulses at the onset of the response whereas other motor neurons, with more localized motor units, produce more prolonged impulse bursts. These bursts are appropriate for their motor effects: the L cell produces a large, fast contraction whereas the other motor neurons produce much smaller, slower contractions. The duration of the motor neuron bursts results from the nature of the pathway between sensory and motor neurons: the excitation of the L cell is predominantly via monosynaptic connections from the tactile sensory neurons (Nicholls & Purves, J. Physiol. 209:647-667, 1970), whereas the excitation of other motor neurons is exclusively polysynaptic. The interneurons responsible for the prolongation of the local contraction are also involved in the generalization of the response to other body segments.

This work was supported by an NSF research grant BN575-23567.

1217 CENTRAL INTERACTIONS UNDERLYING PATTERN GENERATION FOR ESCAPE SWIMMING IN TRITONIA. Paul R. Lennard, Peter A. Getting and Jacqueline M. Grebmeier*. Dept. of Biological Sciences, Stanford Univ., Stanford, CA 94305.

Escape swimming in Tritonia consists of a preliminary reflexive withdrawal of the stimulated area of the body followed by a series of alternating dorsal and ventral flexions. A series of phase shift experiments have been employed to verify that two classes of interneurons, which have been previously identified (Getting, J. comp. Physiol. 121: 325-342, 1977), are directly involved in the pattern generation of the cyclical motor program for escape swimming. The two classes of interneurons include: 1) a population designated as dorsal swim interneurons (DSI), which is composed of three cells in each cerebral ganglion; and 2) a bilaterally symmetric pair of cerebral neurons termed the left and right cerebral cell 2 (C-2). The C-2's and DSI's have reciprocal excitatory connections and fire during the dorsal flexion phase of swimming. Both sets of interneurons receive input from afferents and drive pedal flexion neurons. The C-2's have also been shown to mediate the switch from reflexive withdrawal to the central swimming program and to be both necessary and sufficient for the maintenance of swimming.

Phase shift experiments were conducted in isolated brain preparations. Double-barrelled electrodes were used to impale both C-2's and as many as four DSI's. Depolarizing or hyperpolarizing current was injected into the C-2's or DSI's in order to change the timing and/or duration of activity in these cells during one of the cycles of a swim sequence. Changes in timing of the cycles subsequent to the perturbation were compared to sandwiched control swims during which no current was injected. Temporal manipulations of the burst in either population of interneurons produced permanent phase shifts in both the C-2's and DSI's as well as in pedal flexion neurons. The phase shift data indicates that both classes of interneurons contribute to the patterning of the locomotor output.

A quantitative analysis of the temporal relationships between the activity in the C-2's and DSI's was performed to clarify the role that these cells played in patterning the locomotor output. Both constant latency and constant phase relationships were found in the structuring of burst patterns in these two populations of interneurons. These parameters remain constant even though period increases for each subsequent cycle within a swim sequence. A model for central pattern generation of swimming in Tritonia, which integrates the known functional properties, synaptic connections, and temporal relationships of the DSI and C-2 interneurons, will be proposed.

1218 ASSOCIATIVE-CONTINGENCY LEARNING CAN BE MEDIATED BY A FAMILIAR NEURONAL NETWORK. William B Levy. Dept. of Psychology, Univ. Calif., Riverside, CA 92521.

Models of neural circuits which can accomplish associative forms of learning often require anatomy and physiology which are yet to be discovered in brain. An exception is the model presented by Gardner-Medwin (Nature 223, 916, 1969). This model utilizes a homosynaptic form of plasticity (a well-documented synaptic property) and is characterized by its capability to classically condition while resisting pseudoconditioning and sensitization. Unfortunately this model is not capable of learning or even appreciating CS-UCS contingencies and, in fact, will inappropriately show full conditioning when presented with a random CS-UCS paradigm.

Since animals learn in a manner related to contingencies, we have devised a circuit which would accomplish this form of associative learning while still retaining anatomy and physiology which are well documented in brain.

The circuit uses frequency coding as suggested by Gardner-Medwin. Continuity and noncontinuity of the CS and UCS are recognized and distinguished using spatial summation and lateral inhibition. Memory is stored as a form of post-tetanic potentiation. Contingency based responses are elicited by integrating the relative degrees and amounts of memorized continuity and noncontinuity. This integration is accomplished simply as a convergence of an inhibitory and excitatory input upon the final response output neuron.

In its simpler form the circuit uses five neurons and is strikingly similar to some of the known circuitry of the hippocampus.

1219 TESTING A MODEL FOR THE SPINAL LOCOMOTION GENERATOR. John E. Menzies*, Carol P. Albert* and Larry M. Jordan. Department of Physiology, University of Manitoba, Winnipeg, Manitoba, R3E 0W3.

Although the concept of a mammalian spinal locomotion generator is well established, its precise neuronal organization remains unclear. It has been shown that both Renshaw cells (RC) (McCrea and Jordan, Can. Fed. Biol. Soc., 146, 1976) and Ia inhibitory interneurones (IaIN's) (Feldman and Orlovskii, Brain Res. 84, 181, 1975) are phasically active during locomotion. Furthermore, these cells comprise a neural circuit such that activation of Renshaw cells via recurrent alpha motor axon collaterals would result in inhibition of agonist-coupled IaIN's and subsequent disinhibition of antagonist alpha motoneurones. RC's and IaIN's could therefore contribute to switching between antagonist motoneurone groups during walking, and Miller and Scott (Exp. Brain Res., 30, 387, 1977) have proposed that this neuronal system constitutes the spinal locomotion generator. If this model is correct, motoneurone firing during locomotion must be produced through disinhibition, hence the depolarization giving rise to motoneurone firing should be accompanied by reduced membrane conductance, as compared to the conductance when the membrane is hyperpolarized during the opposite phase of locomotion. In addition, interneurones which are rhythmically active during locomotion should be influenced by activation of montoneurone recurrent collaterals.

In order to test this model, experiments were performed on acutely decerebrated cats induced to walk by stimulation of the mesencephalic locomotor region (MLR) (Shik et al, Biofizika, 11, 659, 1966). Persistence of MLR evoked rhythmic motor axon firing after neuromuscular blockade by Flaxedil was evidence of "fictive" locomotion. Conductance changes in motoneurones were monitored by intracellular recording of the amplitude of short hyperpolarizing current pulses applied through the recording electrode. It was found that there was an increased rather than a decreased conductance associated with the depolarizing phase of the locomotor cycle. Such data indicate that motoneurone discharge during fictive locomotion requires input from excitatory interneurones and is not entirely due to disinhibition.

When interneurones which were rhythmically active during fictive locomotion were examined, only IaIN's were inhibited as a result of ventral root stimulation, and only 1 of a total of 26 rhythmically active interneurones was excited by antidromic stimulation of the ventral roots. It must be concluded that the RC-IaIN system cannot alone constitute the spinal locomotion generator. (Supported by M.R.C. of Canada.)

1220 IDENTIFICATION OF A NON-DECAYING OUTWARD CURRENT IN AN ELECTRICALLY COUPLED BURSTING NETWORK IN THE SNAIL. Michael Merickel and Richard Gray*. Dept. Physiol. and Biophysics, Univ. of Illinois, Urbana, IL 61801.

A single electrode voltage clamp has been used to examine the membrane currents in the bursting cyberchron network in the snail Helisoma. The cyberchron network is a population of approximately 20 small, electrically coupled neurons whose rhythmic output controls the feeding behavior of the animal. Voltage clamp experiments have been performed on these neurons in an attempt to understand the slow membrane currents and neuronal interactions underlying burst generation by this network.

A particularly interesting finding is a slow outward current activated by large depolarizing commands (0 mV and above) which does not undergo inactivation decay during a command potential step maintained for 10 sec or more. In addition, these neurons have an anomalous rectification region in their steady-state I-V plot due to a persistent inward Ca-current. These membrane properties appear to be also reflected in the action potential characteristics of cyberchron neurons. The action potentials of these cells typically have a long duration (at least 20 ms half-amplitude duration) and undergo a two to five fold duration increase with repetitive, low frequency stimulation. The action potentials of these cells, as well as the broadening process, are strongly Ca-dependent.

The lack of inactivation of the outward current in cyberchron neurons is remarkably similar to the behavior of the slow outward current in vertebrate heart cells. The shape of cyberchron action potentials, as well as their Ca-dependence are also very similar to heart action potentials. It is believed that the lack of inactivation of the outward current in cyberchron neurons plays a similar role to the analogous current in heart cells - to insure repolarization after a maintained depolarization. Repolarization after a burst of action potentials in the cyberchron system is particularly important to insure burst termination.

Support is acknowledged from the Research Board and Bioengineering Program at the University of Illinois, Urbana-Champaign.

1221 Non-spiking neurons in the cockroach. D.J. Meyer*and B. Walcott
Dept of Anat. Sci. S.U.N.Y. at Stony Brook, Stony Brook N.Y. 11794.

We have studied the properties of non-spiking neurons in the meta thoracic ganglion of the cockroach, Periplaneta americana. The properties of these neruons were virtually identical to those of the non-spiking interneurons described by Pearson and Fourtner (1975). Depolarization of type I non-spiking neurons resulted in the excitation of coxal flexor motoneurons and the inhibition of coxal extensor motoneurons. The latency of these effects was short (2-6 ms) The membrane potential of type I non-spiking neurons oscillated in phase wtih motoneuron bursts during rhythmic leg movements. The neurons depolarized during flexor bursts and repolarized during extensor bursts. As revealed by intracellular staining with cobalt, the structure of this neuron was very similar to that of interneuron I (Pearson and Fourtner 1975) Depolarization of type 2 non-spiking neurons inhibited flexor motoneuron discharge while hyperpolarization had the opposite effect effect. During rhythmic leg movements the membrane potential of type 2 non-spiking neurons oscillated in phase with motoneuron bursts. The cells depolarized during extensor bursts and hyperpolarized during flexor burst. A depolarizing current pulse applied to a type 2 non-spiking neuron during rhythmic leg movements reset the timing of motoneuron bursts. When depolarized by injected current, type 3 non-spiking neurons inhibited the discharge of the slow extensor motoneuron, and had the opposite efffect when hyperpolarized. Depolarization of type 3 non-spiking neuron reversibly abolished rhythmic leg movements. These observation are consistent with the hypothesis that the non-spiking neurons are part of the central pattern gemerator for stepping, however there are alternative interpretations of the data.

1222 TESTING DIRECT CONNECTIONS IN THE STOMATOGASTRIC GANGLION WITH TEA. Brian Mulloney and Karen A. Sigvardt. Dept. of Zoology, University of California at Davis, Davis, CA 95616.

The synaptic organization of the stomatogastric ganglion of the spiny lobster, Panulirus interruptus, has been described from recordings made from the somata of the ganglion's neurons. The diagram of direct connections which summarizes this description predicts the nature and distribution of synapses which should be discoverable using other anatomical and physiological methods. To test these predictions, we have iontophoretically injected TEA into presynaptic neurons to alter the duration of their impulses, and looked for corresponding changes in PSPs of putative postsynaptic neurons (Kehoe, J. Physiol. 1972). Our results confirm that several connections between motorneurons in the stomatogastric system are monosynaptic. For example, injecting TEA into LGN broadens its spikes, and the resulting PSPs in both the GMs and LPGNs are greatly augmented. One other suspected direct synapse, LPGN's inhibition of MGN, was not confirmed by this test; we think this synapse does not exist and should be removed from the summary diagram.

These experiments are most easily done and most readily interpretable when the putative presynaptic neuron is not a spontaneous pacemaker or endogenous burster. Spontaneously active neurons rapidly begin to fire high-frequency trains of impulses which are difficult to control. As a result, the PSPs in putative postsynaptic neurons sum, the membrane potentials are clamped at the reversal potential of these synapses, and the changes in PSPs amplitude have no meaning. Pacemakers and bursters are best injected iontophoretically by passing current between two intracellular electrodes, and then hyperpolarizing the cell while TEA diffuses.

Controls: King (J. Neurocytol. 1976) demonstrated with EM that several known inhibitory interactions in the ganglion are monosynaptic. We injected some of these same neurons (PD and LP) and confirmed that neurons known from anatomical evidence to be monosynaptic give positive results with the TEA test.

TEA will cross electrotonic synapses (Deschenes and Bennett, Brain Res. 1974). Many neurons in the stomatogastric ganglion are weakly coupled by electrotonic synapses, and if TEA spread rapidly to other neurons, our results would be difficult to interpret. We injected TEA into one of two closely coupled neurons (the PDs) and monitored the rates at which spike width and burst pattern changed in both neurons. The spikes and burst pattern of the injected neuron had changed within one-half hour, while the non-injected control was unchanged after two hours. So, leakage of TEA across electrotonic synapses does not affect the interpretation of results obtained in this system shortly after injection of TEA.

1223 COMMAND FIBER TO MOTOR NEURON CONNECTIONS IN THE LOBSTER SWIMMERET SYSTEM. John A. Paton. Dept. E.E.C.S. and Biol., Princeton U., Princeton, NJ 08540.

Swimmerets are active in a number of different oscillatory behaviors such as righting and larval swimming. The circuitry underlying this behavior consists of command neurons (CN's) which turn on segmental oscillators, which in turn drive swimmeret motor neurons (MN's). Davis and Kenneday (1972) suggested that connections might also exist between CN's and MN's and that these connections would allow different CN's to produce rhythmic motor output and yet use the same oscillator.

The CN to MN pathway was confirmed and characterized by analysis of the time-locking of MN spikes to CN stimulation. In a whole abdomen preparation of Homarus americanus, single CN fibers were dissected from the connective between ganglia one and two and stimulated electrically with pulse trains. The activity of single MN's was identified from multiunit recordings from nerve branches in the base of the swimmerets.

MN spikes were time-locked by about half (14 of 31) of the CN's examined (18 animals). Both powerstroke and/or returnstroke MN's could be time-locked. For stimulation of a given CN the time-locking varied from 1:1 following to undetectable within the group of MN's to a single muscle. In the strongest cases of time-locking the MN spikes were limited to time windows of as little as 5 to 10 ms. In summary then, some CN's which cause oscillatory motor output cause time-locked spikes in some MN's.

The pathway between CN and MN is currently being studied to determine whether the functional connection found is mono- or polysynaptic.

1224 P CELLS: DISTRIBUTION AND COUPLING OF PATTERN GENERATORS IN THE LOBSTER STOMATOGASTRIC NERVOUS SYSTEM. David F. Russell. Biology Dept. B-022, UCSD, La Jolla, CA 92093.

"P cells" are neurons in the commissural ganglia (CG's) of the lobster CNS which fire in bursts coordinated with the pyloric motor rhythm produced in the stomatogastric ganglion (STG). In isolated preparations in which the bilaterally paired CG's are left connected to the STG, a striking feature of the subthreshold activity in many STG neurons is that a train of EPSP's accompanies each cycle of the pyloric rhythm in a rigidly coordinated 1 train: 1 cycle manner. Such EPSP's are observed in the LP, PL, PE, VD, and IC pyloric-follower motorneurons, and in the AM, CP(DG), and LG(LPG) motorneurons and Interneuron 1 of the gastric system. The EPSP's do not originate in the STG since they are abolished by removing the CG's. The EPSP's are due to, and reflect the firing pattern of, P cells which send axons into the STG. P cell inputs to LP had a variable axon pathway, via either the superior- or inferior oesophageal nerves (SON's or ION's).

Several lines of data support a model for P cell organization in which the P cells would intrinsically fire tonically; their "pyloric" firing pattern would be controlled by an ascending axon from the AB "efferent copy" interneuron (in the STG), postulated to make direct inhibitory synapses to the P cells within the CG's; the P cells would then feed back to synapse onto STG neurons. (i) Nerve records showed that the AB sends an axon into the CG's via the SON's. (ii) The P cell EPSP's in CP or LG's became tonic while firing of the AB was shut off for a few seconds by hyperpolarizing it (or an electrically coupled PD neuron). (iii) Blockade of the SON's caused the EPSP's in LP (from P cell inputs travelling in the ION's) to become tonic for long periods of time. (iv) Records from two points along the stomatogastric n. showed that each cycle of the pyloric rhythm was accompanied by a burst of P cell units, travelling towards the STG, which ended at the next burst of AB spikes, travelling towards the CG's. (v) Intracellular records from a P cell in a L-CG showed trains of IPSP's coordinated with the pyloric rhythm (presumably from AB); the IPSP's disappeared and the P cell fired tonically while a PD cell (in the STG) was hyperpolarized for a few seconds. (vi) Bathing the CG's in low Ca++ saline to block synapses caused the P cell EPSP's in LP to become tonic. (vii) Bathing only the oesophageal ganglia in low Ca++ saline to block synapses there did not affect the "pyloric" timing of P cell EPSP's in LP.

The P cell inputs to pyloric follower neurons may be regarded as part of the pyloric pattern generator. The P cell inputs to gastric-system neurons contribute to a marked 1-2 hz modulation, in time with the pyloric rhythm, of their membrane potential and firing pattern. The P cell circuits are remarkably analogous to phasic supraspinal control systems for locomotion of mammals.

NEURONAL SHAPE AND FUNCTION

1225 QUANTITATIVE DESCRIPTION OF THE BIAS OF EXTRACELLULAR UNITARY RECORDING TECHNIQUES TOWARDS LARGER NEURONS. Charles Abzug. Department of Physiology, University of Maryland School of Medicine, Baltimore, MD 21201.

In the mammalian CNS the majority of neurons is of relatively small size. However, it has long been known that extracellular recording techniques are selective for the larger neurons. Previous attempts to describe this bias quantitatively(A.L. Towe & G. Harding. Exptl. Neurol., 29: 366-381, 1970; D.R. Humphrey. Fed. Proc., 34: 445, 1975; D.R. Humphrey & W.S. Corrie. J. Neurophysiol., 41: 216-243, 1978.) have been oriented towards comparison between the distribution of experimentally determined speeds of axonal conduction and the histologically established distribution of axonal diameter. In the present model perikaryal size(cross-sectional diameter, D) is the major independent variable. The probability of detection, $P(\Delta)$, is calculated as the product of two terms. The first term, $P(\gamma)$, is the probability that the track of the recording electrode will pierce a virtual surface of detectability(SD) surrounding the neuron. At any point within the SD the voltage caused by the neuron's action current exceeds the minimum detectable level, V_{min}, of the recording system. $P(\gamma)$ is proportional to the cross-sectional area of the SD, and therefore depends upon biophysical characteristics: the total quantity of neuronal action current and the source/sink distribution along the somato-dendritic tree. The second term, $P(\Delta|\gamma)$, is the probability that an action potential will be generated while the electrode tip lies within the SD. The value of this term depends upon the neuron's firing rate and upon the duration of the electrode's passage through the SD. This duration in turn depends upon the speed of electrode advancement, s, and on the size and shape of the SD. Specific solutions for these terms, and therefore for $P(\Delta)$, have been determined for two different models of somato-dendritic current distribution and for two experimental cases. In one case, where the firing rate, f, is constant(e.g., repetitive antidromic driving), there is an exact solution over the entire range of f and s. For the case of spontaneously firing neurons an exact solution is not possible over the entire range without knowledge of the distribution of impulse intervals. Specific solutions for this case, however, are available for two limiting situations: where s/f is much smaller than the maximum linear dimension of the SD, and where it is much greater. All solutions are of the form: $P(\Delta) = k\, D^{j}\, V_{min}^{-m}$. The values of the positive exponents j and m depend upon the biophysical characteristics of the neurons, which may differ among different neuronal populations. However, $j = 2m$, and therefore the value of j can be determined indirectly for each neuronal population .

1226 IMMUNOLOGICAL RESPONSES TO REPEATED INTRAVENTRICULAR AUTOLOGOUS BLOOD INJECTIONS MAY INDICATE A NEW MECHANISM IN THE PATHOGENESIS OF STROKE. Maurice S. Albin, Bruce S. Rabin*, Leonid Bunegin*, and Julio A. Martinez*. Depts. Neurosurg. Anesth., and Path. (NeuroImmuno), Sch. Med. Univ. Pgh., Pittsburgh, PA 15261.

These experiments were designed to evaluate the immunological, neurological and histological reactions to autologous intraventricular blood. We were testing the hypothesis that the development of neurological symptoms after intraventricular (and subarachnoid) hemorrhage might be associated with a localized immunological response in the brain. Following injections, macaque brains were evaluated by direct immunofluorescence for immunoglobulins, complement and fibrinogen and by routine histological sections - with the tissue adjacent to the (non-injected) contralateral ventricle serving as control. The experimental groups were: 1 - Blood-Blood; 2 Blood; 3 - Blood-Saline; 4 - Saline-Saline. All monkeys were sacrificed one week after their final injection. Multiple injections were given seven days apart.

Immunofluorescence for IgG and C_3 as well as neurological deficits (plegia and paresis) were found only in Group 1 (Blood-Blood) monkeys. Infiltration with lymphocytes was found in Group 1, two and three animals but not in Group 4 (Saline-Saline). No immunoglobulins, complement deposits, lymphocytic infiltrations or referable neurologic symptoms were found in all the noninjected contralateral ventricles. The immunofluorescence appeared to be localized in the microglial cells and the lymphocyte infiltration was predominantly perivascular in localization. These observations indicate that a single exposure to autologous blood was not associated with either neurological changes or deposition of immunoglobulins or complement. It was only after the second injection of blood that IgG and complement were encountered and a neurological deficit occurred. It is possible that the development of marked neurological sequelae after repeated intracranial hemorrhage (i.e., aneurysm rebleed) may involve immunological factors. Critical to this process may be a breakdown in blood brain barrier permeability due to hemorrhage and accompanying lymphocyte infiltration.

1227 CENTRAL ANATOMY OF THE CRAYFISH STRETCH RECEPTOR NEURONS. Michael Bastiani and Brian Mulloney. Dept. of Physiology and Zoology, University of California at Davis, Davis, CA 95616.

The crayfish muscle receptor organs (MRO), tonic MRO1 and phasic MRO2, monitor position and movement of the abdomen. The sensory receptor neurons (SN) associated with MRO1 and MRO2, SN1 and SN2 respectively, send their axons into the ventral nerve cord via the second roots of the abdominal ganglia. The central anatomy of SN1 and SN2 was determined using Co^{++} backfills of second roots followed by Timm's Intensification of the wholemounts. Both SN1 and SN2 send axons anteriorly to the supraesophageal ganglion and posteriorly to the 6th abdominal ganglion. Each have secondary processes lateral to their axons in the neuropile of ganglia through which they pass.

SN1 and SN2 have elaborate bilateral structures in the 6th abdominal ganglion. Bilateral SN1 and SN2 from all of the abdominal ganglia, except the 6th, project to the same area of dorsal neuropile in the 6th ganglion. The structures of SN1 and SN2 are very similar. The primary process of both is U-shaped (open-anterior), centered around the midline with secondary processes projecting bilaterally. All SN1 on the same side and on opposite sides from all abdominal ganglia show considerable overlap of their primary and secondary processes. The same is true for SN2. SN1 and SN2 also have overlapping primary and secondary processes, but to a lesser extent than among homologues.

Intracellular recordings were made from cells post-synaptic to the SNs in the 6th ganglion. Three classes of cells were found: 1. cells receiving input from SN1; 2. cells receiving input from SN2; 3. cells receiving input from both SN1 and SN2. Cells of each class receive input from the appropriate SNs of all abdominal segments. The post-synaptic cells have not yet been identified.

Ipsilateral SN1 and SN2 in the 6th ganglion.

1228 **A COMPARISON OF SYNAPTIC JUNCTION LOCALIZATION ON LAMPREY SPINAL CORD NEURONS BY PHYSIOLOGICAL AND MORPHOLOGICAL METHODS.** **Burgess N. Christensen and Wm. P. Teubl*. Dept. of Physiology and Biophysics, Univ. of Texas Med. Br., Galveston, TX 77550.**

Monosynaptic e.p.s.p.'s were recorded in lamprey spinal cord interneurons following stimulation of a single presynaptic giant axon through an intracellular microelectrode. These e.p.s.p.'s consist of an electrotonic and chemical synaptic component. Estimates of the cable parameters were determined from an analysis of voltage transients produced and recorded at the soma. Using these estimates and the half-width of the electrotonic synaptic potential measured from the e.p.s.p., the location of the electrotonic synaptic junction on the equivalent cylinder was estimated by the procedure of Jack and Redman (J. Physiol. 215: 321, 1971). These same neurons were injected with horseradish peroxidase and the spinal cord processed for light and electron microscopy. The electrotonic distance from the soma to likely sites of synaptic contact on dendrites of the interneuron was determined from a direct morphological analysis. Electrotonic lengths of dendrites likely to receive synaptic contacts were estimated from physical measurements. The analysis indicated that the electrotonic lengths of individual dendrites varied and were considerably shorter than the equivalent cylinder. This suggests that the termination of dendrites at the same electrotonic distance is an invalid assumption of the Rall model for these neurons. Synaptic junctions were distributed over several dendrites but they tended to be at approximately the same electrotonic distance from the soma. This was confirmed by the physiological estimate of synaptic location. In spite of violating two assumptions, simulation of the electrotonic e.p.s.p. indicated that the Rall model can accurately predict the time course of the synaptic potential. It is concluded from this analysis that functionally identical presynaptic neurons tend to make synaptic contact at approximately the same electrotonic distance on functionally similar postsynaptic neurons.

1229 THE MAUTHNER CELL OF THE PREMETAMORPHIC ANURAN. S.L. Cochran, J.T. Hackett, S.M. Hou, and D.L. Brown. Dept. Physiology, Univ. of Virginia Medical School, Charlottesville, Va. 22901.

In fish, a single neuron--the Mauthner cell (M-cell)--acts as a direct interneuron between sensory input and tail movement. Present also in the tadpole (Rana pipiens) is this cell, which degenerates with the tail and lateral line systems after metamorphosis. The M-cell perikaryon is the largest in the tadpole's brain and is situated ventro-lateral to the sulcus limitans. Examination of 5 μm sections reveals that the M-cell possesses two principal dendrites, a lateral and a medial dendrite. A densely-textured material surrounds all portions of the M-cell. Electronmicroscopy of aldehyde-osmium fixed tissue shows this material to be composed of afferent terminals upon the roughly corrugated M-cell surface. Junctions are of three general types: Gray type I; Gray type II; and type I synapses with gap junctions. These mixed synapses are greatly outnumbered by the plethora of type I junctions. Club endings and axon cap, common in fish, are absent. The M-cell axon increases in diameter as it projects spinally in the contralateral ventral funiculus. Functional characterization of this cell was accomplished after removing the nervous system from the tadpole and maintaining it in vitro. Intracellular recording from M-cell somata show that VIIIth nerve activation occurs at a very short and at longer latency ranges, followed by an increase in transmembrane conductance with little change in potential, suggesting inhibition. Spinal cord activation orthodromically occurs only in the longer latency range. Antidromic activation occurs in less than 1 msec. with contralateral stimulation. Absent is the extrinsic hyperpolarizing potential evident in fish, reflecting the absence of the axon cap. The M-cell conduction velocity increases with increasing distance from the soma, verifying the observations that the axonal diameter increases with distance from the soma. Identification of the impaled cell was obtained after inward injection of horseradish peroxidase and subsequent localization of the reaction product within the M-cell. The M-cell thus has three types of afferent activation: short latency VIIIth nerve activation possibly mediated through active, mixed type I-gap synapses; longer latency VIIIth nerve and spinal activation due to active type I synapses; and the subsequent inhibitory phenomena appear to correlate with the type II junctions upon the M-cell. We would conclude that the anuran tadpole M-cell is rudimentary in relation to the M-cell of the teleost. Functionally, however, the tadpole retains many features of the fish M-cell.

Supported by RSDA 5K02 DA 00009 from NIDA and NSF grant BNS 77-155271.

1230 AN ON-LINE COMPUTER-AIDED TECHNIQUE FOR THE RECONSTRUCTION OF NEURONAL STRUCTURES FROM SERIAL SECTIONS. M.L. Dierker* and T.A. Woolsey. Dept. of Anat. & Neurobiol., Washington U. Med. Sch., St. Louis, MO 63110.

In the past decade a number of computer-aided techniques for collection of the quantitative aspects of neuronal morphology from light and electron microscopic images have been introduced. A serious problem with light microscope based systems has been the difficulty in or inability to quantitate data from serial sections. Reconstruction systems utilizing electron micrographs usually require a series of intermediate photographic steps before digitization of the image. The present system allows on-line quantification of neuronal structure, with the alignment and quantification steps sequentially ordered. A continuous gray level T.V. image of the structure(s) being reconstructed (e.g. from the phototube of a microscope) is digitized (8 gray levels) and stored in a computer. By a subsequent digital to analogue conversion, the stored image may be retrieved and displayed at any time. The recalled image can be displayed simultaneously with the T.V. image of the next section and the two images aligned by rotation and translation of either the stored image or the specimen. In this way it is possible to sequentially align a number of sections in a series and to match and measure features, examined at higher magnification, such as neuronal processes which are continuous from one section to the next. Since the digitized T.V. pictures can be stored on magnetic tape, they may be used for subsequent analysis of other objects in the sections without recapitulating the serial section alignment procedure. While at the moment we do not produce a "movie" of a series of sections, to do so would be straight forward. The utility of this procedure has been shown in a computer-aided system for the reconstruction of Golgi impregnated neurons from serial sections. This system allows the on-line quantification of neuronal structure, as well as the number of dendritic spines, process diameters and somal areas. The procedure also has been used in the reconstruction of other objects such as cortical cytoarchitectonic areas. In principle the method is limited only by the range of magnifications available from input devices and the system can be used equally well to reconstruct images of organs from gross anatomical material, outlines of brain nuclei, individually stained neurons or parts of cells seen in serial electron micrographs. The time required to perform a reconstruction of a Golgi stained neuron on the current system varies with structure complexity, but averages 10-15 minutes per section processed.

1231 A MECHANISM FOR THE PRODUCTION OF VERY LOW FREQUENCY REPETITIVE FIRING FROM NERVE ENCODERS UNDER CONSTANT CURRENT STIMULATION. Jürgen Fohlmeister (SPON: C. A. Terzuolo). Laboratory of Neurophysiology, University of Minnesota, Minneapolis, Minnesota 55455.

Many neurones (eg. the slowly adapting stretch receptor neuron of crayfish) are capable of producing very low impulse frequencies of less than 1 imp/sec when stimulated with very small, constant currents. Further, the crayfish neuron shows a sizeable nonuniformity of excitability and reduced current threshold at the impulse trigger zone near the axon hillock. Longitudinal potential differences in the neighborhood of the trigger zone will be small during most of the interspike interval because the trigger zone dimensions are a small fraction of an axonal space constant in that state. Passive properties of neighboring membrane will then dominate the control of membrane potential which, for the electrically isolated trigger zone, would otherwise be controlled solely by the excitation kinetics of local membrane. This dominance can allow threshold potential to be reached at the trigger zone for very small stimulus currents leading to very low impulse frequencies. This behavior is demonstrated with a model for which the trigger zone kinetics are given by "voltage clamp" equations. Ionic channel rate "constants" are derived from neural- and model dynamics. The crayfish neuron threshold condition determines $\bar{g}_K(Tz)$ and $\bar{g}_{Na}(Tz)$. Membrane potential then follows an equation of the form $(C_{Ax}+C_{Tz})\dot{E}=-g_{Tz}(E-E_K)-g_{Ax}(E-E_K)+I$ where $g\equiv g_K-g_{Na}(|E-E_{Na}|/|E-E_K|)$.

The magnitude of C_{Ax}, acting as a distributed capacitance, is time varying and reflects the "amount" of axonal membrane that is influential in moderating the effect of trigger zone channel kinetics on membrane potential control. C_{Ax} is zero for a transverse current density such as during an action potential but can become very large in interspike intervals. The term $g_{Ax}(E-E_K)$ must remain <I in order that stimulus current can reach the trigger zone. This condition is sufficient to remove the excitation kinetics of axonal membrane from the encoding process and to consider it as a subtraction from the stimulus current. The mechanism accurately reproduces the stimulus/impulse frequency behavior of the crayfish neuron to very small frequencies. (Supported by NSF #BNS77-22532 and NIH #EY00029312.)

1232 STRUCTURAL AND FUNCTIONAL CORRELATION FOR SINGLE NEURONS IN CAT DORSAL LATERAL GENICULATE NUCLEUS. Michael J. Friedlander*, C.-S. Lin, and S. Murray Sherman (SPON: Lennart Heimer). Dept. Physiol., Sch. Med., UVA, Charlottesville, VA 22901.

Functional properties of neurons of the dorsal lateral geniculate nucleus of the cat were correlated with cell structure using the intracellular HRP injection technique. Recordings were made using glass micropipettes filled with 3% HRP in 0.2 M KCl at pH 8.6. Electrode tip diameters were <1 μm. Electrodes were beveled to a final impedance of 100-175 MΩ at 200 Hz. A section of tissue approximately 4 mm in diameter and 4-5 mm deep was aspirated from cortex overlying the lateral geniculate nucleus (LGN). This facilitated penetration of the LGN with the electrodes which tended to clog or break if the entire overlying cortex had to be penetrated. Several parameters were tested during extracellular recording which allowed us to classify the geniculate neurons as X- or Y-cells. These parameters included receptive field size, tonic or phasic responses, type of center and surround, latency to optic chiasm shock, linearity of spatial summation, and responsiveness to a large, rapidly moving disc. The electrode was then advanced to impale the cell. A second determination of the receptive field properties was quickly made during intracellular recording to verify that the impaled cell was identical to the unit from which data were obtained with extracellular recording. HRP was passed into the cell by applying 5-10 nA depolarizing pulses for 5-10 min. The brains were subsequently prepared for histology, cut frozen into 120 μm sections, and the sections were reacted with diaminobezidine. To date 8 filled cells have been located and traced under oil with a drawing tube attached to a microscope. Extensive dendritic branching, long sections of axons, and axonal and dendritic processes and varicosities were clearly visible.

Compared to 5 Y-cells, 3 X-cells had smaller somas and finer dendritic and axonal processes. Also, X-cells had complex varicosities and swellings along their dendritic arborizations, whereas Y-cells had few processes on their dendrites. Line drawings of an X- and Y-cell are shown below.

1233 THE MIGRATIONS OF PIGMENT GRANULES WITHIN CRAYFISH RETINAL PHOTORECEPTORS UNDER DIFFERENT IONIC COMPOSITIONS. Eugenio Frixione†, Victor Tsutsumi* and Hugo Aréchiga. Depts. Neurosc. and Physiol. and Biophys., CIEA, IPN. México 14, D.F.

A previous account has been presented on the mechanisms of migration of accesory pigment granules in the retinula cell of the crayfish (Frixione et al. 1977, Soc. for Neurosc. Abs.3, 176), where two phases were described for the nucleofugal movement towards the axon in the dark, and an apparently single expansion from the axon towards the nucleus upon illumination. Since light is known to induce conductance changes in photoreceptor membranes, experiments were performed to explore the dependence of these light-controlled movements on different ions. Isolated eyestalks in the light-adapted (LA) or in the dark-adapted (DA) condition were pre-incubated for two hours in the test solution, and either kept in darkness or exposed to light for adequate periods of time before assessing the position of the pigment in the instantaneously fixed organ. An inhibitory effect on dark-adaptation was found with an increase in concentration of Na^+ (300 mM, i.e. 1.5 fold normal) and K^+ (80 mM), or by substitution of Na^+ with Li^+. The inhibition was restricted to the second phase of movement and was linearly related to the concentration of K^+ below 80 mM. DA eyestalks were also unable to maintain the pigment accumulated along the axons when incubated in the above solutions in the dark, but migration towards the nucleus in the light was normally achieved except for the Li^+ treated eyestalks, where its completion was arrested. In contrast to the action of monovalent cations, the nucleofugal migration of pigment seemed favoured by isotonic $CaCl_2$ or 15 mM $CoCl_2$ added to Van Harreveld's solution, without any appreciable effect on the movement in the opposite direction during light-adaptation. High Ca^{++} opposed an inhibitory effect of elevated temperature (25°) upon nucleofugal migration. Pigment movements in isotonic $MgCl_2$ were indistinguishable from controls. Ouabain prevents DA and promotes a partial LA position in DA eyestalks kept in the dark.
These findings permit to consider the second phase of the nucleofugal migration as being closely associated to a hyperpolarization of the photoreceptor cell in the dark. Thereby conditions opposing such a process, as high K^+ and Na^+ or Li^+ and Ouabain, result in inhibition, whereas those increasing membrane resistance, as Co^{++} or high external Ca^{++}, facilitate the migration towards the DA position. Upon the incidence of light, an influx of Na^+ would depolarize the cell, triggering an expansion of the pigment in a process for which Li^+ could be less suited.

1234 A SYSTEM FOR DETERMINING THE ALIGNMENT OF SERIAL SECTIONS. A. N. Gentile* and E. Harth. Dept. of Physics, Syracuse University, Syracuse, NY 13210.

A method is introduced which achieves the alignment of serial sections, using features appearing at adjacent slide surfaces. An instrument for the measurement and recording of coordinates taken from microscope sections is described. X, Y, and Z coordinates are obtained by a combination of digital encoding of microscope stage, video cursor and microscope focusing. A computer link allows recording and processing of the data via a dedicated PDP-11 minicomputer. It also gives access to the graphics and analysis capabilities of larger computers. The computer assisted digitizer records the positions of easily recognizable gross structures along the surfaces of the sections. These data are used in the determination of areas for alignment. Points in these regions on adjacent slide surfaces are digitized for use in computer programs that perform a spatial filtering process using the two dimensional fast Fourier transform (FFT). Shrinkage and rotation are determined by first taking the complex logarithm of the data from both regions and applying the FFT. These data are then filtered and correlated revealing the precise magnification and rotation between slides. The digitized data are corrected for shrinkage and rotation and then directly reprocessed by the FFT, filtered, and correlated. This determines the precise translation between slides. Hardware implementations of the FFT will permit very rapid alignment of the sections. An example is presented and the significance of each stage in the process is discussed. The method is used in our laboratory for the reconstruction of fiber geometry of Golgi-stained neural tissue, using light microscopes. It may be applied, however, to the spatial analysis of any features appearing in serial sections using light or electron microscopy.

1235 INTRACELLULAR STAINING OF PHYSIOLOGICALLY IDENTIFIED CELLS AND AFFERENTS IN CAT VISUAL CORTEX. Charles D. Gilbert* and Torsten N. Wiesel. Dept. of Neurobiology, Harvard Medical School, Boston, Mass. 02115.

To study intracortical connections and the means by which the receptive fields of cortical cells are synthesized, we used the method of staining physiologically identified cells with horseradish peroxidase. Intracellular recordings were made in the cat primary visual cortex, and after we characterized their receptive field properties, the cells were injected with horseradish peroxidase by pressure or by iontophoresis. Previous studies using extracellular recording techniques have demonstrated a relationship between receptive field type and cortical layer[1,2]. The present technique enabled us to expand upon these studies by making a more precise localization of the cell soma, and by distinguishing cells within a given layer on morphological and functional grounds. The morphological differences between cells were helpful in evaluating which of a given cell's receptive field properties were especially important in defining a particular cell class.

In many instances the filling of the cells appeared to be complete, so that we were able to characterize their axonal as well as dendritic arborizations. This made it possible to extend the general correlation between receptive field type and cell morphology made by Kelly and Van Essen[3] who examined cells after procion yellow injection. We have, for example, been able to penetrate and inject afferents from the lateral geniculate nucleus. By filling their terminal processes and boutons we could determine the columnar and sublaminar distribution of the terminals of particular classes of geniculate neurons. The construction of cortical receptive fields from those of a particular geniculate channel could be deduced after characterizing and injecting cells that lie within the terminal field of a given afferent class, and this analysis could be made for subsequent stages by following the axonal projections of these cells within the cortex. 1236 THE EFFECTS OF NEURONAL GEOMETRY ON TRANSIENT POTENTIALS IN DENDRITIC SYSTEMS. Barry Horwitz, Physics Department, Texas Woman's University, Denton, Texas 76204.

A theoretical study has been undertaken which seeks to examine the way in which the geometrical structure of a neuron's dendritic tree affects the time course and amplitude of transient potentials generated at different locations on dendritic branches. The model which is used is based upon the work of Butz and Cowan (Biophys. J. 14, 661-689, 1974). They extended the Rall model (Rall, Exp. Neurol. 1, 491-527, 1959), which treats a dendrite as a passive cable whose membrane properties can be represented electrically by a distributed network of resistors and capacitors, to dendritic systems of arbitrary geometry. Butz and Cowan produced a graphical calculus which generates analytic expressions for the Laplace transform of the transmembrane potential change at any point on the dendritic tree in response to a synaptic "current" input at any other specified point along the tree. This work discusses a method which has been developed for determining the inverse transform (which is the transmembrane potential change) in analytic form, thus generating expressions for the time course and amplitude of the transient potential changes. The method involves essentially the following: (1) For a given dendritic geometry one associates a set of symmetric geometries for which the inverse Laplace transforms are either known, or can be fairly readily determined; (2) the transient potential changes for the asymmetric geometry are obtained by adding correction terms to the inverse transforms corresponding to the set of symmetric geometries. This method, which will be illustrated with several examples, provides a way to assess the influence of the dendritic geometry upon the neuronal input-output relationship.

1237 A COMPARATIVE STUDY OF VENTROLATERAL AND RECURRENT EXCITATORY POSTSYNAPTIC POTENTIALS IN LARGE PYRAMIDAL TRACT CELLS IN THE CAT. A. Labelle* and M. Deschênes* (SPON: A. Roberge). School of Medicine, Laval Univ., Quebec City, Quebec, G1K 7P4, CANADA.

In acute cats deeply anesthetized with Nembutal, monosynaptic excitatory postsynaptic potentials (EPSPs) triggered by stimulation of the ventrolateral (VL) thalamic nucleus and the pes pedunculus were recorded in large pyramidal tract cells (PT cells). Deep anesthesia, low intensities of stimulation and an averaging technique were used in order to get VL and recurrent EPSPs free of polysynaptic potentials. Comparison of the time course of both EPSPs revealed a much faster rise time and shorter half-width for VL EPSPs than for recurrent EPSPs. This would suggest a more proximal location for VL synaptic contacts than for recurrent ones with respect to the soma of PT cells. The separation of the sites of origin of both EPSPs is further suggested by their almost perfect linear summation. It is suggested that VL EPSPs are produced on the apical dendritic tree while recurrent EPSPs could originate on the basilar dendritic branches. (Supported by MRC grant MA-5788)

1238 STRUCTURAL AND FUNCTIONAL CORRELATION FOR SINGLE NEURONS IN CAT STRIATE CORTEX. C.-S. Lin, Michael J. Friedlander*, and S. Murray Sherman. Dept. Physiol., Sch. Med., UVA, Charlottesville, VA 22901.

We attempted to correlate structure with function by intracellular filling with horseradish peroxidase (HRP) of single neurons in cortical area 17 of adult cats. Beveled micropipettes (3% HRP in 0.2 M KCl buffered at pH 8.6; <1 μm diameter tip; 100-175 MΩ impedance at 200 Hz) were used for recording. Cells with receptive fields within 10^{o} of the *area centralis* were classified as simple or complex by previously described criteria. Several other functional parameters were also measured. The electrode was then advanced to impale the cell. Criteria for intracellular recording included resting potential, spike amplitude, polarity and waveform, and synaptic potentials. The receptive field was quickly remapped to ensure that the impaled cell was identical to the unit from which data were obtained with extracellular recording. HRP filling was then accomplished by applying 5-10 nA depolarizing pulses for 5-10 min. The brains were then prepared for histology, cut frozen in the coronal plane into 120 μm sections, and the sections were reacted with diaminobenzidine. Filled cells were located and traced under oil with a drawing tube attached to a microscope. Extensive dendritic branching, dendritic spines and long sections of axons and axon collaterals were clearly visible.

Simple cells were found to be of several morphological types. Somas were both of pyramidal and non-pyramidal forms. The non-pyramidal group included circular, fusiform, and crescent shaped somata. The pyramidal group contained from 1 to 3 main dendritic ramifications. These included a basal group, a group from 50-100 μm above the soma along the apical dendritic shaft, and a terminal apical group. The apical dendrites of some simple cells were followed to the pial surface, showing only a terminal branching at the surface. In some cases, axons of simple cells were traced into white matter. Axon collaterals were also occasionally seen to ramify locally.

To date, too few complex cells have been successfully filled for analysis. Those that have been are of pyramidal morphology.

These data suggest that the simple/complex functional classification does not correlate in a straightforward manner with the stellate/pyramidal morphological classification.

1239 STIMULATION OF THY-1 SURFACE GLYCOPROTEIN LEVELS ON PC-12 NEUROBLASTS IN RESPONSE TO NGF AND cAMP. Roger Morris*, Wendy Colby*, Bruno Betschart*, and S. E. Pfeiffer. Dept. Microbiol., Sch. Med., U Conn Health Center, Farmington, CT 06032

Pheochromocytoma cell line PC-12 (Greene et al.) has been studied with respect to the levels of the surface glycoprotein Thy-1 as a function of physiological conditions leading to neurite outgrowth. A two-step serological binding assay using either mouse or rabbit antisera against purified rat brain Thy-1 was used, with glutaraldehyde-fixed mouse thymocytes (Thy-1.1) as target cells for PC-12 absorbed antisera. When round proliferating neuroblasts are presented with partially purified mouse salivary gland NGF (streptomycin sulfate precipitation, G-100 column chromatography) at 2 ug/ml, Thy-1 levels increased from 1.5×10^{6} molecules/cell at t_0, to 2.3×10^{6}, 4.8×10^{6}, and 7.4×10^{6} molecules/cell at 24, 48, and 72 h., respectively, at which time the concentration increase had not reached a plateau level. More highly purified samples of NGF are currently being tested. Detergent treatment studies indicated that these increases represented new synthesis rather than exposure of previously synthesized antigen. The phenomena was independent of initial cell density. Treatment of cells with db-cAMP (0.25 mM) or inhibitors of phosphodiesterase (e.g. IBMX, 10^{-5}M) resulted in similar stimulations of Thy-1 with respect to time course and extent. The early elevation of Thy-1 in response to NGF suggests its utility as a biochemical marker for the study of the mode of action of this hormone. (Supported by PHS grant 10861 and NSF grant BNS77-15818; Dr. Morris was a Fellow of the Jane Coffin Childs Foundation).

1240 SUDDEN INFANT DEATH SYNDROME (SIDS): RETICULAR DENDRITIC SPINES IN INFANTS WITH SIDS. James J. Quattrochi*, Nobuhisa Baba*, and Leopold Liss. Dept. Pathology, Sch. Med., Ohio State University, Columbus, Ohio 43210.

Sudden unexpected death in infancy continues to present a problem of major medical significance with the peak incidence occurring between two and four months of age. The role of the central nervous system in the pathogenesis of SIDS has not been fully investigated. The rather narrow age range during the critical period of CNS maturation might suggest a transient developmental abnormality in these infants. Theories have alluded to a dysfunction of central respiratory control, however investigation of specific brainstem pathology has been lacking in SIDS. This study was designed to determine whether the presence of reticular dendritic spines can be implicated as a consistent finding in SIDS victims. It is postulated that during the first month of life in the kitten, spines on reticular dendrites are concerned with primitive control of respiratory rhythms and the rest-activity cycle. The loss of these spines, described by Scheibel, during normal postnatal maturation encodes a more sophisticated program on the dendritic membrane. In the adult cat, smooth, spineless dendrites are seen which then assume a more complex control of sleep-wakeful states of respiration and modulation of chemoreceptor activity. (Exp. Neurology 38:301, 1973.) In our study, Golgi-stained serial sections from the apex of the pons to the caudal end of the medulla exhibited a persistence of reticular dendritic spines in sixteen infants who died of SIDS, while the dendritic spines in the control infants follow a normal maturational scheme,and also confirms findings in cat brainstem. Conceivably, the persistence of reticular dendritic spines in the SIDS infants may indicate a specific lag in the normal maturation of the respiratory control centers. This may bear a causal relationship to prolonged apneic episodes and neuronal dysfunctions often seen in these infants including the final event.

1241 NEURONAL INTEGRATION CONSIDERED AS A DIRECT FUNCTION. Bernard Racine* (SPON: Dalbir Bindra). Dept. Psychol., Univ. de Montréal, Montréal, Québec, Canada, H3C 3J7.

It is shown that the integration of information on the somatodentritic membrane could be considered as a direct function. Formally, a function f: $w_i \longrightarrow w_j$ is a direct function, noted f_d, iff the result-word w_j is a part of the data-word w_i:

$$f_d: w_i \rightarrow w_j \text{ iff } w_j \in P(w_i)$$

(e.g. if w_i = bababc and if w_j = aac, then bababc→aac is a direct function because the result-word aac is a part of the data-word bababc). Neuronal integration could be considered as a direct function f_d if it is accepted that on the somatodentritic membrane (1) an excitation noted e and an inhibition noted i constitute the two letters of a neuronal alphabet noted A, (2) a sequence of excitations and inhibitions constitute a word of the set A* of all the neuronal words where

$$A^* \{\emptyset, e, i, ee, ii \ldots, eiei, \ldots\}$$

and where the empty word $\emptyset$ corresponds to the lack of stimulation. Following these considerations, it happens that the grand slow potential issued from spatial and temporal sommation is a neuronal word $w_i \in A^*$ and that this neuronal word w_i is a part of the neuronal word $w_j \in A^*$ issued from the juxtaposition of the excitatory and inhibitory postsynaptic potentials (e.g. if w_j=eee and w_i = eieieee, then eee ∈ P(eieieee)). Thus, it is possible to conceive neuronal integration as a direct function (e.g. f_d:eieieee→eee because eee ∈ P(eieieee)). From the formal properties of a direct function, it can be shown that the neuron saves at least 300,000 unities of time if its integration of 100,000 postsynaptic potentials is a direct function. More generally, it is suggested from formal properties of a direct function that the neuronal integration would be a direct function for reasons of (I) time economy (II) errors economy and (III) materials economy.

1242 PHYSIOLOGICAL AND MORPHOLOGICAL IDENTIFICATION OF A PROBABLE HIPPOCAMPAL INTERNEURON. Philip A. Schwartzkroin and Lawrence H. Mathers. Depts. Neurol. and Struct. Biol., Stanford Univ. Med. Sch., Stanford, CA 94305

In intracellular recordings from the CA1 pyramidale layer of hippocampal slices, a nonpyramidal cell type has been found which may be a type of hippocampal interneuron. Such cells are seen infrequently compared to the predominant pyramidal cells (about 1:50 ratio). Stimulation of the alveus evokes a short latency, fast rising EPSP; pure antidromic activation such as seen in pyramidal cells, is not observed. These cells also differ from pyramidal cells in the following respects: 1) shorter duration action potentials (0.4-1.2 msec as opposed to 0.8-1.7 msec in pyramidal cells); 2) large hyperpolarizing undershoot following spikes rather than the depolarizing after-potential; 3) high spontaneous activity; 4) considerable baseline "noise" which appears to reflect unitary EPSP activity.

Intracellular labelling of these cells with HRP has shown them to be, morphologically, a nonpyramidal cell type, with extensive dendritic and axonal branching. The orientation of the cell is generally parallel to the pyramidal cell dendritic tree. HRP staining reveals no dendritic spines on these cells (in contrast to stained pyramidal cells), but does show frequent dendritic swellings.

This non-pyramidal cell type has been impaled during electrode penetrations in stratum radiatum as well as in pyramidale. The characteristics of its recorded activity, however, differentiate it plainly from pyramidal cell dendritic impalements. Becuase of their vertical orientation, because of their location, and because no basket plexes have been seen following HRP labelling, these cells appear not to be basket cell interneurons. Their firing characteristics, however, are similar to those often associated with hippocampal inhibitory interneurons (Andersen, Eccles, and Løyning, J. Neurophysiol. 27:592-619, 1964). In addition, the non-pyramidal cell has many of the features of the "theta cell" (which contrasts to the "complex spike cell") recorded in chronically-implanted, behaving animals (Fox and Ranck, Exp. Neurol. 49:299-313, 1975). There are no data showing a definite inhibitory role for these neurons; their function is still to be determined.

1243 AXON CONDUCTION BLOCK IN NERVE TERMINAL REGIONS CAUSED BY AXON DEPOLARIZATION. Dean O. Smith. Dept. of Physiology, Univ. of Wisconsin, Madison, WI 53706

In the terminal arborization of the excitor axon innervating the opener muscle of the crayfish walking leg, action potential propagation fails intermittently during prolonged repetitive stimulation (Hatt and Smith, 1976, J. Physiol. 259: 367-393). Using microelectrode techniques for recording and stimulation, it has been found that the blocks occur at axonal branch points and their onset is coincident with (1) decreasing conduction velocity, (2) decreasing sodium inward current, and (3) increasing rate of spontaneous transmitter release. Conduction failure can be reversed at least temporarily by applying hyperpolarizing current (about 12 μA) and jets of low-K^+ saline. It can also be reversed by reducing K^+ concentration in the bath and by decreasing the rate of nerve stimulation. Conversely, propagation fails after fewer impulses in bath solutions containing higher than normal (5.4 mM) concentrations of K^+ and also as the bath temperature is lowered. Action potentials in the nerve cannot be evoked when extracellular K^+ is 3-4 times normal, when muscle membrane potentials are about -50 mV. Thus conduction block results from axon depolarization.

Possible metabolic deficiencies which might cause propagation failure were estimated by assaying ATP and arginine phosphate concentrations in the nerve bundles at various times during block development in the excitor axon. After 10 min of stimulation during which conduction failed intermittently, the ATP concentration did not differ significantly from control values obtained from unstimulated nerves. Therefore, prolonged shortages of ATP do not appear to occur during intermittent conduction block.

Axon geometry at branch points was examined to determine if the safety factor for conduction was unusually low. Using Hoffman modulation-contrast optics, the diameters of the axon branches at a site of failure were measured. The geometrical ratio, $GR = (d_1^{3/2} + d_2^{3/2})/d_p^{3/2}$, where d_1, d_2, and d_p are the diameters of the two daughter axons and the parent axon, respectively, was calculated at regions of block. The average value was 0.89 (±0.20 s.d.), which is slightly less than the value 1.00 at which failure would be expected to occur because of the large load resistance presented by the daughter branches.

It is concluded that conduction block is caused by depolarization. Neither ATP shortages nor resistance mismatches at branch sites appear to underlie propagation failure. The cause of the depolarization may involve accumulation of extracellular K^+. Using K^+-sensitive microelectrodes, this is being studied currently.

1244 **ESTIMATES OF CABLE PARAMETERS FROM AN ANALYSIS OF VOLTAGE TRANSIENTS IN LAMPREY SPINAL CORD NEURONS.** **Wm. P. Teubl* and Burgess N. Christensen** (Spon: K. I. Naka). **Dept. of Physiology and Biophysics, Univ. of Texas Med. Br., Galveston, TX 77550.**

Voltage transients were produced in lamprey spinal cord giant interneurons by injection of a brief current pulse through an intracellular microelectrode. The transients were recorded by a second intracellular electrode and analyzed according to the procedure suggested by Jack and Redman (J. Physiol. 215: 321, 1971) to estimate the cable parameters governing the passive propagation of transmembrane potentials in neurons. For this approach it was assumed that the Rall neuron model was applicable. This allows reduction of the soma and geometrically complicated dendritic tree to a model soma consisting of a lumped parallel combination of resistance and capacitance attached in parallel to an equivalent cylinder representing the dendritic tree. Membrane time constant (Tm), dendritic to soma conductance ratio (ρ_∞), and electrotonic length of the equivalent cylinder (L) were estimated from the decays of the voltage transients. In twenty two of the thirty two neurons studied it was possible to estimate all three cable parameters. For these twenty two neurons it was found that the electrotonic length of the equivalent cylinder was similar to cat spinal motoneurons (1-2 space constants). A test of the Rall model as an adequate description of these lamprey neurons was provided by computer simulations. Using the estimated cable parameters, a voltage transient was produced from an analytical expression for the Rall model which describes the voltage recorded at the model soma following a brief current pulse. These simulated transients fit closely the experimental transient even during the early part of the voltage decay. This result suggests that the time constant for the soma and dendritic membrane is similar for these lamprey neurons. These results have been used to investigate the location of synaptic junctions made by a specific giant axon on the equivalent cylinder.

NEUROPATHOLOGY AND NEUROIMMUNOLOGY

1245 EFFECTS OF PRENATAL EXPOSURE TO THE CHOLINESTERASE INHIBITOR CARBOFURAN ON MATURATION, BEHAVIOR AND BRAIN MORPHOLOGY OF THE MOUSE. DAVID L. AVERY AND JOAN M. SPYKER, Department of Pharmacology, University of Arkansas for Medical Sciences, Little Rock, Arkansas 72201.

Pregnant mice were given a daily dose of 0, 0.01 or 0.50 mg Carbofuran per kg body weight throughout gestation. Mothers of all experimental groups gave birth to approximately equal numbers of viable, overtly normal offspring. Pups born to mothers receiving the higher dose of the carbamate weighed significantly less at birth but their rate of growth equaled that of control pups. Physical maturation and reflex development were evaluated daily in all offspring. Pups born to Carbofuran mothers developed simple righting, acceleration righting and withdrawal responses at the same time and, therefore, in the same sequence as control offspring. Testes descent was delayed in male offspring from both the 0.01 and 0.50 mg/kg Carbofuran groups, while vaginal opening was delayed in female offspring from the lower treatment group only.

Neuromuscular coordination, learning ability, endurance and activity of offspring were evaluated after weaning using several behavioral techniques. Prenatal exposure to Carbofuran significantly affected the swimming behavior of apparently normal male mice. However, swimming posture and style of female offspring did not appear to be affected by the pesticide. Running speed and frequency of errors were measured in a modified Lashley III maze. The performance of Carbofuran offspring was initially indistinguishable from that of control offspring. As learning progressed, the running speed of offspring of the lower dose group fell behind control values, while the speed of offspring of the higher dose group rose above control values. There were no differences in error frequency in the maze between treated and control animals. Prenatal exposure to Carbofuran did not affect treadmill endurance, rod cling endurance, inclined plane performance or open-field behavior.

Subjects were sacrificed at 101 days of age and brains removed for morphological evaluation. Focal defects were found in the forebrains of offspring prenatally exposed to 0.50 mg/kg/day Carbofuran. Dense aggregations of chromatin-containing cells were observed in an area extending from the anterior commissure to the anterior olfactory nucleus. No neuropathological changes were observed in brains from offspring born of mothers receiving either 0 or 0.01 mg/kg/day Carbofuran. (This research was supported by EPA contract 68-01-1925).

1246 DECREASE IN LIPID SYNTHESIS IN FIBROBLASTS FROM PATIENTS WITH DYSTONIA MUSCULORUM DEFORMANS. John Blass, Gary E. Gibson & Adriana Vasil*. Neuropsychiatric Inst., UCLA, Los Angeles, CA 90024.

Dystonia musuclorum deformans is a neurological disorder which appears to be genetic. However, the biochemical basis of the disorder is unknown. The metabolism of [U-^{14}C]glucose, [1-^{14}C]-pyruvate, and [^{3}H]acetate by human skin fibroblasts from dystonia patients was studied, since their utilization provides a general indication of cellular metabolism. If a defect is found using this general approach, then it can be pursued further to determine the precise molecular mechanism.

In the studies with [U-^{14}C]glucose, cells were grown in a balanced salt solution containing heat inactiviated fetal calf serum. Lack of mycoplasma was confirmed routinely using the Hoechst stain and the uridine/uracil ratio method. Cells were harvested with 0.05% trypsin approximately one day before confluence. They were washed with phosphate buffered saline and finally suspended in Krebs-Ringer phosphate buffer. Incubations were for one hour in one ml of Krebs-Ringer phosphate buffer containing 5 mM-[U-^{14}C]-glucose (2 Ci/ mole) under 95% O_2:5% CO_2 and cell protein concentration of 0.25 - 0.5 mg. The incorporation of [U-^{14}C]glucose into $^{14}CO_2$, protein, lipid and nucleic acids was determined. Three dystonia cell lines were studied on six different days and compared with eight different control lines. The incorporation of [U-^{14}C]glucose into lipids was reduced by 33% ($p<0.01$) [from 2108 $\pm$ 230 (n =27) to 1417 $\pm$ 156 (n=18) picomoles of glucose incorporated per mg protein per hour].There was overlap between dystonia culture and control culture in individual expts. Incorporation of ^{14}C into proteins was similar in dystonia (1317$\pm$ 122, n = 17) and controls (1244 $\pm$166, n = 18). Oxidation of glucose to $^{14}CO_2$ was lower in dystonia cultures (4721$\pm$ 416 n = 17, picomoles/ min per mg protein) than in controls (5827 $\pm$ 377, n = 25) but the difference was not statistically significant ($p>0.1$). Furthermore, oxidation of [1-^{14}C]pyruvate did not differ significantly between dystonia and control lines under a number of incubation conditions.

The decreased incorporation of glucose into lipids may indicate a metabolic defect and serve as a molecular "handle" for helping to determine the molecular basis of hereditary Dystonia Musculorum Deformans. (Sponsored by the Dsytonia Medical Research Foundation.)

1247 IMPAIRED ABSORPTION OF CSF DURING EXPERIMENTAL SUBARACHNOID HEMORRHAGE: EFFECT OF BLOOD COMPONENTS ON VESICULAR TRANSPORT IN ARACHNOID VILLI. Albert B. Butler, M.D., Norman H. Bass, M.D. Richard N. Johnson, ScD. University of Virginia School of Medicine, Depts. of Neurosurgery, Neurology, and Biomedical Engineering, Charlottesville, VA 22901.

Elevated intracranial pressure associated with acute subarachnoid hemorrhage has been attributed to a disturbance of cerebrospinal fluid (CSF) efflux through arachnoid villi. In an attempt to assess the role of various blood components to acutely induce this disorder in CSF dynamics we have combined our previously described technique for manometric assessment of CSF outflow resistance (Ann. Neurol. 3: 156-165, 1978) with ultrastructural examination of the arachnoid villi. CSF outflow resistance in the rat was quantitatively assessed before and 15 and 20 minutes after an intrathecal ten minute constant rate infusion (22µl/min) of the following substances: (A) heparinized whole blood, (B) plasma (fibrinogen content: 440mg), (C) dialysate of plasma (containing substances <6000 mol.wt.), and (D) serum as compared with saline controls, with or without heparin.

For electron microscopy, artificial CSF-horseradish peroxidase was infused into the subarachnoid space of control and experimental animals with flow rates adjusted to achieve a steady state CSF pressure of 800mm in all animals. When steady state pressure was achieved, aldehyde fixation was performed to preserve the arachnoid villus in its pressure induced state. Sections containing arachnoid villi were processed for HRP using routine EM techniques.

The data show that both blood and plasma significantly increase CSF outflow resistance, while plasma dialysate and serum show resistance values which cannot be distinguished from saline controls. Ultrastructural changes within the endothelium covering the villi of animals infused with either saline, serum, or plasma dialysate were similar, demonstrating numerous transendothelial channels seen as single enlarged cytoplasmic vesicles, or confluent vesicles in transcytoplasmic chains, all of which contain HRP. In contrast, animals infused with blood or plasma showed a marked reduction in the number of transendothelial channels associated with a fibrin-like material in the subendothelial space at equivalent pressures. Based on these observations we suggest that during experimental subarachnoid hemorrhage CSF outflow through the endothelial covering of arachnoid villi is not impeded by blood born cellular elements, but by macromolecular substances associated with the clotting cascade.

1248 GANGLIOSIDE METABOLISM IN HUMAN BRAIN AND BRAIN TUMORS CULTURED IN VITRO. Mary Thoesen Coleman and Allan J. Yates. Dept. Path., College of Med., OSU, Columbus, OH 43210.

Gangliosides are cell surface components which may play a role in the regulation of cell growth. In this study we examined cultures of normal human white matter and brain tumors for differences in ganglioside patterns after administration of a radioactive precursor. Cells cultured from a malignant astrocytoma, an oligodendroglioma, a glioblastoma multiforme and adult white matter were seeded at subconfluent densities in 7 petri dishes (Corning P-100's). When cells were almost confluent, ^{14}C-1-D-glucosamine was added to the cultures (0.5µCi/ml media). Twenty-four hours later, the medium was removed and cells were washed with phosphate-buffered saline. Cells were harvested by scraping and aliquots of a cell suspension taken for determination of total cellular protein and total incorporation of radioactive label into the cells. After centrifugation, cell pellets were frozen until used for extraction of gangliosides. Cells from one plate were trypsinized and counted. Gangliosides were purified with modifications of the method of Suzuki (1965, J. Neurochem. 12: 629). Gangliosides were separated by thin layer chromatography and radioactive patterns detected using a beta camera. Individual bands were scraped and counted in 0.1 ml water and Aquasol 2.

The population doubling times were: normal glial cells, 7 days; glioblastoma, 4 days; astrocytoma, 33 days; and oligodendroglioma, 30 days. In normal glial cells and glioblastoma cells 71.97 and 67.39% respectively, of the label recovered, was incorporated into bands which cochromatographed with GM_1, GM_2, and GM_3 standards. In the oligodendroglioma and astrocytoma, the percentage of counts in GM_1, GM_2, and GM_3 was only 36.7 and 41.8% of the counts recovered with a substantial percentage of counts in bands cochromatographic with disialogangliosides. When counts in gangliosides were expressed as a function of cell number, the counts in disialogangliosides were higher in the slower growing cells (oligodendroglioma and astrocytoma) than in the normal glial cells and the rapidly growing glioblastoma. All cell cultures showed significant incorporation of label into monosialogangliosides. Label in GM_1, expressed in terms of cell number, showed little variation. Label in GM_2 was higher in the glioblastoma relative to both normal glial cells and other tumor cells. The correlation of ganglioside metabolism with growth rates in these cultures suggests a possible role of ganglioside metabolism in the mechanism of growth control. (Supported by NIH Research Traineeship #784760, American Cancer Society ACS #In-16P and by The Association for Brain Tumor Research.)

1249 MAST CELLS WITHIN THE VENTRICLES OF THE VERTEBRATE BRAIN. John J. Dropp. Dept. Sci. and Math., Mt. St. Mary's College, Emmitsburg, MD 21727.

The brain ventricles of 11 species (frog, toad, newt, congo eel, lizard, horn toad, sparrow, canary, mouse, dog, man) of vertebrates were examined for the presence of mast cells These cells, as adjudged by their morphological and staining characteristics, were found within the ventricles of only adult frogs, young mice, young dogs and humans. They were either entirely free within the ventricle (frog, mouse, dog, man) or wedged between choroidal epithelial cells with approximately one-half of the cell projecting into the ventricle (frog). That these cells were indeed mast cells was strongly suggested by their morphological and histochemical similarities to mast cells in either non-nervous (e.g. tongue) or nervous (e.g. leptomeninges, choroid plexuses) tissues of the same individual.

1250 THE EFFECT OF PRENATAL METHYL MERCURY TREATMENT ON BEHAVIOR IN RATS. Christine U. Eccles* and Zoltan Annau (SPON: A. Goldberg). Dept. Environ. Hlth. Sciences, Johns Hopkins University, Baltimore, Maryland 21205.

It has been well documented that the developing organism is susceptible to the toxic effects of methyl mercury (MeHg) and that the fetus exposed to utero may actually accumulate higher concentrations of it than the treated mother. Behavioral changes in the neonatal rat that occur after in utero exposure to methyl mercury, however, have not been well described.

In the present study, pregnant female Long-Evans hooded rats received 0, 5 or 8 mg/kg of methyl mercury as methyl mercury chloride dissolved corn oil or 50 mM sodium carbonate on day 7 of gestation.

When the pups were born they were weighed and counted; all litters were culled to a standard size of 8. The pups were also weighed on day 7, 14 and 21.

On days 4, 7, 14 and 21, two to three pups from each litter were individually placed in a Stoelting electronic activity meter. Ten minute subtotals of activity were obtained during the course of the hour.

Neonatal weight data for rat pups exposed to mercury in utero were not different from controls. Activity measures revealed that the animals whose mothers received 8 mg/kg MeHg were significantly more active at 7 days of age than control animals of the same age. The mean activity level at 14 days was also higher for controls but the difference was not statistically significant. Offspring of mothers exposed to 5 mg/kg MeHg in utero did not show any significant changes in activity levels on any of the days tested.

Adult males whose mothers were treated with 8 mg/kg MeHg were tested in a two-way shuttlebox avoidance task. Animals were trained to meet a criterion of ten consecutive avoidances during acquisition. Avoidance behavior was extinguished when the criterion was achieved. This was followed by a period of reacquisition in which the animals were again required to make ten consecutive avoidances. There was no significant difference in the trials to reach initial criterion between mercury exposed and control animals, although the performance of the exposed animals was considerably more variable. During reacquisition the exposed animals required a significantly greater number of trials to reach criterion than controls. The results indicate that prenatal methyl mercury ingestion can lead to learning deficits in the adult animal.

1251 ELECTROPHYSIOLOGIC OBSERVATIONS OF CULTURED DORSAL ROOT GANGLIA CELLS INFECTED WITH HERPES SIMPLEX VIRUS. Howard Gitelson*, Robert Pozos, Richard Ziegler*, Paul Lima*, Julie Moore* and Steven Oakes*. Depts. of Physiology and Microbiology, Univ. of Minnesota-Duluth, School of Medicine, Duluth, Minnesota 55812.

Although Herpes Simplex Virus has been reported to reside in the Dorsal Root Ganglia, no studies have been reported as to the effect of the virus on the electrophysiology of the Dorsal Root Ganglia. Rat Dorsal Root Ganglia were grown in culture for 14-40 days. At that time, Herpes Simplex Virus I of a concentration of 10^6 p.f.u. were placed on the culture for 1 hour. After the incubation period of 1 hour, the media was changed. Electrophysiologic studies were made before and after the infection. Resting membrane potential, evoked action potentials and width of the action potential (full width half maximum) were initial parameters studied.

Results of these experiments indicate that in control cultures, two kinds of evoked action potentials are seen. Those with a pronounced falling phase and those with a prolonged falling phase (plateau). The latter were the predominant response recorded. To detect the plateau the evoked action potential was differentiated.

Approximately three hours after virus infection, there is a decrease in the height of the overshoot of the evoked action potential. The resting membrane potential during the initial three hours of observation remains at -40 to -60 mv. From three to six hours there is no overshoot even with maximal stimuli, however there are graded responses. These responses which vary with the stimulus do not show a further widening than seen at three hours. After six hours, it is extremely difficult to elicit action potentials. Control electrophysiologic observations lasting up to 24 hours did not show the changes observed with virus-infected cultures. Light microscopic observations show that there are no observable cytological changes in the nerve cell bodies at six hours when pronounced electrophysiological changes are observed. EM evidence to confirm virus infection of the DRG cells is currently being conducted.

1252 GRAFT-VERSUS-HOST DISEASE IMPAIRS BRAIN DEVELOPMENT. W. Sue T. Griffin, Mauro F. Pacheco, and Judith R. Head*. Department of Cell Biology, Univ. of Texas Health Science Center at Dallas, Dallas, TX 75235.

We previously described production of brain damage in infant rats subjected to graft-versus-host disease (GVHD) caused by foreign lymphocytes reacting against host alloantigens. Presented here are the effects of GVHD on the cytoarchitecture of the cerebellum. Using hematoxylin and eosin stained 7 μm midsagittal sections, various parameters were assessed including: 1) Counting the number of cells in the cerebellar layers; 2) Calculating the total midsagittal area; and 3) Measuring the surface area of the cerebellum. GVHD was procured by injecting 40 x 10^6 parental strain lymph node cells into (Fischer X DA)F_1 hybrid rats on the day of birth. The grafted lymphoid cells attack the lymphomyeloid tissue of the neonatal host, resulting in a fatal wasting syndrome which was well-developed by postnatal day 14, the day of sacrifice. Uninjected littermates served as controls. Total cerebellar area was decreased in GVHD-affected animals by 9% but the perimeter was not significantly altered, indicating a greater change in the internal organization than external surface area. Compared to other layers the external granular layer was most affected by GVHD, having only 67% of the area found in control tissue ($p < 0.05$). The molecular layer was not significantly affected, but the internal granular layer was obviously smaller (87% of control values, $p < 0.05$). The number of cells in the external granular layer was 2.8 ± 0.1 cells per 100 μm^2 in cerebella from GVHD animals compared to 3.7 ± 0.1 in controls (75%, $p < 0.05$). The number of Purkinje cells in lobule VI was also reduced on a per mm^2 basis (84% of control, $p < 0.05$). These data suggest that in addition to a decrease in the number of cells available for mitosis which would result in a smaller internal granular layer, there may be some cell death as indicated by the decrease in Purkinje cells. The cerebellum appeared normal with regard to gross morphological parameters such as layering, and there was no lymphocytic invasion, ruling out the possibility of a cell-mediated attack on cerebellar cells. We postulate that a blood-borne factor is causing a decrease in cell proliferation and function in this disease which is a potential factor in perinatal induction of mental retardation. (Supported by NIH NS14663-01).

1253 ACTIVITY LEVEL MEASUREMENTS AS AN INDICATION OF MUSCULAR WEAKNESS IN EXPERIMENTAL AUTOIMMUNE MYASTHENIA GRAVIS. I. J. Griffith, J. A. Lettieri*, N. L. Norcross*, M. E. Eldefrawi*. Dept. of Microbiology, New York State College of Veterinary Medicine, Cornell University, Ithaca, NY 14853, and Dept. of Pharmacology and Experimental Therapeutics, University of Maryland School of Medicine, Baltimore, MD 21201.

Recently an animal model of myasthenia gravis (MG) has been developed. This model, designated experimental autoimmune myasthenia gravis (EAMG), has proven to be extremely valuable in elucidating the pathogenic mechanisms involved in MG. It is likely that this animal model can also be a valuable aid in evaluating various agents for their effectiveness in the treatment of MG. This type of study has been complicated by the lack of a simple and objective means of precisely determining the extent of muscular weakness in the experimental animal. We have found that measurements of an animal's normal activity can provide an extremely useful means of assessing the degree of muscular weakness associated with this disease.

Studies were performed in which rats of the Lewis/MA f strain were individually housed in Wahman LC-34 activity cages. EAMG was induced in half of the animals through the inoculation of purified acetylcholine receptor protein (AChR), obtained from Torpedo ocellata, together with adjuvants. The remaining animals served as controls and received inoculation of adjuvant only. The experimental animals' activity was assessed by recording the number of wheel revolutions completed by each group during each 24 hour period and comparing the activity of the experimental group to that of the control group. It was found that animals with EAMG experienced two periods of decreased activity which corresponded to the previously reported acute and chronic phases of EAMG. During the acute phase their activity rapidly decreased from 7 days post inoculation (DPI) to 11 DPI. The experimental animals' activity then increased from 12 DPI to 19 DPI until their activity was equal to that of the control group. During the chronic phase the activity of the experimental animals gradually decreased during the period from 28 DPI to 58 DPI. The animals' activity then remained at a stable level until 80 DPI at which time the level of activity began to increase. Correlations between activity levels and immunological parameters of EAMG will also be discussed.

The results of this study indicate that activity measurements can provide a very simple and objective method of determining the extent of muscle weakness in EAMG and may prove to be a valuable method for evaluating new forms of therapy for MG.

1254 BIPHASIC EFFECTS OF MAM ACETATE ON THE DEVELOPING BRAIN. R.Haddad Ausma Rabe, Judy Shek, Ruth Dumas* and Barbara Canlon.* Neuroteratology Laboratory, New York State Institute for Basic Research in Mental Retardation, 1050 Forest Hill Road, Staten Island, N.Y. 10314.

Methylazoxymethanol (MAM) is a naturally occurring alkylating agent that is carcionogenic, mutagenic, and a CNS teratogen. It has been synthesized and is commercially available as the acetate. A single treatment during pregnancy results in a considerable variety of CNS malformations, the specific forms depending only on the time of gestation at which it is administered. Pathologic ultrastructural changes have been demonstrated within 15 minutes of treatment. Shortly after treatment massive necrotic foci are readily found in the developing brain, their loci depending on the time of treatment. In the rat treated on gestation day (GD) 15, when the cerebral hemispheres are beginning to develop, lesions are found in the cerebral hemispheres and are readily visualized within 8 hours. The result is a massive loss of cerebral neurons, resulting in micrencephaly in the young. Treatment of the rat perinatally, when the highest rate of cellular proliferation is in the developing cerebellum, causes an extensive destruction of Obersteiner's layer resulting in hypoplasia of the cerebellar cortex. However, although the acute lesions determine the subsequent mass of the affected region, there is also a chronic, biochemical, lesion which has effects that contribute to the ensuing pathologic cytoarchitecture of the affected region. Fetal brain DNA, RNA, and protein have been shown to be methylated by MAM. This may be the basis for the neurotoxic effect of MAM during the acute phase. However, the DNA of many of the surviving neurons is also alkylated. A variety of methylated bases have been detected in the brains of adult micrencephalic rats produced by prenatal exposure to MAM. It would appear that these structural alterations of the nucleic acids of the fetal brain result in metabolic changes that affect the course of neuronal migrations in the developing brain. Although all the usual structures are present (including barrels in the somatosensory cortex) in the micrencephalic brain, though on a reduced scale, the cytoarchitecture is altered. Similarly, the perinatally treated rat has not only a hypoplastic cerebellum, but one that is possessed of a grossly abnormal cytoarchitecture. The biphasic consequences of prenatal exposure to MAM Ac have recently been more clearly seen in the lissencephalic ferret (produced by treatment with MAM Ac on GD 32). In this preparation we have been able to experimentally separate the two phases. (Supported, in part, by NIH Grants MH-16610, NS-08856, NS-10409-01A1, HD-08346, 5-S01-FR-05558-08, -09, -10, and allocations from Hoffmann-LaRoche).

1255 INHERITED CANINE NEUROMUSCULAR DISORDER ACCOMPANIED BY HYPERALDOSTERONISM. G. A. Hegreberg and M. J. Hamilton* Dept. Veterinary Micro. and Path., Wash. State Univ., Pullman, WA 99164.

An inherited neuromuscular disorder of the dog characterized by general muscular atrophy and intolerance of cold and exercise stress has been reported. The disorder is not clinically apparent until the affected dogs are 3-4 months old. The disorder has a progressive course in the growing dog. However, the clinical manifestations stabilize after the dogs mature. Preliminary pedigree analysis indicates that the disorder is transmitted as an autosomal recessive trait. Both affected male and female offspring have been produced from apparently nonaffected parent stock. Serum and RBC electrolytes, including Na, K and Mg, appear similar in affected and nonaffected dogs. The disorder is accompanied by an elevation in urinary creatine excretion and depressed urinary creatinine/creatine ratio. Serum creatine phosphokinase (CPK) activity is not elevated in the affected dogs.

The most consistent and severe pathologic change involves the distribution and size of the skeletal muscle fiber subtypes, I and II. The affected dogs have a marked deficiency of type II fibers and increased variation in the diameter size of both type I and type II skeletal muscle fibers. This alteration of fiber type distribution appears to be generalized throughout the skeletal muscles of the body. Other pathologic changes include many fibers with centrally located nuclei, nuclear rowing, and mild increases in perimysial and endomysial connective tissue. Degenerative changes of the skeletal muscle fibers are minimal.

The renin-aldosterone system in adult fasted nonaffected and affected dogs was examined. Plasma aldosterone was measured using a radioimmunoassay (RIA) method adapted from Drewes, et al., on 11 affected and 4 nonaffected dogs. Aldosterone concentrations (mean $\pm$ S.D.) were 276.4 $\pm$ 127.7 pg/ml in affected animals, and 126.8 $\pm$ 54.9 pg/ml in the nonaffected dogs. Plasma renin activity (PRA) was estimated with RIA for angiotensin I, modified from Haber, et al., in 26 affected and 6 nonaffected dogs. PRA (mean $\pm$ S.D.) was 0.930 $\pm$ 0.817 ng/ml/hr in affected dogs and 0.970 $\pm$ 0.912 ng/ml/hr in nonaffected dogs. The plasma aldosterone levels were significantly increased in the affected ($p < 0.05$). The PRA was not significantly different in the affected and nonaffected dogs ($p > 0.1$). Plasma cortisol levels evaluated by RIA in 12 affected and 8 nonaffected adult dogs were not significantly different.

This disorder will provide an important experimental model for the study of the control of aldosterone production and for comparisons to similar human disorders. This disorder will also be useful for comparison with other muscle disorders with similar histochemical changes, including aging changes of muscle.

(Supported by NIH grants RR00515, FR5465, and the MDAA, Inc.).

1256 EFFECT OF INSULIN-INDUCED HYPOGLYCEMIA ON THE BLOOD BRAIN BARRIER. Dora W. Hsu* and E. Tessa Hedley-Whyte. Dept. Path. New England Deaconess Hospital, Harvard University, Boston, MA 02215

Hypoglycemia was induced in mice (30-35 g) by intraperitoneal injection of 8 units of crystalline zinc insulin. Horseradish peroxidase (HRP, 10 mg in 0.1 ml saline) was injected i.v. 15-20 min prior to sacrifice. After per cardiac perfusion with Karnovsky's fixative, brain slices were examined for HRP extravasation along blood vessel walls and into cerebral parenchyma. Plasma glucose levels were determined at time of sacrifice. 16 of 19 mice with severe hypoglycemia (lethargy, stupor) developed generalized seizures. The 3 mice without seizures and 14 of the 16 showed diffuse focal parenchymal extravasations of HRP. A ruptured blood vessel with one or two red blood cells was found in the center of 10 to 18% of the focal exudates. Five of 6 mice with moderate hypoglycemia (40-80 mg%) compared to 2 of 8 normal mice showed occasional HRP parenchymal accumulations. The number of HRP stained segments of vessel walls was less in the insulin treated mice compared to the untreated mice.

These observations contrast with the patterns observed in hypertension and hypervolemia where both the number of stained vessel wall segments and parenchymal accumulation of HRP increase concomitantly. Although experimentally induced seizures are accompanied by increased leakage of HRP into brain, ruptured vessels in the areas of leakage are rarely seen in contradistinction to the severely hypoglycemic mice. We conclude that insulin-induced hypoglycemia is associated with: 1) an increase in cerebrovascular permeability to HRP with focal extravasation into brain parenchyma; and 2) a decrease in the normal transit of HRP across segments of cerebral vessels.

1257 NEUROPATHOLOGY PROBLEM SOLVING EXERCISES. M. Z. Jones, S. Mullis, K. L. Lovell, C. Watson, T. Jenkins, M. Goetting, and B. Vincent. Dept. Pathology, Mich. State Univ., E. Lansing, MI 48824.

Neuropathology Problem-Solving Exercises (NPPSE) were developed to provide the freshman medical student with the opportunity to practice, reinforce and synthesize the basic concepts of cerebrovascular, traumatic and neoplastic diseases of the nervous system. Case materials were adapted by utilizing modified programmed instruction techniques. Objectives, instructions and pretests preceded the clinical problem-solving aspects of the NPPSE. Students were then asked to predict the gross and microscopic pathological findings on the basis of the problem cues. Directions followed which guided the student through the gross and microscopic examination. Completion of a clinicopathological correlation and construction of a final neuropathological diagnosis were expected within one hour. Aids included diagrams, labelled photographs and ancillary diagnostic study reports. The modified programmed instruction format provided immediate feedback. Through this means, real and complex neurological problems were introduced to first year medical students, and objectives relating to common neurological diseases were reinforced. Preliminary analysis of evaluations by students revealed a high level of subjective satisfaction with the effectiveness and efficiency of this learning exercise. Similar exercises can be devised for other clinical or basic neurosciences in order to assure optimal practical experience or to monitor problem-solving ability at different points in a graduate or professional educational program.

1258 IMPROVED METHOD FOR INTRACEREBRAL INPLANTATION OF TUMOR CELLS IN RATS. Naoki Kobayashi*, Nancy R. Clendenon, and Norman Allen. Div. Neurol., Coll. Med., OSU, Columbus, Ohio 43210.

A reproducible tumor model is essential for the study of experimental treatment of tumors. Our present free-hand intracerebral implantation technique, using young rats whose skulls are sufficiently soft so as to permit direct needle puncture has advantages of simplicity and rapidity of procedure. Disadvantages include leakage of cells outside the skull with subsequent growth of large extracranial (EC) masses, intracranial extracerebral (IEC) growth, and intraventricular leakage resulting in spinal cord and brain stem metastases. Studies using a spongioblastoma cell line showed regression of intracerebral (IC) tumor growth with cranial irradiation; however, 38/97 rats inoculated in this manner had spinal or brain stem tumor growth and 8 developed extensive EC masses.

Recently, we compared these results with the following modifications: 1) semi-stereotaxic percutaneous injection with 10 µl tumor cell suspension in phosphate buffered saline; 2) same as 1) but with 1% agar in the cell suspension (Sobue et al,.Igaku no ayumi 101:542, 1977);3) modified stereotaxic injection (Barker et al, Cancer Res.33:976,1973) with the same tumor cell suspension as in 1); 4) same as 3) but with 1% agar; 5) same as 4) but with a 5µl injection volume containing the same cell number. Inbred CDF male rats received 10^4 spongioblastoma cells into the center of the right caudate nucleus. Prior to sacrifice (24 hrs) on day 28, rats were given Trypan blue so that extent of tumor growth and edematous zones would be visually apparent and measurable in formalin fixed samples. Products of the largest diameters (in mm) of three dimensions were taken as indices of tumor size. Dissected tumor samples were blotted dry and weighed. Preliminary studies using Trypan blue established the optimal injection site so as to avoid subarachnoid or intraventricular leakage.

The following results were obtained: in 1) no IC growth was seen in 9 rats studied; 2) IC growth was observed in 6/10 rats but for 5 of 6 the size and weights were very small; in addition, 8/10 had IEC growth of various sizes and 7/10 had EC masses: 3) IC growth was found in 8/9 animals but all 9 had IEC and 2 had EC masses; 4) all 11 rats had adequate IC tumor growth (mean size index = 96.8± 56.3(SEM); 5/11 however, had small IEC and one had a small EC mass; in 5) although 10/11 rats had IC growth, the mean size index was very small (7.8±2.6); 2/11 had small IEC growth, but no EC growth was noted. No spinal cord nor brain stem metastases was detected in these studies. Further studies using method 4 yielded only one IEC, and one EC mass for the 19 animals inoculated.

In conclusion, stereotaxic injection into the center of the caudate nucleus with a 10µl injection volume containing 1% agar (4) appears to be the best method for intracerebral transplantation of tumor cells in rats. (Supported by NIH grant No. CA-20348.)

1259 HISTOENZYMATIC STUDIES ON EXPERIMENTAL BRAIN CONCUSSION. Joseph C. Lee, Hin Ching Liu* and Louis Bakay*. Dept. Anat. Sci., Univ. Okla. Health Sci. Ctr., Box 26901, Okla. City, OK 73190

Brain concussion was produced in rats after absorbing an energy of 1,450gm/cm by a blow of a specially-constructed iron pendulum at the external occipital protuberance. From 5 min to 62 hr, the brain and upper spinal cord were processed for electron microscopic and histoenzymatic studies. Electron microscopy showed severe swelling of neuronal mitochondria in the occipital cortex, cerebral edema in the frontal lobe, and both changes in the craniospinal junction at 30 min, reached a peak at 1 hr and disappeared at 24 hr after concussion. The activities of succinic dehydrogenase (SDH) became stronger in neurons of the cerebellar cortex, medulla and spinal cord 5 min post-concussion, and in the occipital cortex 15 min later, but not in the frontal cortex. The increased activites returned to the normal level 1 hr after concussion. No changes were observed in the activity of cytochrome oxidase in neurons of the above-mentioned regions. In glial cells, these two mitochondrial enzymes remained strong before and after concussion. The alkaline phosphatase (APase) activities reduced in blood vessels at 5 min, disappeared at 15 min, and returned to the normal level 62 hr post-concussion. No significant changes were found in the butyrylcholinesterase activity throughout the experimentation. We conclude that brain concussion activates SDH and reduces APase activities, which result in mitochondrial swelling and cerebral edema, respectively, in those regions of the central nervous system paralleling our electron microscopic observations.

1260 LONGITUDINAL ELECTRORETINOGRAPHIC AND PATHOLOGICAL CORRELATES OF ALUMINUM-INDUCED RETINOPATHY IN RABBITS. A.A. Lidsky, C.M. Miezejeski, G.Y. Wen*, H.M. Wisniewski*. NYS Institute for Basic Research in Mental Retardation, Staten Island, NY 10314.

ERG's were obtained in awake rabbits two and three times weekly, both before and following a single intravitreal injection of 100 µl of 1% aluminum chloride in one eye and an equal volume of physiological saline in the other. Ophthalmic neosynephrine and tetracaine hydrochloride were applied preceeding insertion of Burian-Allen contact electrodes. Each eye was stimulated separately using one per second and 10 µsec duration flashes at each of three stimulus intensities (I=1, 4, and 16 on a Grass PS-22), and 30 Herz flicker of intermediate intensity. Individual animals were sacrificed at intervals from four to sixty days after aluminum treatment and their retinas were assessed morphologically.

Progressive reductions were found in the amplitudes of all components of the ERG, under all stimulus conditions. Single flash stimulation at I=16 produced the earliest nonreversing reductions in b-wave (7-8 days) and c-wave (3-6 days) amplitudes in the aluminum versus saline-treated eye. The a-wave attenuations were delayed to 11-33 days after treatment. Responses to flicker were immediately reduced by approximately 40% in both control and aluminum eyes, but while amplitudes in the former recovered to pre-injection levels within a few days, responses of the aluminum eyes progressively declined to less than 1/3 of either the pretreatment or control eye amplitudes at 40 days. Morphologically, neurofibrillary tangles were identified in both ganglion and bipolar cell layers within 7-14 days after aluminum injection. Other degenerative changes, including fragmentation of rods and cones and focal pyknosis, appeared in individual retinas within 14 days, with progressive loss of pigment epithelium and photoreceptors thereafter. The sequence of tangle formation and cellular degeneration, beginning with ganglion cells, then bipolars and photoreceptors, is consistent with other findings on ocular metallosis, with the ERG identifying both early and progressive events in the bipolar layer, pigment epithelium and photoreceptors.

1261 INFARCTION THRESHOLD IN THE BASAL GANGLIA AND ADJACENT STRUCTURES DETERMINED BY CEREBRAL BLOOD FLOW MEASUREMENT DURING MIDDLE CEREBRAL ARTERY OCCLUSION IN UNANESTHETIZED MONKEYS. Frank W. Marcoux, Richard B. Morawetz*, James H. Halsey, Jr.*, and Umberto DeGirolami*. Neurosciences Program and Departments of Neurosurgery and Neurology, University of Alabama at Birmingham, Birmingham, Alabama, 35294.

Unanesthetized macaque monkeys were subjected to middle cerebral artery (MCA) occlusion. Local cerebral blood flow (CBF) was measured from electrode sites in cortical and subcortical gray and white matter by hydrogen clearance. Two to four weeks following ischemic insult, histologic examination documented cerebral infarction and its precise relation to CBF recording sites.

Residual CBF during MCA occlusion was found to correlate closely with incidence and character of infarction. When residual CBF fell below 12 cc/100/g/min for 2 hrs or more, infarction invariably occurred around the electrode tip. The infarction threshold for ischemic durations of less than 2 hrs is under investigation and appears to fall off rapidly at around 1 hr.

The incidence of infarction correlates with an absolute level of residual CBF rather than a percent fall from pre-ischemic level and this correlation holds for both gray and white matter.

Since blood flow and metabolism are consistently reported lower in white matter than gray matter, it has been presumed that white matter can withstand greater degrees of ischemia than gray. Our data do not support this assumption. When CBF fell and remained below 12 cc/100g/min during 2 or more hrs of MCA occlusion, infarction always occurred in putamen and caudate as well as in capsular and insular white matter.

This finding provides insight into the patho-physiology of ischemic stroke and describes a model with which therapies can be given trial to determine their effectiveness in interrupting the progression to irreversible cell damage.

This work supported in part by NIH Grant NS08802.

1262 FATTY ACID COMPOSITION OF HUMAN ERYTHROCYTES IN DUCHENNE MUSCULAR DYSTROPHY. COMPARISON WITH NORMAL AND NEUROMUSCULAR DISEASE CONTROLS. Jack McLaughlin and W. King Engel. Med. Neurol. Br., N.I.H., Bethesda, MD 20014

Minor compositional changes in phospholipids are among the many reported and disputed "defects" of erythrocyte membranes in Duchenne muscular dystrophy (DMD). Howland and Iyer (Science 198: 309, 1977) have recently reported that a large decrease in palmitoleic acid content of erythrocyte membranes of patients and carriers of DMD was disease-specific and suggested that a defect in membrane triglyceride metabolism is the primary enzymatic lesion in this disease.

We have determined the total fatty acid composition of human erythrocytes from patients with DMD, definite carriers of the disease, and a large number of normal and neuromuscular disease controls. Erythrocytes were thoroughly washed to remove platelets, leukocytes, and plasma, and lipids were extracted, using methods recommended by Nelson (Blood Lipids and Lipoproteins: Quantitation Composition, and Metabolism, Wiley-Interscience, 1972). Sample degradation was avoided by the use of low temperatures, antioxidants, and deoxygenated solvents. Fatty acid methyl esters were prepared with quantitative yield by the method of Morrison and Smith (J. Lipid Res. 5: 600, 1964), purified by thin-layer chromatography, and analyzed using a HP Model 5830A gas chromatograph equipped with a digital integrator. The compositional data obtained for normal controls agreed closely with recent literature values (Nelson, ibid.). We detected no change in any aspect of the fatty acid composition of erythrocytes of patients with DMD or definite carriers of the disease from that of normal controls, from patients with myotonic muscular dystrophy, or from the neuromuscular disease control group (including cases of amyotrophic lateral sclerosis, myositis, polymyositis, myotonia congenita, and other disorders). For example, palmitoleic acid data (area % ± S.D.) were as follows:

Normal Controls (N=11)	0.76 ± 0.14
DMD (N=9)	0.81 ± 0.12
Definite Carriers of DMD (N=3)	0.73 ± 0.08
Myotonic Muscular Dystrophy (N=7)	0.73 ± 0.07
Neuromuscular Disease Controls (N=25)	0.81 ± 0.15

Total plasma levels of palmitoleic acid after an overnight fast were determined in separate experiments and again no significant differences were found: Normal Controls, 2.32 ± 0.38% (N=8); DMD, 2.66 ± 0.51% (N=6); and definite carriers of DMD, 2.43 ± 0.17% (N=3).

We conclude that at this level of analysis erythrocyte total fatty acid composition, including the relatively minor palmitoleic acid component, is not altered in DMD.

1263 PRIMARY TEMPORAL DEGENERATIVE RESPONSE IN THE SEVERED NEWT (Triturus viridescens) OPTIC NERVE. Linda L. Phillips and James E. Turner, Dept. Anat., Bowman Gray Sch. Med., Wake Forest Univ., Winston-Salem, NC 27103.

The primary response to trauma in the CNS involves supportive glia which, invariably participate in the degenerative process. The glial role in removal of cell debris is shown to be underway in the transected newt optic nerve at 6 and 1/2 hours post lesion (p.l.) (Anat. Rec. 187: 291, 1977; Anat. Rec. 190: 510, 1978). The previously reported removal appears to involve an organized interaction of the glia with both non-myelinated (nmf) and myelinated (mf) fibers, however, these studies failed to establish an initiation time and sequential characterization of the response to lesion. The present study examined the transected newt optic nerve at earlier time periods, seeking the initial stages of reactivity. Newts were anesthetized, left orbital nerves cut and animals sacrificed through various fixation procedures 5, 15 and 30 minutes p.l. Nerves were removed, processed for microscopic examination at the light and EM levels. Unoperated and sham operated nerves served as controls. At the light level, nerves examined 5 minutes p.l. appear comparable to controls, with a slight decentralization of the glial nuclei. In addition, a width increase in juxtanuclear cytoplasmic processes of the glia is seen in the 15 minute group. With EM examination, the neuropile at 5 minutes p.l. appears unaltered from that of the controls, intact mf are visible throughout the nerve, and there is absence of any glial organization of the nmf population into 'digestion chambers' seen in the later stages. Movement toward the reactive state of 1/2 hour is seen at 15 minutes p.l., with glia beginning to section groups of nmf into 'chambers' in the central region. Concurrently, 'hillocks' of glial cytoplasm are visible and contain numerous mitochondria at branch points of the 'chamber' segregating processes. These alterations decrease with progression in the central to peripheral direction of the nerve cross-section. At the periphery, glial processes remain attenuated, as in the control nerves. The central mf, adjacent to the reactive glia show a dual population at 15 minutes p.l., some normal in cross section, others collapsed and encircled by the expanding supportive cells. These observations suggest that the degenerative response in the severed newt optic nerve occurs as a temporal sequence of events within the first 1/2 hour p.l. and is carried out in part through a highly reactive glial population.

1264 LOCOMOTOR EFFECTS OF CATECHOLAMINERGIC DRUGS ON HERPES-INFECTED MICE. Richard F. Seegal and John E. Hotchin*. Division of Laboratories and Research, New York State Department of Health, Albany, NY 12201.

Many central nervous system virus infections alter brain catecholamines; yellow fever vaccine virus, West Nile virus, Coxsackie virus (Lycke and Roos, J. Neurol. Sci. 26, 1975). We have employed changes in spontaneous (S) and drug-induced (DI) locomotor activity to assess long-term central nervous system (CNS) infection with herpes type 1 virus (HSV). A dual HSV inoculation procedure was used: the animals received an immunizing foot-pad (FP) dose of .03 ml of a 10^{-2} dilution of HSV followed at two weeks by an identical intra-cerebral (IC) inoculation. Based on IC inoculation in mice, this HSV had a titer of 9.9×10^5 LD_{50}/ml. Animals were tested with IP injections of saline and 0.5 and 2.0 mg/kg d-ℓ-amphetamine (an indirect-acting dopamine agonist) immediately following FP and FP-IC HSV and 4 weeks following FP-IC HSV. FP-HSV had no effect on S or DI activity, whether given as a single or multiple challenge injection. FP-IC HSV when tested days 3-8 post IC depressed both S and DI activity. FP-IC HSV when tested days 28-33 post IC depressed DI but not S activity. IP injection of 5.0 mg/kg d-ℓ-amp overcame the HSV block of DI activity. IP injection of apomorphine (a direct dopamine receptor agonist) in FP-IC HSV mice produced less suppression of DI activity than in controls. These results suggest that chronic CNS HSV produces hypoactivity (compared to hyperactivity in acute IC only herpes, Lycke and Roos, J. Neurol. Sci. 22, 1974) and that based on the differential effects of d-ℓ-amphetamine and apomorphine in HSV infected and control mice, the effect may be due to alterations in either the number of, or the sensitivity of the post-synaptic dopaminergic receptors.

1265 TRANSPLANTED CARCINOMA DEVELOPMENT AND GROWTH: EFFECTS OF ISOLATION, INESCAPABLE SHOCK AND COPING STYLE. L.S. Sklar* and H. Anisman* (SPON: Z. Amit). Department of Psychology, Carleton University, Ottawa, Ontario.

Among the various physiological (ulceration, thymus changes), behavioural (escape deficits) and neurochemical (catecholamine depletions) effects induced by inescapable stressors, several reports are available which indicate that model stressors (e.g. shock, restraint, isolation) will influence the development and growth of carcinomas. Whereas considerable attention has been paid to the role of coping factors in producing the behavioural and neurochemical variations induced by stress, scant attention has been devoted to the role such factors play in affecting carcinogenesis. Moreover, research in this field has not differentiated between other variables (e.g. acute vs. chronic stress, housing conditions) which influence both the neurochemical and behavioural consequences of stress. Work in this laboratory revealed that stress in the form of isolation will exacerbate the appearance and growth of a transplanted tumor line (P815 mastocytoma). Isolation also resulted in reduced survival time among recipient mice. As in the case of isolation, exposure to a single session of 60 inescapable footshocks increased tumor size and rate of death among aggregated mice but not among isolated animals. The effects of a single shock session were ameliorated if mice were chronically exposed to shock. Finally escapable shock was not as effective as inescapable shock in exacerbating the tumor growth. Data are discussed in terms of stress effects on neurochemical activity, hormonal changes and variations in immunosuppression.

1266 A STREPTOZOTOCIN INDUCED MODEL OF DIABETIC NEUROPATHIES IN MICE. Robert W. Stach* and Norman R. West. Depts. Biochem. and Anat., SUNY Upstate Med. Ctr., Syracuse, NY 13210.

Destruction of pancreatic islet β cells with streptozotocin consistently produces hyperglycemia in Jackson Lab C57BL/KSJ mice, a high percentage (>90%) of which express neurological disorders within 3-8 weeks, making this a useful model for studying diabetic -like neuropathies. This is the mouse strain from which the mutant diabetic strain C57BL/Ks(db/db) is derived and in which Sima and Robertson (Acta Neuropath. 41:85,1978) recently reported spontaneously occurring neuropathies after long survival times. Streptozotocin injected male mice, 200 mg/Kg i.p., become progressively hyperglycemic such that 30 days after a single injection their blood glucose levels, obtained by retro-orbital bleeding and the serum assayed with a Beckman Glucose Analyzer, reaches 816 ± 40 mg/100 ml versus control levels of 151 ± 14 mg/100 ml. Despite their greater food and water intake per week, the hyperglycemic mice lose weight, 25.6 ± 1.7 gm and 25.5 ± 0.7 gm in 60 and 90 day old controls respectively versus 19.9 ± 1.3 gm at 30 days post injection (n=12/group). Behavior modification can be described in 5 stages; 1)fore and hindlimb extension, 2)arching of thoracic spine and decreased grooming habits, 3) hindlimb weakness, general slowing of movements, 4) decreased mobility, intension tremor and ptosis, and 5) death. Stages 2 through 5 typically occur over a 3 to 5 day period. The time course for onset and duration of the behavioral affects is quickened in older mice. Muscular alterations, observed by Stearns, et al. (personal communication) are undoubtably responsible for some of the observed behavioral changes. Structural changes observed in hindlimb mixed sensory-motor nerve fibers were similar to those described by Jakobsen (Diabetol. 12:539,1976) in streptozotocin induced hyperglycemia in rats. These include decreased axonal diameter and a slight widening of the nodal gap. In addition, the sympathetic superior cervical ganglia are observed to decrease in size, apparently due to the reduced size and number of unmyelinated fibers which is demonstrable in the postganglionic carotid nerves. The ganglionic neurons do not appear altered although they are more closely packed. The ganglion capsule does not constrict in size. Satellite and Schwann cells do not appear altered when associated with neurons or fibers, but some Schwann cells are associated with very few fibers and therefore more of their cytoplasm is evident. Thus, in later stages of streptozotocin induced hyperglycemia, autonomic neuropathies are present along with the previously described sensory-motor lesions.

1267 CRITERIA FOR HISTOPATHOLOGICAL EVALUATION OF MENINGEAL & CORTICAL CHANGES RESULTING FROM CHRONIC ELECTRICAL STIMULATION. Suzanne S. Stensaas, Dept. of Anatomy, Univ. of Utah, S.L.C., Ut. 84132

A method for quantitatively analyzing histopathological changes resulting from electrical stimulation of meningeal and cortical tissue has been devised, since previous attempts to qualitatively estimate changes had failed to discriminate between different stimulus parameters. The new method combines light and electron microscopy, thus allowing a detailed analysis of all the reactive cellular constituents. Standard values for a square area of normal tissue were established. An average was taken from 3 sample fields of experimental material for comparison. This procedure allows for an analysis of acute changes following short periods of stimulation as well as the detection of subtle changes following long periods of stimulation. Counts were made at fixed levels and consistently revealed a gradient of reactive changes.

Meningeal and cortical samples from beneath electrodes which had been stimulated for various periods of time through a chronic indwelling teflon-platinum array were studied. The reactive changes extended from the electrode surface toward the cortex with clear signs of attenuation by the capsule, neurothelium and leptomeninges. These changes were most pronounced under the reference electrode which served as a common ground. Macrophages within the capsule were engaged in the breakdown and removal of this necrotic material. Analytical electron microscopy revealed the presence of platinum within these capsular macrophages. Leucocytes and plasma cells in the leptomeninges indicated that the localized inflammatory response could extend to the cortical surface.

In general, the cortical changes were less pronounced than those of the capsule. Specific cortical measurements were made in the following general categories: neuronal constituents, glia, blood vessels and exogenous cells. Large dendrites, degenerating myelinated axons, degenerating neurons and normal neurons were counted in the first category. Edematous profiles, hypertrophic astrocytes, phagocytic astrocytes and reactive glial cells were counted in an effort to identify glial changes. In addition, the distribution of macrophages and leucocytes in the parenchyma and around blood vessels as well as the presence of plasma cells was noted.

A standardized quantitative method has now been developed which should permit investigators from different laboratories to evaluate their material in a similar manner. This could facilitate comparisons between different electrode sizes, parameters, materials and species. (Supported by the Surdna Foundation.)

1268 MODULATION OF LYMPHOCYTE RESPONSES BY GANGLIOSIDES. Scott Stewart*, Ronald Whisler* and Allan Yates. Depts. of Path. and Med., Ohio State Univ., Columbus, Oh. 43210.

Gangliosides are sialic acid-containing glycolipids present in high concentration in nervous tissues, especially in cerebral grey matter, but have been found in many extraneural tissues as well. Although their biologic functions are unknown, specific gangliosides present in lymphocytes[1] can modulate B lymphocyte responses to antigen stimulation.[2] In the present study we have investigated the effects of several gangliosides on lymphocyte reactivity in response to concanavalin A (Con A) and to allogeneic cell stimuli.

Normal human peripheral blood mononuclear cells were incubated with an optimal dose of Con A or in a one-way mixed leukocyte reaction (MLR) in the presence of 3.1 nanomoles of a purified ganglioside isolated from normal human cerebral cortex. Cell viability exceeded 85% in all cases as assessed by trypan blue exclusion.

Of the four gangliosides tested, G_{D1B} and G_{T1B} completely inhibited tritiated thymidine uptake both in response to Con A and in the MLR. In contrast, G_{M1} resulted in only 58% and 8% inhibition for Con A and the MLR respectively. A preparation of G_{D1A} containing 10% G_{D1B} inhibited the Con A response 28% and the MLR 37%. These results indicate that G_{D1B} and G_{T1B} can modulate lymphocyte responses to a greater extent than can G_{D1A} and G_{M1}. The mechanism of modulation may involve recognition of the 2→8 sialic acid-sialic acid moiety, the only structure common to G_{D1B} and G_{T1B} but not shared by G_{M1} and G_{D1A}.

1269 REPEATED THIAMINE-DEFICIENT ENCEPHALOPATHY IN THE MOUSE: LIGHT AND ELECTRON MICROSCOPIC STUDY. Itaru Watanabe and Masayo Watanabe.* VAH, Kansas City, MO 64128 and Dept. Path. Oncol., Univ. Kans. Med. Ctr., Kansas City, KS 66103.

Pyrithiamine-induced acute thiamine-deficient encephalopathy in the mouse (PIATDEM) is an animal model of human Wernicke-Korsakoff syndrome, produced in 10 days by combined administration of thiamine-deficient diet and daily injection of pyrithiamine (PT). With a sufficient amount of thiamine (T) (100 X dose of administered PT), the neurologic symptoms can be reversed, if T is given within a few hours after the onset. The early morphologic changes in the brain consist of edema of astroglia and myelin sheath and multiple petechiae, and can also be reversed by T treatment.

In this experiment, 10-day courses of PIATDEM attack were repeated three times within a total 10-weeks period, which also included two alternating courses of T administration consisting of initial therapeutic dose and, after neurological recovery, of maintenance dose.

In the brains of the mice sacrificed at the end of the second T treatment period, gliomesenchymal scar lesions were seen in the thalamus, mammillary body and pontine tegmentum. The mild lesions were recognized only by the presence of some microglial cells and a few hemosiderin-containing macrophages. No cell edema was seen. In the 12 mice sacrificed immediately after the neurological onset of the third PIATDEM attack, there were astroglial and myelinic edema in these sites of the brain. The edematous lesions were fewer, smaller and milder than those after the first attack. In the scarred areas, where no astroglial cells remained, only myelinic edema was seen. In some lesions of the thalamus, only astrocytes in the gray matter selectively showed edema necrosis. In the mammillary body, only hemorrhagic lesions were seen, but edema-necrosis did not occur. In all the lesions examined, the nerve cell alteration was slight. These findings suggest that PIATDEM is primarily a vascular and glial disorder in the brain. There are significant differences in sensitivity to this condition among vasculature, astroglia and myelin (or oligodendroglia) from a lesion to the other, depending upon local anatomical and pathological conditions. This has become more obvious in the repeated encephalopathy.

1270 NEUROPATHOLOGY OF "VIBRATOR" - A NEUROLOGICAL MUTATION OF THE MOUSE. William R. Weimar and Richard L. Sidman, Dept. of Neuroscience, Children's Hosp Med. Center and Dept. of Neuropathology, Harvard Medical School, Boston, MA. 02115.

Vibrator (vb) is an autosomal recessive mutation on chromosome 11 (P. Lane, The Jackson Laboratories, Bar Harbor). Affected mice display a coarse tremor of trunk, head and limbs during activity, beginning on about postnatal day 9 (P9) (Sidman et al., "Catalogue of Neurol. Mutants of the Mouse"). Initially vb/vb executes tasks such as grooming, exploring and nibbling food with almost the same facility as its +/- littermates. However its condition deteriorates rapidly during the 4th week of postnatal life and affected mice are not known to live beyond 30 days.

Following fixation by perfusion with 1/2 strength Karnovsky's fixative, brains were embedded in celloidin and sectioned serially at 20 um. Alternate sections were stained with cresylecht violett and by the Loyez method for myelin respectively. The brains of 5 vb/vb (P24) and 3 +/- littermate controls were surveyed in coronal (2 + 1), sagittal (2 + 1) and horizontal (1 + 1) planes of section Macroscopically, the vb/vb CNS appeared normal.

In all vb/vb brains examined, abnormal neurons were a consistent and prominent feature of the following CNS regions: (1) lat. vestibular nuc. ++++; (2) red nuc. ++++ (esp. magnocellular div.) (3) large neurons in the brain stem reticular formation +++ (including magnocellular nuc., central-caudal pontine nuc., reticular nuc. of pontine tegmentum, central-oral pontine nuc., and the central nuc. of ventral medulla oblongata); (4) the medial, interpositus and lateral deep cerebellar nuclei +++; (5) mesencephalic reticular formation +/++; (6) thalamic reticular nuc. +/++; (7) nuc. of the incertotectal tract +; (8) zona incerta +; and (9) lat. corticohypothalamic tract +. Signs of cellular abnormality included perinuclear chromatolysis, nuclear eccentricity, and ballooning of the soma with varying degrees of severity. In addition, most abnormal neurons contained large, clear cytoplasmic vacuoles, sometimes to the apparent exclusion of the usual organelles. Larger neurons were particularly prominently affected.

The Loyez method revealed no primary abnormalities in myelin. Also of interest is the lack of pathological changes in either the cerebellar cortex or the olivary nuclei, despite the marked changes in deep cerebellar nuclei and in most cerebellar-related nuclei of the brain stem.

Allelism tests between vb and cerebellar outflow degeneration (cod), a mutation showing a somewhat similar distribution of neuron loss were negative.

1271 HEXACHLOROPHENE RETINOPATHY IN THE DEVELOPING RATS. G. Y. Wen* and A. L. Rose*(SPON: A.A.Lidsky). Dept. of Neurology,Downstate Medical Center, Brooklyn, NY 11203 and Dept. of Pathological Neurobiology, NYS Institute for Basic Research in Mental Retardation, Staten Island, NY 10314.

Myelinopathy caused by hexachlorophene(HCP) in the CNS and PNS of rats was found to be reversible except in the optic nerve (Rose et al, 1975). This study of the retina was undertaken to clarify the pathogenesis of optic nerve degeneration in the developing rats.

A series of suckling rats (Sprague-Dawley) were intoxicated with 100-500 ppm of HCP added to the mother's diet from 9-23rd day of life and the weanling rats' diet from 23-37th day of life. There was no mortality in the animals intoxicated with 100 and 250 ppm of HCP. The LD_{50} was 400 ppm of HCP. Twelve rats were sacrificed by perfusion 7,14,21,28 days after the onset of treatment. Another eleven rats were intoxicated for 28 days and were then switched to normal diet. They were sacrificed after 30,60, 90,120,150 days of recovery period.

No retinal pathology was found in the rats acutely intoxicated with 100 ppm of HCP. The retinae of all rats treated with 250, 400, 500 ppm of HCP showed pathological changes. Mild vacuolation first appeared in the outer segment layer of retina 7 days after intoxication. Severe vacuolation in the same layer and degeneration of photoreceptor cell bodies appeared after 14-28 days. Electron micrographs showed that the vacuolation of the outer segment was due to the breakdown of disc membranes and outer membranes of rods.

In the recovery group there was no improvement in the outer segment of the photoreceptor cell. Further loss of photoreceptor cell bodies and degeneration of the inner nuclear layer were found to occur after several weeks.

This study showed that photoreceptor cells in the newborn rats are highly sensitive to HCP. The lesions are irreversible and progression due to trans-synaptic degeneration continues after withdrawal of the toxic agent. The optic nerve pathology appeared to be due to direct effect of HCP on it.

1272 EFFECT OF 5-HYDROXYTRYPTOPHAN ON THE AMPLITUDE OF LUMBAR MONOSYNAPTIC REFLEXES IN RATS WITH EXPERIMENTAL ALLERGIC ENCEPHALOMYELITIS (EAE). Susan R. White. Faculty of Medicine, Memorial University of Newfoundland, St. John's, Newfoundland, Canada A1B 3V6.

Recent evidence indicates that there is depressed sensitivity of peripheral neuronal receptors to 5-hydroxytryptamine (5-HT) in guinea pigs paralyzed with EAE (Weinstock et al., Brain Res. 125 192, 1977). The purpose of the present study was to examine responsiveness of the central nervous system to the increased levels of 5-HT in EAE paralyzed animals. The effect of 5-hydroxytryptophan (5-HTP), the immediate precursor of 5-HT, on the amplitude of lumbar monosynaptic reflexes (MSR) was tested in normal rats and in rats with hindlimb paralysis following the induction of EAE.

Intravenous injections of 50 or 75mg/kg 5-HTP failed to increase the amplitude of L_4 or L_5 MSR in EAE paralyzed rats while having a marked facilitatory effect on normal rats. Since post-tetanic potentiation tests revealed that the amplitude of the MSR could be increased above control levels in EAE paralyzed rats, these results suggest that sensitivity to 5-HT is reduced in the central nervous system as well as in the peripheral nervous system in EAE rats with hindlimb paralysis.

This research was supported by a grant from the Medical Research Council of Canada.

NEUROPEPTIDES

1273 β-ENDORPHIN-LIKE IMMUNOREACTIVITY BY RIA IN RAT BLOOD: NORMAL LEVELS AND COMPARISON TO HUMAN PLASMA. Huda Akil, Stanley J. Watson, Jack D. Barchas, and C. H. Li*.

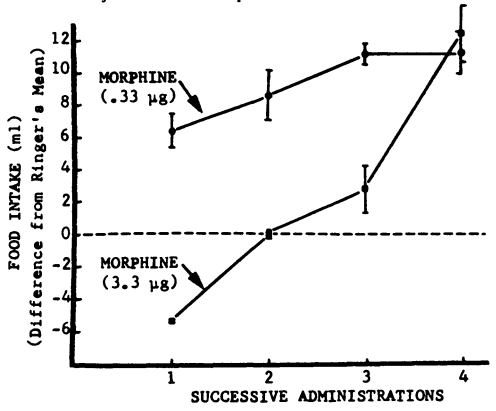
Antiserum against the C-terminus of β-lipotropin (β-LPH) has been obtained from rabbit. β-Endorphin (β-END) conjugated by carbodiimide with immunoglobulin was injected and harvested from New Zealand rabbits. The antiserum, diluted 1/1500, bound I^{125}-β-END, demonstrating an effective range from 4 pM to 10 nM. The sensitivity of the assay is 1-2 fmoles. This antibody exhibits 6-10% cross-reactivity with β-LPH. β-END-like immunoreactivity in rat blood has been detected in unextracted samples when compared to blood from hypophysectomized rats. The whole assay and calibration curves are carried out in plasma from hypophysectomized animals. β-END-like immunoreactivity can be detected in normal rat plasma (110 ± 9 fmole/ml), and exhibits substantial increases with adrenalectomy (1200 ± 24 fmoles/ml). In contrast, samples from 5 healthy normal human males gave significantly lower values when compared to plasma from hypophysectomized humans (12 fmoles ± 3.9 per ml of plasma). The human levels are at the limits of sensitivity of the assay and may be due to β-LPH or other cross reactivities.

1274 CRUSTACEAN NEURO-DEPRESSING HORMONE ACTIVATES A SODIUM PUMP IN CRAYFISH MOTONEURONS. Hugo Aréchiga and Jorge Aceves*. Dept. Physiol. and Biophys. CIEA, IPN, México 14, D.F.

The nervous system of crustaceans synthesizes and releases to the circulation a peptide which diminishes the responsiveness of sensory and motor elements, hence the denomination of Neurodepressing Hormone (NDH) (Aréchiga, H., Huberman, A. and Martínez-Palomo, A. Brain Res. 128: 93-108, 1977). The effect of NDH on crayfish motoneurons is a lowering of the spontaneous firing rate. On the other hand, in some motoneurons, the rate of firing is modulated by the activity of an electrogenic sodium pump, thus suggesting as a likely possibility, that NDH could exert its effect by acting on this mechanism. To explore this possibility, three types of experiments were conducted on isolated abdominal ganglia of the crayfish Procambarus bouvieri. a) The spontaneous electrical activity of the superficial flexor motoneurons was extracellularly recorded under continuous flow of Van Harreveld solution. NDH and other test substances were topically applied to the bathing fluid. Ouabain, a well known inhibitor of active sodium extrusion was tested on its effect on the depression induced by NDH on the firing rate of motoneurons. At concentrations between 1×10^{-5} M and 1×10^{-4} M, it reversibly blocks the depressing effect of NDH, in a concentration-dependent manner. A complete blockage of NDH action can be also obtained by removing the K^+ from the bathing fluid, another manipulation known to interfere with the activity of Na^+- K^+ exchange systems. b) The intracellular concentration of sodium and potassium was analytically determined in isolated abdominal ganglia, incubated in K^+-free solutions and then transferred to normal Van Harreveld, and the rate of the subsequent Na^+ extrusion and K^+ incorporation was found to be enhanced by NDH. c) The rate of binding of ^3H Ouabain as determined in isolated abdominal ganglia, after incubation in K^+-free solutions was decreased as a function of NDH concentration.
These results are consistent with the view that NDH depresses the spontaneous activity of motoneurons by stimulating a sodium pump.

1275 DO ENKEPHALIN SYSTEMS MEDIATE DRIVE REDUCTION? James D. Belluzzi and Larry Stein. Wyeth Laboratories, Philadelphia, PA 19101.

The possibility that enkephalin systems may regulate some aspect of reward function has been suggested by the results of self-administration, self-stimulation, and learning experiments (Belluzzi & Stein, 1977). Since narcotics "seem to produce a state of total drive satiation" (Jaffe, 1965) it has been proposed that enkephalins may mediate drive-reduction reward. If so, administration of enkephalin-like compounds should produce satiation in hungry animals. Rats had access to sweetened milk during daily 75-minute sessions. After intakes had stabilized, D-Ala^2-D-Leu^5 enkephalinamide (L, 1 μg), morphine (1 μg) or the Ringer's solution vehicle were intraventricularly administered before the daily session. Contrary to prediction, mean food intake in ml was increased over baseline both by morphine (13.8 ± 4.1) and L (5.8 ± 2.5), but not by Ringer's (1.8 ± 1.1). In a second experiment, different groups of rats received morphine (0.33 or 3.3 μg) or vehicle after partial satiation induced by 15 minutes of free access to the milk. Dosings were repeated weekly for four successive weeks. The Figure shows that on first administration the 0.33-μg morphine dose facilitated feeding whereas the 3.3-μg dose suppressed feeding. This suppressant or drive-reducing effect, like opiate analgesia, exhibited tolerance over successive administrations. Although these results are not entirely consistent with a simple drive-reduction hypothesis, they are reminiscent of, and may be related to, the dual suppressant and facilitatory effects of opiates on self-stimulation reward.



1276 POSSIBLE PHYSIOLOGICAL IMPORTANCE OF METAL BINDING BY CARNOSINE Charles Eric Brown and William E. Antholine*. Depts. of Biochemistry and Radiology, The Medical College of Wisconsin, Milwaukee, WI 53233.

Carnosine (β-alanyl-L-histidine), which has been postulated to have a role in olfaction, was observed with ^{1}HMR spectrometry to bind to the crude particulate fraction of nasal olfactory epithelium in a sterically specific orientation (Neurochemical Research 2 (1977) 555-579). In an attempt to obtain additional information that could suggest both the significance of and a possible mechanism for the observed binding, we investigated the ability of carnosine and several of its analogues to bind metal cations. The binding of Mn^{++}, Co^{++} and Cu^{++} was measured with ^{1}HMR, ESR and UV-visible absorption spectroscopy at varying concentrations of peptide and metal cation. Both the strength of binding and the structure of the complex are highly dependent upon the identity of the metal cation and of the peptide.

Mn^{++} binds only very weakly to the imidazole ring of carnosine, anserine, homocarnosine and glycyl-L-histidine ($K_{diss} \approx 40$-100mM). In contrast, Cu^{++} exhibits well defined ESR spectra when complexed to these peptides. Cu^{++} binds to the imidazole ring of these peptides when they are present in excess. In addition, carnosine and anserine produce a different complex when the concentrations of both Cu^{++} and peptide are equal. This complex is a dimer of two Cu^{++} cations that is stable in aqueous solution at room temperature and physiological pH. This complex appears to have the same structure as Cu^{++}-carnosine in the crystal. Co^{++} binds only with carnosine. The Co^{++}-carnosine complex yields an ESR signal immediately after mixing that decreases to undetectable intensity over a period of hours. Several hours after mixing the Co^{++}-carnosine complex exhibits a UV-visible absorption spectrum that is characteristic of diamagnetic Co^{++} dimers containing oxygen. Histidine and cysteine do not compete with carnosine for Co^{++}-binding; instead they produce stable mixed complexes.

Thus carnosine and anserine should affect the metabolism and availability of at least certain metal cations in those tissues that contain these peptides in high concentration (i.e. nasal olfactory epithelium and skeletal muscle). Considering reports that metals regulate heme metabolism (Maines, M. D. and Kappas, A., Science 198 (1977) 1215-1221), metal-binding by these peptides may modify the oxidative metabolism of these tissues. In addition, the observed structures of these complexes can be used to explain the substrate specificity of carnosinase.

1277 HIGH AFFINITY BINDING SITES FOR THYROTROPIN RELEASING HORMONES IN BRAIN AND RETINA: RESEMBLANCE TO PITUITARY RECEPTORS. David R. Burt. Dept. Pharmacology & Exp. Ther., Sch. Med., University of Maryland, Baltimore, MD 21201.

Thyrotropin releasing hormone (TRH) binds with high affinity (K_D = 10-30 nM) to sites in the anterior pituitary which appear to represent its physiological receptors. Similar sites were previously detected in rat brain (Burt and Snyder, Brain Res. 93: 309, 1975), but their properties were mostly obscured by the presence of a large excess of low affinity binding sites. Recently these studies have been extended to calf and sheep brains using higher specific activity [^{3}H]TRH (115 Ci/mmol) with the more potent and specific 3-methylhistidyl TRH in blank tubes. Incubations were performed in dilute phosphate buffer at 0° C for 30 or 60 min. Under these conditions no breakdown of [^{3}H]TRH was detected. Bound radioactivity was separated by filtration. High affinity binding was over half of the total binding in the results discussed below.

Discrete regions reported to contain relatively numerous variscosities immunoreactive for TRH (Hokfelt et al., Eur. J. Pharmacol. 34:389, 1975) have been found to possess relatively greater [^{3}H]TRH high affinity binding, with the nucleus accumbens possessing the greatest number of sites (1-3 pmol/g tissue wet weight in preliminary results). The retina has been found to possess a similar high level of high affinity binding, in interesting agreement with the previous report of its light-dependent TRH content (Schaeffer et al., Proc. Nat. Acad. Sci., 74:3579, 1975). Both nucleus accumbens and retina binding sites resemble pituitary receptors in their affinities for TRH and for 15 structural analogs of TRH (generously supplied by Abbott Laboratories). All 3 classes of sites appear to have the same kinetics of association and dissociation. Other aspects of this resemblance are being explored. (Supported by NIMH grant MH 29671-01.)

1278 STUDY OF OPIATE RECEPTOR SITES USING A FLUORESCENTLY LABELLED ENKEPHALIN ANALOGUE. Robert G. Canada* and M. Ashraf El-Bayoumi (SPON: J. I. Johnson). Biophysics Dept., Coll. of Human Med. and Natural Sci., Michigan State Univ., East Lansing, Mi., 48824

The objective of this investigation was to develop a new technique for visually mapping the distribution of the opiate receptor sites on the soma and/or neurites of the single amygdaloid neuron, and to examine the conformation of the met-enkephalin pentapeptide and to examine the nature of the opiate receptor's activation site(s). To achieve these goals we have successfully labelled met-enkephalin with a dansyl group at the unprotonated amino terminal, yielding N-dansyl-met-enkephalin. The attachment of the dansyl group to the pentapeptide was detected by a blue shift in its emission peak and an increase in its quantum yield; because of the nonpolar nature of the dansyl binding site on enkephalin. The unbound dansyl group in ethanol exhibited a fluorescence peak at 528 nm hence the fluorescence maximum of N-dansyl-met-enkephalin was found to be at 472 nm, and its fluorescence intensity was more than 10 times that of the free dansyl group. The fluorescence excitation spectrum of N-dansyl-met-enkephalin in ethanol has a maximum of 340 nm and a secondary peak at 270 nm. The single neurons were taken from the amygdaloid nuclear complex of a 15 da. old albino rat, maintained in dissociated cell culture for 52 days, and stained with 1.57×10^{-6}M N-dansyl-met-enkephalin in ethanol. The enkephalin-dansyl-receptor complexes appeared as a continuous green covering on the surface membrane of the neuron, with discrete blue or turquoise patches; with a fluorescence peak at 442 nm and a shoulder around 478 nm. It is argued that the hydrophobicity of the opiate receptor sites caused the blue shift in the fluorescence peak of the bound N-dansyl-met-enkephalin. The blue clusters were varied in size and shape, and located at soma-soma and neurite-soma contacts between two cells and near the connection of the neurite and soma of the same cell. Evidence suggests that the N-dansyl-met-enkephalin may stereospecifically bind to opiate receptors on isolated membrane from rat brain. The fluorescence emission maximum of 3.6×10^{-10}M N-dansyl-met-enkephalin bound to isolated membrane fragments, from rat brain regions containing a high concentration of opiate receptors, was found to be at 455 nm in 0.05M tris buffer, pH 7.0.

1279 A CLUE TO THE MECHANISM OF ACTION OF ASPIRIN: ROLE OF THYROTROPIN RELEASING HORMONE (TRH). Marthe Cohn, Stephan J. Cohn* and Major L. Cohn. Dept. Anes., Magee-Womens Hosp., Univ. Pgh., Sch. Med., Pittsburgh, PA 15213.

We have previously shown that TRH, luteinizing hormone releasing hormone (LHRH) and substance P-induced tight head to tail rotations are dopamine mediated. We have also shown that somatostatin-induced barrel rotations are acetylcholine mediated. To determine whether dopamine and acetylcholine are the only neurotransmitters mediating or modulating the peptides' functions, we studied here the effects of TRH on body temperature (T^o). We selected this particular system because: 1) TRH-induced hyperthermia in hypophysectomized and thyroidectomized rats strongly suggests that a) TRH acts centrally, b) its regulation of T^o is not contingent upon pituitary-thyroid axis; and 2) investigators reported that T^o is regulated centrally by controlled release of endogenous monoamines (i.e. epinephrine, norepinephrine, serotonin) from nerve terminals in the hypothalamus where the monoamines are found in high concentrations. Groups of male Sprague-Dawley rats were anesthetized and cannulae stereotaxically implanted into either the lateral ventricle (ICV), cerebral cortex, caudate nucleus, thalamic nuclei, hypothalamus or preoptic/anterior hypothalamic (PO/AH) areas, at least one week prior to experiment. After filtration through a millipore filter, freshly prepared solutions were microinjected into the different brain areas in concentrations ranging from 0.03 to 0.14 µM in a constant volume of 0.5 µl. While at room temperature (21-22°C), sterile solutions of saline 0.9%, LHRH, substance P, leu and met enkephalin were without effect, TRH increased T^o from 0.8 to 2.4 C for 2 to 3 hours in all brain sites tested. Exposure to either heat (38°C) or cold (6 to 8°C) did not alter TRH-induced hyperthermia, suggesting that TRH does not elicit paradoxical temperature responses. However, the PO/AH responded most dramatically to microinjection of TRH (0.014 µM) with T^o increases up to 3°C lasting from 6 to 8 hours and occasionally 24 to 48 hours. Pretreatment with cholinergic, serotonergic and catecholamine blockers (atropine, propranolol, phentolamine, pimozide, haloperidol, α-methyl-paratyrosine, parachlorophenylalanine, 5, 6 dihydroxytyramine or 5, 7 dihydroxytyramine) did not alter TRH-induced hyperthermia. However, indomethacin (50 mg/kg) injected intraperitoneally or lysine acetylsalicylate (.22-2.2 nM) injected ICV, dose-relatedly, inhibited hyperthermia induced by TRH in all brain areas. Our findings suggest that 1) T^o is centrally regulated but not in one specific brain center; 2) TRH-induced hyperthermia is not mediated by monoamines; and 3) based on dose-related inhibiting actions of indomethacin and soluble aspirin, prostaglandins may be involved in TRH T^o regulation.

1280 DISTRIBUTION OF BRADYKININ-LIKE IMMUNOHISTOFLUORESCENCE IN THE RAT BRAIN. Fernando M.A. Corrêa*, Robert B. Innis and Solomon H. Snyder. Dept. Pharmacol., Johns Hopkins Sch. Med., Baltimore, MD 21205.

In the last 10 years, several peptides first described in blood and peripheral organs have also been found in the central nervous system.

Bradykinin, a nonapeptide derived from the α_2-globulin fraction is involved in several pathophysiologic phenomena. In addition, autonomic and behavioral effects following intracerebral injection suggest a neurophysiologic role for bradykinin (J. Pharmacol. Exptl. Ther., 193:1, 1975; Neuropharmacol., 15:713, 1976). However, bradykinin and other related kinins have not been consistently shown to exist in the brain.

We have identified bradykinin-like immunoreactive structures in frozen brain slices of colchicine-treated rats by indirect immunohistofluorescence methods. The fluorescence labeling is selective since preincubation of the antibody with bradykinin but not with other peptides tested prevents its development. Cell bodies are observed only in the hypothalamus. Groups of cells are located lateral and dorsal to the third ventricle (in the hypothalamic periventricular nucleus); in a narrow arcuate zone comprising the reuniens nucleus, the zona incerta and the lateral hypothalamus; and in the ventral portion of the hypothalamic dorsomedial nucleus. Fiber-like structures appear as clearly stained, moderately dense varicosities with fine intervaricose segments. They are found in the dorsal and lateral portions of the cerebral cortex; in the pre-hypothalamic area, oriented from the diagonal tract of Broca to the lateral septal area; in the caudate and the border between the lateral hypothalamus and the globus pallidus; in the medial preoptic area, anterior hypothalamus and periaqueductal grey. Fibers are most dense in the reuniens nucleus and the ventromedial portion of thalamus and are radially oriented relative to the dorsal portion of the third ventricle. F.M.A.C. is recipient of a fellowship from FAPESP, Brasil.

1281 NEUROPEPTIDES AND PROTEIN PHOSPHORYLATION IN BRAIN MEMBRANES. Leonard G. Davis and Yigal H. Ehrlich. Univ. Mo.-Columbia, Sch. of Med., Mo. Inst. of Psychiatry, St. Louis, Mo. 63139

Recent investigations indicate that neuroactive peptides may play both mediatory and modulatory roles in synaptic function. However, the nature of the biochemical interactions underlying the involvement of peptides in neuronal activity is still largely unknown. We have selected to study the molecular mechanisms of action of neuropeptides by investigating the opiate-receptor system. In previous studies, we reported that long-term morphine treatment causes a 70% decrease in the endogenous phosphorylation of a group of specific membrane proteins designated H (MW 15-20K) and suggested that such phosphorylative modifications may be affected by changes in the balance of naturally occurring neuropeptides (Ehrlich et al, Life Sci. in-press). In the present study, we have investigated the effects of methionine-enkephalin (Met-enk) on the phosphorylation of endogenous protein substrates in brain membranes. Fractions enriched in synaptic membranes were prepared by differential centrifugation, osmotic shock and dialysis. These membrane preparations were incubated with γ-^{32}P-ATP in the presence and absence of met-enk. Reactions were stopped by the addition of SDS and solubilized membrane proteins were separated by slab polyacrylamide gel electrophoresis. Specific protein components which incorporated radioactive phosphate were identified by autoradiography of the gels. Inclusion of met-enk in the reaction mixture resulted in a decreased incorporation of radiophosphate into one group of specific proteins (MW 15-20K). The selective inhibition of phosphorylation by met-enk was found to be concentration dependent as well as a time dependent phenomenon. Both Leucine- and met-enk altered the phosphate incorporation into apparently the same specific proteins, but in a different fashion. The inhibition of the phosphorylation of these protein(s) by met-enk could be blocked by including naloxone in the reaction. Naloxone itself caused a slight elevation of radiophosphate incorporation into most all ^{32}P accepting proteins. The findings that chronic morphine treatment in vivo and met-enk in vitro selectively affect the phosphorylation of the same synaptic-membrane proteins support our suggestion that endorphine-regulated phosphorylation may play a role in mechanisms underlying narcotic dependence. Moreover, the present results and those of others suggest that neuropeptides may exert their modulatory effects on neuronal activity through mechanisms that also involve the phosphorylation of specific proteins. Supported by intramural funds from the Mo. Inst. of Psychiatry to E. G. Brunngraber.

1282 ENKEPHALINS: NEUROPHARMACOLOGICAL ROLE IN THE EXTRAPYRAMIDAL SYSTEM. B.I. Diamond, H.S. Havdala* and R.L. Borison. Anesthes. Dept., Mount Sinai Hospital, Chicago, Illinois 60608

Studies on the distribution of opiate receptors in brain have shown them to be most heavily concentrated in both the limbic and extrapyramidal systems. Moreover, it has been demonstrated that enkephalin regional distribution is largely localized to the corpus striatum. Given these facts, what role must the enkephalins play in regulating the activity of the extrapyramidal system? We have now studied this role by investigating the action of methionine-enkephalin and agents which modulate its brain levels, upon two different animal models of Parkinson's disease. One model is the induction in white male Sprague-Dawley rats of hunched back ptosis, tremor, rigidity and akinesia after the administration of reserpine (10 mg/kg). We found that the specific narcotic antagonist, naloxone, by itself, produced a reversal of reserpine-induced neurological signs (latency to reversal of 3.5 minutes). Similarly, in animals also pretreated with the catecholamine depleter α-methyl-para-tyrosine, naloxone alone was still capable of reversing the parkinsonian-like reserpine syndrome. We have also used another animal model in which rats received a unilateral injection of 6-hydroxydopamine (8μg in 4μl) into their substantia nigra. These animals rotate ipsilateral to the side of the lesion after the administration of agents which work via presynaptic dopamine release, namely d-amphetamine or phenylethylamine. The animals rotate in a direction contralateral to the lesion after the administration of directly acting postsynaptic agents such as L-dihydroxyphenylalanine (L-DOPA) or apomorphine. We found that pretreatment of animals with naloxone antagonized the rotations produced by the presynaptic agents while potentiating the number of rotations induced by the postsynaptically active agents. In contrast, administration of the amino acid d-phenylalanine, which blocks the enkephalinergic degradative enzyme carboxypeptidase A, or administration of methionine-enkephalin itself, both potentiate the actions of presynaptically active drugs, while antagonizing the effects of those compounds with a postsynaptic site of action. These data suggest to us the presence in the nigro-striatal pathway of a presynaptic enkephalinergic neuron with a facilatatory action, and a postsynaptic enkephalinergic neuron which produces an inhibiting effect. Manipulation of these endogenous systems may lead to new treatment modalities for Parkinson's disease and other extrapyramidal disorders.

1283 DEETECTION OF ENKEPHALINS IN THE SYMPATHETIC GANGLIA. A.M. Di Giulio*, B.E. Lutold*, W. Fratta*, H.-Y.T. Yang* and E. Costa (SPON: N.H. Neff). Lab. Preclin. Pharmacol., NIMH, Saint Elizabeths Hosp., Washington, D. C. 20032

Methionine-enkephalin (ME) as well as leucine-enkephalin (LE) have been detected in some sympathetic ganglia of Sprague Dawley rats, i.e., the paravertebral paired superior cervical ganglion (SCG) and the prevertebral unpaired coeliac ganglion (CG), by the radioimmunoassay with ME and LE specific antisera. The identity of the two peptides was tested in tissue extracts by Biogel P-2 chromatography column, followed by radioimmunoassay. Enkephalins levels in rat sympathetic ganglia, expressed as ng/mg prot±S.E.M, are: 3.3±05 ME and 0.95±0.1 LE for coeliac ganglion and 3.0±0.6 ME and 1.4±0.3 LE for superior cervical ganglion. Both methionine and leucine-enkephalins were found to be present also in rabbit coeliac and superior cervical ganglia. We were not able to detect any beta-endorphin and beta-lipotropin in the ganglia studied. Enkephalins were measured in CG and SCG of spontaneously hypertensive rats (SHR) and normotensive Wistar Kyoto controls (WKY), aged 4,8 and 12 weeks. The content of ME and LE in the CG was lower in spontaneously hypertensive rats than in Wistar Kyoto controls. No significant difference was found in enkephalins levels of the two experimental groups in the superior cervical ganglion, caudate nucleus and hypothalamus. Whether these alterations in the enkephalin content of coeliac ganglion in spontaneously hypertensive rats is dependent on the integrity of the afferent innervation or on the efferent vagal brunch will be discussed.

1284 MOUSE BRAIN ENKEPHALINS: STUDIES OF LEVELS AND SYNTHESIS CORRELATED WITH NOCICEPTIVE SENSITIVITY. R.C.A. Frederickson, D. L. Hesche*, J. D. Edwards*, C. E. Harrell* and V. Burgis*. The Lilly Research Laboratories, Eli Lilly and Co., and Department of Pharmacology, Indiana University, Indianapolis, IN 46206 & 46202.

There is substantial evidence that small opioid peptides may function as neurotransmitters in brain and elsewhere. We have observed a diurnal rhythm in responsivity of mice to noxious stimuli and a corresponding time dependence of naloxone-induced hyperalgesia (Frederickson et al., Science 198: 765, 1977). Further studies performed on hypophysectomized mice compared to sham-operated controls have indicated that this rhythm is mediated by brain rather than pituitary. In order to examine the role of brain opioid peptides in this phenomenon we first compared whole brain total opioid activity at the times of minimum and maximum sensitivity to noxious stimuli. Mice were sacrificed by microwave irradiation, the brains were homogenized in acid, the homogenate was centrifuged and enkephalins were extracted from the supernatant over columns of Amberlite XAD-2 resin and bioassayed on the mouse vas deferens. The levels were 55.8 ± 3.3 ng/brain for mice sacrificed at 7:30 a.m. and 93.7 ± 12.1 ng/brain for mice sacrificed at 3:30 p.m. ($p<0.01$, df = 22, Student's t test). Studies with radioimmunoassay methodology are underway but we have not yet conclusively established whether the diurnal change occurs specifically in Met^5- and/or Leu^5- enkephalin. We are also utilizing the incorporation of ^{3}H-tyrosine into opioid peptides after intraventricular injection to compare the rate of synthesis of various opioids as a function of time of day. Thin layer chromatography and high pressure liquid chromatography methodology have provided strong evidence for incorporation of ^{3}H-tyrosine into Met^5-enkephalin and Leu^5-enkephalin. There was substantial incorporation into Met^5-enkephalin but that into Leu^5-enkephalin was barely detectable. The greatest incorporation, however, was into a third component which may be a unique opioid peptide, a precursor to the enkephalins, or merely a breakdown product of one of the brain endorphins. A study of the time course of incorporation into the various components is in progress and the nature and role of the third component is being investigated. The data to date support a role for opioid peptides in modulating reaction to noxious stimuli but we have not yet identified the specific opioid peptide which mediates the diurnal rhythm in behavior and total opioid activity.

1285 MORPHINE OR STRESS INDUCED INCREASES OF PLASMA β-ENDORPHIN AND PROLACTIN ARE PREVENTED BY DEXAMETHASONE PRETREATMENT. Edward D. French*, Floyd E. Bloom, Catherine Rivier, Roger Guillemin, Jean Rossier. A.V. Davis Center for Neurobiology, The Salk Institute, La Jolla, CA 92037.

Under conditions of stress, plasma levels of β-endorphin (B-E) and ACTH are concomitantly increased. Opiates are also known to alter anterior pituitary function and to increase plasma levels of corticosteroids (CS) through hypothalamic mechanisms. Rats receiving morphine sulfate (MS) 20 mg/kg s.c.showed a 9-fold increase in B-E immunoassayable like material 1 hr after injection and a return to control values by 6 hr. Prolactin (PRL) (as determined by radioimmunoassay) levels also were elevated 3-fold at 30 min post injection but returned more rapidly to preinjection levels. Additional studies also showed that MS i.v. and i.p. (20 and 10 mg/kg, respectively) produced comparable increases in plasma B-E and PRL. Prior treatment with two injections of dexamethasone (DX) (400 µg/kg at 24 hrs and 200 µg/kg at 2 hrs before) blocked the MS induced rise of both B-E and PRL. Also, the simultaneous administration of either 0.2 or 10 mg/kg of naloxone with MS completely blocked the MS produced elevations of plasma B-E and PRL. Tolerance to the plasma hormonal changes were found to occur by 7 days of MS (twice daily-stepwise increased injections). In the MS-tolerant rat, anterior lobe B-E content increased 50% over controls while posterior lobe content remained unchanged. However, the long-term administration of MS failed to alter regional brain levels of either B-E or enkephalins. In an additional study, rats were fitted with indwelling venous catheters and footshocked for 30 min. Plasma B-E increased 6-fold with peak levels at 15 min and returning to control values by 150 min. Footshock (15 min) also increased plasma PRL. In both instances DX pretreatment blocked the stress-induced rises of these hormones. In rats subjected to even more prolonged stress, (footshock-1 hr) anterior pituitary B-E was decreased with no change in posterior lobe content. These results indicate that common central mechanisms may mediate the MS- and stress-induced increases of plasma B-E and PRL.

1286 TRANSMITTER-LIKE EFFECTS OF ENKEPHALIN ON CULTURED SPINAL NEURONS. D.L. Gruol, L.M. Huang*, J.L. Barker, and T.G. Smith*, LNP, NINCDS, NIH, Bethesda, Md. 20014

The direct effects of the opiate peptide, leucine-enkephalin (ENK), and an antagonist, naloxone (NAL), on cultured fetal mouse spinal neurons were studied using intracellular recording techniques and extracellular iontophoresis of ENK and NAL. When applied to the neuronal soma, ENK frequently produced dose-dependent membrane polarizations which were accompanied by a conductance increase and which varied in amplitude as a function of membrane potential (Vm) and position of the iontophoretic pipette. The responses could be divided into two categories. The most common response was a slowly developing and desensitizing polarization (several sec. to peak of response), most clearly seen when ENK was applied for a long period of time (> 1 sec.). The second type of response was less frequently observed and required critical placement of the iontophoretic pipette for detection. This response was faster in time course (≤ 1 sec. in duration), desensitized rapidly and had a more positive reversal potential than the slow ENK response. Occassionally both fast and slow responses were simultaneously evoked by ENK application. The fast ENK response evoked spikes and thus appeared to be excitatory in nature. The functional significance of the slow response remains to be determined. NAL reversibly supressed both ENK responses but interpretation of this result has been complicated by the direct effects of NAL on membrane properties. Two types of NAL responses were observed: (1) a depolarization accompanied by a conductance increase and (2) a hyperpolarization accompanied by a conductance decrease. Both NAL effects were reversible, dose-dependent and varied in amplitude as a function of Vm.

Thus, ENK can alter membrane properties of cultured spinal neurons in ways which are similar to responses evoked by putative neurotransmitters. Like transmitter actions, the peptide responses are associated with a conductance increase, have a reversal potential, desensitize and show a topographical variation in amplitude of the response. These results, coupled with previously published observations demonstrating non-transmitter-like (neuromodulatory) effects of ENK (Science 199 (1978) 1951) suggest that ENK can have multiple actions in the nervous system, both as a neuromodulator and as a neurotransmitter.

1287 SPECIFICITY OF ACTION OF SUBSTANCE P (SP) IN THE LOCUS COERULEUS (LC). P. G. Guyenet, E. Mroz*, S.E. Leeman, and G.K. Aghajanian, Depts. Psychiat. and Pharmacol., Yale Univ. Sch. Med., New Haven, CT 06508 and LHRRB, Harvard Med. Sch., Boston, MA 02115.

In the LC of the rat, SP is localized within boutons that make axodendritic synapses with the noradrenaline-containing neurons. The iontophoretic technique was used in the present study to determine the effect of SP on the firing rate of LC neurons in this species. In addition, the specificity of para-chlorophenyl-GABA (baclofen) as an SP antagonist was examined and a pharmacological approach was used to assess whether SP might modulate cholinergic transmission or have any opiate agonist potency as recently suggested.

SP had an excitatory effect on all LC neurons tested. This effect was also produced by the 4-11 octapeptide derivative of SP and by tachykinins with SP-like activity (elidoisin and physalaemin). By contrast, TRH, bradykinin and neurotensin were inactive while metenkephalin (ME) inhibited all neurons tested. SP excited the neurons with a latency that varied greatly with the intensity of the retaining current applied between ejection periods (3 to 6 sec to more than 40 sec at 10 nA). In order to investigate this variability further, the release of SP (3 mM, pH 4.5) from iontophoretic pipettes was monitored "in vitro" using a sensitive radioimmunoassay. Its transport number was found to vary from 1.6 10^{-2} in the presence of 17.5 mM Na^+ to 0.08 10^{-2} in presence of 170 mM Na^+. The effect of a retaining current on subsequent ejections paralled exactly the kinetics of the neuronal response "in vivo": higher retaining currents resulted in prolonged delays in release. These characteristics of SP release can be accounted for by its low diffusibility, the latter being a direct consequence of its high molecular weight. Thus, the reported sluggishness of neuronal responses to the iontophoretic application of SP might be due for the most part to the physicochemical characteristics of its ejection from glass micropipettes.

Baclofen did not exhibit any specificity as an SP antagonist since it also blocked the response to ACh and glutamate. Muscarinic antagonists and naloxone were remarkably specific in antagonizing the excitation caused by ACh and the inhibition due to mE respectively. Neither of these compounds, however, had any influence on the increase in firing rate due to SP, thus providing evidence that SP in the LC neither interferes with cholinergic transmission nor possesses any opiate agonist potency. In conclusion, the present data suggest that neuronal responses to SP are rapid in the CNS and are due to an interaction with highly specific receptors (USPHS Grants, MH-17871, MH-14459, the State of Connecticut, and the CNRS, France).

1288 GENERAL ACTIVITY CHANGES INDUCED BY D-ALA^2-MET^5-ENKEPHALINAMIDE IN RATS. Craig T. Harston*, Morris A. Spirtes, William P. Dunlap* and David H. Coy*. Dept. Pharm., Tulane Med. Sch.; Veterans Admin. Hospital; Dept. Psych., Tulane U., New Orleans, La.

Morphine is known to increase behavioral activity with low doses and following a period of decreased activity with higher doses. To test whether intracranioventricular (ICV) injections of endorphins act similarly, cannulae were implanted stereotaxically into the right lateral ventricles of male albino rats. Seventeen to 18 days after surgery, groups of 6-9 rats were injected ICV with either 10 µl .9% saline, 12.5, 25, 50 or 100 µg D-ala^2-met^5-enkephalinamide (ENK). Uncannulated controls were not injected but handled similarly. Following injection, each animal was observed for 5 hr in a 31 cm diameter activity chamber. Quadrant crossing, rearing, grooming, head movement, and wet-dog shakes were observed via a video system. Activity was also recorded automatically with 2 photocells.

Quadrant crossing, rearing and photocell interruptions of the ENK groups decreased initially but later increased as compared to the saline-injected controls. Grooming and head movement were decreased and wet-dog shakes were increased by ENK.

In the second experiment, the activity chambers were modified to maintain the rats on ad lib. food and water. Seven days post surgery the rats were put in the activity chambers and injected each morning with saline for three days to habituate them to the procedure. Beginning on day 4, 16 subjects were injected ICV with 25 µg ENK and another 16 with 2.5 µl saline. Twenty-five min after the ICV injection, half of each group was injected IP with 5 mg/kg naloxone or 1 cc/kg saline.

On day 4, the overall activity of the ENK-injected group was higher than that of the saline-injected group. Also on day 4, naloxone reduced activity of both the ENK- and saline-injected rats. The overall activity of the ENK-treated rats increased further over successive days of ENK treatment.

These results suggest that the increased activity was due to the direct effects of ENK and not to a rebound or recovery from the depressive effects. Some naturally occurring activity may involve endorphins, since activity was decreased by naloxone in saline controls.

1289 DISSOCIATION OF EFFECTS OF SOMATOSTATIN ON TURNOVER OF CATECHOLAMINES IN THE CNS. Viktor Havlicek, Robert Herchl and Milan Rezek, Dept. of Physiology, U. of Manitoba, Winnipeg, Canada.

Somatostatin (SRIF) administered into rats intracerebroventricularly (ICV) or into various brain regions (neostriatum, amygdala, hippocampus or supracortically) produces a graded excitatory response: animals begin running in circles; grooming activity may be replaced by excessive and stereotyped scratching, animals become hyperexcitable, uncoordinated, tremulous and finally akinetic and some rats develop tonic-clonic motor seizures. Milder forms of central irritation resemble those produced by amphetamines. Since dopamine (DA) and norepinephrine (NE) are implicated in the mechanism of action of several CNS active drugs, we have examined the effect of SRIF on turnover of catecholamines. SRIF (10 μg) was administered ICV twice (a) 5 min prior to intraperitoneal (i.p.) injection of α-methyl-p-tyrosine (α-MT 250 mg/kg) and (b) 25 min after α-MT injection. Controls were injected with saline or α-MT i.p. and with saline ICV. Rats were sacrificed by decapitation 60 min after receiving α-MT. The brain was rapidly dissected into three regions: forebrain, hindbrain and cerebellum. The fluorescence method for the measurement of DA and NE was used. Results are presented in table below:

Brain Region	Treatment	N	NE ng/g	P	DA ng/g	P
Forebrain	sal & sal	24	291 ± 8	> 0.001	835 ± 28	> 0.001
	α-MT & sal	18	230 ± 8	> 0.05	484 ± 20	> 0.05
	α-MT & SRIF	17	202 ± 12		603 ± 68	
Hindbrain	sal & sal	10	495 ± 11	> 0.001	27 ± 10	
	α-MT & sal	6	328 ± 16	> 0.1	a	
	α-MT & SRIF	6	282 ± 22		a	
Cerebellum	sal & sal	19	190 ± 4	> 0.001	a	
	α-MT & sal	17	118 ± 9	N.S.	a	
	α-MT & SRIF	16	121 ± 10		a	

a-quantities were too small for accurate estimations

As shown in the table α-MT decreased NE by 21% and DA by 42% in forebrain. Pre- and post-treatment with SRIF significantly altered these changes potentiating the effect on NE and inhibiting that on DA. Similar changes for NE were seen for hindbrain, while cerebellum did not show any differences in NE turnover. Thus there was a dissociation in the effect of SRIF in the metabolism of these amines. Decrease in dopaminergic neurotransmission in neostriatum might be related to parkinsonian symptoms seen after somatostatin. (Supported by MRC of Canada).

1290 β-ENDORPHIN INDUCED EPILEPTIFORM ACTIVITY: EFFECTS OF LESIONS AND SPECIFIC OPIATE RECEPTOR AGONISTS. S.J. Henriksen, F. McCoy,* E. French* and F.E. Bloom. The Salk Institute, A.V. Davis Center for Behavioral Neurobiology, La Jolla, CA 92037.

Opiate agonists and endogenous opioid peptides can induce limbic epileptiform activity that can be electroencephalographically recorded from a variety of subcortical loci. β-endorphin (B-E) is the most potent in eliciting this activity when compared on a molar basis to either morphine sulfate or the naturally occurring enkephalin pentapeptides. Intraventricularly (i.c.v.) administered B-E (1-3mm) induces, in rats, subcortically generated paroxysmal waves and cortical slow-waves at doses devoid of other opiate agonistic effects, such as analgesia or behavioral immobility and rigidity. Similar electroencephalographic (EEG) abnormalities are seen in mice, guinea pigs and squirrel monkeys following (i.c.v.) B-E. However, both guinea pigs and squirrel monkeys exhibit less intense epileptiform activity particularly at the onset of paroxysmal activity(initial ictal episode). Intravenous injection of B-E (20-26 mg/kg) in albino mice, but not in rats, produces paroxysmal activity, analgesia and rigidity. In an attempt to anatomically specify the subcortical loci participating in either the generation or elaboration of this phenomena, radio frequency lesions have been made in a variety of sub-cortical limbic loci in rats who were later implanted with chronic electrode arrays and tested for the effect of B-E on spontaneous EEG activity. Lesions have been made in the amygdala (bilateral; medial, central and basal nuclei), the pre-optic area of the anterior medial hypothalamus, and the dorsal-medial nuclear complex of the thalamus (including periventricular, anterior medial and lateral portions, as well as the nucleus reuniens). For pharmacological studies rats implanted with similar chronic electrode arrays have been treated with specific opiate agonists of the μ,κ, and σ type (Martin et al, 1976) alone or following B-E administration. The following agents have been utilized: SKF-10047, a σ agonist; WIN-35, 197-2, a κ agonist; cyclazocine, a κ and σ agonist and ketocyclazocine, a κ agonist. B-E (I.C.V.) induced substantially the same electrographic response in lesioned rats as compared to controls, indicating generating loci located in areas other than amygdala or medial thalamus.

Pharmacological studies will be presented indicating B-E interaction with specific opiate receptors.

1291 IMMUNOHISTOCHEMICAL AND RADIOIMMUNOASSAY STUDIES ON THE DEVELOPMENT OF SOMATOSTATIN CONTAINING PRIMARY AFFERENT NEURONS IN THE RAT. Raymond H. Ho, Robert Elde, and Robert Sorenson*, Departments of Anatomy, The Ohio State University, Columbus, Ohio, 43210; University of Minnesota, Minneapolis, Minnesota, 55455.

Some small diameter, primary afferent neurons have been shown to contain somatostatin immunoreactivity in their peripheral and central processes, as well as in some small diameter dorsal root ganglion perikarya. Neurons with these characteristics may play a role in nociception. Antibodies raised in rabbits against synthetic somatostatin were used for immunofluorescence histochemical localization and radioimmunoassay studies in a series of fetal and neonatal Sprague Dawley rat spinal cords. Immunofluorescence histochemistry was performed on 10μ cryostat sections of spinal cords that were fixed by whole-animal intracardiac perfusion of 4% paraformaldehyde in phosphate buffer. Somatostatin-like-immunoreactivity was demonstrable in nerve fibers and/or terminals in Laminae I and II of the spinal cord dorsal horn in animals as early as the day 4 neonate. The specificity of immunostaining was established in control experiments in which anti-somatostatin serum pretreated with an excess of somatostatin was unable to localize such structures. Radioimmunoassay data from whole spinal cord extracts indicated very small quantities (approaching limit of assay sensitivity) of somatostatin in cords younger than the day 4 neonate. There was an abrupt rise of somatostatin content in the spinal cord between the day 3 and the day 4 neonate; beyond that stage of development there was a general tendency for the spinal cord somatostatin content to increase with age. Although the rat somatostatin-containing primary afferent neuronal system may be capable of synthesizing and transporting the peptide at an earlier time, it does not store sufficient quantities of somatostatin to be detected until day 4. Supported in part by the Graduate School, University of Minnesota.

1292 EVIDENCE FOR ENDORPHIN RELEASE DURING ELECTROCONVULSIVE SHOCK. John W. Holaday, Gregory Lucas Belenky, Horace H. Loh*, and James L. Meyerhoff. Dept. of Medical Neurosciences, Walter Reed Army Institute of Research, Washington, DC 20012.

Available evidence implicating an endorphin involvement in various behavioral disorders has been contradictory and inconclusive. We have demonstrated the possibility that the therapeutic consequences or side effects of electroconvulsive therapy (ECT), which uses electroconvulsive shock (ECS) to produce a generalized seizure, may involve a functional release of endorphins.

Male Wistar rats (Walter Reed Strain) weighing 250-300g were affixed with wound clips on the pinna of each ear to serve as electrodes for transauricular ECS. Naloxone (10 mg/Kg) or saline were injected intraperitoneally in a volume of 0.1 ml/100g body weight. Ten min. later, electroshock was delivered (2 sec, 210 v, 62 mA, 60 Hz). The first group of rats were evaluated for duration of seizure and ECS-induced catalepsy, as well as for changes in tail-flick latencies and respiratory rates. Raters were blinded as to whether naloxone or saline had been injected. In a second group of similar rats, tail arteries were cannulated [Chiueh and Kopin, Am. J. Physiol. (in press)] two days prior to experiments. Cardiovascular parameters were then monitored via the tail-artery cannula both prior to and following ECS in these conscious, freely moving rats following preinjection with naloxone or saline as before.

ECS produced a tonic-clonic seizure, the duration of which was unaffected by naloxone. Following the seizure, a state of catalepsy characterized by a loss of righting reflex was observed. This catalepsy was behaviorally indistinguishable from opiate-induced catalepsy. Naloxone preinjection significantly diminished this ECS-induced cataleptic state. Tail-flick latencies were elevated following ECS treatment, an effect that was significantly decreased in the naloxone injected rats. The decline in respiratory rates following ECS was also significantly less in the naloxone group.

Blood pressure in the ECS-treated rats rose from approximately 108 mm Hg to 228 mm Hg within the first second of electroshock. Naloxone was without effect on this hyptertensive surge. Comparison of saline and naloxone treated rats following this surge demonstrated significant effects of naloxone on blood pressure and heart rate which persisted during the first 35 sec. post-shock.

Our data suggest that endorphins are released during ECS in rats and that they play a role in post-ECS behavior. We suggest that a release of endorphins may play a role in the therapeutic effects or complications of ECT in man.

1293 ELEVATION OF β-ENDORPHIN-LIKE SUBSTANCE LEVELS IN THE VENTRICULAR CSF BY CENTRAL GRAY STIMULATION (CGS) IN HUMANS. Yoshio Hosobuchi*, Jean Rossier*, Floyd Bloom*, and Roger Guillemin* (SPON: Nancy M. Lee). Dept. Neuro. Sur. UCSF Sch. Med., San Francisco, CA 94143 (YH) and The Salk Institute, La Jolla, CA (92037) (JR,FB,RG).

Electrical stimulation of the periaqueductal and periventricular gray matter provides significant relief from severe intractable pain in humans; it is totally reversed by the specific opiate antagonist naloxone. At the initial implantation of chronic brain electrodes, ventricular CSF was collected from six patients undergoing the operation; base levels of β-endorphin-like substances were determined on each sample by a radioimmunoassay. This technique may also detect molecules larger than β-endorphin; it will certainly exclude smaller peptides such as enkephalin. Series of pre- and post-stimulation CSF samples were collected from a ventricular catheter placed at the foramen of Monro during the stereotactic surgery necessary to perform a ventriculogram. In three patients electrodes were implanted in the posterior limb of the internal capsule; stimulation of this area produced no increase in ventricular levels of β-endorphin-like substances. However, in three other patients who had electrodes implanted in the periaqueductal area, stimulation of this area produced a two- to four-fold increase in the levels of β-endorphin-like substances. Intraventricular administration of human β-endorphin has been shown to produce a dose-dependent, prolonged analgesic effect in humans. The current results represent the first evidence of *in vivo* release of β-endorphin-like substances in humans and suggests that stimulation may have produced the release of the substances.

1294 ENKEPHALIN MODULATION OF AMINO ACID RESPONSES ON CULTURED SPINAL NEURONS. L.M. Huang*, D.L. Gruol, J.L. Barker and T.G. Smith*, (SPON: H.G. Wagner) LNP, NINCDS, NIH, Bethesda, Md. 20014.

The effects of the opiate peptide leucine-enkephalin (ENK) and its antagonist naloxone (NAL) on amino acid responses of cultured fetal mouse spinal neurons were studied using intracellular recordings of membrane potential and current made with conventional and voltage clamp techniques. The putative inhibitory amino acids γ-aminobutyric acid (GABA) and glycine and ENK and NAL were applied by iontophoresis. The results reported here were mainly obtained from cells where ENK evoked a slow membrane polarization. NAL also had direct effects on membrane conductance in some neurons. However, similar modulatory effects were seen in the absence of any change in membrane properties due to ENK or NAL. ENK and NAL depressed the GABA responses in a reversible, dose-dependent manner. A depression of the GABA currents by ENK was also observed under voltage clamp. Pharmacological analysis of the ENK-GABA interaction showed a parallel shift to the right of the GABA dose-response curve without a change in the limiting slope of the log-log plot. In some neurons a depression of V_{max} was also observed. ENK and NAL enhanced or depressed the glycine response in a dose-dependent, reversible manner. In those cells where the glycine response was enhanced there was a parallel shift of the glycine dose-response curve to the left in the presence of ENK without a change in the limiting slope of the log-log plots. In neurons studied under voltage clamp, low iontophoretic ENK currents enhanced the glycine response while at higher ENK currents the glycine response was depressed.

While some of the depressant effects of ENK on amino acid responses are likely due to shunting of the membrane, enhancement of the glycine response and depression of amino acid-induced currents cannot be explained by this mechanism. Two alternative explanations are that ENK may directly modulate inhibitory amino acid responses (1) by acting on the receptor-coupled conductance mechanism as has been observed for ENK modulation of glutamate events (Science 199 (1978) 1451) or (2) by altering the Cl^- ion gradient across the membrane and thus altering the driving force on the Cl^- conductance activated by GABA and glycine in these cells.

1295 DISTRIBUTION OF CHOLECYSTOKININ OCTAPEPTIDE-LIKE IMMUNOREACTIVITY IN THE RAT BRAIN. Robert B. Innis, Fernando M.A. Correa* and Solomon H. Snyder. Dept. Pharmacol., Johns Hopkins Sch. Med., Baltimore, MD 21205.

Several peptides, including neurotensin, vasoactive intestinal peptide, enkephalin, cholecystokinin (CCK), and the C-terminal octapeptide of CCK (CCK-8) are present in both the brain and the gut and CCK-like immunoreactivity has been observed histochemically in rabbit brain (Proc. Natl. Acad. Sci., 74:3033, 1977). With an antiserum raised against CCK-8 we have identified and mapped the distribution of CCK-8-like peptides in the rat brain by indirect immunohistofluorescence. At every level, control sections were stained with antiserum preadsorbed with CCK-8 and with pre-immune serum. Cellular and fiber staining was removed by preadsorption of the antiserum with CCK-8 of gastrin but was unaffected by preadsorption with a large series of unrelated peptides.

Immunoreactive cells are observed diffusely throughout the cerebral cortex. These neurons are usually 10-20 μ in length, bipolar, and radially oriented to the surface of the brain. They are located in layers II-VI but predominantly in layers II and III. In rostral portions of cortex, positively stained cells appear in the midline and shoulder regions' caudally, these cells tend to be in lateral cortical areas. Varicose fibers are located diffusely in the cortex with the most dense network near the rhinal sulcus, lateral to the central nucleus of the amygdala. Sparse cell bodies are observed in the hippocampus. Dense cell clusters occur in the periventricular and dorsomedial nuclei of the hypothalamus. Varicose fibers run dorsally and laterally from these two hypothalamic clusters. Caudally, a neuronal cluster is found in the midline, just ventral to the aqueduct at the level of the substantia nigra. Fibers tend to run dorsally and ventrolaterally from this cluster. In the brainstem, a neuronal cluster is located in the midline, just ventral to the fourth ventricle at the level of exit of the fifth cranial nerve. F.M.A.C. is recipient of fellowship from FAPESP, Brasil.

1296 "OPIOID" BEHAVIORAL EFFECTS FOLLOWING ADRENOCORTICOTROPIN OR β-ENDORPHIN INJECTIONS IN PERIAQUEDUCTAL GRAY OF RATS: SIMILARITY TO "PARADOXICAL" MORPHINE EFFECTS SUGGESTS MECHANISM FOR OPIATE DEPENDENCE. Yasuko F. Jacquet. NY State Research Institute for Neurochemistry, Ward's Island, New York City, N.Y. 10035.

Microinjection of adrenocorticotropin (ACTH 1-24) in the periaqueductal gray (PAG) of rats resulted in a dose-dependent hyperreactivity characterized by repeated and rapid high leaps ("flying") similar to the behavior seen in opiate-dependent rats undergoing precipitated abstinence. This was followed by a period during which other opiate abstinence signs were manifested, i.e., wet-dog shakes, teeth chatter, abnormal posture, squeal on touch, etc. Shorter analogs, i.e., ACTH 1-13, ACTH 4-10, resulted in an attenuated form of the abstinence syndrome. Naloxone pretreatment failed to block this behavior.

We previously reported (Jacquet and Lajtha, Science, 1974) that morphine microinjection in the PAG resulted in 2 "paradoxical" effects: (1) analgesia/catatonia, and (2) hyper-reactivity, characterized by rapid and repeated high leaps. Pretreatment with naloxone blocked (1) but not (2). Significantly, injections of β-endorphin in the PAG resulted only in (1) but not (2) (Jacquet and Marks, Science, 1976), while injections of the unnatural (+)-morphine in the PAG resulted only in (2) and not (1) (Jacquet et al, Science, 1977). These observations suggested that morphine effects in the PAG were mediated by 2 classes of receptors, one being stereospecific for opiates and naloxone-sensitive, of which the endogenous ligand appeared to be β-endorphin, and the other which was not stereospecific for opiates and was naloxone-insensitive. Our present evidence suggests that ACTH may be the endogenous ligand of this latter class of receptors.

Systemic injections of morphine never resulted in "flying." Moreover, pretreatment of rats with systemically-administered morphine blocked "flying" following morphine microinjection in the PAG, but did not block analgesia/catatonia. (Similarly, pretreatment with systemically-administered morphine blocked "flying" following ACTH microinjection in PAG while naloxone did not.) These differential effects of morphine following systemic or local administrations suggest that following systemic administration, morphine achieves distribution throughout the CNS, activating endorphin receptors in neuronal circuits which exert an inhibitory influence on the excitatory effects of morphine acting at ACTH receptor sites. The opiate abstinence syndrome may be due to excitation by morphine of the ACTH receptor following removal by naloxone blockade, or weakening by tolerance development, of the inhibitory influence exerted by the endorphin receptor.

1297 ACTION OF INTRAHYPOTHALAMICALLY INJECTED β-ENDORPHIN ON THE BODY TEMPERATURE OF THE RAT. G. E. Martin and C. B. Bacino.* Merck Institute for Therapeutic Research, West Point, PA 19486.

Injected into the lateral cerebral ventricle (LCV), β-endorphin evokes hypothermia in the rat (Bloom et al., Science, 1976, 194: 630). The site of this action could be thermoregulatory neurons in the preoptic/anterior hypothalamus (POAH), but the LCV route of administration does not preclude the involvement of other structures which form the walls of the ventricles. Hence, we measured rectal temperature (T) after the injection of β-endorphin into the POAH.

A 24 ga guide cannula was implanted above a POAH or LCV site in 34 male Sprague-Dawley rats. POAH and LCV injections were made via a 30 ga injector over a 30 sec interval. The volume of injection was 0.5 or 1.0 µl in the POAH and 5 µl in the LCV. Artificial CSF vehicle or β-endorphin, in doses of .74, 1.48 and 3.7 nmoles (nM) was microinjected in the POAH (n=6), whereas the LCV doses (n=5) were .74, 3.7 and 7.4 nM. T was measured by inserting a thermometer into the rectum of the unrestrained rat.

β-Endorphin evoked a hypo- or hyperthermia depending on the dose and route of administration. Compared with the increase in T to 38.4 ± 0.2°C (Mean Peak T, MP) from the 37.2 ± 0.1°C baseline after the microinjection of the vehicle, β-endorphin, at doses of 0.74, 1.48 and 3.7 nM, caused a significant but non-dose-related rise in T. The MP was 39.7 ± 0.1, 39.6 ± 0.2 and 39.3 ± 0.3°C for the respective doses of β-endorphin after the POAH microinjections. In the LCV, on the other hand, 0.74 and 3.7 nM of β-endorphin caused no significant change in T (MP = 37.7 ± 0.3, 38.1 ± 0.5°C). The LCV injection of 7.4 nM of the opiate, however, evoked a marked but naloxone reversible drop in T to 34.0 ± 0.9°C which was accompanied by catatonia and respiratory depression. Pretreatment with either naloxone (2 or 5 mg/kg) or Indocin (15 mg/kg), slightly attenuated the rise in T seen after the POAH injections. Indocin, but not naloxone, blocked the slight rise in T evoked by the CSF injection into the POAH. Pretreatment with both naloxone and indocin reduced significantly the hyperthermia evoked by POAH injections of β-endorphin. These data suggest that the β-endorphin-induced rise in T may be mediated in part by synthesis or release of prostaglandins in the POAH.

Since catatonia and respiratory depression accompanied the hypothermia caused by the LCV injection of β-endorphin, the drop in T may not reflect a specific action on thermoregulatory processes in the POAH region. In fact, at the doses of β-endorphin examined, a marked increase in T followed the direct injection of β-endorphin into the POAH. Further studies will be required to determine whether β-endorphin has an endogenous role in T regulation, and whether its hyperthermic action is, at least partly, mediated by prostaglandins.

1298 CORRELATIVE ANALYSIS OF HYPOTHALAMIC PEPTIDES AND CATECHOLAMINES IN THE AGED NON-HUMAN PRIMATE. J.A. McConnell, T.H. McNeill and J.R. Sladek, Jr., Univ. of Texas Med. Schl., Houston, TX 77030 and Univ. Rochester, Rochester, NY 14642.

Aging is accompanied by a decreased adaptability of certain homeostatic mechanisms under hypothalamic regulation. One such function, water balance, is controlled by vasopressin. This magnocellular peptide is synthesized in the paraventricular (PVN) and supraoptic (SON) nuclei, both of which are heavily innervated by catecholamine (CA) varicosities.

Hypothalami from six female macaques (M. nemestrina), three each of 4 and 20 years of age, were prepared for the simultaneous visualization of peptides and CA by the technique of McNeill and Sladek (Science 200:72-74, 1978). Quantitative analyses were performed on one animal of each age at comparable levels of the PVN. Various analyses were made of cell size and number in Nissl and PAP stained sections. Sections were stained with the PAP technique for bovine neurophysin (BNP), human estrogen-stimulated neurophysin (ESN), and human nicotine-stimulated neurophysin (NSN). Sections adjacent to those stained for neurophysin were examined for CA fluorescence and the degree of CA varicosity/neurophysin perikaryal interaction was determined with the use of a microscope comparator bridge system. A range of cell sizes (15-45 µ) was seen in both ages, but fewer of the largest cells (>35µ) were present in the 20 year old. Total numbers of neurophysin-stained cells remained constant, but fewer heavily stained cells were seen in the older animal. This decrease was especially prominent following BNP (84%) and NSN (54%) staining and the change was accompanied by a concomitant increase in lightly stained cells. A proportionate shift was not seen in ESN perikarya. Apart from numerical changes, a general decrease was noted in neurophysin staining in older specimen with all antisera, especially in the processes of the hypothalamo-neurohypophyseal tract. Herring bodies also accumulated with age. CA varicosity patterns within the PVN were similar in both ages, although a somewhat reduced appearance of fine-sized varicosities was noted. The number of CA varicosities and the number of neurophysin (ESN, NSN,BNP) containing perikarya with apparent CA contacts were comparable in both ages. These data indicate that the amount of immunoreactive neurophysin decreased with age and that the use of the more specific antisera focus on a possible alteration in vasopressin content. Whether this represents an alteration in synthesis, storage or another cellular mechanism is unknown.

We thank Earl A. Zimmerman for the antisera and Douglas M. Bowden for the animals. Supported by NS 11642 (JRS).

1299 COMPARATIVE IMMUNOHISTOCHEMISTRY OF MET-ENKEPHALIN, VASOPRESSIN, AND OXYTOCIN IN THE MEDIAN EMINENCE AND HYPOTHALAMUS OF THE CAT. Paul Micevych* and Robert Elde (SPON: David Coulter). Dept. of Anatomy, Un. of Minnesota Medical School, Minneapolis, MN 55455

Several immunohistochemical studies have reported the distribution of enkephalins in the nervous system of the rat. The present study reveals striking differences in enkephalin immunoreactivity in the hypothalamus of the cat. Normal and colchicine treated cats (30 ug in third ventricle, 48 hour survival) were perfused with 4% paraformaldehyde. Ten-micron cryostat sections were taken of the hypothalamus and stained using the indirect immunofluorescence method. Antiserum directed against met-enkephalin (M-ENK) and used in this study cross-reacted less than 0.1% with leu-ENK and β-endorphin. Antisera directed against vasopressin (VP) and oxytocin (OT) were used for comparative purposes.

Immunoreactive M-ENK axons, terminals, and Herring bodies were observed in the internal layer of the median eminence, pituitary stalk, and posterior pituitary. This immunofluorescence distribution agreed closely with the staining pattern obtained with VP and OT. VP and releasing factors have been localized in the external layer of the median eminence. M-ENK immunoreactive axons and terminals were visualized here also, especially near the capillary loops of the hypothalamo-hypophyseal portal system.

In normal animals M-ENK immunoreactive cell bodies were seen in the hypothalamic paraventricular and supraoptic nuclei, as was staining for VP and OT.

Localization with M-ENK antiserum in colchicine treated cats revealed a greater number of supraoptic and paraventricular cell bodies, but additionally, an extensive system of periventricular neurons was positive. In contrast to the supraoptic and paraventricular nuclei, the periventricular cell bodies remained negative after incubation with VP and OT antisera.

VP and OT containing neurons of the paraventricular and supraoptic nuclei project primarily to the posterior pituitary. In the cat, M-ENK perikarya in these nuclei may be the cells of origin of M-ENK fibers, terminals, and Herring bodies in the internal layer of the median eminence. This is totally distinct from what has been visualized in the rat, where there is no M-ENK immunoreactivity in the median eminence, posterior pituitary, supraoptic or paraventricular nuclei. The M-ENK immunofluorescence in the external layer of the median eminence may arise from the supraoptic/paraventricular neurons or the periventricular area neurons. M-ENK immunoreactive terminals in the external layer of the median eminence may participate in the regulation of release of anterior pituitary hormones.

Supported in part by the Graduate School at the University of Minnesota.

1300 EXCITATORY ACTION OF NEUROTENSIN ON CAT DORSAL HORN NEURONES IN LAMINAE I-III. Vjekoslav Miletic and Mirjana Randic, Iowa State Univ. Sci. Tech., Ames, IA 50011.

Neurotensin has been recently shown by immunohistochemical technique to be present in substantia gelatinosa of rat spinal cord. Since it is known that this area contains neurones principally excited by an input in nociceptor afferent fibres, and that, in addition, it is particularly rich in opiate receptor binding sites and enkephalin, it was of interest to study the central effects of neurotensin by applying it microelectrophoretically to dorsal horn nociceptive and other types of neurones at the level of Rexed's laminae I-III.

We have observed that synthetic neurotensin causes a slight to moderate excitation of about 65% of all tested units located in Laminae I-III. Excitation was observed as initiation of firing in a previously quiescent unit, or as an increase in the rate of spontaneous and/or evoked firing. The excitant response to neurotensin was relatively slow in onset and recovery. Neurotensin proved to possess an excitatory action in all categories of neurones recognized in spinal preparations of cats in this area on the basis of their excitability by different kinds of cutaneous afferent input. Units excited by sodium-L-glutamate were also excited by neurotensin. The latter result and the temporal characteristics of neurotensin-produced excitation are consistent with the possibility that neurotensin acts on postsynaptic sites in Laminae I-III of the spinal cord as a neuromodulator. 1301 CHARACTERIZATION OF THE BOMBESIN RECEPTOR IN MAMMALIAN BRAIN. Terry W. Moody* and Candace B. Pert (SPON: W. E. Bunney, Jr.). Biological Psychiatry Branch, NIMH, Bethesda, MD 20014.

Bombesin, a tetradecapeptide isolated from frog skin, produces hyperglycemia and hypothermia with a well-defined structure-activity relationship when injected intracisternally in rats. Also, bombesin-like immunoreactivity has been demonstrated in rat brain. Since bombesin-like peptides may function as neurotransmitters or modulators of neural activity in the central nervous system, we undertook the characterization of the bombesin receptor in mammalian brain. A radiolabeled tyrosine^4 analogue of bombesin bound specifically to rat brain membranes with high affinity (K_d = 1 nM). The high affinity binding was noncooperative and saturable, with an estimated 3 pmoles of sites/g wet tissue. The association and dissociation rate constants were 1.1×10^8 $M^{-1}min^{-1}$ and 1.0×10^{-1} min^{-1} respectively. Subcellular fractionation studies revealed that the density of sites is 3-fold greater in synaptic than nuclear or mitochondrial membranes. Regional distribution studies revealed that the density of sites in the hippocampus, the highest region, is 7-fold greater than the medulla pons, the lowest region. Pharmacological studies indicated that those bombesin analogues which possess high biological activity inhibit the binding of tyrosine^4-bombesin with greater affinity than do those analogues which possess lower biological activity. In particular, numerous amino acid residues near the CO_2 terminal, e.g., Trp^8 and His^{12}, appear to be essential for interaction with the bombesin receptor whereas numerous amino acid residues near the NH_2 terminal, e.g., Leu^4, Gly^5 and Asn^6 are not essential. Other putative neurotransmitters and brain receptor antagonists are not competitive for the high affinity tyrosine^4-bombesin binding site. These results suggest that synaptic membranes from rat brain contain a unique receptor which mediates the effects of bombesin-like peptides in the central nervous system.

1302 EFFECTS OF PHARMACOLOGICAL AND ENDOCRINOLOGICAL MANIPULATION ON NEUROTENSIN-INDUCED HYPOTHERMIA. C. B. Nemeroff, G. Bissette*, P. J. Manberg*, A. J. Osbahr III*, G. R. Breese, P. T. Loosen*, M. A. Lipton and A. J. Prange, Jr.*, Biol. Sci. Res. Ctr., Univ. North Carolina, Sch. Med., Chapel Hill, N. C. 27514.

Neurotensin (NT), an endogenous central nervous system tridecapeptide, has been demonstrated to produce a marked dose-dependent hypothermia after intracisternal (IC) administration in microgram quantities in a variety of laboratory animals. The present study sought to determine the mechanism of the hypothermic action by utilizing pharmacological treatments which alter the function of brain neurotransmitter systems. In each experiment adult male albino rats (300 g) were divided into 4 groups (n=6/group): (1) Saline IP + Saline IC; (2) Saline IP + NT (30 µg IC); (3) Pretreatment IP + Saline IC; (4) Pretreatment IP + NT (30 µg IC). After drug pretreatment rats were lightly anesthetized with ether, injected IC with NT or saline and placed in a cold room (4°C). Rectal temperature was monitored at 0,30,60,90 and 120 min after IC injection. Pretreatment of rats with anticholinergic (atropine), antinoradrenergic (propranolol and phenoxybenzamine) or anti-opiate (naloxone) agents did not significantly alter NT-induced hypothermia. Paracholorophenylalanine (PCPA) and 6-hydroxydopamine (6OHDA) were utilized to deplete brain serotonin and catecholamines respectively and these depletions were confirmed by radioenzymatic assay as previously described (Endocrinol. 101, 613, 1977). Specific depletion of brain serotonin using PCPA did not alter NT-induced hypothermia. Although depletion of both norepinephrine (NE) and dopamine (DA) with 6 OHDA potentiated NT-induced hypothermia, selective depletions of either brain NE or DA did not exert a significant effect. Haloperidol pretreatment (2 mg/kg IP) markedly potentiated NT-induced hypothermia, though lower doses of this neuroleptic did not exert this action. Pretreatment with thyroid hormone (T_3) did not alter NT-induced hypothermia but central (IC) injection of microgram quantities of thyrotropin-releasing hormone (TRH), the tripeptide which releases TSH from the anterior pituitary, significantly antagonizes NT-induced hypothermia. Treatment with Pro-Leu-Glu-NH_2 (MIF-I), another hypothalamic peptide, did not significantly effect NT-induced hypothermia. Furthermore, IC NT injection into thyroidectomized (TX), but not control rats, resulted in a significant reduction in the characteristically high levels of serum immunoreactive TSH observed in TX animals. These results demonstrate that two endogenous neuropeptides, NT and TRH, appear to be antagonists in certain systems. 1303 IMMUNOHISTOCHEMICAL IDENTIFICATION AND MAPPING OF αMELANOCYTE STIMULATING HORMONE-CONTAINING NEURONS IN THE RAT BRAIN. Thomas L. O'Donohue* and David M. Jacobowitz. Lab. Clin. Sci., NIMH, Bethesda, Md. 20014 and Dept. of Pharmacology, Howard University, Washington, D.C. 20059.

αMelanocyte stimulating hormone (αMSH) is a biologically active pituitary peptide capable of exerting potent behavioral effects in rats. Recent studies have demonstrated the presence of immunoreactive αMSH in mammalian brain. In this study we have used a highly specific and well-characterized αMSH antibody to identify and localize αMSH immunoreactivity in nerve fibers and cell bodies of the rat brain.

αMSH-containing neurons were observed within discrete varicose beaded fibers distributed throughout the rat brain. In the forebrain particularly dense populations of αMSH-containing fibers were present in the medial preoptic, periventricular, anterior hypothalamic and dorsomedial nuclei. Moderate numbers of fine varicose fibers were also noted in the internal layer of the median eminence, and the arcuate, paraventricular and posterior hypothalamic nuclei as well as in the mammillary body. A heavy fiber distribution is present in the lateral septum, dorsal and ventral parts of the nucleus interstitialis stria terminalis, and a moderate number of fibers were localized in the tractus diagonalis. A substantial number of fibers were also present in the periventricular and rhomboid nuclei of the thalamus. Many fibers were located in parts of the medial, central and basal amygdaloid nuclei.

In the mesencephalon and pons numerous fibers were observed in the central gray adjacent to the cerebral aqueduct with a medio-lateral projection of fibers through the nucleus cuneiformis and also passing ventral to the nucleus parabrachialis dorsalis. The locus coeruleus contained few, if any, fibers. A moderate number of fibers was observed in the nucleus tractus solitarius.

Intraventricular injections of vinblastine (20 µg) demonstrated that αMSH-containing cell bodies were present in the entire rostral-caudal extent of the arcuate nucleus.

It is apparent that αMSH has joined the growing list of biologically active peptides present in nerves in the central nervous system. The physiological significance of this neuropeptide awaits elucidation.

1304 ACCUMULATION OF ^{3}H-THYROTROPIN RELEASING HORMONE (TRH) BY RAT CEREBELLUM SLICES. M. Pacheco, D. J. Woodward and J. F. McKelvy. Depts. of Cell Biology and Biochemistry, Univ. Texas Hlth. Sci. Ctr., Dallas, TX 75235.

The extrahypothalamic distribution of TRH (Endocrinology 95: 540, 1974)suggests a widespread central action for this neuropeptide in addition to its hypophysiotropic function. The current work was done to investigate the possible existence of a transport mechanism for TRH in extrahypothalamic brain areas - which might be related to its synaptic actions. Two hundred µm sagittal slices of rat cerebellum were incubated with (^{3}H)-TRH (5×10^{-5} M final concentration) in a medium containing Bacitracin to prevent its degradation (Biochem. and Biophys. Res. Com. 73: 507, 1976). Time course studies showed a rapid accumulation of labeled TRH in slices incubated at 27°C or 37°C. Maximum uptake occurred at 60 min of incubation. The process responsible for (^{3}H)-TRH uptake had many of the properties of a high affinity transport system: 1) it was temperature sensitive (Q_{10} = 1.48); 2) it showed saturation kinetics; and, 3) tissue: medium ratios of 5 : 1 were attained after 60 min incubation at 37°C. Bacitracin in the incubation medium increased the uptake of label by 38%; however, chromatographic analysis revealed that in these conditions 30% of the total dpms were TRH metabolites and 70% were (^{3}H)-TRH. This indicates that Bacitracin protection is incomplete but that the majority of the label is in the form of TRH. Iontophoretic studies in the cerebellum have shown TRH to produce inhibition of the basal firing rate of the Purkinje cells (Nature 255: 233,1975 and Pharm. Biochem. & Behav. 5 : 171, 1976). Such results in combination with those of the current work support the hypothesis of a functional role for TRH in the cerebellum, as well as in other extrahypothalamic areas of the Central Nervous System.

1305 UPTAKE AND DISTRIBUTION IN MOUSE BRAIN OF A C^{14} LABELED DIPEPTIDE PROTECTIVE AGAINST PUROMYCIN AMNESIA. T. C. Rainbow, J. B. Flexner*, L. B. Flexner*, R. Walter* and P. L. Hoffman.* Dept. Anat., Sch. Med., University of Pennsylvania, Phila., Pa. 19104 and Dept. Physiol., Sch. Med., University of Illinois, Chicago, Ill. 60612.

We have found previously that subcutaneous injection of Cyclo (Leu-Gly), a stable derivative of the C-terminal fragment of oxytocin protects against puromycin amnesia in mice when given immediately after or 24 hr before Y-maze training. Cyclo (Leu-^{14}C (U) Gly) was used to determine the level of peptide in regional and subcellular fractions of mouse brain up to 96 hr after injection of a fully protective dose (1 μ mole = 170 μg). Brains were dissected into the following regions: brainstem + midbrain, hippocampus + entorhinal cortex, diencephalon, basal ganglia and cerebral cortex. At 0.5 hr and all succeeding times there was no significant difference in the level of peptide among the several brain areas. Cyclo (Leu-Gly) was identified intact 4 days after injection in brain and plasma. The ratio of the concentration of the peptide in the intracellular space to that calculated for the extracellular space was greater than 1 by 7 hr after injection and this ratio increased continually up to 96 hr indicating that the peptide was restricted in its passage out of brain tissue.

Cyclo (Leu-Gly) was found in all subcellular fractions. The amount present of Cyclo (Leu-Gly) in the synaptosomal fraction correlated highly with the degree of protection provided against puromycin-induced amnesia ($R=0.92$, $P < .005$). No other subcellular fraction showed a significant correlation. This suggests to us that the anti-amnestic effects of Cyclo (Leu-Gly) may be related to its presence in brain synaptic fractions.

1306 ENKEPHALIN ACTS TO INHIBIT LOCUS COERULEUS MEDIATED BEHAVIORS. D.E. Redmond, Jr., M.S. Gold and Y.H. Huang, Dept. of Psychiatry, Yale University, New Haven, Connecticut 06510.

Both intravenously[1] and iontophoretically[2] administered morphine diminishes the neuronal activity of the noradrenergic nucleus locus coeruleus, an effect directly mediated by opiate receptors,[3] as shown by naloxone blockade.[1,2] Similar effects of iontophoretically or intravenously administered α-adrenergic agonists are specifically blocked by low doses of the α-adrenergic antagonist piperoxane.[4] This paper will present further evidence that interactions of these receptors may be important to rated behaviors in non-human primates which may be related to human anxiety.[5] Behaviors were scored by two raters from videotape recordings. Mean threat-associated behaviors per 5 minute period from four adult *Macaca arctoides* were compared after morphine, naloxone, piperoxane, or a parenterally active synthetic pentapeptide (Sandoz FK 33824) were infused intravenously from outside a sound dampened isolation chamber. Piperoxane (1.0 mg/kg) increases behaviors indistinguishably from the effects of human threats, or of low intensity electrical stimulation of the locus coeruleus.[6] Morphine sulfate (0.2 mg/kg) or FK 33824 (0.4 mg/kg) will reduce these behaviors to below the baseline. The specificity of these effects on opiate receptors is demonstrated by their reversibility by naloxone. Administered alone FK33824 (0.4 mg/kg) blocked the effects of locus coeruleus electrical stimulation at stimulation parameters which had behavioral effects prior to drug administration and after 0.4 mg naloxone. These data suggest that exogenous opiates may have therapeutically useful effects in clinical doses because of their inhibition of noradrenergic nuclei and may be abused partly for the same "anxiety-reducing" effects.[5] Endogenous endorphin or enkephalins may function to diminish anxiety-fear symptoms and behaviors under some circumstances such as combat, shock, or extreme pain, where they would be maladaptive. Unfortunately, these conditions will be difficult to reproduce experimentally to test this hypothesis in humans. Relative opiate deficiency may lead to opposite effects, as suggested by our recent report.[7]

1307 NEUROHYPOPHYSEAL PEPTIDES, NOREPINEPHRINE AND ETHANOL TOLERANCE. R. F. Ritzmann , Paula L. Hoffman*, and Boris Tabakoff. Dept. of Physiology & Biophysics, University of Illinois Medical Center, Chiago, Illinois 60680.

The functional tolerance which develops during chronic ethanol consumption has been postulated to resemble other adaptive phenomena such as the acquisition of a learned response or memory (Tabakoff and Ritzmann, J. Pharmacol. Exp. Ther. 203:319, 1977). Brain noradrenergic (NE) systems have been shown to be involved in the processes of learning, memory and the development of tolerance to sedative hypnotic drugs. Neurohypophyseal peptides have also been shown to influence learning and memory, and these peptides have in turn been reported to alter NE turnover in various brain regions. We therefore investigated the effect of vasopressin (AVP) and oxytocin (OXT) on ethanol tolerance. Mice were fed a liquid diet containing 7% ethanol or pair-fed an iso-caloric control diet for 7 days. On the morning of the 8th day, ethanol diets were replaced with control diet; 30 hours later mice from each group received a subcutaneous injection of either 10 μg AVP, 10 μg OXT, or an equal volume of saline. These injections were repeated at 24-hour intervals for 9 days. At 3-day intervals after withdrawal, tolerance was assessed by monitoring the hypothermia and duration of the loss of righting reflex produced by the intraperitoneal administration of ethanol (3 g/kg). By the 6th day, tolerance was found to have dissipated in ethanol-fed mice treated with OXT or saline. On the other hand, no diminution in acquired tolerance was observed in the ethanol-fed mice treated with AVP. When AVP treatment was terminated 9 days after withdrawal, tolerance subsequently disappeared with its normal time course of approximately 6 days. In a second series of experiments, mice were removed from the ethanol diets and 8 hours later, injected icv with 6-OHDA (50 μg). Half of these mice were then treated daily with AVP while the remaining half received saline injections. AVP did not prolong the duration of tolerance in the 6-OHDA-injected ethanol-fed mice. Tolerance disappeared with a similar time course in AVP- and saline-injected mice, i.e. within 6 days following the termination of ethanol treatment. These results indicate that AVP may be acting through the NE system to maintain ethanol tolerance.

1308 Similarity in Structure Between MIF-I and Dopamine: Reason For Anti-Parkinsonian Activity? T. A. Robert*, R. L. Snell*, and R. M. Kostrzewa, East Tennessee State University, College of Medicine and College of Arts and Sciences, Johnson City, Tennessee, 37601.

Although the tripeptide L-prolyl-L-leucyl-glycine amide (MIF-I) has been found to be effective in preclinical trials for the treatment of Parkinson's Disease (Lancet 2:683, 1973), the mechanism of action of this agent has not been determined. Previous studies by this group and others have suggested that MIF-I may be a dopamine (DA) receptor agonist. In the present study, CPK (Ealing Corporation) models of MIF-I and DA were constructed in order to examine the possibility that MIF-I structurally mimics the DA molecule.

Three primary conformations with similarities to DA have been revealed upon examination of the space-filling molecular models. Of these three, one particular conformer appears to possess minimal bond strain and notable similarities to DA. The proline amine and terminal carbonyl oxygen of MIF-I can be superimposed upon the terminal amine and 4-hydroxy groups of DA respectively. Approach to the tripeptide surface which presents these exposed functional groups and resembles the topology of the DA molecule is not sterically hindered. The spacial position and Π-cloud orientation of the oxygen atoms from the two molecules are similar, and the possibility of tautomerism within the peptide bonds of MIF-I may produce a hydroxyl group chemically similar to that of DA. The ability of the MIF-I carbonyl and DA hydroxy oxygens to form hydrogen bonds may prove to be a significant factor in ligand-receptor interaction.

1309 ENKEPHALIN FIBERS ARE PRESENT IN THE PARS NERVOSA OF THE RAT PITUITARY. DEHYDRATION DECREASES MARKEDLY THEIR ENKEPHALIN CONTENT. Jean Rossier, Elena L.F. Battenberg, Alejandro Bayon*, Tamotsu Shibasaki*, Roger Guillemin, Richard J. Miller+, and Floyd E. Bloom. The Salk Institute, La Jolla, CA 92037. +Univ. of Chicago, Illinois 60637.

Radioimmunoassays of β-endorphin (B-E), α-MSH and Leu^5-enkephalin (L-e) were performed on extracts of the pars distalis, pars intermedia and pars nervosa dissected under microscope from the rat pituitary. B-E was concentrated in pars distalis and pars intermedia and was absent from pars nervosa, α-MSH was mostly concentrated in pars intermedia, L-e was found mostly in pars nervosa.

	Total content whole pituitary	Per cent per pars distalis	intermedia	nervosa
B-E i.l.*	1.3 µg	60%	35%	5%
α-MSH i.l.	450 ng	20%	68%	12%
L-e i.l.	750 pg	9%	13%	78%

i.l.= immunoassayable like material.

By immunocytology, fibers visualized with L-e antiserum were seen only in pars nervosa. The L-e i.l. of the pars intermedia extracts was coeluted with synthetic L-e on gel filtration columns. Neither vasopressins (AVP and LVP) nor oxytocin cross-react with our L-e assay at doses up to 100 µg/assay tube. Our assay shows a 3% cross reactivity with Met^5-enkephalin which may thus be a part of our L-e i.l.

After dehydration (NaCl 2% drinking fluid for 5 days) L-e levels in the posterior lobe of the rat pituitary were 37% of the value of the control animals while no changes were noticed for B-E. Enkephalinergic cell bodies were visualized by immunocytology in the paraventricular nuclei of the hypothalamus after cochicine pretreatment. Although we have measured L-e in the hypothalamus there were no changes after dehydration. These results indicate that enkephalinergic fibers may play an important role in the regulation of the response to dehydration. It is known that morphine injections release vasopressin from the pars nervosa and that most of the opiate receptors from the pituitary are located in the pars nervosa. All these data may indicate the existence of an hypothalamic pars nervosa enkephalinergic pathway which may project onto vasopressin fibers and which may play a role in the regulation of vasopressin secretion.

1310 MIMICRY OF DOPAMINE STIMULATION OF HYPOTHALAMIC PATHWAYS BY C3a ANAPHYLATOXIN. Brian Seeman*, Nicole Schupf and Curtis A. Williams. Div. Nat. Sci. SUNY College at Purchase and Dept. Psychology, Manhattanville Coll., Purchase, New York 10577.

A soluble exogenous antigen reaction (EAR) system has been shown to alter eating and drinking patterns when administered directly to the perifornical hypothalamus (Williams and Schupf, Neurosci. Abstr. 1273, 1977). An immunological mechanism is suggested by the aggregation of PMN cells at the site the day following EAR treatment. The leucotaxic anaphylatoxin (AT) C5a might have been produced in a complement cascade initiated by the immune complex of EAR. The nonleucotaxic AT C3a would also have been produced, however, and both peptides are cytoactive via specific receptors, causing smooth muscle contraction, vasoconstriction and degranulation of mast cells. The purpose of this experiment was to determine the possible receptor specificity and/or releasing activity of AT on the one hand and, on the other, to eliminate the role of PMN cells as a participant factor in the phenomenon. Accordingly we tested the nonleucotaxic human AT C3a (supplied by Dr. A. Hugli) for its ability to modify pharmacologically induced appetitive behaviors in sated rats.

Rats were prepared with cannulae in the perifornical hypothalamus, a region where direct chemical stimulation in sated rats with Norepinephrine (NE) will elicit excessive eating and stimulation with carbamyl choline (CC) will elicit excessive drinking. Treatment with C3a 20 minutes before drug stimulation caused increased eating in NE-stimulated rats and increased drinking in CC-stimulated rats. C3a appears selectively to potentiate ongoing behaviors; no change in consummatory behavior is observed in saline control animals. The enhancement of drug-induced behaviors is confined to the relevant reinforcer: NE-stimulated rats increase food but not water intake, CC-stimulated rats increase water but not food intake. Similar effects on food and water intake in hungry and thirsty rats following injection of L-DOPA and dopamine (DA) into this region of the hypothalamus have been reported by Friedman et.al. (Life Sci, 1973), Coons and Starr (EPA, 1975) and Friedman (EPA, 1978). Since our data suggest that C3a may release endogenous DA or stimulate DA receptor sites, we confirmed the effect of DA in these animals.

The results with C3a, however, do not mimic the effect of the EAR. which potentiates NE-stimulated eating but not CC-stimulated drinking, and which induces eating in saline control rats. Thus while C3a activity is worthy of further study, it does not seem to be the mechanism of action of EAR. C5a will be investigated by similar procedures.

1311 OPIATES AND OPIOID PEPTIDES MAY EXCITE HIPPOCAMPAL (HPC) PYRAMIDAL NEURONS (HPN) BY INHIBITING ADJACENT INHIBITORY INTERNEURONS. G.R. Siggins, W. Zieglgänsberger*, E. French, N. Ling, and F. Bloom. Behav. Neurobiology Lab and Neuroendocrinology Lab, The Salk Institute, La Jolla, CA 92037.

Microiontophoretically applied opiates and endorphin peptides depress single unit activity in most areas of the CNS via specific opiate receptors (Zieglgänsberger and Fry, In: Developments in Opiate Research, M. Dekker, 1978). An apparent exception is the predominantly excitatory response of rat HPN's, which is often naloxone-sensitive (Hill et al, J. Physiol. 272:50P, 1977; Nicoll et al, PNAS 74:2584, 1977) and not due to an interaction with the muscarinic cholinergic input to HPN's (French et al, Proc. Soc. Neurosci. 3:291, 1977). To investigate the mechanism of this excitatory response, HPN's were tested with conventional five-barrel iontophoretic pipettes, or with multi-barrels glued to one or more recording barrels with tip separations of 30-60 µm. When opioid peptides (Met^5-enkephalin, D-ala^2-met^5-enkephalin, β-endorphin) were applied by iontophoresis or by a micro-pressure ejection method most neurons with burst-like firing patterns (probable HPN's) were excited while cells with non-bursting spontaneous activity (probable interneurons) were only inhibited. Employing tip separations up to 150 µm, a probable interneuron at one recording tip on occasion could be inhibited while a bursting neuron at the other tip could be reciprocally excited. Low iontophoretic currents of Mg++ (10-30nA), applied to depress local transmitter release, blocked opioid excitation and/or reversed them to inhibitions, without affecting ACH-evoked excitations. Bicuculline, known to block postsynaptic GABA inhibitory actions, often directly excited HPN's and antagonized opioid-induced excitations. Stimulation of contralateral HPC was used to evoke inhibition of ipsilateral HPN's via recurrent activation of basket cells, thought to release GABA onto HPN's. This basket cell-evoked inhibition was often specifically antagonized by iontophoretically applied enkephalin. These results suggest that the naloxone-sensitive excitatory response of HPC pyramidal neurons is due to inhibition of adjacent inhibitory basket cells, resulting in loss of tonic recurrent inhibition (excitation by disinhibition). Thus, while specific opiate receptors may generally mediate inhibitory responses in all brain regions, including hippocampus (Fry et al, J. Physiol. Mar 78, 21P), the ultimate action of opiates on a brain region depends upon the local circuitry. This excitatory mechanism in HPC could provide a basis for the limbic epileptiform activity produced by intracerebroventricular opiates (Henriksen et al, Proc. Soc. Neurosci. 3:292, 1977). *Permanent address: Max Planck Inst. f. Psychiatry, Munich. Supported by USPHS Grant DA 01785 and a Bosch Fellowship.

1312 NEUROPEPTIDES AND THE BLOOD-BRAIN BARRIER IN GOLDFISH. Dolores M. Smith*, Richard D. Olson, Abba J. Kastin, Gayle A. Olson*, David H. Coy*, and Gary F. Michell*. Dept. of Psychology, Univ. of New Orleans, VA Hospital, Tulane Med. School, New Orleans, LA 70122

The general activity level of a goldfish is easily monitored by placing it in an inch of water in a standard, 10 gallon aquarium placed on top of a Stoelting activity meter. After an initial burst of activity, goldfish become less active over time and usually generate approximately 300 activity counts during a standard 30 minute session.

Using this paradigm, goldfish were administered a 5 µl (80 µg/kg) ICV or IP injection of one of 21 test substances and tested for general activity. Results indicated that activity decreased reliably over time and that significant differences existed as a function of site of injection, with ICV injections producing greater decreases. Of the substances evaluated, no reliable differences existed between the diluent control and melanin, MIF-I, substance P, Met-enkephalin, D-Ala^2-enkephalin, DSIP, and D-Ala^3-DSIP. Significant decreases in activity were obtained using D-Ala^4-DSIP, α-MSH, neurotensin, and somatostatin. Further, all endorphins tested produced reliable decreases: α-endorphin, β-endorphin, γ-endorphin, Leu^5-β-endorphin, D-Thr^6-D-Leu^{17}-D-Lys^{19}-β-endorphin, D-Leu^{17}-D-Lys^{19}-β-endorphin, and D-Ala^2-β-endorphin. Finally, the greatest decreases in activity were produced by two new enkephalin analogs.

General results indicated that activity decreased approximately 3 minutes after a central injection and 6 minutes after a peripheral injection. The longer latency after IP injections may indicate the amount of time required for the substance, either in original or fragmented form, to reach and cross the blood-brain barrier. Accordingly, since both ICV and IP injections produced reliable decreases in activity, it would seem reasonable that the action of the substance is not a function of the site of injection. Some peptides or their metabolites appeared to readily cross the blood-brain barrier (e.g., γ-endorphin) as no difference existed between ICV and IP injections, with both producing reliable decreases from the control. In summary, peptides can exert behavioral effects after both central and peripheral administration in goldfish.

1313 COMPARISON OF PEPTIDE AND AMINO ACID DEPRESSION OF EXCITABILITY ON CULTURED SPINAL NEURONS. T.G. Smith*, J.L. Barker, D.L. Gruol, L.M. Huang* and J.H. Neale, LNP, NINCDS, NIH, Bethesda, Md. 20014 and Dept. Biology, Georgetown University, Washington, D.C.

Spinal neurons derived from mouse embryos were grown in tissue culture for 4 weeks or more. Intracellular recordings coupled with extracellular iontophoresis were used to study the effects of leucine-enkephalin (ENK) and the putative inhibitory amino acid transmitters γ-aminobutyric acid (GABA) and glycine on neuronal membrane properties. ENK depressed spike generation induced by constant-current, suprathreshold pulses by two mechanisms. ENK elevated threshold for generation of action potentials (1 to 20 mV) in a dose-dependent, reversible manner without change in membrane potential or input resistance. The increase in threshold was accompanied by a dose-dependent increase in the current required to attain threshold (rheobase). This effect was observed in the absence of any change in the current-voltage relations of the cell and clearly outlasted the iontophoretic application of the peptide. It did not desensitize and was reversed by naloxone at doses which did not alter membrane properties. A second form of depression of excitability by ENK occurred through a slight increase (∿ 10%) in membrane conductance without observable change in membrane potential. Rheobase was again increased in a dose-dependent, reversible manner but threshold for spike generation was unaltered. This effect did not desensitize and outlasted the peptide application.

GABA and glycine also depressed spike generation induced by constant-current, suprathreshold pulses by two mechanisms. Both amino acids greatly increased (50-1000%) membrane conductance, markedly altering the current-voltage relations of the cell. These effects decreased excitability by hyperpolarizing the membrane potential away from threshold and by shunting the cell. These actions only briefly outlasted the amino acid application. Threshold for spike generation was not altered, but the rheobase increased in a dose-dependent reversible manner. Both amino acid actions desensitized, GABA typically more than glycine.

Thus, there are similarities and differences between the depressant effects of the opiate peptide and the amino acid transmitters. The peptide can directly depress excitability either by elevating threshold or by slightly increasing membrane conductance. The amino acids depress excitability by intensively activating Cl^- conductance (J. Physiol., in press) which then dominates resting membrane properties. The results thus suggest that some of the pharmacologic effects of ENK fall outside operational definitions for neurotransmitter action.

1314 THYROTROPIN RELEASING HORMONE: AROUSING ACTION IN THE HIBERNATING GROUND SQUIRREL. T.L. Stanton, A. Winokur and A.L. Beckman. Depts. Physiol., Psychiat. and Pharm., Sch. Med., Univ. of Pa., Philadelphia, PA 19104.

Several laboratories have demonstrated that thyrotropin releasing hormone (TRH) antagonizes the CNS depression and hypothermia induced by a variety of neurotropic agents. These experiments were conducted to investigate the effects of intracerebral application of TRH in the adult golden-mantled ground squirrel (Citellus lateralis) during deep hibernation, a naturally induced depressed state that is entered through slow wave sleep and considered to be an extension of natural sleep.

Bilateral, 1 µl-injections of TRH (1.0 ng/µl to 1.0 µg/µl) were delivered through injection cannulae inserted via chronically implanted guide tubes into either the hippocampus (HPC) or preoptic/anterior area of the hypothalamus (PO/AH), two areas implicated in the neural control of hibernation. Metabolic rate and brain temperature (T_b) were recorded continuously during the experiments.

Intrahippocampal administration of TRH, in a dose as low as 1 ng/µl, was observed to be a potent agent for arousing animals from a state of deep hibernation. Full arousal, in which a dramatic rise in oxygen consumption accompanied an increase in T_b from approximately 5 to 37 C, was triggered with a dose-dependent decrease in latency associated with increasing dose of TRH. This effect was evident in the early period of the hibernation bout when the animals are most resistant to arousing stimuli. TRH, in the same dose range, was ineffective in triggering arousal from hibernation when microinjected into the PO/AH.

These data compliment previous pharmacological demonstrations of an arousing action of TRH during drug-induced depressed states and suggests that TRH may have physiological significance as a modulator of CNS excitability. Such a role may be particularly evident during the state of hibernation in which the level of inhibition in the CNS appears to be high. Increasing evidence indicates that the HPC may be the likely source of this inhibitory influence. In view of this, and considering the predominantly inhibitory action of TRH at the single unit level, it is possible that intrahippocampal microinjection of TRH may be triggering arousal from hibernation by disinhibiting the ongoing inhibitory control. (Supported by NSF grant # BNS 77-11352.)

1315 ENKEPHALIN CATABOLISM IN THE PRESENCE OF AN OPIATE RECEPTOR PREPARATION FROM RAT BRAIN. Susan O. Sullivan*, Huda Akil and Jack D. Barchas.

A washed membrane preparation from rat brain, containing opiate receptors, was incubated under conditions used for the opiate receptor binding assay (90 min., 0°C). At the completion of incubation, centrifugation was used to precipitate membranes, and the supernatant was analyzed for breakdown products of ^{3}H-Tyr-Met^5-enkephalin. Two thin layer chromatography systems and a Biobead-SM2 column were used. A peak of radioactivity that did not correspond to tyrosine, tyr-gly, tyr-gly-gly or met-enkephalin was observed. This peak may be tyr-gly-gly-phe suggesting that breakdown of met-enkephalin can occur at the phe-met bond. Previous reports in plasma and unwashed whole brain homogenates indicate that the initial cleavage in met-enkephalin breakdown is at the tyr-gly bond. It is suggested that a soluble enzyme is responsible for the tyr-gly cleavage. Upon further washing of the membrane fraction, a membrane bound enzyme capable of phe-met cleavage is exposed. Further identification of the breakdown product and the subcellular localization of this enzyme is under investigation.

1316 EXTRA-HYPOPHYSIAL OXYTOCIN-CONTAINING PATHWAYS IN THE BRAIN AND SPINAL CORD OF THE RAT AND MONKEY. L.W. Swanson. Dept. Anat. and Neurobiol., Washington Univ. Sch. Med., St. Louis, MO 63110.

The distribution of fibers cross-reacting with antisera to oxytocin and antidiuretic hormone (ADH), and to bovine neurophysin I, was studied in the rat and monkey CNS with the indirect immunofluorescence method. All three antisera labeled the hypothalamo-neurohypophysial tract. A number of other fiber systems, which appeared to arise within the magnocellular neurosecretory system, were also stained with anti-oxytocin and anti-neurophysin I. In the rat a small group of stained fibers could be traced through ventral parts of the reticular formation to sacral levels of the spinal cord. Branches of this pathway appeared to innervate the locus coeruleus and parabrachial nucleus, the vagal complex, the spinal nucleus of the trigeminal nerve, and the marginal zone and central gray of the spinal cord. The intermediolateral column was particularly densely labeled at levels T1-T2, T11-T12, and L2-L3. Of particular interest, other labeled fibers were found to pass through medial parts of the septal region and subfornical organ to the interior of the choroid plexus of the third ventricle, and still other varicose fibers were found running parallel, and immediately adjacent to some of the major penetrating arteries supplying the paraventricular nucleus. A less complete analysis in the monkey has thus far shown the presence of neurophysin I and oxytocin-stained fibers in the vagal complex and spinal cord (including the intermediolateral column), as well as stained fibers closely associated with hypothalamic blood vessels and ependymal cells of the third ventricle. In the monkey, fewer oxytocin-stained fibers were found in the dorsal motor nucleus of the vagus and the nucleus of the solitary tract, and more were found in the intermediolateral column, than in comparable regions of the rat. The evidence suggests that the paraventricular nucleus projects to the pituitary and to a number of regions within the CNS itself, including cell groups associated with both divisions of the autonomic nervous system. Furthermore, at least some of the oxytocin-stained fibers end in relation to capillaries (median eminence and pituitary), arterioles (hypothalamus), ependymal cells (third ventricle) and the choroid plexus (third ventricle). (Supported in part by PHS Grant NS13267).

1317 EFFECT OF NEUROPEPTIDES ON ACUTE STRESS-INDUCED HORMONAL CHANGES. Y. TACHE* and R. COLLU. Dept. Péd., Hosp. Ste-Justine, U. de Montréal, Montréal, P.Q.

We have recently reported that various neuropeptides distributed throughout the brain and the gastrointestinal track could affect hypothermia and the susceptibility to gastric ulcerations induced by cold+restraint stress (Taché, Y. and Collu, R., 60th Ann. Meet. End. Soc., 1978). In the present study, we further investigated the interaction between neuropeptides and stress-induced hormonal changes.

Adult male rats were injected intraventricularly-through a chronic cannula implanted two days previously into a lateral brain ventricle- with saline or oligopeptides. Immediately after the injection rats were exposed for 1 hr to various stressors (cold, restraint, fasting + restraint at 4°C) and killed at the end of the stress procedure. Bombesin (5-0.1μg) and neurotensin (5μg) further enhanced the hyperglycemic response to stress whereas somatostatin and thyrotropin releasing hormone (TRH) decreased plasma glucose levels in stressed rats; β-endorphin (5-1μg) and substance P had no effect. Stress-induced inhibition of growth hormone (GH) secretion was not affected by any of the neuropeptides tested, whereas prolactin (PRL)-releasing effect of the various stressors was antagonized by bombesin (5-0.1μg), neurotensin (5μg), TRH (5μg) and to a lesser degree by substance P (5μg). β-Endorphin (5-1μg) and somatostatin (5μg) did not modify plasma PRL levels in stressed rats. Adrenalectomy prevented the enhancing effect of bombesin on stress-induced hyperglycemia but did not modify the inhibitory effect on PRL release. Bombesin was 10^3 more potent when given intraventricularly than when injected intravenously in decreasing plasma PRL levels in stressed rats.

These results show that various neuropeptides affect the hormonal response to stress. In particular, bombesin appears a very active neuropeptide capable of interfering centrally with stress manifestations.

1318 SUBSTANCE P-CONTAINING PROCESSES VISUALIZED BY A MODIFIED PAP PROCEDURE IN THE RAT SPINAL CORD. Linda L. Vacca, Susan J. Abrahams*, and N. Eric Naftchi*. Dept. of Path. & Anat., Med. Coll GA, Augusta, GA 30902 and IRM, NYU Med. Ctr., New York, NY 10016

Using a modified peroxidase anti-peroxidase (PAP procedure (J. Histochem. Cytochem. 26: 226, 1978), the peptide substance P (SP) has been localized within beaded processes and punctate bodies in the ventral, lateral, and dorsal horns of the rat spinal cord. The modified procedure, which employs a double bridge and diaminobenzidene in solution at low pH, increases the sensitivity of the PAP method and enables us to see staining patterns not previously reported. These patterns include staining around the motoneurons, in the region of the central canal including the dorsal and ventral gray commissures, in association with myelinated fibers, and in occasional cell bodies in the dorsal horn.

At most cord levels, a sparce number of beaded processes traverse the ventrolateral extent of the ventral horn. At high cord levels, SP-containing processes occur within the lateral horn. Since the processes in the lateral horn cannot be traced for long distances, their relationship with the ventrolateral and commissural processes remains obscure.

In some regions of the spinal cord, SP is closely associated with myelinated fibers. In the dorsal part of the lateral funiculus, punctate bodies containing SP lie within the white matter. Many are associated with fasciculus dorsolateralis, but some occur more laterally. Punctate bodies also appear within the anterior white commissure and ventral to it along the anterior fissure. The punctate bodies are embedded within the matrix of myelinated fibers in these regions where certain spinal cord pathways occur.

In the dorsal horn, as previously reported, numerous SP-containing punctate bodies can be seen in the substantia gelatinosa (SG) region. Rows of punctate bodies stud the large bundles of myelinated dorsal root collaterals which sweep around the dorsal horn medially and penetrate the SG. Fewer punctate bodies follow linear patterns along the myelinated collateral fiber bundles which course through the SG radially. As these fiber bundles penetrate deeper into the dorsal horn and are distributed to various cell groups within the grey matter, the associated SP-containing bodies become less abundant. The close association between SP and these myelinated collaterals from the dorsal root may indicate a modulatory role for the peptide on other primary afferent fibers.

Occasional cell bodies appear stained for SP. They are bipolar and extend their processes along the dorsolateral part of the dorsal horn. Their relationship to immunoreactive fibers is at present unknown. (Supported by Medical College of Georgia Biomedical Research Grant 10-16-04-3611-23).

1319 DETECTION OF TWO NOVEL ENDORPHIN LIKE PEPTIDES IN RAT AND BOVINE STRIATUM. H.-Y. T. Yang*, W. Fratta*, J. S. Hong*, A. M. Di Giulio* and E. Costa. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

Constant rate infusion with ^{3}H tyrosine or glycine (150 μCi) into the cerebral ventricles for thirty minutes causes little or no incorporation of radioactivity into striatal [met5]-enkephalin (MET). The formation of radioactive MET increases during the following two hrs. These observations suggested that the in vivo synthesis of MET in striatum may involve the formation of one or more precursors. Since we failed to detect β-endorphin in rat and bovine striatum we searched for possible precursors of striatal MET. For this purpose we have developed a MET antibody which possesses some affinity for endorphins with molecular weight larger than MET but smaller than β-endorphin. By this antibody, two endorphin-like peptides with molecular weight larger than MET were detected in the eluate of a Biogel P-2 column loaded with the extract of a bovine caudate. The retention volume of these two peptides is smaller than that of MET. The study on the immunoreactivities of these two endorphin like peptides with antibody directed toward β-endorphin and β-lipotropin revealed that the novel endorphin are neither β-endorphin nor β-lipotropin. Moreover we have found that after trypsin hydrolysis they can generate a peptide similar to that generated by trypsin hydrolysis of α-endorphin. With Sephadex G-75 column and thin layer chromatography techniques, we have excluded that the novel peptides are α-endorphins. In order to decide whether these two endorphin-like peptides are formed post mortem during the handling of the bovine brain, we have attempted to identify these two peptides in the brain of rats killed by a focused microwave irradiation. In rat brain we detected at least 2 endorphin-like peptides, which in the Biogel P-2 column chromatography behave similarly to the two endorphin-like peptides of bovine brain. These results suggest that in the striatum of rat or bovine brain, there are two endorphin-like peptides with molecular weight larger than MET which are structurally different from α- and β-endorphins and β-lipotropin. Whether these two peptides function as precursors of MET in striatum will be discussed.

NEURO-PHARMACOLOGY

1320 PROGRESSIVE INCREASE OF SENSITIVITY TO SEROTONIN IN CHRONIC SPINAL RATS. Hugues Barbeau*, Paul Bédard* and Michel Filion. Laboratoires de Neurobiologie, Université Laval, Québec, Canada, G1K 7P4.

A few hours after spinal transsection in rats, 5-hydroxytryptophane (5-HTP), the precursor of serotonin, increases spinal reflexes elicited below the transsection (Anderson et al. (1966) J. Pharmacol. Exp. Therap. 153: 352). The present study provides quantitative data showing that the effect of 5-HTP on the activity of neurons below a complete spinal transsection varies over a period of days. Spontaneous EMG activity of tigh flexor and extensor muscles was recorded chronically and quantified in spinal rats free to move their hindlimbs. A few hours up to about 4 days after the transsection the spontaneous EMG activity is low and is not altered or barely increased by a single standard dose of 5-HTP (100 mg/kg, i.p.). After the 4th day the same dose of 5-HTP clearly increases the EMG activity and induces obvious movements of the paralyzed limbs for about 6 hours. There is a parallel increase in the activity of the autonomic nervous system (micturition, defecation, erection, ejeculation). This effect of 5-HTP is manifest within the first minute after the injection and reaches a maximum within 10 minutes. The amplitude of the effect increases from 3 to 5 times the preinjection level of EMG activity, around day 5, to over 10 times the preinjection level, around day 20. It remains at this maximum amplitude up to day 30. The effect is blocked rapidly by cyproheptadine (10 mg/kg) and various antagonists of serotonin. It is mimicked by LSD (0.5 mg/kg) and several other compounds thought to act as agonists of serotonin. Methysergide (5 mg/kg) shows mixed properties. The changes in the intensity of the response to 5-HTP can be interpreted in terms of denervation supersensitivity of serotonin receptors. The sensitivity to serotonin is thus maximum 3 weeks after spinal transsection and the preparation provides a good model to test agonists and antagonists of serotonin.

1321 HIGH AFFINITY BINDING SITES FOR N,N-DIMETHYLTRYPTAMINE ON PURIFIED RAT BRAIN SYNAPTOSOMAL MEMBRANES. L.J. Bearden, L. Burrow* and S.T. Christian. Neurosciences Program and Department of Psychiatry, Medical Center, University of Alabama in Birmingham, Birmingham, Alabama, 35294.

The possibility that the endogenous hallucinogen N,N-dimethyltryptamine (DMT) serves as a neuroregulatory agent is suggested by several observations. Both DMT and an immediate precursor, tryptamine, have been found in brain tissue from humans and animals. Appropriate biosynthetic enzymes and metabolites of DMT have also been found in neural tissue. In addition, DMT has been detected in synaptic vesicle fractions isolated from rat brain. Thus, the in vivo biosynthetic reactions and a possible endogenous storage site for DMT have been demonstrated. However, the precise role which DMT plays in the central nervous system has not been elucidated.

Experiments conducted in our laboratory have shown that $5 \cdot 10^{-10}$M DMT stimulates the production of cAMP in synaptosomal membrane preparations to levels greater than twice those observed in control samples. In the same experiments, lysergic acid diethylamide (LSD) was found to stimulate cAMP production to similar levels. But when 5-hydroxytryptamine was present with either DMT or LSD, similarly additive effects on membrane cAMP production were observed. These findings are supported by other experiments which indicate that DMT does not inhibit the binding of 5-hydroxytryptamine ($5 \cdot 10^{-10}$M) to synaptosomal membranes, whereas DMT ($1 \cdot 10^{-5}$M) displaces LSD which is bound to synaptosomal membranes.

Studies of the binding of DMT to synaptosomal membranes at concentrations down to 10^{-10}M have now been conducted by means of equilibrium dialysis. These experiments have utilized ^{3}H-DMT and synaptosomal membranes prepared in buffered sucrose media by conventional differential centrifugation techniques. Results from these studies have indicated the presence of high affinity, synaptosomal membrane binding sites for ^{3}H-DMT which are sensitive to low concentrations of LSD. (This work was supported in part by a grant from NIDA #2R01 DA01235-03.)

1322 STRESS INDUCED CHANGES IN WHOLE BRAIN INDOLEALKYLAMINE LEVELS IN THE RAT: USING GAS LIQUID CHROMATOGRAPHY-MASS SPECTROMETRY, John M. Beaton and Samuel T. Christian. Neurosciences Program, and Department of Pharmacology and Psychiatry, University Station, Birmingham, Alabama 35294.

Many theories of schizophrenia are predicated on the belief that the illness is caused by a chemical substance which, if isolated and administered to normals, would mimic the clinical aspects of schizophrenia in these normals. The indolealkylamines, (N,N-dimethyltryptamine-DMT; bufotenin-BUF and O-methyl-bufotenin -OMB), have been implicated as possible compounds. Environmental stress is thought to be an important precipitating factor in schizophrenia. Therefore, the aim of the studies to be presented here was to expose rats to various stresses and to examine the effects of these stresses on the levels of DMT and other indolealkylamines in the brains of the rats. Groups of six rats were exposed, individually, to one of the following conditions: no stress, electric shock, electric shock plus restraint, cold, swimming to exhaustion, or swimming to exhaustion in cold water. Purified synaptic vesicles were prepared from the groups of six rats. The vesicles were then extracted with methylene chloride and the extract derivatized with heptafluorobutyryl imidazole. Samples of the derivatized extracts were then analyzed on a GLC-MS. The electron impact mass spectrum of both DMT and OMB (as heptafluorobutyryl derivatives - HFB) exhibits m/e 58.2 as the base peak due to alpha-cleavage of the tertiary amino group. Thus selected ion monitoring of this mass fragment provides simultaneous determination of both compounds in a single run. Aliquots of 1 to 3 ul were chromatographed over a six-foot glass column, 2 mm i.d., of 3% SP-2250 on 160°C for 4 minutes followed by a programmed temperature increase of 10°/min. to 225°C. Helium was used as the carrier gas at a flow rate of 40 ml/min. Under these conditions, DMT-HFB eluted at 4.7 minutes and OMB-HFB at 7.3 minutes. Instrumentation used was a Hewlett-Packard 5985 A GC/MS data system. Identification of DMT and OMB was based upon retention time and simultaneous monitoring of mass fragments other than m/e 58.2 which are diagnostic for these compounds. Absolute sensitivity of this method is 2 pg DMT-HFB and 3 pg OMB-HFB per injection. Quantitation was achieved by an isotope dilution method using alpha, alpha, beta, beta-tetradeuterated DMT and OMB as internal standards. The results of this study indicated that both DMT and O-methyl-bufotenin (OMB) were present in normal rat brain. The control levels of one or both of these compounds was increased to varying degrees by the different stresses. Electric shock plus restraint increased the levels of DMT by the greatest amount.

1323 EFFECTS OF CHOLINOMIMETICS ON PENTOBARBITAL ANESTHESIA IN MICE. Srinath N. Bellur, M.D., Walter Wojcik, B.S. and Miodrag Radulovački, M.D., Ph.D. Dept. Pharmacology, U of I Med. Center, Chicago, IL 60612.

Previous reports of physostigmine pre-treatment on pentobarbital anesthesia in mice have varied from no effect to prolongation or shortening of duration of anesthesia. Latencies and duration of anesthesia were calculated in mice by measuring the time for loss and resumption of righting reflex after pentobarbital administration (60 mg/kg i.p.). Physostigmine (0.25 mg/kg), neostigmine (0.25 mg/kg), choline chloride (120 mg/kg) and saline control (0.2 ml) were given i.p. 600 sec prior to pentobarbital administration (experiment I) and 1800 sec after the loss of righting reflex (experiment II). Control latency was 147 ± 21 sec (mean ± SD) and duration was 4623 ± 852 sec. There were no significant changes in latency or duration of anesthesia in experiments with choline or neostigmine. Physostigmine significantly shortened latency to 109 ± 16 sec (26%) without changing the duration of anesthesia when given prior to pentobarbital (experiment I). However, it significantly shortened the duration to 3042 ± 745 sec when given during the anesthesia (35%) (experiment II). The above data indicate that a peripheral or central effect of acetylcholine does not seem to be involved in physostigmine action. It is more likely that an enhanced blood-brain barrier permeability to barbiturates may explain the obtained findings (Greig and Mayberry, 1950). These results are of interest in suggesting a role for physostigmine therapy and for its proper timing in barbiturate intoxication.

1324 HIGH AFFINITY BINDING SITE FOR [^{3}H]-L-GLUTAMIC ACID ON BRAIN MEMBRANES. K. Biziere* and J.T. Coyle (SPON: M.E. Molliver). Dept. Pharmacol., Johns Hopkins Univ. Sch. Med. Balto., MD 21205.

L-glutamic acid (L-Glu) has excitatory effects when iontophoresed onto most neurons in the mammalian CNS. There is growing evidence that L-Glu may be the excitatory neurotransmitter for several neuronal pathways including the cortico-striatal projection. With [^{3}H]-L-Glu of high specific radioactivity (50 Ci/mmol), we have examined the binding of the amino acid to brain membranes in an attempt to characterize physiologically relevant receptor binding sites.

Rat brain membranes were prepared by sonication of fresh, frozen brain in Tris-citrate buffer (0.05 M, pH 7.1 at 2° C); the membranes were isolated by centrifugation, washed extensively, and pre-incubated for 20 min at 25° C. Typically, 300 µg membrane protein was incubated for 20 min in 2 ml of Tris-citrate at 2° C with 3 nM [^{3}H]-L-Glu in the absence or presence of 100 µM L-Glu; membranes were then isolated by centrifugation. Specific binding is the difference between total binding and non-specific binding in the presence of 100 µM L-Glu. The binding was rapid and reversible with equilibrium reached by 10 min incubation. The amount of [^{3}H]-Glu bound was linear with membrane protein up to 500 µg. A saturation isotherm for forebrain membranes revealed an apparent K_D of 11 ± 1 nM and a B_{max} of 110 ± 15 fmol/mg protein; however, anomolous kinetics occurred at concentrations of [^{3}H]-L-Glu in excess of 10^{-8} M. The specific binding of [^{3}H]-L-Glu varied in brain regions (fmol/mg protein): parietal cortex, 43 ± 4 ≥ frontal; 38 ± 2 > hippocampus, 29 ± 2 ≥ striatum, 28 ± 2 > cerebellum, 13 ± 2 ≥ pons-medulla, 10 ± 2. The IC_{50} for several excitatory amino acids and analogues were examined: L-Glu, 0.003 µM; D,L-homocysteic acid, 0.7 M; D-Glu, 1 µM, D-aspartic acid, 0.9 µM; L-aspartic acid, 1 µM. Notably, kainate, dihydrokainate, quisqualate, ibotenate did not displace [^{3}H]-L-Glu at 10^{-5} µM; GABA, glycine, taurine, phenytoin, phenobarbital, carbachol, norepinephrine and diazepam were also ineffective at 10 µM.

Decortication produced a 45 ± 5% reduction in [^{3}H]-L-Glu synaptosomal uptake and a 55 ± 4% reduction in endogenous Glu in the striatum but did not significantly alter the specific binding of [^{3}H]-L-Glu; thus, it is unlikely that [^{3}H]-L-Glu is labelling a presynaptic transport site for Glu. In contrast, a striatal lesion with kainic acid, which selectively ablates striatal intrinsic neurons, produced a 51 ± 8% reduction in the specific binding of [^{3}H]-L-Glu. These studies suggest that [^{3}H]-L-Glu is binding to an high affinity site primarily localized on neurons that may be a receptor mediating the neurotransmitter action of Glu. (Supported by USPHS Grants NS 13584, RSDA KO2-MH 00125).

1325 **INCREMENTAL DOSES OF MORPHINE PROVIDE METHOD TO IDENTIFY DIFFERENT PATTERNS OF RESPONSES RECORDED FROM EIGHT BRAIN NUCLEI.** M. Brown*, B.M. Rigor*, and N. Dafny (SPON: T.F. Burks). The University of Texas Medical School at Houston, Houston, Texas 77025.

From preliminary experiments using single doses of morphine (10 mg/kg ip), it has become evident that neurons in the central gray (CG), mesencephalic reticular formation (RF), parafasciculus thalami (PF), caudate nucleus (CN), anterior hypothalamus (AH), ventromedial hypothalamus (VMH), lateral septum (Spt), and dorsal hippocampus (Hipp) exhibit either increased or decreased activity in response to morphine treatment. In the present study, incremental doses of morphine were given in an attempt to identify differences between these nuclei. Experiments were conducted in unanesthetized, unrestrained, morphine-naive rats. Permanent electrodes (60µm in diameter) were implanted stereotaxically one week before the experiment. The amplified signals were then put through a waveform discriminator, and the digital output was interfaced parallel to an integrator connected to a polygraph, to plot online the frequency firing rate in spikes/sec. Recordings were taken for 30 min for control periods and 30 min for each treatment. Each animal was given an ip injection of saline followed by 5 incremental doses of morphine sulfate (0.5, 1.0, 5.0, 10.0 and 30.0 mg/kg) at 30 min intervals and by 1.0 mg/kg naloxone 30 min after the last morphine treatment. A total of 180 units were recorded. In general, as the dose of morphine increased, more units responded. Seven patterns of responses were observed. Each structure exhibited a pattern of response different from that of the other 7 nuclei. In conclusion, the 5 incremental doses of morphine and the dose of naloxone provided data demonstrating that each nucleus in the brain responded to morphine in its own pattern. In addition, it was shown that the dose of 10 mg/kg was the most effective dose for all structures. (Supported by USPHS DA 00803)

1326 BEHAVIORAL ASSESSMENT OF ANTICHOLINERGIC PROPERTIES OF METHADONE, MORPHINE AND ENKEPHALIN. William T. Chance and John A Rosecrans. Dept. Pharmacol., Med. Col. Va., Richmond, Va. 23298.

We have previously reported (Nature 270: 167, 1977) that intrahypothalamic injection of 4.0 nmol (1 µl) of morphine effectively antagonized drinking elicited by either a subsequent (5 min) injection of an equimolar dose of carbachol or 24-hr food and water deprivation. The lack of effect of morphine on food intake indicated that this inhibition was not due to non-specific behavioral depression. Furthermore, we demonstrated that this antagonism of drinking was reversed by pretreatment with an equimolar dose of naloxone. In the present experiment, we have extended these data to other opiate and opioid compounds. Across two experiments, cannulae (24 ga) were implanted into the perifornical hypothalamus of 61 adult, male, Sprague-Dawley rats. These rats were maintained ad lib. on ground rat chow and water. Injection (1 µl) of carbachol (4.0 nmol) was observed to reliably elicit both eating and drinking during the subsequent 1-hr period. Pretreatment (5 min) with l-morphine (4.0 nmol) reduced drinking by 67%, while not affecting eating. Pretreatment with d-morphine (4.0 nmol) had no effect on either behavior. Injection of l-morphine (4.0 nmol) also selectively antagonized drinking elicited by 24-hr (86% reduction) and 48-hr (84% reduction) food and water deprivation, while d-morphine was again without effect. Pretreatment with either 4.0 or 8.0 nmol of d- or l-methadone had no effect on drinking or eating elicited by the subsequent (5 min) injection of carbachol (4.0 nmol), while 8.0 nmol of l-methadone selectively reduced drinking (47% reduction) elicited by 48-hr food and water deprivation. Pretreatment (5 min) with the enzyme-resistant enkephalin analogue, d-ala^2-met^5-enkephalin (4.0 nmol), effectively antagonized drinking elicited by an equimolar dose of carbachol (92% reduction) or 48-hr food and water deprivation (91% reduction), while not affecting food intake. In a subsequent experiment, the reduction of carbachol-elicited drinking by pretreatment with d-ala^2-met^5-enkephalin (66% reduction) was completely reversed by pretreatment (5 min) with 4.0 nmol of the opiate antagonist, naltrexone.

These results extend out initial findings concerning inhibition of the muscarinic-cholinergic drinking response by opiate compounds, suggesting that these effects are specific cns narcotic effects. In addition, differences in anti-cholinergic effects are indicated between the compounds tested in this report, with morphine and enkephalin being much more effective antagonists of exogenously-stimulated drinking (carbachol-elicited) than methadone. These differences may represent a selective action of morphine and enkephalin, acting not only to inhibit the release of acetylcholine (as assessed by deprivation-induced drinking) but also serving to block the post synaptic muscarinic receptor. (Supported by: NIH DA-00296-04 and NIDR DE-00116)

1327 EXCITATORY EFFECTS OF COCAINE ON THE LIMBIC SYSTEM. Jeremiah P. Collins, Henry Lesse and James Gaffney*. Department of Psychiatry and Brain Research Institute, School of Medicine, University of California, Los Angeles, CA 90024.

The effects of cocaine on epileptiform afterdischarge (AD) activity within the limbic system of cats were studied. Subjects were chronically prepared with bilateral stimulating and recording electrodes in amygdala and hippocampus. Unilateral focal stimulation at low frequency (3 Hz) and at threshold intensity was employed in order to detect initiation of the AD during stimulation. Electrophysiological responses were monitored, and stimulation was discontinued when a focal AD was elicited. The latency for spread of the epileptiform activity to other brain areas was then determined. To separate drug effects from those of repeated brain stimulation, all tests were conducted at 48-hr intervals following alternating administrations of saline or cocaine. Three subconvulsant doses were tested in a counterbalanced order.

Results indicated that cocaine significantly increased the speed at which AD activity spread to amygdala and to hippocampus, both ipsilaterally and contralaterally. This was true whether amygdala or hippocampus was being stimulated, and the effects were dose-related. The latency of propagation of seizure activity to amygdala following hippocampal stimulation was then compared to the latency of propagation to hippocampus following amygdala stimulation. This analysis indicated a greater effect of cocaine in accelerating propagation to the hippocampus. There were changes in the pattern in which limbic seizure activity spread as well. After stimulating amygdala, the AD normally was propagated to contralateral amygdala prior to contralateral hippocampus. Following cocaine administration, this order was altered. Cocaine thus facilitates the spread of epileptiform activity to both hippocampus and amygdala but with a greater effect on hippocampus. This finding of an excitatory effect of cocaine on certain limbic structures is consistent with our previous studies showing that cocaine lowers the current threshold necessary to induce ADs in amygdala and hippocampus. These data suggest that in individuals with temporal lobe dysfunction, subconvulsant doses of cocaine may exacerbate focal epileptiform activity. (Supported by NIDA Grant DA-1351.)

1328 PRODUCTION IN RATS OF RESPONSES CHARACTERISTIC OF NEUROLEPTIC DRUGS IN THE ABSENCE OF DOPAMINE (DA) RECEPTOR BLOCKADE BY ETHANOLAMINE-O-SULFATE, A GABA-TRANSAMINASE INHIBITOR. B.R. Cooper*, K. Viik*, H.L. White*, R.M. Ferris*. (SPON: J.L. Howard). Dept. of Pharmacology, Wellcome Research Labs., Research Triangle Park, North Carolina 27709.

Intracisternal injections of ethanolamine-O-sulfate (EOS), an irreversible selective inhibitor of GABA transaminase (GABA-T: Fowler and John, Biochem. J., 130:569-573, 1972) were used to determine the effects of elevated GABA levels in brain on certain behavioral and pharmacologically-induced responses in rats which are frequently used as screens for antipsychotic drugs. EOS (200 µg - 800 µg/brain) resulted in a dose dependent elevation of GABA (2 fold-5 fold) and a corresponding decrease in GABA-T (52% to 85% inhibition) 24 hours after injection. At this time interval EOS also produced a dose-related antagonism of stereotyped behavior induced by apomorphine or d-amphetamine, and an antagonism of apomorphine-induced aggression. Hypoactivity and catalepsy also accompanied the higher doses of EOS. Study of the relationships of EOS to the function of the dopamine systems in brain revealed that EOS (800 µg/brain) did not alter DA levels, and that EOS (10^{-4}molar) did not compete with H^3-spiroperidol for binding to the presumed "dopamine-receptor" in vitro. Unlike chlorpromazine which blocks DA receptors, 24 hrs pretreatment with EOS (800 µg/brain) did not effect the accumulation of H^3DA in brain after i.v. injection of H^3 tyrosine, or the accumulation of DOPA after decarboxylase inhibition. Even though 800 µg EOS blocks completely the behavioral effects of 5 mg/kg apomorphine, there was no change in the biochemical effects of apomorphine in producing a reduction of H^3DA formed after H^3Tyr injection, suggesting presynaptic DA receptors were functional. Results indicate that EOS shares several behavioral but not biochemical effects with neuroleptic drugs. The mechanism for these unique effects is not presently clear, but the correlation of elevated GABA levels with the actions of EOS may implicate GABA.

1329 ETHANOL: ELECTROPHYIOLOGICAL EVIDENCE OF TOLERANCE REMAINS AFTER ISOLATION OF THE HIPPOCAMPUS IN VITRO. William A. Corrigall and P.L. Carlen, Dept. Medicine (Neurology), Addiction Research Foundation, Toronto, Ontario, Canada, M5S 2S1

While changes due to ethanol tolerance have been observed in the EEG, there have been no electrophysiological studies at a more reduced level in the vertebrate central nervous system. We have therefore examined the effect of acute ethanol exposures on the field potential elicited in the CA1 pyramidal neurons of the in vitro hippocampal slice preparation from animals administered ethanol chronically versus controls.

Male Sprague-Dawley rats were allowed ad libitum but measured access to a nutritionally balanced liquid diet containing 36% of its calories as ethanol; paired control animals received isocaloric amounts of the same diet except with the ethanol calories replaced by maltose-dextrins. Both groups of animals increased their caloric intake and weight over the 5 month duration of the experiment. At the time of electrophysiological experiments there was no significant difference in the weights of the groups. The average dose of ethanol consumed at this time was 14 gm/kg/day, corresponding to blood alcohol levels between 130-260 mg%.

Field potentials were recorded in the CA1 region of the slice with stimulation in the stratum radiatum. In brain slices from control animals, acutely applied ethanol at increasing concentrations up to 600 mM resulted in decrement and, at 600 mM, in block of the field potential. The high concentrations of ethanol necessary to produce an acute effect in this brain slice preparation are typical of studies of ethanol in vitro. When ethanol was bath-applied to slices from animals which had been administered ethanol chronically, significantly less decrement was observed for a given concentration of the drug and complete block of the response did not occur until considerably higher concentration. As yet we are uncertain as to the specific cellular locale of this tolerance; however, we have noted that the component of the field potential which signals the presynaptic fiber volley often decreased in parallel with the population spike. The tolerance observed in this tissue may be due therefore to changes in the presynaptic cells/fibers rather than in transmitter release and/or postsynaptic responsiveness. Irrespective of the cellular site, it is apparent that ethanol tolerance is a local phenomenon within the central nervous system, demonstrable in a single, identifiable neuronal pathway. That is not to say that ethanol tolerance in our animals exists within the hippocampus only, but rather that evidence of tolerance is not contingent on interaction with the remainder of the brain.

(supported by Medical Research Council of Canada grant MA-6019)

1330 EFFECTS OF BARBITURATES ON POSTSYNAPTIC INHIBITORY RESPONSES IN APLYSIA. Ila L. Cote* and W. A. Wilson (SPON: J.Parmentier). Dept. Physiol., School. Med., U.N.M., Albuquerque, N. M., Dept. Pharmacol., Duke Univ. Med. Ctr., Durham, N. C. 27710.

The effects of barbiturates on responses produced by iontophoretic application of acetylcholine (ACh) and γ-aminobutyric acid (GABA) were studied in Aplysia californica using the voltage clamp technique. Dose-response data was obtained for barbiturate concentrations ranging from 10 uM to 3 mM. Previous studies of invertebrate systems have shown that barbiturates selectively depress excitation while sparing or enhancing inhibition. In contrast, we have found that both phenobarbital and pentobarbital depress chloride-dependent inhibitory responses to both ACh and GABA. This depression occurs at approximately the same concentrations at which excitatory responses are attenuated. At these concentrations, potassium-dependent responses were minimally affected. In no case was enhancement of inhibitory responses seen, even at concentrations considerably below those which depressed the responses. These results, taken with previous studies, demonstrate that barbiturates can have varying effects on inhibitory processes.

1331 A STUDY OF THE PROCONVULSANT EFFECTS OF MEPERIDINE AND NORMEPERIDINE IN THE RAT FLUROTHYL TEST. A. Cowan, M.W. Adler, R.F. Kaiko*, C.E. Inturrisi* and M.M. Reidenberg*. Temple Univ. Sch. of Med., Philadelphia, PA 19140, Memorial Sloan-Kettering Cancer Center, New York, NY 10021 & Cornell Univ. Med. Coll., New York, NY 10021.

The proconvulsant effects of meperidine (M) and normeperidine (NM), and their interaction with naloxone (N), have been examined in rats exposed to the convulsant inhalant, flurothyl.

In the first experiment, dose-response curves were obtained for both compounds using male, albino S.D. rats (300-350 g). Different groups of 6-12 animals each received a s.c. injection of saline (S), M, or NM at 0.25,0.50,1,2,3, or 18 hr prior to challenge with flurothyl. The proconvulsant effects of each dose of NM tested (6.25,12.5, and 25 mg/kg) were always greater than the corresponding proconvulsant effects of the same 3 doses of M at 0.25, 0.5,1,2, or 3 hr respectively. The maximum decrease in seizure threshold (S.T.) with the 25 mg/kg dose of M (15-17% relative to controls) occurred between 0.5 and 1 hr whereas peak effects with the 25 mg/kg dose of NM (30-32%) occurred between 1 and 2 hr. All S.T.'s had returned to control levels by 18 hr.

In the second experiment, the effect of N (10 mg/kg, s.c.) on the proconvulsant properties of M and NM was examined (1 mg/kg of N had no influence on M or NM). Different groups of 8-12 rats were treated as indicated in the Table. Each rat was decapitated immediately after convulsing and plasma samples were obtained, frozen, and subsequently analyzed by GLC for levels of M and NM.

Treatment (at 0 hr)	S.T. (at 0.5 hr) mean ± s.e.(sec)	Plasma: mean ± s.e.(ng/ml) M	NM
S-S	387 ± 12		
N-S	387 ± 13		
S-M (12.5 mg/kg)	380 ± 12	65 ± 10	< 9
N-M (12.5 mg/kg)	341 ± 13	67 ± 14	<11
S-M (25.0 mg/kg)	369 ± 10	116 ± 24	125 ± 30
N-M (25.0 mg/kg)	284 ± 18	123 ± 23	100 ± 18
S-NM (12.5 mg/kg)	326 ± 10		1054 ± 51
N-NM (12.5 mg/kg)	303 ± 10		1253 ± 79
S-NM (25.0 mg/kg)	309 ± 9		2687 ± 385
N-NM (25.0 mg/kg)	284 ± 10		2702 ± 176

Three conclusions may be drawn from the 2 experiments: a) M, and particularly NM, can lower S.T. in the rat flurothyl test; b) N can potentiate the proconvulsant effects of M and NM, and c) the lowered S.T.'s are not a consequence of N altering plasma levels of N or NM.

1332 ELECTROPHYSIOLOGICAL EVIDENCE FOR TOLERANCE TO MORPHINE: UNIT ACTIVITY RECORDINGS FROM HYPOTHALAMUS AND PARAFASCICULUS NUCLEUS IN FREELY MOVING RATS. N. Dafny and B.M. Rigor**. The University of Texas Medical School at Houston, Houston, Texas 77025.

In previous experiments using 5 different doses of morphine, it was found that 10 mg/kg morphine was the most effective dose to induce changes in spontaneous multiunit activity in naive rats. The present experiment was initiated to investigate whether this dose (10 mg/kg) would induce changes in the electrophysiological activity recorded from physically dependent rats. Rats physically dependent on morphine were obtained by injection of multiple (3) incremental doses of morphine, a maximum of up to 130 mg/kg/day daily for 5 days. The response to morphine (10 mg/kg ip) and the morphine antagonist naloxone (1 mg/kg) were examined on day 1 (naive animals) and on day 5 of the experiment (physically dependent animals). Permanent electrodes (60μm in diameter) were implanted previously in the parafasciculus (PF) and within the ventromedial hypothalamus (VMH) under a stereotaxic guideline. A total of 52 units were recorded. Morphine in naive rats modified the spontaneous activity of all the units (26) recorded from PF and 84% (22) of the VMH units. An increase and a decrease in activity following morphine treatments were observed in both structures. Those units recorded from the VMH which responded on day 1 with increased activity, did not respond at day 5 to morphine. Those units recorded from the PF which responded on day 1 with increased activity, exhibited at day 5 a variety of patterns. All the units recorded from the VMH which exhibited decreased activity (12) on day 1 following morphine; at day 5 the same dose induced increased activity. However, the units recorded from the PF which exhibited decreased activity on day 1 (14) following morphine did not respond to this challenge dose at day 5. In conclusion, both the VMH and the PF exhibited neurophysiological evidence of tolerance to morphine, but the pattern of tolerance in each structure was different. (Supported by USPHS DA 00803)

1333 ANATOMICAL AND ELECTROPHYSIOLOGICAL EXAMINATION OF NEURONS IN THE NUCLEUS A10 REGION OF THE RAT. M. Dalsass*, D.C. German and R.S. Kiser (Spon: H. Roffwarg). Depts. of Psychiat. and Physiol., U. of Texas Health Sci. Ctr., Dallas, TX 75235.

The dopamine (DA)-containing cells in the ventral tegmental area (nucleus A10) have been related to brain stimulation reward and locomotor mechanisms. In the present study the anatomical and electrophysiological properties of these neurons were examined in the rat. In the anatomical study, S^{35}-methionine (567-1065 Ci/mmole) was iontophoretically ejected into the A10 region, and the ascending projections of these cells were subsequently traced autoradiographically (survival = 1-4 days; emulsion exposure = 7 days). Labelled axons were traced through the medial forebrain bundle and entopeduncular nucleus and further rostrally into the cingulum bundle. Evidence of labelled axon terminals was found in the nucleus accumbens, olfactory tubercle, and anterior medial cortex of the frontal lobe.

Single unit activity was recorded from the A10 region in the chloral hydrate (400 mg/kg) anesthetized rat. Glass micropipettes filled with 2M NaCl and fast green dye were used for the recordings. Slowly-firing cells (1-9 Hz), with long action potential durations (> 2 msec.), and histologically localized within the A10 region had their firing rate transiently reduced to greater than 50% by an intravenous injection of the DA agonist, apomorphine (20-40 μg/kg). Cells with these electrophysiological and pharmacological characteristics are thought to represent DA-containing cells (Bunney, et al., 1973). These cells were antidromically activated, by stimulation in the nucleus accumbens area, as judged by either constant latency, or collision testing (latency - 10-24 msec., mean estimated conduction velocity = 0.43 m/sec.). This conduction velocity is similar to that reported for the DA neurons of the substantia nigra zona compacta (Guyenet & Aghajanian, 1977). These slowly-conducting fibers often had long refractory periods (e.g., about 1.8 msec.). Other cells in the A10 region were orthodromically activated at longer latencies than cells which were antidromically activated (latency = 25-30 msec.). The results of the present study indicate that, (1) nucleus A10 DA neurons can be antidromically activated from forebrain sites, (2) they have slow conduction velocities typical of small unmyelinated fibers, and (3) they can also be orthodromically influenced by descending fibers to nucleus A10. (Supported by USPHS grant MH-27574.)

1334 INHIBITORY EFFECTS OF TYPE A AND B MONOAMINE OXIDASE INHIBITORS ON THE SYNAPTOSOMAL ACCUMULATION OF ^{3}H-DOPAMINE. K.T. DEMAREST* AND A.J. AZZARO* (SPON: D.E. HAINES). WVU MED CTR, MORGANTOWN, WV 26506

Monamine oxidase (MAO) inhibitors were the first clinically useful antidepressant drugs. Previous studies have demonstrated a correlation between the relative potency of clinically used MAO inhibitors as inhibitors of the CNS catecholamine neuronal reuptake system and their clinical efficacy as antidepressant drugs (Nature 220: 1330, 1968). In other words, clinical efficacy seems more closely related to inhibition of catecholamine neuronal accumulation than inhibition of MAO. With the demonstration of multiple forms of MAO and the more recent development of selective inhibitors of these enzyme forms, it became of interest to us to examine the selective properties of various MAO inhibitors and to compare these properties to the ability of each agent to inhibit dopamine (DA) neuronal accumulation.

Accumulation of ^{3}H-DA was examined in rat brain synaptosomes. MAO activity was determined in osmotically lysed rat brain synaptosomes. ^{14}C-serotonin and ^{14}C-phenylethylamine deamination were used as an index of type A and B MAO activity, respectively. A wide concentration range (10^{-10} to 10^{-3}M) of each inhibitor was examined. ID_{50} values were obtained by probit analysis.

MAO INHIBITOR	ID_{50} VALUES OF DA ACCUMULATION	TYPE A MAO	TYPE B MAO
Clorgyline	34.0 μM	11.7 nM	88.3 μM
Lilly 51641	5.5 μM	40.5 nM	5.3 μM
Harmaline	12.9 μM	4.9 nM	0.3 μM
Deprenyl	23.3 μM	49.3 μM	49.7 nM
Pargyline	378.1 μM	5.0 μM	46.7 nM
Tranylcypromine	4.4 μM	1.6 μM	0.6 μM
Nialamide	3.1 mM	51.0 μM	70.1 μM

Both type A and B as well as common inhibitors of MAO produced a dose-related inhibition of ^{3}H-DA accumulation. All agents were quite potent in this regard with the exception of nialamide. No clear relationship was observed between specific MAO inhibitors and their ability to alter DA accumulation. However, each group of selective inhibitors was approximately 1000x more potent in inhibiting MAO than DA accumulation. Therefore with these newer agents it is possible to selectively inhibit type A or B MAO activity without altering the neuronal reuptake of DA. These results confirm the correlation between the clinical efficacy of such agents as tranylcypromine (highly effective), pargyline (moderately effective) or nialamide (ineffective) and their relative potencies to inhibit the neuronal reuptake of brain catecholamines. Since clorgyline, Lilly 51641, harmaline, and deprenyl are all more potent inhibitors of ^{3}H-DA accumulation than pargyline, these newer agents may prove beneficial in the treatment of depressions.

1335 THE EFFECT OF MORPHINE ON APOMORPHINE INDUCED STEREOTYPY IN RATS. J.J.I. Feigenbaum,* B.H. Moon*, and H.L. Klawans. Dept. Neurosci., Rush Presbyterian St. Lukes Med. Center, Chgo. Ill., 60612 (SPON: T. Pencek)

A number of recent reports have suggested that morphine (M) may exert an inhibitory effect on central dopaminergic(DA) mechanisms. Consistent with this proposal are experimental observations that M produces catalepsy in rodents; decreases DA neurotransmission in the rat due to a direct action on central DA neurons; produces denervation supersensitivity of striatal DA receptors (SDA_r) following chronic administration; and inhibits the stereotyped behavior induced by the direct DA agonist apomorphine (AISB). However, despite this and other evidence that M directly blocks the SDA_r, it has recently been found that highly specific SDA_r blocking agents could not be displaced by doses of M as high as 10^{-5}M. Furthermore, reports concerning the effect of M on AISB have been inconsistent. While most findings indicate that M has an inhibitory effect on AISB, a recent report suggested that M has an excitatory effect on AISB, which would preclude a direct effect of M on blocking the SDA_r. To resolve this discrepancy, we studied the effect of doses doses of M ranging from .10 to 70 mg/kg on the stereotypy induced by 0.5 mg/kg apomorphine in Sprague-Dawley rats, us using 10 mg/kg increments of M. Doses of M ranging from .10 to 30 mg/kg produced a significant, sigmoidal enhancement of AISB relative to control animals, characterized by high intensity components of stereotypy (licking, and biting of the metal cage bars with very little jaw movement) accompanied at lower doses by head movement and prolonged rearing. Doses beyond 30 mg/kg (40-70 mg/kg) were progressively less effective in potentiating AISB, with 60 mg/kg significantly inhibiting AISB and 70 mg/kg M completely abolishing it. The discrepancy in findings reported previously regarding the effects of M on AISB may thus be due to differences in the dosage of M used. The inhibition of AISB seen after extremely high doses of M is probably due to the pronounced sedative effect of this drug at high doses. Since drugs which block the SDA_r inhibit rather than potentiate AISB, the enhancement of AISB by low to moderate doses of M suggests that M does not block the SDA_r. This effect could be explained by a pre-synaptic inhibition of striatal DA neurons however, as we and others have found that drugs diminishing the availability of striatal DA tend to enhance AISB.

1336 IONTOPHORESIS OF LSD: EFFECTS ON RESPONSES OF SINGLE CORTICAL NEURONS TO VISUAL STIMULATION. P. C. Fox and A. Dray*. Department of Physiology, Duke University Medical Center, Durham, North Carolina 27710.

Microelectrophoretic techniques were used to study the effects of LSD on single neurons in striate cortex of cats anesthetized with 75% nitrous oxide. Cells were driven by physiological stimuli and their receptive field characteristics classified.

The evoked activity of most cells was enhanced or depressed by LSD. Enhancement occurred with small ejections (0-10 nA); while depression was seen at 0-10 nA, but more frequently when currents >10 nA were used. Also inconsistant changes in unstimulated background firing were observed. In some neurons there was clear impairment of directional selectivity. Tolerance of LSD appeared in many cells after repeated administrations. Methysergide sometimes produced similar effects to LSD, on the same neurons, but generally these were weaker and required more prolonged administration with higher currents (30-40 nA). 2-Bromo-LSD (BOL) however, was generally inactive on cells which LSD had clearly influenced. These observations using direct administration of LSD to cortical neurons are similar to those seen in visual cortex after its systemic administration.

Overall, the responses of cells to physiological stimulation were exquisitely sensitive to LSD. Since the effects of LSD were mimicked less frequently with larger administrations of methysergide (a hallucinogen in large systemic doses) and not with BOL (the inactive analogue of LSD) we suggest that some of the changes are related to the hallucinogenic properties of LSD.

1337 COMPARISON OF DRUGS PURPORTED TO ANTAGONIZE SPECIFIC ETHANOL ACTIONS. G.D. Frye, R.A. Vogel, R.B. Mailman, G.R. Breese and R.A. Mueller. Biol. Sci. Res. Ctr., UNC Sch. Med., Chapel Hill, NC 27514.

The present studies compare the specificity of several putative "ethanol antagonists"--thyrotropin releasing hormone (TRH), fenmetozole (F), and apomorphine (A) against a spectrum of ethanol actions. These included ethanol-induced impairment of airborne righting reflex, increased locomotor activity, increased shock-punished drinking in water-deprived rats, decreased cerebellar guanosine 3',5'-monophosphate (cGMP), and physical dependence.

Ethanol (3 g/kg, ip) impaired motor coordination in an airborne righting reflex test. Treatment ip with TRH (20-80 mg/kg) or F (15-30 mg/kg) significantly reversed ethanol induced impairment, whereas A (3-10 mg/kg) was without effect. A proposed "stimulatory" action of ethanol (2.0 g/kg, ip) to increase spontaneous locomotor activity was observed in HA/ICR mice but not in Sprague-Dawley rats. In mice ip treatment with ethanol and TRH (20 mg/kg) produced the same stimulation of activity as ethanol alone. Both A (2.5 mg/kg) and F (15 mg/kg) significantly reduced the increased activity in mice. Ethanol (0.5-1.5 g/kg) increased shock-punished water consumption in water-deprived rats in a manner parallel with clinically used anxiolytic drugs. F (15 mg/kg, ip) completely reversed increased punished responding while TRH (20 mg/kg) potentiated this anxiolytic effect of ethanol. In rat cerebellum ethanol produced a dose dependent decrease in the content of the proposed second messenger, cGMP. TRH (20 mg/kg), but not A (5 mg/kg) or F (5-30 mg/kg), significantly reduced the fall in cGMP after ethanol, although all three drugs elevated cGMP when given alone. Physical dependence was induced by feeding of rats 6-8% w/v ethanol liquid diet for 12 days, as indicated by the occurrence of 70-80% audiogenic seizures following ethanol withdrawal. None of the compounds studied precipitated seizures or other signs of withdrawal when given to dependent rats maintaining sufficient blood ethanol levels to suppress withdrawal reactions.

The observed differences in interactions of purported "ethanol antagonists" compared across a spectrum of ethanol's actions indicate that cGMP levels in cerebellum do not correlate with the behavioral effects of ethanol. Furthermore, these data support the concept of a general action of ethanol on a large variety of neural systems. (Supported by HD-10570, AA-02334, MH-00013, MH-05636 and AA-05047.)

1338 NALOXONE AND THE EFFECTS OF SYSTEMICALLY ADMINISTERED KAINIC ACID. T. Fuller* and J.W. Olney, Washington University School of Medicine St. Louis, MO 63110

Kainic acid (KA) is a heterocyclic structural analog of glutamate (Glu) with both the neuroexcitatory and the neurotoxic properties like the putative neurotransmitter Glu, although more potent. When systemically administered to mice, KA showed much greater potency than Glu as a convulsant and neurotoxin specifically affecting neurons of the arcuate nucleus of the hypothalamus (AH). In subsequent studies, KA has demonstrated neurotoxic effects in many brain regions when introduced directly into the brain or the ventricles, and has induced both wet dog shakes (WDS) and convulsions in rats when introduced intraventricularly. It has been postulated that WDS, a behavior seen in rats undergoing morphine withdrawal, relates to an interaction of morphine with the Glu excitatory system. The WDS induced by KA and by intraventricular endorphins are reportedly blocked by the narcotic antagonist Naloxone (Nal).

Here we report that KA, when administered systemically to adult male rats, induces WDS, convulsions and brain damage with the latter following a different pattern of distribution than was originally described in mice. As is documented more fully elsewhere (Schwob et al., N.S. Abst., 1978) this pattern involves olfactory cortex, amygdala, lateral septum, hippocampus and several thalamic nuclei but spares AH. Both glial and neuronal elements are affected with lesions tending to have a bilaterally symmetrical pattern. Glial swelling and dendritic dilation are prominent early findings (4-6 hrs) while neuronal soma degenerate on a slightly more delayed schedule (6-36 hrs). The WDS and convulsions were dose related such that animals given 5 mg/kg KA had neither symptom (50%) or WDS without convulsions (50%), but 88% given 12 mg/kg KA had both WDS and convulsions. The occurrence of brain damage correlated positively with convulsions; virtually all animals manifesting significant convulsive activity sustained brain damage and those manifesting only WDS escaped damage.

Subcutaneous administration of Nal (2-4 mg/kg) 5 min prior to KA administration (12 mg/kg) reduced the incidence of convulsions from 88% to 50% and increased the percentage of animals sustaining only WDS or having neither symptom. Whether Nal modified KA-induced brain damage remains under study. The modification of KA neurotoxicity by Nal is of great interest because it suggests a specific interaction between a glumimetic agent and an opiate antagonist, the further study of which may shed light on both Glu neurotransmission and opiate action. NIH grants NS-09156, DA-00259, ES-07066 and R.S.D. Award MH-38894 (J.W.O.).

1339 IN VIVO DEMONSTRATION OF AN INTERACTION BETWEEN BENZODIAZEPINES AND GABA SYSTEMS IN THE CNS. Dorothy W. Gallager, John W. Thomas and John F. Tallman. Biological Psychiatry Branch, NIMH, Bethesda, MD 20014.

Many of the pharmacological actions of the benzodiazepines (BZs) can be attributed to their actions on γ-aminobutyric acid (GABA) systems in brain. In the present study we have demonstrated electrophysiologically a synergistic effect between GABA and the BZs using microiontophoretic and single-cell recording techniques. BZs do not affect the spontaneous firing rate of dorsal raphe (DR) cells. However, both the intravenous and iontophoretic administration of BZs were found to potentiate the inhibitory response produced by GABA on these neurons. Following pretreatment of rats with an inhibitor of GABA catabolism, aminooxyacetic acid (AOAA) or the GABA agonist, muscimol, BZs decreased the firing rate of DR neurons. This inhibition was reversed by the i.v. administration of the GABA antagonists picrotoxin or bicuculline. Since direct binding studies using [^{3}H]diazepam ([^{3}H]DZ) have indicated that a specific high affinity binding site may be relevant to the actions of BZs in brain, we have also examined the effects of AOAA and muscimol on [^{3}H]DZ binding. Five minutes after the intravenous injection of [^{3}H]DZ via a tail vein, [^{3}H]DZ bound specifically to high affinity binding sites was found in rat brain. Compatible with results obtained in electrophysiological studies, specific BZ binding in brain was enhanced by pretreatment of animals with AOAA and muscimol. This increase in binding in vivo produced by AOAA and muscimol is a result of an increased affinity of the binding site for BZ. An increase in binding site affinity was obtained in in vitro binding assays where the binding of [^{3}H]DZ to washed cortical membranes is enhanced in the presence of GABA and muscimol. This effect was blocked by bicuculline and involves an increase in the affinity but not number of high affinity binding sites on the membrane. Taken together this data suggests that the interaction between GABA and BZ in brain is relevant to a pharmacological action in vivo.

1340 EVIDENCE FOR SEROTONIN PARTICIPATION IN GUT WITHDRAWAL FROM OPIATES. Alan R. Gintzler, SPON: Taube P. Rothman. Department of Anatomy, Columbia University, P&S, NY, NY 10032.

The ileum of the guinea pig chronically exposed to opiates develops tolerance/dependence as does the central nervous system. Therefore this preparation may be used to study the processes that are involved in the manifestation of dependence. Tolerance/ dependence was induced by the subcutaneous implantation of five morphine pellets (each containing 75 mg morphine base) under light ether anaesthesia. On the fourth day following implantation, animals were killed by decapitation, and the terminal portion of the ileum was removed, washed and mounted in a 25 cc organ bath. All experiments were performed on pieces of whole ileum suspended in Krebs-bicarbonate buffer which was maintained at 37°C and bubbled with 95% O_2 and 5% CO_2. Naloxone (10^{-7} M) produced a well sustained contraction which was totally blocked by a 15 min pretreatment with tetrodotoxin (10^{-6} g/ml). This naloxone induced contraction was only partially blocked by a 15 min pretreatment with $2x10^{-6}$M atropine, a concentration sufficient to abolish contractile response to 10^{-6}M acetylcholine. To examine the possibility that 5-HT was involved in mediating the atropine resistant contraction the response to naloxone (10^{-7}M) was examined after the excitatory response to 5-HT was inhibited by a 1 hour incubation with 10^{-5}M 5-HT. Under these conditions the atropine-resistant component of the naloxone-induced contraction was reduced by about 80%. Washout of the 5-HT and a brief rest resulted in the reappearance of the excitatory response to 5-HT and the partial restoration of the atropine-resistant naloxone induced contraction. Therefore, 5-HT appears to mediate at least a portion of the naloxone-induced contraction observed in guinea-pig ileum made tolerant to morphine. These experiments indicate that in addition to acetylcholine, serotonin may be involved in the manifestation of gut dependence on morphine. Supported by DA01772.

1341 EFFECTS OF BLOCKING NIGROSTRIATAL IMPULSE FLOW ON AMPHETAMINE-INDUCED MOTILITY. Larry P. Gonzalez and Everett H. Ellinwood, Jr. Dept. Psychiat., Behav. Neuropharm. Sect., Duke Univ. Med. Ctr., Durham, NC 27710.

Release of dopamine in the caudate nucleus following systemic d-amphetamine has been suggested to depend upon impulse flow in the dopaminergic nigrostriatal pathway. Since this pathway has been implicated in the mediation of amphetamine-induced stereotyped behaviors, these behavioral effects of amphetamine might also depend upon impulse-coupled dopamine release. In the present study, impulse flow in the nigrostriatal pathway was inhibited through local injection of apomorphine, and its effects on amphetamine-induced motility were observed.

Forty male Sprague-Dawley rats received chronic bilateral implants of 25-guage guide cannulae in the substantia nigra pars compacta. Following recovery from surgery, the changes in movement frequency induced by systemic injection of d-amphetamine (0, 3, or 6 mg/kg) were observed and quantified with an electronic transducer. Thirty minutes after systemic amphetamine, apomorphine (0, 15, or 30 µg) was administered through a 32-guage injection cannula into the substantia nigra. Movement frequencies were observed for 60 minutes following intranigral apomorphine.

Amphetamine produced dose-dependent alterations in the distribution of movement frequencies. Intranigral injection of apomorphine did not significantly affect motility and did not alter the amphetamine-induced changes in motility. These results suggest that the behavioral effects of amphetamine occur independently of nigrostriatal impulse flow.

1342 EFFECTS OF ETHANOL ON THE SPONTANEOUS ACTIVITY OF SINGLE UNITS IN THE HIPPOCAMPUS OF THE AWAKE SEMI-RESTRAINED RAT. Larry A. Grupp. Department of Pharmacology, University of Toronto, Toronto, Canada, M5S 1A8 and Addiction Research Foundation, Toronto, Canada.

The spontaneous firing rates of single units in the dorsal hippocampus of semi-restrained rats chronically prepared with bundles of fine wire nichrome microelectrodes, were monitored during an ethanol challenge. Several doses were administered to all rats, each dose being given on a separate day with an inter-dose interval of at least 48 hrs. Each ethanol injection was preceded by two control recording periods: 1) baseline period to obtain a general picture of the rate and pattern of firing and 2) a saline injection period to control for injection and volume effects. The results indicated that single cells in the hippocampus are sensitive to ethanol, and that this sensitivity which is reflected by a depression in firing rate is dose dependent with larger doses producing greater degrees of depression. The simultaneously recorded EEG indicated a marked bias in frontal cortical activity towards high amplitude slow waves while the hippocampal activity showed less marked but more varied changes including a bias to high amplitude slow waves and to "theta" activity at higher doses, and a bias to low amplitude fast activity at the lowest doses. These findings suggest that the hippocampus is among those structures whose activity and function are particularly sensitive to ethanol. Supported by the Alcoholism and Drug Addiction Research Foundation of Ontario.

1343 EFFECTS OF BARBITURATES ON ASTROCYTIC FUNCTIONS. L. Hertz, E. Hertz and S. Fedoroff*, Dept. of Anatomy and B.R. Sastry*, Dept. of Physiology, University of Saskatchewan, Saskatoon, Saskatchewan S7N 0W0 Canada.

During recent years a considerable amount of information has accumulated suggesting that astrocytes are involved in the homeostasis of putative amino acid transmitters and of potassium at the cellular level of the brain by accumulating these compounds (1-3). Barbiturates are known to inhibit the uptake of γ-amino butyric acid (GABA) into brain slices (4) and to prolong presynaptic inhibition, in which GABA has been implicated (5), as well as to counteract the potassium-induced stimulation of oxygen uptake in brain slices (1) and to delay removal of potassium from the extracellular space in vivo and prolong the metabolic manifestation of this process (6). Conceivably, some or all of these effects could be brought about if barbiturates exerted an action on uptake processes, and on the metabolic manifestations of these processes, in astrocytes. To investigate this possibility we studied the effect of pentobarbital upon GABA uptake and potassium-induced stimulation of oxygen uptake in mouse astrocytes in primary cultures.

GABA uptake was studied by incubating cultures briefly with ^{14}C labelled GABA in media with different concentrations of nonradioactive GABA and calculating the uptake per mg protein from the specific activities in the media and the accumulation of radioactivity in the tissues. 2 mM pentobarbital caused an inhibition in the GABA uptake of about 30% regardless whether the medium contained 5, 20, or 50 µM GABA, but lower concentrations of pentobarbital, i.e., 1 mM (which caused an inhibition of 15-30%) and 0.5 mM (which caused an inhibition of 10-15%) seemed to be most efficient at a GABA concentration of 5 µM.

Potassium effects on oxygen uptake were studied by aid of an oxygen electrode and using the closed culture flask as the respirometer chamber. In a medium with 5 mM potassium the rate of oxygen uptake by the cultured astrocytes was initially about 300 µmol/hr per g wet wt.; this value was almost doubled by 50 mM potassium which caused an initial stimulation but subsequently (i.e., after the first ½-1 hr) led to an increased rate of respiratory decline. In the presence of 1-2 mM pentobarbital the inital stimulation of respiration by excess potassium was almost completely abolished and also the increased rate of respiratory decline seemed to be counteracted.

Supported by the MRC of Canada (grant MT 5957 and MA 6193).

1344 EFFECTS OF ETHANOL, MORPHINE, AND PENTOBARBITAL ON CALCIUM LOCALIZATION IN BRAIN. Wm. F. Hood* and R. Adron Harris, Dept. of Pharmacology, Univ. of Missouri, Columbia, MO 65212.

Whole brain homogenates from Sprague-Dawley rats or Swiss-Webster mice were fractionated as previously described by Harris et. al. (Life Sci. 20:501, 1977) and the effect of acute ethanol, morphine, or pentobarbital on calcium localization was studied. Other groups of mice were chronically fed a liquid diet of 7% ethanol or were implanted with a pentobarbital pellet for three days. The calcium and magnesium content of myelin, extra-synaptosomal mitochondria, synaptosomes, SPM-1, SPM-2, intra-synaptosomal mitochondria, microsomes, and microsomal supernatants were measured by atomic absorption spectroscopy.

Acute administration of morphine (25 mg/kg s.c.) decreased rat brain synaptosomal calcium content by 20% ($p<.01$) and acute pentobarbital (75 mg/kg i.p.) decreased mouse brain synaptosomal calcium by 17% ($p<.02$). Moreover, acute pentobarbital decreased the calcium content of myelin 27% ($p<.005$) while increasing that of extra-synaptosomal mitochondria 17% ($p<.01$). However, the acute administration of ethanol to rats (3 g/kg i.p.) or to mice (4 g/kg) failed to change the calcium content of brain synaptosomes or any other fraction. None of the fractions showed a change in the magnesium content following acute ethanol, morphine or pentobarbital. Subsequently, while attempting to correlate our in vivo results with earlier in vitro studies which had demonstrated that morphine (10^{-7} M; End & Dewey, Fed. Proc. 37:763, 1978) and pentobarbital (.15 mM; Blaustein & Ector, Mol. Pharm. 11:369, 1975) inhibited rat synaptosomal K^+ stimulated calcium uptake, we found that 25 mM and 50 mM ethanol did not affect this uptake but 100 mM ethanol significantly inhibited the uptake by 31% ($p<.02$).

Chronic pentobarbital decreased mouse brain SPM-1 magnesium 6% ($p<.02$). In addition, ethanol withdrawal produced a decrease in brain myelin magnesium of 10% ($p<.005$). Also, mice in withdrawal from ethanol showed a decrease in serum magnesium and an increase in free fatty acids in agreement with clinical studies of alcoholics. Mice in withdrawal from ethanol and mice chronically exposed to pentobarbital showed no change in calcium levels in any of the brain fractions.

The results from the acute and in vitro studies suggest that the lower calcium content of synaptosomes following acute pentobarbital and morphine may be related to the inhibition of depolarization stimulated calcium uptake. The data also imply that a decrease in synaptosomal calcium content may occur at higher acute doses of ethanol than were used in our in vivo studies.

Supported by grants from the Pharmaceutical Manufacturer's Association Foundation to R.A.H.

1345 THE EFFECTS OF ANTIDEPRESSANT DRUGS ON ^{3}H-MONOAMINE RELEASE FROM SYNAPTOSOMES. W. D. Horst and G. Bautz*. Hoffmann-La Roche Inc., Nutley, N. J. 07110

Crude synaptosomes were prepared from rat brain cortex and preloaded with either ^{3}H-5-hydroxytryptamine (5-HT), ^{3}H-L-norepinephrine (NE) or ^{3}H-dopamine (DA). ^{3}H-Amine release was determined from superfused synaptosomes according to Raiteri et al (Eur. J. Pharmacol. 25: 411, 1975). The ED_{50} value is the drug concentration required to increase release 50% during a 3 min superfusion. ED_{50}'s (x 10^{-5}M) were determined for desipramine (0.9), nortriptyline (1.7), amitriptyline (1.7), iprindole (1.5), mianserin (2.6) and imipramine (3.0) induced ^{3}H-5-HT release. None of these drugs at concentrations of 10^{-4}M influenced the release of ^{3}H-NE or ^{3}H-DA. These drugs are not releasing 5-HT from intraneuronal amine storage vesicles since the drug induced release of ^{3}H-5-HT was not calcium dependent and was demonstrated in synaptosomes derived from reserpinized brains. Low Na^+ concentrations increased the spontaneous release of ^{3}H-5-HT from synaptosomes but prevented the drug induced release, suggesting that these drugs are transported into the synaptosomes by an active transport process. If these drugs must be transported across the neuronal membrane in order to release 5-HT, the medium drug concentration required to cause this effect may be much higher than the drug concentration at the site of action. Iprindole and mianserin are antidepressants with weak amine uptake inhibiting properties. Their ability to release 5-HT suggests that this phenomenon deserves further study with respect to the mechanism of action of antidepressant drugs.

1346 ERGOT DRUGS INHIBIT SPIROPERIDOL AND SEROTONIN RECEPTOR BINDING. R.E. Hruska and E.K. Silbergeld. Experimental Therapeutics Branch, NINCDS, NIH, Bethesda, MD 20014.

Bromocriptine is of therapeutic value in the treatment of Parkinson's disease because of its proposed dopamimetic effects. Other ergot drugs may also be beneficial; however, they have not been fully evaluated. Unfortunately, the ergot drugs have been reported to produce some undesirable psychiatric and vasomotor effects, which may be attributed to their serotonergic properties. In order to analyze the relative dopaminergic versus the possibly undesirable serotonergic effects of the ergot drugs, we have tested the effects of these drugs on synaptic receptors. We have measured the ability of the ergot drugs to inhibit the receptor binding of ^{3}H-spiroperidol (SPIRO), a compound reported to label dopamine receptors, and ^{3}H-serotonin (5HT), which has been used to label serotonin receptors. The binding of SPIRO, at a concentration of 40 pM, to homogenates of rat caudate nuclei is potently inhibited by the ergot drugs. The binding of 5HT, at a concentration of 7 nM, to homogenates of rat cerebral cortex was also inhibited by the ergot drugs. The estimated IC_{50} values are listed below in the table. In general, the ergot drugs were weaker inhibitors of 5HT binding than SPIRO binding. The ratio of the IC_{50} values for the inhibition of 5HT to that for the inhibition of SPIRO binding are also listed in the table. The magnitude of the ratio indicates that bromocriptine and lisuride are much more potent inhibitors of SPIRO than 5HT binding, while only 29-712 was a better inhibitor of 5HT than SPIRO binding.

Inhibitor	IC_{50} (nM) 5HT	IC_{50} (nM) SPIRO	Ratio $\frac{5HT}{SPIRO}$
Bromocriptine	49.1	1.6	30.69
Lisuride	39.7	1.8	22.06
25-397 (Sandoz)	115.7	11.2	10.33
29-717 (Sandoz)	110.9	17.7	6.27
Lergotrile	510.8	221.1	2.31
Metergoline	29.1	18.7	1.56
29-712 (Sandoz)	92.0	327.8	0.28

These results may be of interest in the prediction of the therapeutic value of the ergot drugs in Parkinson's disease. Bromocriptine has the highest ratio of effects on the dopaminergic system and is known to be of therapeutic value. These results suggest that in Parkinson's disease, lisuride may also be of therapeutic value. Additionally, metergoline, which was the most potent inhibitor of 5HT binding tested, has been successfully used in the treatment of migraine and has been suggested to be a 5HT antagonist. Despite the great structural similarity of the ergot drugs, small changes in the side-chain substitution may be responsible for the large differences which occur in their inhibition of receptor binding.

1347 EFFECTS OF APOMORPHINE AND RO 20-1724 ON CYCLIC AMP AND CYCLIC GMP LEVELS IN VIVO IN PITUITARY, CEREBELLUM, N. ACCUMBENS-O. TUBERCLE AND STRIATUM. G. Jean Kant, James L. Meyerhoff and R.H. Lenox. Dept. Medical Neurosciences, Division of Neuropsychiatry, Walter Reed Army Inst. of Research, Washington, DC 20012.

The primary sites of action of the drugs apomorphine and RO 20-1724 are different but cyclic nucleotides have been postulated to be involved in the mechanism of action of both drugs. Apomorphine, which is considered to be a dopamine agonist that interacts with the dopamine receptor and stimulates adenylate cyclase, has been shown to increase levels of cyclic AMP in vitro (Kebabian et al., Proc. Natl. Acad. Sci. 69, 2145-2149, 1972) and to increase striatal cyclic AMP and cerebellar GMP in vivo (Stratten and Aylott, Fed. Proceedings, 33, 493, 1974; Gumulka et al., N.S. Arch. Pharmacol. 295, 21-26, 1976). RO 20-1724, has been shown to be a potent inhibitor of phosphodiesterase in vitro (Sheppard et al., Advan. Cyclic Nucleotide Res. 1, 103-112, 1972) and to increase levels of cyclic AMP in brain slices in vitro (Schwabe et al., Mol. Pharmacol. 12, 900-912, 1976). We were interested in determining whether RO 20-1724 could serve as a pharmacological amplifier for in vivo effects of a neurotransmitter receptor agonist such as apomorphine.

We examined the effects of apomorphine and/or RO 20-1724 in vivo on cyclic AMP and cyclic GMP levels in pituitary, cerebellum, striatum and n. accumbens-o. tubercle. Rats were injected with vehicle or RO 20-1724 (30 mg/kg) 30 minutes prior to a second injection of saline or apomorphine hydrochloride (1 or 10 mg/kg). The animals were then sacrificed by microwave irradiation 7 minutes after the second injection. Cyclic AMP and cyclic GMP were determined by a modification of the radioimmunoassay described by Steiner et al., (J. Biol. Chem. 247, 1106-1113, 1972).

RO 20-1724 significantly increased cyclic AMP levels in all 4 regions tested but especially in the pituitary where cyclic AMP levels increased over 10 fold. RO 20-1724 significantly increased cyclic GMP levels in only 2 regions: n. accumbens-o. tubercle, and striatum. Cerebellar cyclic GMP was increased but the elevation was not statistically significant at $p<.05$.

Apomorphine significantly increased cyclic AMP levels only in the pituitary where there was also a significant apomorphine dose effect. Levels of cyclic GMP were increased after apomorphine in the cerebellum and n. accumbens-o. tubercle. RO 20-1724 failed to produce supra-additive effects with apomorphine.

The most responsive system to both drugs involved cyclic AMP in the pituitary. Levels of cyclic AMP increased approximately 10 fold after either apomorphine or RO 20-1724.

1348 SEROTONERGIC-DOPAMINERGIC EFFECTS OF ERGOT DRUGS. S. Kennedy*, R. Hruska & E. Silbergeld, NINCDS, NIH, Bethesda, MD 20014.

On the basis of behavioral assays, such as rotation in rats with unilateral nigral lesions, several new ergot derivatives are proposed to possess dopamimetic properties. However, their indole structures suggest serotonergic activity as well. We have studied the effects of the following ergot drugs: bromocriptine, lergotrile, lisuride, metergoline, and Sandoz 25-397, 29-712, and 29-717. The behaviors studied in rats were stereotypy, which is thought to express stimulation of dopamine (DA) pathways; the "serotonergic syndrome" (Jacobs, Life Sci. 19:777, 1976), which may reflect stimulation of serotonin (5-HT) receptors; and post-decapitation convulsions, a behavior affected by changes in both DA and 5-HT function (Thut & Myslinski, Life Sci. 19:1569, 1976).

Induction of stereotypy was measured by a relative rating scale based on intensity. Bromocriptine, lergotrile, 29-712 and 29-717 all induce stereotypy at doses of 5 mg/kg and greater. The effects of all 4 drugs can be blocked by pretreatment with haloperidol (HAL) but not, in all cases, by inhibition of DA synthesis. Lisuride, metergoline, and 25-397 do not produce stereotypy.

The "serotonergic syndrome" was produced by pretreating rats with pargyline and then 5-hydroxytryptophan methyl ester (5-HTP). The syndrome was rated by number of characteristic signs present. Bromocriptine and lergotrile, at 5 mg/kg, potentiated response to 5 and 10 mg/kg 5-HTP. These potentiating effects, like the syndrome itself, can be blocked by pretreatment with HAL. Lisuride, at doses as low as 0.1 mg/kg, produces the syndrome in the absence of pargyline-5-HTP pretreatment. The apparently direct 5-HT-like actions of lisuride are not blocked by HAL, methysergide, or PCPA. 25-397, 29-712, 29-717, and metergoline do not affect the syndrome.

Post-decapitation convulsions (PDC) were studied in rats at the termination of other behavioral studies. Lergotrile (5 mg/kg), metergoline (25 and 50 mg/kg) and 25-397 (20 mg/kg) increase the latency and decrease duration of PDC. At higher doses, lergotrile and metergoline block PDC completely. These effects are not reversed by HAL, PCPA, or methysergide. Bromocriptine, lisuride, and 29-712 have no effect on PDC.

The results suggest that the ergots possess significant but varied behavioral effects in systems thought to involve DA and 5-HT modulation. The separation of DA from 5-HT in producing these behavioral effects is difficult, and this complicates the definition of the ergot drugs as relatively dopaminergic or serotonergic. However, on the basis of their behavioral activity, 29-712 and 29-717 may be relatively more dopaminergic, while lisuride is relatively more serotonergic. Bromocriptine and lergotrile affect both stereotypy and the "serotonergic syndrome" and may thus possess mixed actions on DA and 5-HT pathways.

1349 EFFECTS OF SYSTEMICALLY APPLIED GABA-ANTAGONISTS AND GABA-MIMETICS ON WAVE-SPIKE EEG ACTIVITY IN RAT. Gary A. King* (Spon: H.C. Kwan). Dept. Pharmacol., Univ. of Toronto, Toronto, Ont., Canada.

Drugs that antagonize inhibitory effects of GABA in the CNS (picrotoxin, bicuculline & pentylenetetrazol), and drugs that mimic GABA's actions when applied directly onto neurons (muscimol & imidazole acetate), were used to investigate the role of GABA in wave-spike EEG activity. In one experiment, wave-spike afterdischarges triggered by light-flash stimuli were recorded from occipital cortex in freely moving rats. IP injection either of GABA-antagonists or of GABA-mimetics caused a dose dependent increase of flash-evoked afterdischarges. Spontaneously occurring wave-spike activity was seen with the highest doses of all the drugs. Strychnine, however, did not enhance wave-spike EEG activity. In a second experiment, picrotoxin, bicuculline & imidazole acetate were examined for their effects on the ongoing EEG and behavior of freely moving rats. Subconvulsant doses of all three drugs induced generalized wave-spike seizures that were accompanied by immobility and varying amounts of forearm and facial clonus. These results will be discussed in terms of a correlation between the ability of some drugs to induce wave-spike EEG activity and to also block presynaptic inhibition, and in terms of hypotheses to explain the paradoxical effect of the GABA-mimetics.

1350 ENHANCEMENT OF NUCLEUS A10 SELF-STIMULATION BY THE NON-AMPHETAMINE STIMULANT, AMFONELIC ACID. R. Sanford Kiser, D.C. German, C.A. Brown* and P.A. Shore. Depts. Psychiat., Physiol. and Pharm., U. of Texas Health Sci. Ctr., Dallas, TX 75235.

Amfonelic acid (AFA) is a potent nonamphetamine psychotogenic stimulant. Biochemical and electrophysiological studies (German, et al., 1978) have indicated that, although AFA and amphetamine (AMP) both potentiate the function of the dopamine (DA) neuron, they do so by different means. Whereas AMP increases the release of newly-synthesized DA, AFA's action is not dependent upon newly-synthesized DA. Instead AFA appears to act by potently blocking DA reuptake and causing impulse-dependent overflow from reserve DA pools. The purpose of the present study was to test, in a rat behavioral model, the hypotheses that AFA, like AMP, would potentiate intracranial self-stimulation (ICSS) of DA cell bodies (nucleus A10) and that AFA effects, unlike AMP effects, are not dependent upon the availability of newly-synthesized DA.

Rats were stereotaxically implanted with chronic bipolar stimulating electrodes in nucleus A10 and beginning one week later were shaped for stable ICSS behavior. Each bar press produced a 0.3 sec. train of 0.2 msec. duration cathodal shocks at 100 Hz. In the first study, AFA was found to increase bar pressing rates at a wide range of stimulation currents (10-120 μa, peak pulse). In the second study, dose-response curves were obtained for both AFA and d-AMP. AFA (0.05, 0.1, and 0.2 mg/kg) was considerably more potent than d-AMP (0.1, 0.25, and 0.5 mg/kg) in increasing bar-pressing rates. In the third study, animals were pretreated with the DA synthesis inhibitor, α-methyl-para-tyrosine (AMPT, 100 mg/kg) before receiving either AFA (0.2 mg/kg) or d-AMP (0.5 mg/kg). In the AMPT-pretreated rats, AFA, but not d-AMP, increased bar-pressing rates above baseline levels. Furthermore, the AFA potentiation of ICSS seen in the AMPT-pretreated rats equalled the AFA potentiation seen in the normal rats. These data thus suggest that the effects of AFA, unlike those of d-AMP, are not dependent upon the availability of newly-synthesized DA.

The results of the present study are consistent with previously observed electrophysiological and biochemical findings which suggest that AFA and AMP both enhance the function of DA systems, although by different mechanisms. (Research supported by USPHS grants MH-27574 and MH-05831.)

1351 STREPTOZOTOCIN-INDUCED IMPAIRMENT OF BRAIN UPTAKE AND HYPOTENSIVE ACTION OF ALDOMET IN THE SPONTANEOUSLY HYPERTENSIVE RAT. M.C. Klein*, J.J. Poulakos*, A. Saha* and J.H. Jacoby. Depts. of Pharmacology and Microbiology, N.J. Med. Sch. (CMDNJ) Newark, N.J. 07103.

Recent observations indicate that elevation of plasma large neutral amino acids (NAA) in response to either their pharmacologic injection or ingestion of a protein meal (Markovitz, D. & Fernstrom, J.D., Science, 197,1014,1977) can act to impair brain uptake of aldomet (α-methyldopa; a NAA), presumably as a result of increased competition at a common transport site along the blood-brain barrier. Furthermore, concurrent injection of these competitive NAA, also attenuates the hypotensive effect of aldomet administered to hypotensive rats (Zavisca, F.G. & Wurtman, R.J., J. Pharm. Pharmacol., 30,60,1978).

Such results indicate that a similar alteration of the central actions of aldomet may occur in response to hyperamino acidemias of varying etiology. To further investigate this possibility we have made male spontaneously hypertensive rats diabetic as a result of injection of the pancreatic β-cell cytotoxin streptozotocin (70 mg/kg, i.v.) and measured the brain entry and hypotensive action of aldomet 3 days later. Animals were fasted the night prior to study and sacrificed 3 hrs. after aldomet injection (50 mg/kg, i.p.). All plasma NAA except tryptophan (which decreased by 50%) increased markedly in diabetic animals compared to controls. Branched-chain NAA (i.e., leucine, isoleucine, valine) were especially elevated (7-9 fold). Associated with this diabetes-induced hyperamino acidemia was a greater than 50% reduction of brain aldomet levels. Systolic blood pressure (BP) (measured by a tail-cuff transducer) in preconditioned non-diabetic rats fell about 20% 3 hrs. after aldomet. Diabetic animals showed no significant aldomet-induced reduction of BP. Diabetic rats receiving insulin replacement therapy (4 I.U. Protamine Zinc Insulin daily; 0.5 I.U. Semi-lente on last day) showed improvement of aldomet brain entry and hypotensive action.

Apparently altered plasma NAA patterns in disease states such as diabetes are also associated with impaired brain entry of certain centrally acting drugs.

1352 PHYSIOLOGICAL CONCENTRATIONS OF CALCIUM ACTIVATE RAT BRAIN TRYPTOPHAN HYDROXYLASE VIA INCREASED Vmax. Suzanne Knapp. Dept. Psychiatry, Sch. Med., UCSD, La Jolla, CA 92093

It was demonstrated previously that tryptophan hydroxylase (TPOH) prepared from rat midbrain, an area rich in serotonergic cell bodies, is activated in vitro by calcium (Ca^{++}) at concentrations of 1.0 mM or greater (Knapp et al., Life Sci. 16: 1583, 1975; Boadle-Biber, Biochem. Pharmacol. 24: 1455, 1975). Activation by such high concentrations of Ca^{++} was achieved by an increase in enzyme affinity both for pterin cofactor, biopterin, and for substrate, tryptophan. Having used a fluorometric assay in which cofactor and substrate are saturating to determine TPOH activity, we now report that EGTA pretreatment of midbrain TPOH followed by dialysis for 16 hours resulted in a 25- to 30-fold increase in the sensitivity of TPOH to Ca^{++}. The elevated activity of this enzyme preparation in the presence of physiological Ca^{++} concentrations was achieved by an augmented V_{max}, without demonstrable changes in affinity for either cofactor or substrate. Similar patterns of activation (by increased V_{max}) and sensitivity to Ca^{++} were demonstrated using midbrain TPOH that had been either dialyzed for 16 hours without EGTA pretreatment or allowed to stand at 20°C for 1 to 2 hours. Subsequently we examined TPOH from corpus striatum, an area rich in serotonergic nerve endings, to determine its response and sensitivity to Ca^{++}. In response to intermediate Ca^{++} concentrations ($\sim$ 200 µM) this preparation (without EGTA pretreatment, dialysis, or incubation at 20°C) demonstrated increased activity resulting from augmented V_{max} and no change in affinity for cofactor or substrate.

TPOH activity has been reported to be elevated by increased V_{max} following an acute load of phenylalanine (Neckers et al., J. Pharmacol. Exp. Ther. 201: 110, 1977), and a "prolonged" activation of tyrosine hydroxylase (TOH) also by increased V_{max} has been reported following cholinergic stimulation by oxotremorine (Lewander et al., Nature 258: 440, 1975). In neither case could changes in the enzyme's affinity for cofactor or substrate be shown. Immunochemical experiments showed that the increase in TOH activity was by activation rather than an increase in enzyme molecules. The TPOH activation by physiological concentrations of Ca^{++} which we have demonstrated, i.e. an effect resulting from increased V_{max} rather than increased affinity for cofactor or substrate, might account for such changes in neurotransmitter biosynthetic enzymes.

1353 EFFECTS OF GABA AND STRUCTURALLY-RELATED COMPOUNDS ON CONDUCTANCE OF CRAYFISH ABDOMINAL STRETCH RECEPTOR. Diana N. Krause*, Kazuo Ikeda and Eugene Roberts. Division of Neurosciences, City of Hope National Medical Center, Duarte, CA 91010.

The interaction of potential agonists with the postsynaptic γ-aminobutyric acid (GABA) receptor was investigated physiologically and quantitatively in an isolated crustacean neuron. The crayfish slowly-adapting, abdominal stretch receptor neuron, which receives direct GABAergic inhibitory innervation, was mounted in a constant perfusion chamber and impaled with two intracellular electrodes for monitoring membrane input conductance. Increase in conductance, the postsynaptic response to GABA, was measured for bath-applied GABA and compared with the effect of various structurally-related compounds. Non-cumulative log concentration vs. conductance change (Δg) plots were obtained, and in each case the concentration producing the half-maximal response was determined. The following compounds, listed in order of decreasing potency, produced a reversible increase in input conductance: muscimol> GABA>isoguvacine>(-)γ-amino-β-hydroxybutyric acid>3-aminopropane sulfonate>(+)γ-amino-β-hydroxybutyric acid>isonipecotic acid. All agonists acted in a dose-dependent manner with no apparent receptor desensitization and appeared capable of producing the same maximal response as GABA. When the dose-conductance data were analyzed with Hill plots [log(Δg/Lg$_{max}$-Δg) vs. log concentration], a steeper Hill slope was found for GABA (n≈3) than for the other agonists (n≈2). Nipecotic acid, guvacine, and L-α,β-diaminopropionic acid (L-DAPA), which are all thought to be blockers of GABA uptake processes, had essentially no effect by themselves on the membrane input conductance at concentrations up to $5x10^{-3}$M. However, when applied at 10^{-3}M simultaneously with GABA, nipecotic acid and L-DAPA significantly shifted the GABA dose-conductance curve to the left (towards lower concentrations) without altering the maximal response. In addition, the steepness of the GABA curve was reduced, i.e. the apparent cooperativity of the GABA response as assessed by the Hill slope was changed. The muscimol dose-conductance curve, on the other hand, was not affected in any way by nipecotic acid. β-(4-chlorophenyl)GABA (Lioresal) at concentrations up to 10^{-2}M had no significant effect on either the resting membrane conductance or the GABA response. (Supported by USPHS grants NS-12116 and 1615).

1354 NOREPINEPHRINE AND CYCLIC AMP: EVIDENCE AGAINST SECOND MESSENGER CONCEPT IN CENTRAL NERVOUS SYSTEM (CNS), SPINAL CORD (SC) AND PERIPHERAL NERVOUS SYSTEM (PNS). Barry J. Kraynack, Linda L. Kraynack* and Major L. Cohn. U.S. Naval Base, Guantanimo, Cuba and Univ. of Pgh. Sch. Med., Pittsburgh, PA 15213.

Based on the findings that norepinephrine (NE) and epinephrine (E) are potent adenyl cyclase stimulants, it is generally assumed that all the actions of NE and E are mimicked intracellularly by the second messenger adenosine 3':5'-monophosphate (cAMP). However, our in-vivo studies increasingly demonstrate that cAMP does not mimic NE and E in neural tissues. In the CNS, we showed that administered centrally to rats anesthetized with amobarbital, dbcAMP dose-relatedly shortens while NE prolongs narcosis. Here, we studied the actions of dbcAMP and E in SC and PNS. Adult mongrel cats were permanently implanted with epidural catheters. To control cats, 30 mg of lidocaine in 7.5% glucose was injected through catheter. To the same lidocaine preparation was added either 1.5 or 3 mg of dbcAMP or 10 µg of E. Each cat served as its own control. DbcAMP dose-relatedly shortened epidural blocks by 30-40 and 55 to 59% while E prolonged blocks by 29-66%. Next, we tested whether dbcAMP and E actions are the result of altered vascular blood flow, metabolism or displacement of lidocaine, by studying clearance of ^{14}C lidocaine from cerebrospinal fluid (CSF) of rhesus monkeys. Lidocaine 30 mg/7.5% glucose was administered through first catheter implanted in subarachnoid space between L_2 and L_3 either with ^{14}C lidocaine or ^{14}C lidocaine to which was added either 3 mg of dbcAMP or 5 µg of E. Through a second catheter implanted between T_{11}-T_{12} samples of CSF were withdrawn at 0, 5, 10, 15, 30, 45, 60, 90, 120, 150 and 180 minute intervals. DbcAMP significantly shortened while E potentiated the blocks but neither dbcAMP nor E altered CSF ^{14}C lidocaine concentrations. Next, in the PNS we investigated the interactions of dbcAMP and E with lidocaine, procaine, mepivacaine, tetracaine, bupivacaine, benzocaine, amobarbital, meperidine, naloxone, ketamine, E, ephedrine and tetrodotoxin. DbcAMP shortened and E prolonged the sciatic nerve blocks produced in rats by all 13 structurally different local anesthetics. Based on our findings that dbcAMP dose-relatedly shortens sciatic nerve blocks produced by the specific channel blocker tetrodotoxin, we propose that the nucleotide may regulate the duration of conduction blocks by overcoming local anesthetic's inhibition of sodium ion flux through sodium channel. Finally E (30 µg) injected alone produces sciatic nerve blocks for 131 minutes; 2 mg of dbcAMP shortens the blocks by 92%, suggesting that E-induced potentiation is the result of a direct neural blocking action. Our findings that in the CNS, SC and PNS dbcAMP shortens while NE and E potentiate anesthesia, suggest that in the 3 neural systems, cAMP is not the second messenger of NE or E. (NIDA 00605)

1355 THE K^+ LIQUID ION EXCHANGE ELECTRODE: RESPONSES TO DRUGS AND NEUROTRANSMITTERS. Taketeru Kuramoto*, David H. Shine and Bernard Haber. The Marine Biomedical Institute, and Dept. of Human Biological Chemistry & Genetics and Dept. of Neurology, The University of Texas Medical Branch, Galveston, Texas, 77550.

Neuronal activity is associated with transient potassium fluxes, and the accumulation of that ion in the extracellular space appears possible. The changes in extracellular K^+ may in turn modulate the behavior of both neurons and glia. The development of liquid cation exchange resins with a large selectivity for K^+ over Na^+, the major extracellular cation, has made possible the utilization of such resins for K^+ specific microelectrodes, to measure both intracellular and extracellular K^+ changes in a variety of preparations. As a result of neuronal activity, extracellular changes of many organic molecules as well as ions may occur. Therefore, neurotransmitters or their precursors may well contribute to the potential change recorded by the K^+ ion specific electrodes, which are interpreted as specific changes in extracellular K^+ concentration. In fact, such electrodes have been shown to respond to acetylcholine (Ach) at 10^{-3}M suggesting that responses might be obtained at lower and more physiological concentration of Ach. The paucity of data on the chemosensitivity of the K^+ ion exchange electrode to organic compounds of physiological significance prompted the present study.

K^+ sensitive liquid ion exchange micro electrodes respond with a significant potential change to acetylcholine, choline, anticholinergic drugs, such as curare, biogenic amines, l-propanolol in most cases it is at extremely low concentrations (10^{-7}- 10^{-5}M). The direction of the potential change varies, but in most instances is additive to that produced by external K^+. The K^+ electrode is further sensitive to decreasing pH, within a narrow and possible physiological range of pH (7-5.5). These findings suggest that small measured changes in extracellular K^+ are biased by the chemosensitivity of the ion exchange resin to some drugs and neurotransmitters at physiologically relevant concentrations.

1356 ETHANOL AND ACETALDEHYDE EFFECTS ON THE COUPLING OF CEREBRAL METABOLISM AND FUNCTIONAL ACTIVITY. Joseph C. LaManna, Roger L. Novack*, B. Wyatt Younts* and Myron Rosenthal. Depts. Neurol. and Physiol/Biophys. Univ. Miami Med. School, Miami, Florida 33156

Electrical and metabolic responses to direct cortical stimulation were measured in cats administered ethanol and acetaldehyde i.v. Stimuli were presented in pulse trains of 1-2 sec at 20 Hz which produced a shift of steady potential up to 6mV and a decrease in the ratios of reduction/oxidation of the mitochondrial respiratory chain components, NAD and cytochrome a,a_3. The latter were measured noninvasively by reflection microfluorometry and spectrophotometry. The rates of oxidation and re-reduction of each of these were slowed by ethanol and acetaldehyde. The slowing of oxidation is similar to the effect of ouabain when microinjected under the cortical surface and probably reflects an inhibition of $Na,^+K^+$-ATPase in the in situ tissue. The slowing of the rate of re-reduction following stimulation is reminiscent of the effect of barbiturate and could be due to direct drug effects in the respiratory chain or to a prolonged utilization of energy due to a slower rate of reestablishment of ion gradients altered during increased tissue activity. Under control conditions, the amplitude of the stimulus-evoked shift in steady potential is proportional to the oxidation of cytochrome a,a_3 or NADH. However, ethanol or acetaldehyde each produced characteristic alteration in this relationship. Low ethanol doses (up to approx 1g/kg) decreased the NAD response relative to the electrical response. Above approx 2g/kg, ethanol had an opposite effect. Acetaldehyde, from its lowest effective dose (approx 20 mg/kg) to 200 mg/kg always showed this latter effect, i.e. a larger metabolic response with respect to the SP shift. Both electrical and metabolic signals were decreased in amplitude as toxic dose levels of each drug were approached. It appears that dose levels which result in large metabolic amplitudes for give SP shift responses are producing an uncoupling of the function-metabolism relationship suggestive of an "inefficiency" in the capability of the metabolic apparatus to meet metabolic demand. (Supported in part by PHS grants NS 14319 and NS 14325).

1357 INHIBITION OF CATECHOLAMINE UPTAKE BY NATURALLY-OCCURRING TETRAHYDROISOQUINOLINES AND ITS POSSIBLE RELEVANCE TO BOTH L-DOPA CHEMOTHERAPY IN PARKINSONISM AND TO PHENYLKETONURIA. John M. Lasala* and Carmine J. Coscia*, Dept. of Biochem., St. Louis Univ. Sch. of Med. and Theodore J. Cicero, Dept. of Anat. and Neurobiol., Washington Univ. Sch. of Med., St. Louis, MO 63110.

A class of naturally occurring tetrahydroisoquinoline derivatives, norlaudanosolinecarboxylic acids (NLCAs), were found to be competitive inhibitors of dopamine and norepinephrine uptake into ouabain-sensitive synaptosomes. Using a 1000 g supernatant from whole rat brain, (±)-NLCA (K_i 6.30×10^{-6} M), blocked [1-^{14}C] dopamine uptake (K_m 8.48×10^{-8}M) into synaptosomes. NLCA was about two-thirds as potent as (+)-amphetamine in blocking dopamines uptake. In rat striatal tissue the K_i of (±)-NLCA decreased to 5.10×10^{-6} M ($r \geq 0.997$) because of the higher affinity for dopamine (K_m 6.4×10^{-8} M) in this dopamine-rich region. Two trace constituents of normal brain, 3',4'-desoxynorlaudanosolinecarboxylic acid (DNLCA) and 3'-O-methylnorlaudanosolinecarboxylic acid (MNLCA) also restricted dopamine uptake into both whole brain (K_i 2.11×10^{-5} M) and striatal (K_i 1.06×10^{-5} M) synaptosomes. Interestingly the NLCAs also blocked noradrenergic uptake in whole brain: (±)-norepinephrine K_m 2.30×10^{-7}M, (±)-NLCA 4.93×10^{-6} M, (±) DNLCA and (±) MNLCA 6.55×10^{-6} M, (±)-amphetamine, 3.22×10^{-6} M. In addition to competing with catecholamines for uptake, [^{3}H]NLCAs exhibited saturation kinetics (K_m 1.59×10^{-6} M and 1.51×10^{-5} M for NLCA and DNLCA, respectively) suggesting that they may be taken up and stored in synaptic vesicles. In other studies the NLCAs did not inhibit the binding of ^{3}H-spiroperidol to striatal synaptic membranes suggesting that they do not occupy post-synaptic receptor sites. These results are consistent with the hypothesis that the NLCAs interfere with catecholaminergic transport mechanisms in presynaptic terminals. The NLCAs described above are formed by condensation of α-keto acids with dopamine which can occur spontaneously under physiological conditions. MNLCA can be derived from NLCA in vivo by enzymatic methylation, while NLCA and DNLCA are the condensation products of dopamine with 3,4-dihydroxyphenylpyruvate and phenylpyruvate, respectively. MNLCA and DNLCA have been detected by computerized mass fragmentography in regions of normal human and rat brain at concentrations ranging from 10-200 ng/g of tissue. After L-dopa administration, MNLCA levels are elevated several-fold (C.J. Coscia et al., Nature 269, 617, 1977), whereas in experimentally induced hyperphenylalaminemia DNLCA rises 10-fold. Therefore, NLCAs can reach concentrations in certain brain regions which are within the range of K_i values obtained in this study. These data suggest that it is possible that NLCAs may account for certain therapeutic effects observed in L-dopa chemotherapy, beyond that attributable to dopamine replenishment alone.

1358 APOMORPHINE INHIBITION OF AUTOMATIC SWALLOWING IN THE RAT: EVIDENCE FOR MEDULLARY DOPAMINE RECEPTORS. Jon Levine* and Detlef Bieger. Neural and Behavioral Biology Program and Sch. Basic Med. Sci., Univ. Illinois, Urbana, IL 61801.

Previous experiments have shown that automatic swallowing (AS) in the urethane-anesthetized rat is a sensitive indicator of dopaminergic and serotoninergic activity in the brain (Bieger et al., 1977, Neuropharm., 16:245). The dopaminomimetic apomorphine (APO) exerts both an excitatory as well as inhibitory effect on AS, the former being dependent, the latter being independent of the integrity of certain forebrain structures. The present investigation provides further evidence for a locus of action within the lower brain stem. Thus, APO activation of AS was eliminated, but inhibition was unaffected in animals subjected to premammillary complete or partial transection or electrothermic coagulation (acute or subacute). This inhibition was manifest with AS driven by the serotonin agonist quipazine as well as rebound AS following acute knife cuts. Pimozide (1.5 mg/kg, i.p. or i.v.) and haloperidol (1 mg/kg, i.v.) blocked APO inhibition, this antagonism being surmountable. However, recovery was not evident even after periods up to 9 hours.

APO inhibition and its blockade by pimozide and haloperidol could also be demonstrated when these drugs were administered via the left vertebral artery at 10-fold lower concentrations. When injected onto the area postrema, APO and dopamine inhibited AS after a latency of approximately one minute. However, this effect persisted after coagulation of the area postrema. Interestingly, the inhibition of AS was accompanied by an increase in respiratory frequency. Animals pretreated with massive intracerebroventricular doses of 6-hydroxydopamine (400 µg) failed to show activation of AS by moderate doses of APO (100-200 µg/kg) and displayed lowered threshold and greater intensity of APO inhibition, compared to controls.

Our observations provide suggestive, if circumstantial, evidence for medullary dopamine receptors located in the immediate vicinity of the area postrema which modulate bulbar motor functions. These receptors do not appear to be prejunctional with respect to local catecholamine neurons, as postulated by other workers in reference to blood pressure and respiration (Bolme et al.., 1977, Adv. Bioch. Psychopharm., 16:281). The possible significance of these dopamine receptors in the production of involuntary movements by neuroleptic drugs calls for careful examination.

1359 EVIDENCE FOR CENTRAL MEDIATION OF ANTICONVULSANT ACTIONS OF MUSCIMOL. W. D. Matthews, A. P. Intoccia* and G. McCafferty*. Dept. Biol. Res., Smith Kline & French Labs, Philadelphia, PA 19101.

Muscimol (MCL) is a potent in vivo agonist of γ-aminobutyric acid (GABA) when tested iontophoretically (Krogsgaard-Larsen et al., J. Neurochem. 25:803, 1975). MCL also binds to central GABA receptors in vitro (Enna et al., Brain Res. 124:185, 1977). However, passage of MCL into brain after systemic administration has not been demonstrated. A study of MCL actions on seizures induced by drugs which impair GABA neurotransmission was performed in the rat. To ascertain that intravenously injected MCL penetrates brain tissue, whole brain levels of radioactivity were determined at various intervals after ^{14}C-muscimol and compared to the time-course of anticonvulsant activity. MCL delayed the onset of isoniazid and picrotoxin-induced convulsions; doses which produced a significant ($p<0.05$) increase in seizure onset in 50% of animals tested were 0.4 and 0.9 mg/kg, respectively. Bicuculline (BIC) treated rats exhibit clonic-tonic seizures within 5 secs of i.v. injection. The tonic forelimb extension component of BIC seizures was abolished by MCL (ED_{50}=1.0 mg/kg). Inhibition of forelimb extension was chosen as an end-point for comparison of other antiepileptic drugs with MCL. The order of potency against this component of BIC seizures was diazepam>MCL>> phenobarbital>diphenylhydantoin. MCL had no effect on strychnine-induced convulsions in doses up to 8 mg/kg i.v., however tonic metrazol seizures were prevented by MCL (ED_{50}=0.5 mg/kg). The time course of anticonvulsant activity of MCL (2 mg/kg, i.v.) against BIC convulsions was determined. Maximal protection (92% of rats tested) occurred 15-30 min after MCL and gradually declined over 300 min. ^{14}C-Muscimol experiments reveal that intravenously administered drug (2 mg/kg; 66.4 µc/kg) rapidly enters brain tissue. Ninety percent of maximum brain radioactivity was present 5 min after injection. Peak brain ^{14}C concentration (0.18±0.02 µg/g tissue) occurred 30 min after ^{14}C-MCL. Radioactivity decreased very slowly over the next 360 min to 58% of maximum. Twenty-four hrs post injection 0.046±0.001 µg/g of radiolabel remain in the brain. Thus peak brain concentration of radioactivity occurred simultaneously with maximum protection against BIC seizures. Further studies in progress will determine amounts of parent compound and metabolite(s) present with time. These results suggest that systemically administered MCL readily penetrates rat brain and parent compound and/or metabolite antagonizes BIC blockade of GABA receptors.

1360 LITHIUM TREATMENT EFFECTS ON CHOLINE TRANSPORT AT THE BLOOD-BRAIN BARRIER. A. L. McCall,* W. R. Millington, L. J. Botticelli and R. J. Wurtman. MIT, Cambridge, MA 02139.(Spon:J.Fernstrom)

We have characterized lithium chloride's (LiCl) effects on choline transport into the brain using the Brain Uptake Index (BUI) technique described by Oldendorf. This technique measures the percent extraction of a test compound (e.g., choline) from the blood (carotid artery) into the brain by comparing the carrier-mediated transport of a ^{14}C-labeled test substance to the passive diffusion of $^{3}H_2O$.

We observed that: 1) Single injections of LiCl (50 mg/kg-200 mg/kg) decrease the carrier-mediated transport of choline into the brain in a dose-dependent fashion (Table 1) without affecting the transports of glucose, tyrosine, glutamate or adenosine; 2) Addition of LiCl to the solution injected into the carotid artery (in doses of 5mM and 10mM) also decreases blood-brain barrier choline transport (from 6.71 ± 0.46% extraction for controls to 5.85 ± 0.42% and 4.56 ± 0.68%, respectively, for 5mM and 10mM); 3) Chronically administered LiCl, given in the rats' diets, elevates serum lithium levels and decreases choline transport into the brain; 4) Other group IA elements, cesium and rubidium, also decrease the barrier transport of choline.

TABLE 1. Acute Effects of LiCl Injection on Serum Lithium Levels and Choline Transport into the Brain

Dose of LiCl	% Choline Extraction 30 min later	Serum Lithium meq/liter
Control	6.71 ± 0.46*	-
50 mg/kg	4.94 ± 0.45	1.69 ± 0.61
100 mg/kg	4.63 ± 0.53	2.45 ± 0.48
200 mg/kg	3.57 ± 0.18	6.71 ± 0.78

*All values expressed as means ± SEM.

Addition of 20 mmoles of LiCl per kg dry weight to an 18% casein diet given to rats for 5 weeks produced no change in the choline transport into the brain. However, addition of 50 mmoles LiCl per kg dry weight decreased brain choline extraction by about 57%. Serum lithium levels were 0.34 ± 0.03 and 0.56 ± 0.04 respectively in these two groups of animals. Cesium or rubidium (10mM as the chloride salt), added to the carotid artery injection solution, each decreased the extraction of choline by 32%.

Our observation that acute or chronic lithium administration decreases choline transport into the brain raises the possibility that lithium also alters central cholinergic neurotransmission.

1361 ACUTE MORPHINE ADMINISTRATION INCREASES INCORPORATION OF ^{3}H-THYMIDINE INTO BRAIN STRIATAL DNA. Rita B. Messing, Jack C. Waymire*, Gary S. Lynch, Sam A. Deadwyler and Cort Flinchbaugh*. Dept. of Psychobiol., Univ. of Calif., Irvine, CA 92717.

The extremely long time-course of some morphine effects suggests that opiates may induce a permanent anatomical alteration in brain. One possibility is that morphine induces changes in glial cell proliferation. For this reason we undertook a study of tritium uptake into DNA fractions of rat brain regions following in vivo administration of [methyl-^{3}H] thymidine and morphine. The spleen was also examined as a control tissue. In acute experiments adolescent male rats were treated with 10 mg/kg of morphine SO_4 or vehicle and 1 mg/kg of naloxone HCl or vehicle 30 and 45 min, respectively, prior to administration of 800-900 μCi/kg of ^{3}H-thymidine. In chronic experiments rats were given 3 injections at 72 hr intervals of 150, 300 and 450 mg/kg of a slow-release preparation of morphine or vehicle. On the tenth day following the first injection, some rats were given naloxone 15 min prior to ^{3}H-thymidine. Rats were sacrificed one hr after thymidine injections and DNA fractions were isolated from tissues Acute morphine administration increased incorporation of ^{3}H-thymidine into DNA of rat striatum to 150% of control. This effect was antagonized by naloxone. No effect of morphine on thymidine incorporation was observed in the diencephalon or midbrain. In contrast, in the spleens of morphine-injected rats incorporation into DNA dropped to 45% of the control value. This effect was also antagonized by naloxone. No change in ^{3}H-thymidine incorporation into DNA was observed in any area of the brains of morphine-addicted rats or in rats undergoing withdrawal. In spleens, however, ^{3}H-thymidine incorporation was decreased to 60% of control in rats undergoing naloxone-precipitated withdrawal. To see if the observed changes in incorporation of ^{3}H-thymidine into DNA in striatum and spleen could be accounted for by differences in the local availability of the label in morphinized rats, amounts of tritium in DNA were correlated with amounts in supernatants of the tissue homogenates. Again, thymidine incorporation was higher in striatal DNA of morphinized rats, even though there was less tritium in supernatants. There was again less label in DNA in spleens, but this was correlated (r = 0.92) with lesser amounts of label in the supernatants from morphine-injected rats. The apparent decrease in mitosis in the spleen is therefore probably due to a decrease in the availability of the label, but the increased incorporation of ^{3}H into striatal DNA cannot be a consequence of greater access of thymidine to the striatum. The increase of thymidine incorporation into DNA in the striatum probably reflects an increase in glial cell proliferation induced by morphine. Supported by grant DA 01685.

1362 MORPHINE DOES NOT PRODUCE CATALEPSY. B. H. Moon*, J. J. I. Feigenbaum*, W. J. Weiner, and H. L. Klawans (SPON: C. Schauf). Dept. Neurosci., Rush Presbyterian St. Lukes Med. Center, Chicago, Ill., 60612

The administration of morphine (M) produces a dose-dependent catalepsy (C) in the rat which is regarded as one of the primary behavioral features of this drug. A few investigators have objected to the classification of M as a cataleptic because it produces skeletal muscle rigidity. Such objections are not relevant to low doses of M, however, which induce C that is indistinguishable in appearance from that produced by drugs which induce C without rigidity (e.g. neuroleptics: Costall and Naylor, 1974).

Among the several most commonly used test models of C are those measuring the length of time an animal will rest its forepaws on an elevated bar (1); or one of its hindlegs on an elevated surface (2); the number of times an animal inverted by its tail will pass through a cylinder (3); and the length of time an animal requires to right itself from a prone position (4). All four tests were used to determine their relative sensitivity, reliability, and specificity in measuring C in Sprague-Dawley rats injected with M (20-70 mg/kg) or haloperidol (H)(1-10 mg/kg). Of the tests used, (1) proved the most sensitive and reliable, and (4) the least sensitive and reliable. However, all four tests proved to have poor specificity. While measuring the ability to initiate movement, they failed to measure the ability to sustain exogenously stimulated movement as they provided little or no external stimulation. To measure this important but widely ignored parameter of immobility, a fifth test of C providing external stimulation was administered to M or H injected rats. Each animal was flipped by its tail into the air to determine if it could right itself (i.e. land on its feet). Throughout the entire dose range of H, none of the animals could properly right themselves and were inert after landing. By contrast, the M injected animals all righted themselves irrespective of the dose used, and exhibited a dose-dependent locomotor hyperactivity upon landing. Apparently, M inhibits only the initiation of movement, but once external stimulation is provided, M can stimulate and sustain movement in a dose-dependent manner. We propose that any definition of C should include: 1) an inability to initiate movement, 2) an inability to respond to external stimulation with movement, 3) an absence of somnolence or paralysis.

1363 LIDOCAINE MAY BE A CENTRAL STIMULANT. P. A. Nausieda, J. J. I. Feigenbaum*, H. L. Klawans, Dept. Neurlogical Sci., Rush Presbyterian St. Lukes Med. Center, Chgo. Ill., 60612

Lidocaine (L) is a synthetic local anaesthetic related to cocaine and widely used in the treatment of cardiac arrhythmias. Though sharing the nerve blocking effect of cocaine, L is thought to be devoid of central stimulant activity. A number of observations, however, suggest that this concept is erroneous. L is known to demonstrate reverse tachyphylaxis relative to seizure threshold when chronically administered, and to induce compulsive stereotyped behavior (SB) in sub-human primates, properties which suggest a similarity to the actions of cocaine centrally. The ability of L to induce SB in rodents was studied. The induction of SB in the rat is a well accepted model of central stimulant activity which is felt to represent dopaminergic activity at the level of the corpus striatum. L was administered s.c. to Sprague-Dawley rats at doses of 5-20 mg/kg. SB was rated at 5 minute intervals using a previously described scale. At low doses of L a clear-cut SB was induced. At intermediate doses, SB was seen initially, but was inhibited by the induction of sedation, only to reappear as the apparent sedative effect cleared. At doses above 10 mg/kg, the induction of sedation was of shorter latency and longer duration, and at 20 mg/kg, only an initial sedative effect was observed. The effect of L on the SB induced by amphetamine (5 mg/kg) or apomorphine (.5 mg/kg) was also studied. L showed mild potentiation of amphetamine induced SB at low dosages. Amphetamine at this dosage did not appear to reverse L induced sedation. Apomorphine (Ap) .5 mg/kg appeared to shorten the latency of onset of sedation induced by L and it enhanced the sedative effect at all dosages. Low doses of Ap were employed and inhibition of Ap induced SB was observed when low doses of L were concomitantly administered. L was unable to reverse reserpine induced cataplexy, and could not induce SB in animals pretreated with α methyl-para-tyrosine. Haloperidol (H) completely blocked L induced SB. Our data clearly demonstrate that L possesses central stimulant-like activity in this animal model. In addition, it appears that L possesses a sedative effect which predominates when higher doses are employed and may mask the central stimulant effect of this agent. Finally, the blockade of L induced SB by H, reserpine, and α methyl-para-tyrosine suggests that L induces SB via a central dopaminergic mechanism.

1364 DIFFERENTIAL EFFECTS OF CARBON MONOXIDE ON DOPAMINE AND NOREPINEPHRINE TURNOVER IN RAT BRAIN. M.B. Newby*, R.J. Roberts*, and R.K. Bhatnagar, (SPON: R. Roskowski, Jr.) The Toxicology Ctr., Dept. of Pharmacology, Univ. of Iowa, Iowa City, IA 52242.

Carbon monoxide (CO) poisoning produces neurological disorders which may involve damage to catecholaminergic neurons. Exposure to CO produces a reduction in turnover of dopamine (DA) in rat striatum as indicated by the decline of DA levels subsequent to synthesis inhibition by α-methyl-p-tyrosine (AMPT) (Newby, et al. JPET, in press). We now report the specificity of the CO effect on catecholamines and the dependence of the effect on DA turnover on the concentration of CO. Adult rats were injected with AMPT (250 mg/kg) or saline. This dose of AMPT blocks the conversion of ^{3}H-tyrosine to ^{3}H-DA or -norepinephrine (NE) for at least 5 hr in the presence of air or CO. One hr after injection the rats were exposed to CO (1700 ppm), hypoxia (7.5% O_2) or air and killed after 3 hr of exposure. Various regions of the brain were dissected for assay of DA and NE levels. Both CO and hypoxia exposures significantly decreased the DA turnover in the caudate nuclei and olfactory tubercles but were without effect on NE depletion in the hippocampus and olfactory tubercles. In contrast, NE turnover in the hypothalamus was increased by both CO and hypoxia.

In separate experiments the effect of varying the concentration of CO and duration of CO exposure on DA turnover were studied. AMPT was injected as above and 1 hr later rats were exposed to CO. After 3 hr of exposure, DA levels in the striata were elevated 12, 24, and *64% above air controls in rats exposed to 500, 1000, and 1500 ppm CO, respectively (*P<.05). Other groups of rats were given a second injection of AMPT (175 mg/kg) and exposures to 500 or 1000 ppm CO were continued for an additional 3 hr. The turnover of DA was reduced in the striata of rats subjected to 7 hr of 1000 ppm CO; 500 ppm CO did not produce this effect. In addition, steady-state DA levels in saline treated rats exposed to 1000 or 1500 ppm CO were significantly elevated above levels in the saline treated air controls; this effect was absent in the rats exposed to 500 ppm CO.

In conclusion, the effects of CO and hypoxia on NE turnover differ from their effect on DA turnover. Moreover, the effect of CO on DA turnover is concentration-dependent. The reasons for the differential sensitivity of DA and NE neurons are not known but likely involve alterations in the catabolism or release of the transmitters. (Supported in part by PHS Grant 5T32GM07069-03).

1365 ELECTROPHYSIOLOGY OF ETHANOL WITHDRAWAL COMPARED WITH THE BARBITURATE WITHDRAWAL IN THE SPINAL CORD. Masako Nozaki, and Michiko Okamoto, Cornell Univ. Med. Coll., New York, N.Y. 10021.

The segmental reflex system for the low spinal cord has long been an important model system for studying drug effects on the CNS. This system has been effectively utilized to uncover the synaptic alterations produced during barbiturate withdrawal (Rosenberg & Okamoto, JPET, 1976). Although electrophysiological changes in the spinal cord produced by a single acute dose of ethanol are known (Kolmodin, Acta Physiol. Scand., 1953; Miyahara, et al., JPET, 1966; Eidelberg & Wooley, Archiv. Int. Pharmacol., 1970; Meyer-Lohmann, Arch. Pharmacol., 1972; Lathers & Smith, JPET, 1976), no studies have been reported on ethanol withdrawal. Therefore, the present study was conducted in ethanol dependent animals (1) to uncover the neuronal alteration produced during withdrawal in the spinal cord (2) to compare the results of ethanol and barbiturate withdrawals (3) to correlate as much as possible these findings with behavioral withdrawal.

Cats were made physically dependent on ethanol administered twice daily via intragastric route for 30 days. All animals treated this way exhibited signs of severe dependence, including spontaneous grand mal type convulsions. 24 hours after abrupt withdrawal of ethanol, and when the animals display near peak intensity of withdrawal signs, electrophysiological measurements of spinal cord activity were made. The method used in the present study has been described for barbiturate withdrawal (Rosenberg & Okamoto, JPET, 1976, 1978). The excitatory functions measured by the amplitude of 2N spikes, polysynaptic discharge pattern, 2N discharge zone, frequency response curve for post-tetanic potentiation, and synaptic recovery time have been little affected by ethanol withdrawal compared to that produced by barbiturate withdrawal. On the other hand, the inhibitory functions treated by "direct" (post-synaptic) and pre-synaptic inhibitions were markedly attenuated.

These findings indicate that the primary role in alcohol withdrawal is a loss of functions in inhibitory pathways while excitatory functions are little affected. These may contribute to the general hyperexcitation (Kalant, et al., Pharm. Rev. 1971) and behavioral characteristics produced during alcohol withdrawal (Okamoto et al., Comm. Probl. Drug. Depend. 1978). (Supported by NIDA Grant DA-00591).

1366 ANTIDEPRESSANT RECEPTOR BINDING IN BRAIN. R. A. O'Brien*, N. M. Spirt* and W. D. Horst (SPON: E. B. Sigg). Hoffmann-La Roche Inc., Nutley, N.J. 07110

Antidepressant drugs bind specifically to rat brain synaptosome fractions. The binding, using [^{3}H]-imipramine as the radioligand, is rapid, saturable, reversible and of low affinity; half-maximal saturation occurs at 8-16 μM. Specificity of the interaction of antidepressants with receptor sites correlates with clinical efficacy but not with the inhibition of monoamine uptake. Thus, the clinically-active antidepressants, iprindole and mianserin, which are active in inhibiting [^{3}H]-imipramine binding (IC_{50}'s of 7 and 48 μM, respectively) are inactive in standard antidepressant evaluations such as inhibition of monoamine uptake and prevention of tetrabenazine effects in vivo. Amphetamines and a number of monoamine oxidase inhibitors are inactive or have only a slight effect on imipramine binding. Binding does not correlate with an effect on dopaminergic, cholinergic, histaminergic or other recently described aminergic receptor systems. Chronic treatment of animals with imipramine for three weeks (15 mg/kg i.p. twice daily) causes a 20-30% diminution in the amount of [^{3}H]-imipramine bound. In contrast to other types of specific drug receptor binding (e.g. benzodiazepine) which are reported to be inhibited only by structural analogs, imipramine binding is blocked by structures other than the classical tricyclics This binding phenomenon may be a valuable tool for investigations on the mechanism and site of action of antidepressants and the search for endogenous antidepressant- or depressant-like compounds in brain.

1367 CONTRALATERAL TURNING AFTER INTRANIGRAL KAINIC ACID IS INDEPENDENT OF THE TELENCEPHALON, INCLUDING THE STRIATUM. Georges Papadopoulos+, Joseph P. Huston. Inst. Psychol., Lab. Comp. & Physiol. Psychol., Univ. Düsseldorf, D-4000 Düsseldorf, West Germany.

Rats, under Equithesin anesthesia, were injected unilaterally into the substantia nigra with kainic acid (0.5 - 1 μg in a volume of 0.5 μl), and at the same time the whole telencephalon (including cortex, hippocampus striatum, globus pallidus and septum) was removed by suction, resulting in the so-called "thalamic rat" preparation. 24 hours after the operation the rats exhibited contralateral turning to various degrees. In some cases it was very intense, while in animals suffering movement difficulties, it could only be induced by tactile stimulation or had the form of contralateral asymmetry. In a "control" group of rats only kainic acid was injected unilaterally in the same dosage. All these animals showed intense spontaneous contralateral turning 24 hours after the operation in accordance with previous reports. However, in the first twelve hours after the operation ipsilateral turning was sometimes present for intervals up to several hours duration. The animals of the latter group showed an unusually strong sensitivity of tactile stimuli, to which they reacted with a very vigorous and persistent biting of any available object, so that handling of these rats was virtually impossible. A possibly comparable form of "supersensitivity" to tactile stimuli was sometimes observed in the thalamic animals with kainic acid lesion in the substantia nigra, who reacted with unusually and intense opening and closing of the mouth when grasped.

The above findings show that contralateral turning after unilateral nigral lesion with kainic acid is not dependent on the presence of telencephalic structures, including the striatum. This is possibly also true of other behavioral consequences of such lesions.

1368 A COMPARISON OF ETHYLKETOCYCLAZOCINE, KETAMINE AND PHENCYCLIDINE ON EEG AND BEHAVIOR IN THE DOG. Wallace B. Pickworth and Lawrence G. Sharpe. NIDA Addiction Research Center, Lexington, Kentucky 40583

We have found that ethylketocyclazocine (Win 35,197-2), an opiate antagonist of the κ type, has a pharmacological spectrum of activity similar to that reported for the disassociative anesthetics. In this study we compared the effects of Win 35,197-2 with those of ketamine and phencyclidine, two chemically related disassociative anesthetics with growing abuse potential. The compounds were studied in unrestrained adult beagle dogs with chronic electrodes implanted for recording cortical and hippocampal EEG. During a 2 hr experiment, the animals were placed in a dimly lit sound-attenuated chamber while their behavior was observed on a videomonitor. Intravenous drug injections and EEG records were made remotely. Ketamine (4 mg/kg) and Win 35,197-2 (0.05, 0.1 and 0.2 mg/kg) caused EEG-behavioral dissociation in that the dogs displayed cortical synchrony in non-sleeping positions. Both drugs decreased total sleep, abolished paradoxical sleep, and produced ataxia and hyperthermia. Ketamine, but not Win 35,197-2, caused stereotypic head bobbing. Phencyclidine (0.1, 0.25 and 1.0 mg/kg) caused stereotypic head bobbing, licking, EEG and behavioral activation at the lower doses, but grand mal seizures (in one animal) after the highest dose. No EEG-behavioral dissociation followed phencyclidine administration. Instead, sleep was abolished and cortical EEG desynchronized, accompanied by hippocampal theta activity. These results indicate that, in the dog, ketamine has agonistic activities similar to those of the κ agonists and that phencyclidine has opposite effects which are more amphetamine-like.

1369 MORPHINE IS NOT A SUBSTANCE P RECEPTOR ANTAGONIST. M. F. Piercey, R. P. Hollister*, L. A. Schroeder*, P. J. K. Dobry and F. J. Einspahr*. The Upjohn Company, CNS Research, Kalamazoo, MI 49001.

Morphine is reported to depress nociceptive neurons in the spinal cord dorsal horn. Since substance P (SP) is currently the leading candidate for the neurotransmitter released by primary pain afferents, morphine might depress dorsal horn neurons by antagonizing SP. In order to test the hypothesis that morphine is an SP receptor antagonist, we examined morphine's capacity to modify SP's effects on a variety of assays. Morphine concentrations as high as 9×10^{-4}M did not alter SP-induced contractions of the in vitro guinea pig ileum. Nevertheless, 3×10^{-6}M depressed serotonin-induced contractions by 50%. Morphine was also incapable of antagonizing in vivo effects of SP. Thus, concentrations as high as 10 mg/kg (i.v.) did not depress the SP induced hypotensive effects in urethane-anesthetized rabbits nor the sialagogic effects observed in pentobarbital-anesthetized rats. Finally, in a direct test of the hypothesis, morphine was found not to antagonize the discharges evoked in dorsal horn neurons by iontophoretically released SP. In these experiments, unanesthetized decerebrate cats with low (L1) spinal sections were used. Conventional 5 and 7 barrelled microelectrodes were used to eject drugs onto L6 and L7 dorsal horn neurons whose firing rates were monitored via the central recording barrels. Dorsal horn locations were verified by histological recovery of pontamine sky blue spots electrophoresed during the experiments. Morphine, 50-100 nA, did not antagonize SP-induced discharges for any of the cells studied. For some cells, morphine actually potentiated the responses. This effect was not specific for SP since morphine also sometimes potentiated responses to noxious cutaneous heat and iontophoretic glutamate. These weak excitatory effects of morphine, which were often accompanied by small increases in spontaneous activity, are considered to be due to the accumulation of supratherapeutic doses of morphine at the electrode tip. In confirmation of this theory, iontophoretic naloxone did not antagonize the excitatory actions of morphine. It is concluded that morphine is not an SP antagonist. Thus any spinal antinociceptive effects of morphine must be due to some other mechanism [e.g. decrease in SP release, Jessel and Iversen, Nature (1977) 268:549].

1370 IBOTENIC ACID: EXCITATORY AND INHIBITORY ACTIONS IN CEREBRAL CORTEX. E. Puil and K. Krnjević, Dept. of Anaesthesia Research, McGill University, 3655 Drummond St., Montreal, P.Q. Canada. H3G 1Y6

Ibotenic acid is generally considered as an excitatory agent, closely related to L-glutamic acid. In our experiments on neurons in the cat's cerebral cortex, when DL-ibotenic acid was applied microiontophoretically, we indeed observed a strong excitation but with a much slower time course than is seen when glutamate is applied (a long latency of onset and prolonged after-discharge was more prominent in cats under Dial than under methoxyflurane anaesthesia). Even minute, subthreshold amounts of ibotenic acid could strongly potentiate responses evoked by L-glutamate, applied either simultaneously or several seconds later. However, this potentiation could be prevented by a concurrent iontophoretic application of methohexital.

An even more impressive effect of ibotenic acid was a powerful and very prolonged depression of glutamate-evoked activity. This was produced by releasing ibotenic acid in conjunction with regular applications of constant amounts of glutamate: this would typically first enhance the glutamate responses, and then lead to ongoing firing; after the end of the release of ibotenic acid, there would be a 4-5 min period of silence before the continuing regular applications of glutamate started to become effective again. It is unlikely that the silent period was caused by a depolarizing type of block, since responses could be temporarily restored by increasing the iontophoretic dose of glutamate, or even by a short application of ibotenic acid. It is also unlikely that ibotenic acid antagonized specifically the action of glutamate, since responses evoked by acetylcholine were blocked just as effectively (and took even longer to recover). These observations confirm previous findings in the spinal cord (MacDonald & Nistri, 1978, J. Physiol., 275, 449). They are consistent with the possibility that ibotenic acid has a dual action on neuronal receptors: a relatively quickly reversible one on receptors to glutamate, leading to excitation, and a much more prolonged interaction with inhibitory receptors. One possible explanation for the inhibitory effect is a very slowly reversible combination of this close relative of muscimol with GABA receptors.

1371 CHANGES IN NEOSTRIATAL AND MESOLIMBIC NEURONAL ACTIVITY PRODUCED BY HALOPERIDOL AND CLOZAPINE. George V. Rebec. Dept. Psychol., Indiana Univ., Bloomington, IN 47401

Some recent behavioral and biochemical evidence has indicated that whereas the "classical" neuroleptics (e.g., haloperidol) may be acting equieffectively at neostriatal and mesolimbic dopamine (DA) sites, the "atypical" neuroleptics (e.g., clozapine) may exert selective effects on the mesolimbic DA system (see, Anden, J. Psychiat. Res., 1974, 11: 97). Other studies, however, have not supported this notion (see, Stanley and Wilk, Eur. J. Pharmacol., 1977, 44: 293).

In order to further elucidate the possible mechanism of action of these drugs, spontaneous neuronal activity in the neostriatum and accumbens nucleus of immobilized, locally anesthetized rats (350-450g) was recorded in response to intraperitoneal (i.p.) injections of haloperidol (1-2 mg/kg) or clozapine (20-80 mg/kg). Both drugs generally produced a prolonged dose-dependent increase in firing rate in the neostriatum which ranged in magnitude for individual neurons from 200-800 percent. Comparable results were obtained in the accumbens nucleus. In a separate group of animals, i.p. administration of 2.5 mg/kg d-amphetamine sulfate or 1.0 mg/kg apomorphine produced a prolonged depression of unit activity in the neostriatum and accumbens nucleus, and in each instance this response was rapidly reversed by either haloperidol or clozapine. The results of these experiments, which suggest that the neostriatal and mesolimbic DA systems are not differentially sensitive to the actions of haloperidol and clozapine, may have important implications for the behavioral pharmacology of the neuroleptics and related drugs.

This research was supported, in part, by Biomedical Research Support Grant #46-314-02 from Indiana University.

1372 MICROIONTOPHORESIS OF INHIBITORY AMINO ACIDS IN THE MEDIAL HYPOTHALAMUS : EVIDENCE FOR GABA AS AN INHIBITORY HYPOTHALAMIC NEUROTRANSMITTER. Leo P. Renaud, Quentin J. Pittman and Howard W. Blume. Division of Neurology, Montreal General Hospital and McGill University, Montreal, Canada, H3G 1A4

Recent electrophysiological studies on the connections of medial hypothalamic neurons have indicated the presence of a prominent postsynaptic inhibition presumably mediated by local inhibitory interneurons activated through recurrent or afferent pathways. This report details our preliminary observations on the neuropharmacology of these hypothalamic inhibitory pathways, with emphasis on the possible contribution of the inhibitory amino acids.

Experiments were conducted on pentobarbital anaesthetized male Sprague Dawley rats implanted with stimulation electrodes in several extrahypothalamic areas known to be connected to the medial hypothalamus. Using a transpharyngeal approach, extracellular recordings were obtained from 181 medial hypothalamic neurons. The excitability of these neurons was tested with the microiontophoretic application from multibarrel micropipettes of several test compounds. L-glutamate and L-aspartate enhanced the excitability of the majority of tested neurons. Both the glutamate evoked and spontaneous activity of these cells could be depressed in a dose dependent manner by application of GABA, glycine and related amino acids according to the following order of potency : β-guanidinopropionic acid (β-GP)> GABA > β-alanine > δ-aminovaleric acid (δ-AVA) > glycine. Simultaneous microiontophoretic application of picrotoxin or bicuculline appeared to selectively antagonize depressions evoked by β-GP, GABA and δ-AVA, whereas strychnine appeared to cause a selective antagonism of the actions of glycine and β-alanine.

Picrotoxin, bicuculline and strychnine were also tested for possible antagonistic effects on postsynaptic inhibition evoked by stimulation of extrahypothalamic sites. The microiontophoretic and intravenous administration of picrotoxin and bicuculline, but not strychnine, could be shown to partially or completely antagonize postsynaptic inhibition. However, with intravenous administration, this action usually required administration of antagonists in convulsive doses.

These observations suggest that hypothalamic neurons have both GABA and glycine receptors, but that GABA is the more likely candidate as a hypothalamic inhibitory neurotransmitter. (Supported by the MRC).

1373 DIFFERENTIAL EFFECTS OF ANESTHETIC-LIKE DRUGS ON ISOLATED NEURON PREPARATION. Sheldon H. Roth and Bruce M. MacIver*. Department of Pharmacology and Therapeutics, Faculty of Medicine, University of Calgary, Calgary, Alberta, Canada, T2N 1N4.

The isolated abdominal muscle receptor organ (MRO) of the crayfish (Procambarus clarkii) provides an excellent neuronal model system for a study of the effects of anesthetics and various other depressants on cellular activity. It is generally accepted that the mechanism of action of all anesthetics is similar at the molecular (membrane) level, and the basic mechanism of action is purely a physicochemical interaction of a lipid soluble substance with a hydrophobic region. We propose that all anesthetics do not act via a common mechanism, but can demonstrate a spectrum of activity (e.g. depression and excitation) at the cellular level which suggests a selectivity of effect. Several neurophysiological parameters of the MRO are monitored simultaneously, using both intra and extracellular techniques, in the absence and presence of drugs. Input stimulus (i.e. stretch) is varied and quantitatively measured via a sensitive strain gauge while simultaneously recording neuronal activity. The preparation is sensitive to relatively low concentrations of depressant drugs, such as ethanol, pentobarbital, methoyflurane and harmaline. All the agents are capable of depressing the characteristic output activity of the MRO in a dose and time related fashion. However, in addition to the general depressant activity, most of the agents elicit an initial excitatory effect, and some are capable of producing a unique alteration of the temporal pattern of discharge.

Harmaline, at concentrations of the order of 10^{-5}M changes the characteristic single action potential output to a rhythmical doublet or paired activity. Ethanol is effective at concentrations as low as 0.1mM, and at 10mM produces a periodic discharge of high frequency bursts, consisting of between 7 to 15 spikes/burst. Other burst patterns and lack of burst patterns have been observed with various other drugs. These distinct changes in action potential discharge are both drug and dose dependent, and may result from direct interactions with neuronal membranes in a selective manner.

1374 THE EFFECT OF MONOACYLATED DIAMINES ON THE SLEEP-WAKING BEHAVIOR OF THE RAT. Steven K. Salzman* and Matej Stepita-Klauco, Dept. Biobehavioral Sci., Univ. of Conn., Storrs, Conn. 06268.

Cadaverine (1,5-diaminopentane) and its acylated derivatives occur in mammalian brain (Dolezalova et al., 1974, 1977) but a physiological function unique to the nervous system has not been ascribed to these compounds. Cadaverine has been shown to be taken up by brain slices (Picolli, 1972) and along with its acyl derivatives (acetyl and propionylcadaverine) is purportedly elevated in the urine and blood of schizophrenics (Perry, 1967, Dolezalova, 1977). Single cell microiontophoresis studies by our group showed that while cadaverine had no effect on the membrane potential of molluscan neurons its acyl derivatives caused a long-lasting, slowly decrementing depolarization (Miller, 1977). It was suggested that masking of one of the amine groups of cadaverine by acylation rendered a pharmacologically active monoamine. The purpose of this study was to test if the same pharmacological profile could be seen in a mammalian system. Black-hooded rats were chronically implanted with screw electrodes for recording both the EEG and EMG. One week was allowed for recovery, then the rat was connected to a recording cable and habituated for two days in a temperature controlled chamber before records were taken. After a 4-5 day period acetylcadaverine was administered. Drug delivery was done with an osmotic minipump providing continuous doses at 100ng/hr, 10ug/hr and 100ug/hr, respectively. EEG power spectra were calculated for each behavioral stage. Acetylcadaverine caused a biphasic change in the average duration of NREM sleep and the average NREM to waking interval. At the low dose (100 ng/hr), the average duration of sleep, NREM, and the NREM to waking interval were all decreased. With the middle dose (10 ug/hr) these parameters were all increased. At the highest dose (100 ug/hr), only NREM duration was increased, with an increased variance of values for other parameters. Interesting day-night differences also emerged. With the lowest dose, the average NREM epoch was shorter only at night, while the middle dose had the same effect at night as it had during the day. Spectral analysis of the EEG signal revealed an increase in its power in the bandwith between 15-18 Hz during NREM with no change in either the waking or REM corticogram. Studies are in progress on the effects of chronic intracerebral administration of cadaverine, putrescine and their acyl derivatives on sleep-waking behavior and the EEG spectral components.

1375 ELECTROPHYSIOLOGICAL EVIDENCE FOR A DIFFERENCE IN THE NOREPINEPHRINE (NE) AND DOPAMINE (DA) NEUROTRANSMITTER STORAGE MECHANISMS. M.K. Sanghera*, D.C. German, R.S. Kiser and P.A. Shore. Depts. of Physiol., Psychiat. and Pharmacol., U. of Texas Health Sci. Ctr., Dallas, TX 75235.

Biochemical studies provide evidence for the existence of a fundamental difference between the NE and the DA neurotransmitter storage systems. For example, rapid equilibration occurs between stored and releasable NE pools (McMillen & Shore, 1977), whereas the rate of movement of stored DA to an impulse-releasable site occurs only slowly (Shore & Dorris, 1975). The slow equilibration between the stored and releasable (newly-synthesized) DA pools is consistent with the electrophysiological finding that inhibition of tyrosine hydroxylase with α-methyl-para-tyrosine (AMPT) blocks or reverses the d-amphetamine (d-AMP)-induced depression of DA unit activity; the d-AMP action being dependent upon the presence of a newly-synthesized transmitter pool (cf., German, et al., 1978).

The aim of the present study was to examine, by electrophysiological means, the hypothesis that the NE and DA storage systems differ. If the stored and releasable NE pools are in rapid equilibrium, then AMPT should not influence the inhibitory action of d-AMP on NE neuronal impulse flow. In the chloral hydrate-anesthetized rat, recordings were made from single cells in the locus coeruleus (LC). The identification of these neurons was based upon electrophysiological characteristics as reported by Cedarbaum & Aghajanian (1977), and subsequent histological verification. All drugs were given via a jugular catheter. Animals were pretreated with AMPT (50 mg/kg), 20-60 min. prior to the administration of d-AMP. All LC neuron firing rates were reduced to below 50% of their basal level with 0.5-1.0 mg/kg of d-AMP. The d-AMP-induced suppression in LC unit activity was subsequently increased to or above basal levels by an injection of the α-adrenoreceptor-blocking agent, dibozane. These electrophysiological data are consistent with the above-mentioned biochemical and electrophysiological studies which provide evidence for a difference between the NE and DA neurotransmitter storage mechanisms. 1376 ALTERATIONS OF CENTRAL AUTONOMIC CARDIOVASCULAR RESPONSES BY Δ^9-TETRAHYDROCANNABINOL. William T. Schmeling* and Michael J. Hosko. Department of Pharmacology, Medical College of Wisconsin, Milwaukee, Wisconsin 53226.

Δ^9-Tetrahydrocannabinol, the primary psychoactive component of marijuana, has a pronounced ability to induce hypotension and bradycardia in experimental animals. This hypotensive effect and induced bradycardia have been postulated to occur partially through reduction of sympathetic tone to the cardiovascular system. The ability of Δ^9-THC to induce hypotension is not compromised by transection of the neuraxis at the midcollicular level but is abolished by high cervical section. Experiments were conducted in rats and cats to determine the effect of Δ^9-THC on carotid sinus nerve (CSN) baroreceptors. Cats and rats were anesthetized with a combination of α-chloralose (50-60 mg/kg) and urethane (500-600 mg/kg) or transected at midcollicular levels. Bipolar tungsten hook electrodes were placed on the stumps of proximal (PV) and distal vagus (DV) in those animals in which the vagi were sectioned. Square wave pulse trains of 10 second duration (16-80 Hz, 0.1-0.2 msec, 0.25-4.0 ma) were delivered to the CSN, PV and DV. Stimulus current was selected to produce "threshold," two, and four times threshold stimuli to the PV and CSN. A single maximal stimulus was delivered to DV. Stimulus induced alterations in blood pressure (BP) and heart rate (HR) were recorded.

In both vagotomized, nonvagotomized and midcollicular rats and cats Δ^9-THC (2.0 mg/kg, iv) essentially abolished the pressor response to carotid occlusion and significantly attenuated (0.0-30.0% of control) the depressor response to CSN stimulation within 5 min of administration. In some animals, Δ^9-THC reversed the blood pressure response to CSN stimulation. PV stimulations graded to produce pressor responses were augmented after Δ^9-THC, while those producing depressor responses were attenuated. The response to DV stimulation was unchanged. These results would be consistent with altered central neuronal processing of cardiovascular afferent information following administration of Δ^9-THC. These findings are consistent with the hypothesis that Δ^9-THC induces significant disruption of sympathetic and parasympathetic tonic homeostatic cardiovascular control mechanisms. (Supported by USPHS NIH Grant DA00124.)

1377 EFFECTS OF DIETARY AND PARENTERAL CHOLINE ADMINISTRATION ON AMBULATORY ACTIVITY IN RATS. Dennis E. Schmidt*, Robert J. Barrett* and Lynn Wecker (SPON: D.M. Buxbaum). Dept. Pharmacol., Vanderbilt Univ. Sch. Med., Nashville, TN 37232.

Parenteral administration of choline (Ch) to rats has been shown to alter the sensitivity of discrete regions of the brain to biochemical manipulation by pharmacological agents (Sci.199:86, 1978;Fed.Proc.37:820,1978). In light of clinical findings that Ch loading may be beneficial in alleviating mood or movement disorders, we have extended our biochemical studies and investigated the effects of dietary and parenteral Ch administration on behavior. Male Sprague-Dawley rats (145g) were maintained for 2 weeks, with water available ad libitum, on a dietary regimen consisting of: a) a Ch free (CF) diet, b) a "normal" (N) rat diet, 1.6g free Ch/kg chow or c) a high Ch (HC) diet, 11.4g free Ch/kg chow. At the end of the 2 week period, rats were injected (ip) with either saline, ChI (60 mg/kg free base), atropine sulfate (20 mg/kg) or Ch followed by atropine at 60 min. Rats were placed in a symmetrical Y-maze and ambulatory activity was recorded automatically for a 30 min period following drug administration. Basal activity (saline injected) did not differ between rats in the N and CF groups, whereas, rats on the HC diet exhibited a basal activity 186% of the activity of rats on the N diet. Ch administration did not affect ambulatory movement in any of the dietary groups,while atropine significantly (P<.05) increased the activity of animals in both the N and CF groups to 171% and 159% of basal activities, respectively.The activity of rats on the HC diet was not different from basal HC group activity after atropine administration, but was 249% of basal N group activity.When Ch was administered 60 min prior to atropine, the atropine-induced increase in activity in N rats was prevented (P<.05) and activity was not different from basal activity for rats in the N group. In the CF group, Ch pretreatment potentiated the actions of atropine to 263% of basal activity (148% of the atropine responses). Ch pretreatment did not alter the responses to atropine in rats on the HC diet. Therefore, it is apparent that dietary levels of Ch may be involved in the mechanisms regulating locomotor activity in rats.In addition, we have extended our previous observation on the modification of the central actions of atropine by Ch pretreatment to include behavioral as well as biochemical parameters.Therefore, the nutritional status of an animal,i.e.,Ch availability,may be significant in determining the efficacy, both behavioral and biochemical, of pharmacological agents affecting cholinergic function in the central nervous system.Further studies will hopefully elucidate the specific mechanisms involved in this interaction. (Supported by a Biomedical Research Support Grant RR-05424-16 and an NIMH Grant MH-29182.)

1378 A TONIC MUSCARINIC INHIBITORY INPUT TO PUPILLOCONSTRICTOR NEURONS IN THE EDINGER-WESTPHAL NUCLEUS OF THE DOG. Lawrence G. Sharpe and Wallace B. Pickworth. NIDA Addiction Research Center, Lexington, Kentucky 40583

Male and female beagle-type dogs had indwelling guide cannulae (19 ga) implanted with the tips located above the Edinger-Westphal (EW) nucleus. The animals were acclimated to sling restraints, and during experimentation a concentric chemitrode (30 ga inner, 23 ga outer, insulated except at the tips) was lowered through the guide cannula into a site where electrical stimulation (20 Hz, 0.5 msec, 2-6 V) had produced marked miosis without ocular movements. Drugs dissolved in sterile saline were injected in a 0.5 µl volume over 1 min into this site. The injection cannulae were located within the EW nucleus as verified by standard histological procedures. Pupil diameter was measured photographically. Carbachol (0.05 to 0.25 µg) and physostigmine (5 to 10 µg) produced a dose-dependent pupillodilatation. Pretreatment with microinjections of methylatropine nitrate (2.73 nmol, in 1.0 µl) completely antagonized the mydriatic activity of carbachol (0.1 µg) and physostigmine (5 µg). Microinjections of the nicotinic antagonists mecamylamine (2.73 nmol) and hexamethonium (2.73 nmol) did not block the carbachol-induced mydriasis. Methylatropine, but not mecamylamine and hexamethonium, produced miosis. Microinjections of carbachol (0.1 µg) into sites 2 mm above or below the site that yielded stimulation-produced miosis caused either no change or a delayed mydriasis. The mydriatic activity of the cholinomimetics was unrelated to peripheral sympathetic activation. These data suggest that the tonic inhibitory input to the EW nucleus is muscarinic. Drugs that act centrally to produce miosis (morphine) and mydriasis (amphetamine) may act on this proposed cholinergic inhibitory pathway.

1379 EFFECTS OF CHRONIC FLUPHENAZINE ON STRIATAL CHOLINERGIC AND DOPAMINERGIC MECHANISMS: A NEUROCHEMICAL AND BEHAVIORAL ASSESSMENT. Kathleen A. Sherman,* Ann L. Acheson,* Michael J. Zigmond, and Israel Hanin. Departments of Psychology, Biological Sciences and Psychiatry (WPIC), University of Pittsburgh, Pittsburgh, PA 15260.

Tolerance is known to develop to the clinically observed extrapyramidal effects of neuroleptics such as fluphenazine. Since these drugs are believed to act in part by blocking striatal dopamine (DA) receptors, we have compared some of the effects of acute and chronic fluphenazine treatment (0.5 mg/kg, s.c.) on two indices of the post-synaptic response to DA. First, we examined the effect of such treatments on striatal acetylcholine (ACh)-containing interneurons, cells which are known to receive an inhibitory DA innervation. We had previously shown that a single injection of fluphenazine decreases striatal ACh concentration without altering high affinity choline (Ch) uptake, the rate-limiting step in ACh synthesis. This is consistent with reports that such treatments increase ACh release. In the present studies rats were injected daily with fluphenazine or saline, and striatal ACh concentration was determined 60 min after the last injection. After a single injection of fluphenazine, striatal ACh concentration was reduced by 40%. Striatal ACh content was reduced by 30% after 5 daily injections, but was unchanged after the tenth day of injection. High affinity Ch uptake was unchanged throughout these studies. These data suggest that, after 10 daily repeated injections, ACh release is no longer increased by fluphenazine, perhaps because the drug is no longer effective in blocking the inhibitory action of DA. In the second series of experiments we examined the ability of fluphenazine to block the behavioral effects of apomorphine (.05-32 mg/kg, s.c.), a dopaminergic agonist. A method of scoring was used which permitted a detailed analysis of the drug-induced behavior. A single dose of fluphenazine completely blocked the effects of apomorphine at all but the highest doses tested (>16 mg/kg). In contrast, the tenth daily injection of fluphenazine was approximately 16-fold less effective in blocking these effects (although significantly more effective than saline). These neurochemical and behavioral studies both suggest that the ability of fluphenazine to inhibit the post-synaptic effect of striatal DA is considerably reduced after chronic pretreatment with this drug.
(Supported, in part, by USPHS grants MH20620, MH00055, and MH 26320.)

1380 IN VIVO SYNTHESIS RATE OF SEROTONIN (5-HT) AND CATECHOLAMINES (CA) IN BRAIN AND SPINAL CORD OF YOUNG SPONTANEOUSLY HYPERTENSIVE (SH) RATS. M. L. Smith*, R. A. Browning and J. H. Myers* (SPON: D. G. King). Southern Illinois University, School of Medicine, Carbondale, Ill. 62901.

Recent work in several laboratories, including ours (Browning et al., Fed. Proc. 36, 4059, 1977), has led to considerable controversy regarding the role of central serotonergic neurons in the development and maintenance of hypertension. Moreover, several laboratories have implicated centrally occurring CA in the regulation of blood pressure in the SH rat. Accordingly, we have now examined the simultaneous in vivo synthesis rates of 5-HT and the CA in hypothalamus (HYP), pons-medulla (P-M) and spinal cord (SC) of 4-week-old (prior to the development of hypertension) and 8-week-old SH and normotensive (NT) rats. Synthesis rates of 5-HT and CA were obtained by measuring the accumulation of 5-hydroxytryptophan (5-HTP) and DOPA following inhibition of aromatic amino acid decarboxylase with Ro4-4602. Blood pressure was recorded in all rats using the indirect tail cuff method on the day prior to decarboxylase inhibition and sacrifice. Animals were sacrificed at 0 or 30 min following pretreatment with Ro4-4602 (800 $mg \cdot Kg^{-1}$; i.p.). 5-HTP and DOPA in tissue samples were measured fluorometrically after separation on Dowex-50 W columns. No differences in CA synthesis rates between SH and NT rats could be detected at 4 or 8 weeks of age. However, as shown in the table below, we did find a significant increase in the rate of synthesis of 5-HT in P-M and SC of pre-hypertensive, 4-week-old SH rats. This difference was not detected in the 8-week-old SH rats with established hypertension. These findings show a transient increase in 5-HT turnover during the development of hypertension which is not continued during the maintenance phase.

1381 6-METHOXY-1,2,3,4-TETRAHYDRO-β-CARBOLINE: A SPECIFIC MONOAMINE OXIDASE-A INHIBITOR IN CF1 MICE. David L. Sparks* and Neil S. Buckholtz., Dept. Biochem. and Dept. Psychiat. Behav. Sci., Med. Univ. S.C. Charleston, S.C. 29403.

Buckholtz and Boggan (Biochem. Pharmac. 26, 1991, 1977) reported a time course of inhibition of brain monoamine oxidase-A (MAO-A) by 6-Methoxy-1,2,3,4-tetrahydro-β-carboline (6-MeO-THβC; 100 mg/kg ip) with a maximal inhibition (22%) by 1 hr. They also showed an inhibition (13%) of MAO-B. This was done in whole brain homogenates of CF1 mice, using a column method for metabolite extraction. Meller et al. (J. Neurochem 28, 995, 1977) showed an inhibition (55%) of MAO-A and no inhibition of MAO-B by MeO-THβC (100 mg/kg) in rat hypothalamus, using an organic metabolite extraction. They also reported an IC50 of 3.7 μM for 6-MeO-THβC in vitro. The present study was done to determine if difference in amount of inhibition by 6-MeO-THβC was due to strain difference or extraction technique, and also to characterize further the MAO inhibition produced.

These studies were done using Meller et al.'s extraction procedure. First, the lowest concentration of substrates giving linear MAO activity over a 30 min period was determined. These were 1.5 μM serotonin (5-HT) for MAO-A and 4.0 μM β-Phenylethylamine (PEA) for MAO-B. It was then determined that there were no differences in inhibition patterns seen whether using [H^3] or [C^{14}]-5-HT as substrate for MAO-A. 6-MeO-THβC had an IC50 of 1.6 μM, in vitro, using whole brain homogenate. A time course of apparent in vivo MAO-A inhibition using 6-MeOTHβC (100 mg/kg) showed a maximal inhibition by 1 hr (56%), a decline to 30% at 12 hr, and no inhibition at 24 hr. There was a maximal inhibition of MAO-B by 1 hr (16%), a decline to 5% at 12 hr, and no inhibition at 24 hr. A dose study done at 1 hr. after injection showed 6-MeO-THβC to inhibit MAO-A by 25% at 25 mg/kg, 43% at 50 mg/kg, and 58% at 100 mg/kg; for MAO-B there was no inhibition at 25 and 50 mg/kg and 15% inhibition at 100 mg/kg. In vivo kinetic studies showed MAO-A to have a Vm of 0.19 μM product/hr/μg protein and a Km of 61.2 μM, with 6-MeO-THβC showing competitive inhibition. MAO-B had a Vm of 0.15 μM product/hr/μg protein and a Km of 11.4 μM, with 6-MeO-THβC showing non-competitive inhibition.

These data indicate that more accurate MAO values can be obtained by using organic extraction of metabolites. Any strain and/or brain region differences in MAO inhibition seem to be in the B form. The data also indicate that, at doses ≤ 50 mg/kg, 6-MeO-THβC is a specific MAO-A inhibitor. The kinetic data confirm the existence of two distinct MAO enzyme forms, due to differential inhibition patterns caused by 6-MeO-THBC. Supported in part by P.H.S. grant MH-26712.

1382 SPECIFIC BINDING OF ^{3}H-DIPHENYLHYDANTOIN TO RAT WHOLE-BRAIN HOMOGENATE. L. Spero* and M. Burnham. Dept. Pharmacol., Fac. Med., University of Toronto, Toronto, Ont., Canada.

Radioreceptor assays have been conducted on rat whole-brain homogenate using ^{3}H-diphenylhydantoin (^{3}H-DPH) and a modified filter-assay technique. These studies indicate the existence of a high-affinity, saturable binding site. Spirodilantin A, an active anticonvulsant enantiomer, competes for ^{3}H-DPH binding whereas Spirodilantin B, the inactive stereoisomer, does not. The anticonvulsant barbiturates also show significant competition for the high-affinity binding site, but the anti-petit mal drugs, trimethadione and ethosuximide, do not. These results suggest that the anticonvulsant drugs effective against grand mal seizures may act via a specific receptor system in the brain. Research in progress will attempt to determine the regional distribution of the specific binding sites, and to establish a correlation between binding potencies and clinical effectiveness within a large series of anticonvulsant drugs, including some with stereoisomer pairs.

(This research was supported by grant MT 5611 from the Medical Research Council of Canada.)

1383 BENZODIAZEPINE BINDING IN THE RAT BRAIN: EFFECT OF VARYING TEMPERATURE. Speth, R.C. and Yamamura, H.I.: Dept. of Pharmacology, University of Arizona Health Sciences Center, Tucson AZ 85724.

Several investigators have measured [^{3}H]diazepam binding to mammalian brain between 0° and 37° and have shown decreased binding with increased temperature. Therefore in routine studies of [^{3}H]diazepam binding, the incubation medium has been chilled to 4° prior to separation of the bound from free [^{3}H]ligand. The binding kinetics of [^{3}H]diazepam at 37° have not yet been determined, presumably because the rate of dissociation of the diazepam-benzodiazepine binding site complex is too rapid. [^{3}H]Flunitrazepam has a higher affinity for the benzodiazepine binding site than does diazepam, in addition, its rate of association with the benzodoazepine binding site is slower than that of diazepam. Consequently the rate of dissociation of [^{3}H]flunitrazepam with the benzodiazepine binding site is considerably slower than diazepam. We have taken advantage of this property of [^{3}H]flunitrazepam to determine its binding kinetics at varying temperatures.

In our initial studies, we observed an activation (34%) of [^{3}H]flunitrazepam binding when incubations were carried out at 37° prior to cooling at 4° as compared to incubations done at 4° alone. To ascertain whether the increase in [^{3}H]flunitrazepam binding occurring at 37° was due to an increase in the number of binding sites or an affinity change, saturation studies were performed at several temperatures and the results analyzed by Scatchard analysis. [^{3}H]Flunitrazepam binding was examined under 5 different conditions: 0° with prior 37° incubation, 0°, 12°, 25°, and 37°. The results of our studies showed a systematic decrease in [^{3}H]-flunitrazepam's affinity for its binding sites with increasing temperature. The K_D values obtained at the various temperatures were 0.7 nM, 1.3 nM, 2.1 nM, 2.0 nM and 5.7 nM, respectively. There appeared to be little alterations in maximal [^{3}H]flunitrazepam binding with increasing temperatures. These data suggest that benzodiazepine binding sites may undergo conformational changes with increasing temperatures or perhaps an endogenous substance is liberated in varying amounts as a function of increasing temperature. Supported by USPHS grants, a Postdoctoral Clinical Pharmacology Training Grant (GM-07533) and a Research Scientist Development Award from the NIMH (MH-00095).

1384 LOW CALCIUM LEVELS ENHANCE ETHANOL-INDUCED MULTIPLE FIRING AT THE CRAYFISH NEUROMUSCULAR JUNCTION. Allan L. Staiman and Juan Acosta-Urquidi. Dept. Pharmacology and Toxicology, Univ. of Mississippi Medical Center, Jackson, Miss., Dept. Zoology, Univ. of Toronto, Toronto, Ont., Can. and Addiction Res. Fdn., Toronto, Ontario, Canada.

The effects of ethanol were examined on the leg opener-neuromuscular junction preparation of the crayfish. The excitatory junctional potential (EJP) mediated by glutamate was studied intracellularly using selective stimulation of the excitor axon. Ethanol in the concentration range of 0.4M to 1M with a mean of 0.8M produced hyperexitability of the nerve terminals on stimulation of the excitor axon. One stimulus to the axon would produce an EJP followed by 1 to 10 other EJPs. The frequency of the multiple firing averaged approximately 80 hertz. Spontaneous multiple firing was not observed unless a stimulus was previously applied. The technique of focal extracellular recording was used to examine the origin of the ethanol-induced multiple EJPs. It was observed that each EJP was preceeded by an action potential and therefore the multiple EJPs observed were spike-triggered events. In order to examine whether ethanols action was via a depolarizing action, 15 mM potassium was applied to the preparation. The size of the EJP was slightly depressed and there was no sign of multiple spiking after stimulation in the presence of high potassium. The effect of calcium ion on the ethanol-induced multiple spiking was examined. In most experiments, raising the normal Ca^{++} concentration 2-fold abolished ethanol induced multiple firing. When the concentration of ethanol was slightly below the threshold concentration for induction of multiple spiking and the Ca^{++} concentration was reduced by 2-fold, still in the presence of the ethanol, multiple release occurred on stimulation of the excitor axon. In some experiments, concentrations as low as 0.2 M ethanol could produce multiple spiking when the Ca^{++} concentration was lowered by 2- to 4- fold. It is suggested that ethanol-induced multiple spiking may be mediated through ethanols action on a Ca^{++} pool and that this action may be of significance in the production of part of ethanols central pharmacological and toxicological actions. The observation that ethanol can produce seizure-like activity in a low Ca^{++} environment may be of significance clinically.

1385 LACK OF TOLERANCE DEVELOPMENT IN THE RAT SUBSTANTIA NIGRA FOLLOWING LONG-TERM AMPHETAMINE ADMINISTRATION. David A. Staunton*, Steven J. Young*, and Philip M. Groves. Dept. of Psych., Univ. of Colorado, Boulder, CO 80309.

There is substantial evidence to suggest that amphetamine acts in part to enhance the release of catecholamines from central catecholaminergic neurons. While several of the physiological and behavioral effects of amphetamine show tolerance development following long-term administration of the drug, a number of such effects do not. Indeed, several of the behavioral effects of amphetamine show a progressive augmentation following administration of low doses for periods of several days or more. In the experiments reported here, rats were given daily intraperitoneal d-amphetamine sulfate injections for periods of 8 (2.5 mg/kg twice daily, n=5; or 5.0 mg/kg twice daily, n=9) or 16 days (2.5 mg/kg twice daily, n=8) or equivalent injections of saline then prepared for extracellular recording of single neuron activity utilizing chloral hydrate anesthesia. After an initial baseline period during which spontaneous activity was recorded, 0.25 mg/kg d-amphetamine sulfate was injected intravenously every four minutes until a 50% reduction in neuronal firing rate was achieved. The cumulative dose necessary to produce such a criterion inhibition of neuronal firing was not altered following any of the above amphetamine pretreatment regimens when compared to saline control values. There were also no significant differences in mean baseline firing rates between any of the pretreatment groups. Such evidence is consistent with the view that for many of the physiological and behavioral effects of amphetamine, tolerance does not develop following long-term administration of the drug. (Supported in part by grant DA 01467 from the National Institute on Drug Abuse and Research Scientist Development Award K02 MH 70706 from the National Institute of Mental Health. Data reported here will be used to satisfy, in part, the requirements for the Ph.D. degree in Pharmacology from the University of Colorado Medical Center by DAS.)

1386 BRAIN NORADRENERGIC SYSTEMS AS A PREREQUISITE FOR DEVELOPMENT OF BARBITURATE TOLERANCE. Boris Tabakoff, R.F. Ritzmann*, Gary Oltmans* and Paula L. Hoffman*. Dept. of Physiology & Biophysics, Univ. of Ill. Med. Ctr. and Dept. Pharmacol., Chicago Medical School, Chicago, Illinois 60612.

Chronic exposure of the CNS to barbiturates results in the development of functional tolerance to these drugs. Mice, fed laboratory chow containing phenobarbital (Ph), and rats, fitted with Alza Minipumps^{R} for intraventricular delivery of Ph, were shown to develop tolerance to the hypothermic and hypnotic effects of barbiturates. In our studies, the CNS "functional" tolerance was distinguished from the metabolic tolerance which develops with oral administration of barbiturates. After withdrawal of the animals from the chronic treatment regimen, the animals were challenged with an acute hypnotic dose of barbiturate. Brain levels of barbiturate at the time of regaining of righting reflex were found to be significantly higher in animals fed or infused with Ph compared with brain barbiturate levels in control animals. In trying to ascertain which neuronal systems were important in development of functional tolerance, we injected 6-OHDA into the lateral ventricle of mice prior to chronic feeding with Ph. The dose of 6-OHDA was chosen to deplete brain NE levels ~50% and to produce little change in other neurotransmitter systems of brain. This partial destruction of NE neurons resulted in a blockade of development of functional tolerance to barbiturates. To more closely determine the anatomical distribution of the NE systems responsible for tolerance development, ascending dorsal and ventral NE bundles were selectively lesioned in rat brain. Destruction of either the dorsal or ventral bundle and subsequent lesion-specific depletion of brainstem and forebrain NE levels resulted in a block in development of functional barbiturate tolerance. Since depletion of hypothalamic NE was common to both lesions, the results of our experiments will be discussed with consideration of the importance of hypothalamic/hypophyseal hormones in development and maintenance of tolerance to sedative hypnotics.

1387 6-HYDROXYDOPA DEPLETES BOTH BRAIN EPINEPHRINE AND NOREPINEPHRINE: INTERACTIONS WITH ANTIDEPRESSANTS. Philip F. VonVoigtlander and Elizabeth G. Losey*. The Upjohn Company, Kalamazoo, MI 49001.

The neurotoxic agent, 6-hydroxydopamine, and its precursor 6-hydroxydopa, have been widely used to selectively destroy neurons containing the catecholamines, dopamine and norepinephrine. These effects have been particularly useful in the study of the function of catecholaminergic neurons. The basis of the specificity of 6-hydroxydopamine is its ability to be accumulated into these neurons via the dopamine and norepinephrine uptake systems. Once within the cell it exerts cytotoxic effects leading to disruption of the neuron and subsequent loss of dopamine and norepinephrine from the tissue. Certain tricyclic antidepressant drugs (imipramine, protriptyline) that are known to inhibit the membrane norepinephrine uptake system, block the neurotoxic effects of 6-hydroxydopamine at norepinephrine-containing neurons. Thus these compounds have been used to enhance the specificity of 6-hydroxydopamine; after pretreatment with protriptyline, 6-hydroxydopamine depletes dopamine but not norepinephrine. The converse may be achieved by the administration of 6-hydroxydopa after pretreatment with a monoamine oxidase inhibitor; this results in norepinephrine but not dopamine depletion. The ability of antidepressant drugs to antagonize 6-hydroxydopamine and 6-hydroxydopa provides a useful assay for identifying antidepressant drugs.

We have recently found that intravenous administration of the neurotoxic agent, 6-hydroxydopa, to mice treated with pargyline lowered both epinephrine and norepinephrine concentrations in the brainstem. Pretreatment with the tricyclic antidepressant drugs (imipramine, iprindole and protriptyline) differentially blocked these depletions. Imipramine and protriptyline blocked the effects on both epinephrine and norepinephrine, although higher doses were required to protect epinephrine. Iprindole selectively blocked epinephrine depletions.

Thus previous studies which involved the use of 6-hydroxydopa or 6-hydroxydopamine to lesion noradrenergic and/or dopaminergic neurons may well have also resulted in degeneration of adrenergic (epinephrine-containing) neurons. Our results indicate that pretreatment with iprindole would have eliminated this potentially confounding effect. The ability of antidepressant drugs to block the effects of 6-hydroxydopa upon noradrenergic neurons is related to their ability to block norepinephrine uptake. We assume that blockade of epinephrine depletion, demonstrated here, involves a similar mechanism. Thus we interpret these results to indicate that iprindole, protriptyline and imipramine block the catecholamine uptake system of adrenergic (epinephrine) neurons. This action of antidepressants may play a role in their clinical effects, particularly in those of iprindole which does not block the uptake of other biogenic amines.

1388 BRAIN TRYPTAMINE : EVIDENCE FOR EXTRACEREBRAL ORIGIN. Jerry J. Warsh, Donald V. Coscina, Peter W. Chan* and Damodar D. Godse*. Depts. of Neurochemistry and Biopsychology, Clarke Institute of Psychiatry, University of Toronto, Toronto, Canada, M5T 1R8.

The presence of tryptamine (TA) in rat brain has been unequivocally demonstrated by mass spectrometric (MS) and gas chromatographic-MS methods (Philips et al., Can. J. Biochem. 52; 447, 1974; Warsh et al., Biochem. Med. 18; 10, 1977). As TA penetrates the blood-brain barrier (Oldendorf and Braun, Brain Res. 113; 219, 1976), brain TA may derive from peripheral tryptophan (TP) decarboxylation, particularly after monoamine oxidase inhibition.

Two groups of male Wistar rats (190-240g) received pargyline (75 mg/kg) or pargyline (75 mg/kg) plus MK-486 (100 mg/kg) i.p. in an acid saline vehicle (ph = 1.4). The animals were sacrificed by cervical decapitation 2 hours later and whole brains removed for determination of brain TA, 5-HT and TP. Two additional groups of rats received pargyline or pargyline plus MK-486, as above, followed one hour later by TP (100 mg/kg) i.p. Rats were sacrificed 1 hour later and brains removed for assay. Brain TA and 5-HT were determined by GC-MS and brain TP by spectrophotofluorometry.

Administration of the selective peripheral decarboxylase inhibitor MK-486 produced a 40-50% reduction in brain TA accumulation after pargyline or pargyline plus TP. A slight (8%) but significant decrease also occurred in brain 5-HT accumulation. Co-administration of MK-486 did not affect brain TP levels.

TREATMENT	BRAIN INDOLES			
	TA (ng/g)	5-HT (µg/g)	TP (ng/g)	N
pargyline	36.8 ± 9.0	1.22 ± 0.02	5.91 ± 0.24	6
pargyline + MK-486	18.7 ± 1.3*	1.12 ± 0.02**	6.29 ± 0.20	6
pargyline + TP	120 ± 5.9	1.70 ± 0.03	44.5 ± 6.3	4
pargyline + MK-486 + TP	75.1 ± 3.1**	1.67 ± 0.04	54.1 ± 1.9	6

* $p < 0.05$ and ** $p < 0.01$ compared to non-MK-486 treated rats

These data indicate that following MAO inhibition at least 40% of brain TA originates from the periphery and suggest that a substantial fraction of endogenous brain TA may also be derived from the decarboxylation of TP in extracerebral pools.

1389 **EFFECTS OF MUSCIMOL UPON THE ACTIVITY OF SUBSTANTIA NIGRA PARS RETICULATA NEURONS.** **Barbara L. Waszczak, Joan M. Lakoski and Judith R. Walters. NIH, NINCDS, Bethesda, Md. 20014.**

GABAergic neurons, which originate in the striatum and globus pallidus and terminate in the substantia nigra pars reticulata, have been postulated to tonicly inhibit the activity of the nigral (pars compacta) dopamine (DA) neurons. However, recent studies have shown that muscimol, a potent GABA agonist both in vivo and in vitro, did not inhibit the firing rate of nigral DA cells (Walters and Lakoski, Europ. J. Pharmacol. 47: 469,1978). Furthermore, i.p. administration of 3.5 mg/kg muscimol produced increases in the firing rate of 64% of DA neurons recorded in gallamine-paralysed rats. Since substantia nigra pars reticulata neurons might also be considered possible sites of termination of the striato-nigral GABA pathway, the effects of muscimol (i.p. and i.v.) upon the extracellular, single-unit activity of these cells in chloral hydrate-anesthetized rats was investigated. The reticulata cells do not show consistent (dose-dependent) responses to drugs which alter the rate of firing of DA neurons by interacting with DA receptors. However, i.p. administration of 3.5 mg/kg muscimol caused a complete inhibition of firing of 90% of the reticulata cells recorded (n=10). The average time required to inhibit firing was approximately 25 minutes (range: 5-60 min). I.v. administration of successively increasing doses of muscimol caused a dose-dependent decrease in activity of all of the cells recorded (n=6). The amount of drug required to produce the first significant inhibition of firing was variable over a wide range of doses. In a separate series of experiments, administration of a single i.v. dose of muscimol (1.6 mg/kg) produced significant decreases in activity in 79% of cells recorded, increases in 14%, and no change in rate in 7% of cells studied (n=14). The average effect of muscimol upon the firing rate of reticulata cells in these experiments was inhibition to 70% of the control rate. The onset of the inhibitory response could be observed as rapidly as 20-30 sec after a single i.v. dose of 1.6 mg/kg, and the rate remained depressed for more than 30 minutes. In several experiments, picrotoxin was administered after the muscimol-induced inhibition of firing, and the activity of these cells was restored to control levels. Although non-specific or peripheral actions of muscimol at sites other than nigral GABA receptors remain to be considered, these studies suggest that a population of cells in the substantia nigra pars reticulata is sensitive to inhibition by muscimol (i.p. or i.v.) at doses which do not alter the firing rate of the nigro-striatal, pars compacta DA neurons. In addition, these findings are consistent with the observation that the reticulata cells are more sensitive to iontophoresed GABA than the nigral DA cells.

1390 PHARMACOLOGICAL MANIPULATION OF BRAIN ACETYLCHOLINE:DEPENDENCE ON DIETARY CHOLINE CONCENTRATION. Lynn Wecker and Dennis E. Schmidt*. Dept. Pharmacol., Vanderbilt Univ. Sch. Med., Nashville, TN 37232.

A discrepancy exists concerning the effect of acute choline (Ch) administration on brain acetylcholine (ACh) levels and it has been suggested that these results may be due to variations in the Ch concentration of rat diets used by various investigators. Furthermore, acute administration of Ch to rats has been shown to modify the biochemical effects of atropine and it was postulated that the nutritional status (i.e., Ch availability) of an animal may be important in determining the responsiveness of cholinergic neurons to pharmacological manipulation (Sci.199:86,1978). This study was designed to measure the effects of diets containing varying levels of Ch on the efficacy of atropine and acute Ch administration in altering regional ACh levels in rat brain. Male Sprague-Dawley rats (145g) were maintained for 2 weeks, with water available ad libitum, on a dietary regimen consisting of: a) a Ch free (CF) diet, b) a "normal" (N) rat diet, 1.6g free Ch/kg chow or c) a high Ch (HC) diet, 11.4g free Ch/kg chow. At the end of the 2 week period, rats were injected (ip) with saline, ChI (60 mg/kg free base) or atropine sulfate (20 mg/kg). Rats were sacrificed by head-focused microwave irradiation and the concentration of ACh was quantitated by pyrolysis-gas chromatography. No significant differences in ACh levels were measured in the hippocampus of saline injected rats in any of the dietary groups. The ACh level in the striatum of N and HC rats did not differ, whereas, the ACh level in the striatum of CF rats was reduced to 85% of control N rats. Acute Ch administration (40 min) also failed to alter hippocampal ACh levels in any dietary group. In the striatum, no changes were noted in ACh levels in the N and HC groups while in CF rats, acute Ch administration increased ACh levels in striata to 133% of CF controls, but these levels were not significantly greater than ACh levels in striata of N controls. Atropine (30 min) caused a 30% decrease in ACh levels in both the striatum and hippocampus of N and CF rats. In HC rats, however, atropine reduced ACh levels in the striatum and hippocampus by 52% and 43%, respectively. From these results, it is concluded that acute or dietary modification of Ch availability does not alter hippocampal ACh levels.Similarly in striata, a 10-fold increase in dietary Ch does not cause either an increase in ACh levels or a response to acute Ch administration. The CF diet does, however, cause a modest reduction in striatal ACh levels which is reversed by acute Ch administration. The efficacy of atropine in depleting ACh levels does appear to be Ch related, for animals maintained on a HC diet exhibited a greater sensitivity to ACh depletion by atropine than animals on a N or CF diet. Hence, dietary modification of Ch levels does influence the responsiveness of cholinergic neurons to pharmacological manipulation. (Supported by BRSG RR-05424-16 and NIMH MH-29182.)

1391 STUDIES ON THE ANTINOCICEPTIVE EFFECTS OF INTRATHECAL BACLOFEN IN THE RAT AND CAT. Peter R. Wilson* and Tony L. Yaksh (SPON: F.W.L. Kerr). Mayo Foundation, Rochester, MN 55901.

Baclofen, a GABA-like compound noted clinically for its antispasticity actions has been shown by several workers to exert an antinociceptive effect which can be distinguished from its effects upon motor function when administered systemically. Though its mode of action is not clear, physiological experiments have indicated that it exerts a direct effect upon spinal function. To determine whether its antinociceptive effects are mediated by this spinal action, rats and cats were prepared with polyethylene (PE-10) catheters chronically placed within the lumbar spinal subarachnoid space. The L- and D- isomers of baclofen were injected and their effect upon the hot plate and tail flick response of the rat and the escape response to a thermal probe applied to depilated regions in the cat was assessed. In the rat, L-baclofen (0.01 to 1.0 µg) produced a dose dependent block of the hot plate and tail flick response. At the 1.0 µg dose a complete block of these measures was noted though less than 25% of the animals tested showed any detectable signs of flaccidity. Lower doses produced a significant antinociception but no sign of flaccidity. Higher doses (10-100 µg) produced both a block of the responses as well as debilitating amounts of flaccidity. In the cat, over the dose range employed, (4-25 µg) no signs of motor flaccidity were noted, but a significant increase in the escape response latency to the thermal probe was readily observed. In both the rat and the cat, the regions rendered non-responsive to the thermal probe or to forceps pinch were limited to the caudal regions of the body in those dermatomes associated with the spinal segments affected by the intrathecal baclofen. In contrast to L-baclofen, the D-isomer failed to show any antinociceptive effect at doses up to 100 times the effective dose of the L-isomer, though a significant degree of flaccidity was in fact noted. Neither the antinociceptive or flaccidity effects were antagonized by naloxone (1 mg/kg, i.p.). Similarly, rats made tolerant to the antinociceptive effects of morphine (20 mg/kg, i.p. twice each day) showed no change in the dose response effects of intrathecal L-baclofen either in terms of antinociception or flaccidity. These data suggest that baclofen is not acting directly upon an opiate receptor or indirectly through an opiate sensitive link. The present experiments demonstrate a focal site of action of baclofen in the cord. Importantly, this demonstration of dose dependency and stereospecificity suggest an action upon a specific, though as yet undetermined receptor system, within the spinal cord. Importantly, as with the opiates, the functional characteristics of this spinal system affected by baclofen at these doses appears closely associated with the throughput of nociceptive stimuli. This work was supported by funds from the Mayo Foundation.

1392 THE SYNERGISTIC INTERACTION OF THREE PHARMACOLOGICALLY DISTINCT SPINAL SYSTEMS MEDIATING ANTINOCICEPTION: THE INTRATHECAL ACTION OF MORPHINE, SEROTONIN AND BACLOFEN. Tony L. Yaksh. Mayo Foundation, Rochester, MN 55901.

It has been shown that morphine (MOR) with an action limited to the spinal cord can produce elevations in the nociceptive threshold. More recently, both serotonin (5-HT) and baclofen (BAC) have also been shown to produce a significant elevation in the nociceptive threshold of the rat and cat when given intrathecally. To demonstrate that these three drugs were exerting their effects through pharmacologically independent spinal systems, it was shown in the present experiments that while naloxone (0.5 mg/kg, i.p.) antagonized MOR, it had no effect upon the antinociceptive effects of intrathecal 5-HT, but failed to have any effect upon intrathecally injected MOR or BAC. To examine the interaction of these three spinal systems, dose response curves in rats on the hot plate and tail flick were obtained for intrathecally administered MOR either alone or injected together with doses of BAC (0.01 µg) of 5-HT (50 µg) which alone were insufficient to produce any antinociceptive effects. Similarly, dose response curves for intrathecal BAC were obtained in the presence of doses of MOR (1 µg) or 5-HT (50 µg) which alone had no detectable effect. Finally, such curves were obtained for 5-HT, again with a dose of MOR (1 µg) or BAC (0.01 µg) which was ineffective. These experiments revealed that each drug produced a multiplicative potentiation of the antinociceptive effects of the other. Thus dose response curves were shifted such that MOR (1 µg) and 5-HT (50 µg) or MOR (1 µg) and BAC (0.01 µg) for example produced a 98 and 80% elevation in the nociceptive thresholds, respectively. As with each agent alone, the antinociceptive effects of the combined doses were not associated with any signs of motor dysfunction or flaccidity. Importantly, for all drug conditions, during the periods when the tail flick and hot plate thresholds were elevated, the response to forcep pinches applied to the caudal, but not rostral portions of the body were blocked. This indicates a local action on the spinal cord. It is suggested that this multiplicative interaction evidence through the action of these agents on these three pharmacologically distinct spinal systems is not due to altered metabolism or clearance but may represent a common model for the functional interaction of spinal modulatory systems controlling sensory throughput. This work was supported by the Mayo Foundation.

1393 CENTRALLY MEDIATED RESPIRATORY ARREST FOLLOWING INFUSION OF THE LOCAL ANESTHETIC AND OPIATE ANTINOCICEPTIVE AGENTS, LIDOCAINE, COCAINE, CHLORDIMEFORM, AND MORPHINE. G.K.W. Yim, W.R. Pfister*, J. Rolley* and M.L. Holsapple*. Dept. Pharmacol. and Toxicol., Purdue Univ. West Lafayette, IN 47907.

We have recently reported that the local anesthetic agents cocaine, chlordimeform (CDM), and lidocaine possess antinociceptive activity on the rat tail flick test (Pfister and Yim, Pharmacologist 19(2): 216, 1977). Since local anesthetics and CDM (Wang and Narahashi, Pest. Biochem. Physiol. 5: 119, 1975) depress neuromuscular transmission, these studies were initiated to identify whether respiratory depression was of central or peripheral origin. Rats were lightly anesthetized with urethane (1.2 g/Kg, i.p.), and the agents were infused over a period of 20-30 min via the jugular vein until respiratory arrest. The decreasing order of lethality and dose resulting in respiratory arrest were: cocaine (35.3 ± 11 mg/Kg), lidocaine (35.4 ± 9.6 mg/Kg), CDM (62.3 ± 6.0 mg/Kg), and morphine (93.5 ± 11.0 mg/Kg). In lidocaine treated rats, the amplitude and rate of diaphramatic movements and of phrenic nerve bursts gradually decreased until respiratory arrest. In contrast, respiratory rate was initially increased by cocaine and CDM. Diaphramatic contractile force and the amplitude of phrenic nerve bursts remained near control values, but abruptly disappeared upon respiratory arrest. The profile of morphine on the phrenic nerve activity was unique in that continuous inter-burst discharge preceded the abrupt decrease in phrenic nerve amplitude and respiratory arrest. Naloxone reversed both actions of morphine but did not reverse the respiratory depression induced by the other agents. Following respiratory arrest produced by all of these agents, the diaphram and gastrocnemius muscle still contracted following electral stimulation of the phrenic and sciatic nerves, respectively. These results indicate that respiratory arrest induced by these agents is central in origin. Supported in part by grants from NIH (NS 12077) and EPA (5-803965).

1394 PRENATAL MATERNAL PHENOBARBITAL REDUCES CONVERSION OF TYROSINE TO CATECHOLAMINES IN BRAINS OF YOUNG OFFSPRING. John W. Zemp, Lawrence D. Middaugh, Thomas A. Grover, and Larry W. Simpson*. Dept. Biochem., Med. Univ. of S.C., Charleston, S.C. 29403.

We have previously reported (Zemp & Middaugh, Perinatal Addiction, Harbison, R.D., ed. p. 307-331, Spectrum, N.Y. 1976) that phenobarbital injected into mice for the last third of pregnancy, causes a dose related increase in neonatal mortality and decrease in brain growth of surviving offspring. The effects of early exposure to phenobarbital appear to be long lasting since offspring of animals injected with the drug differ from control animals in a number of behavioral tasks after maturity (Middaugh et al., Devel. Psychobiol. 18, 305-313, 1975; Middaugh et al., Pharmac. Biochem. Behav. 3, 1137-1139, 1975; Zemp & Middaugh, Perinatal Addiction, Harbison, R.D., ed. p. 307-331, Spectrum, N.Y. 1976). Some of the behavioral abnormalities noted have also been reported in animals with manipulations of the central catecholaminergic systems (Antelmann & Caggiula, Sci. 195, 646-653, 1977.). The purpose of this experiment was to determine if maternal injections of phenobarbital for the last third of pregnancy would alter catecholamine metabolism in the brains of offspring. We have examined concentrations and the turnover of radioactive tyrosine (TYR), dopamine (DA), and norepinephrine (NE) in the brains of offspring of C57 BL/6J mice injected daily with phenobarbital for the last 6 and 7 days of pregnancy. Brain concentration of TYR, DA, and NE were not altered by prenatal drug exposure; however, one hour after injection of ^{3}H-TYR the specific activity of ^{3}H-TYR was significantly increased by 15-23% in the brains of 21-day-old mice exposed prenatally to the drug. The conversion of ^{3}H-TYR to DA and NE in 21-day-old offspring was also reduced in the drug treated mice in a dose dependent manner when compared to controls (Table 1.)

Table 1. Prenatal injections of phenobarbital reduces the conversion of ^{3}H-TYR to DA and NE in brains of 21-day-old offspring.

Treatment	Dopamine (nmole/g/hr) $\bar{X}$ ± SEM(N)	Norepinephrine (nmole/g/hr) $\bar{X}$ ± SEM(N)
Saline	7.55 ± .46(11)	2.95 ± .23(11)
Phenobarbital(20mg/kg)	5.41 ± .43(12)	2.03 ± .18(12)
Phenobarbital(40mg/kg)	4.74 ± .37(14)	1.73 ± .13(14)

The results suggest that neural systems using catecholamines as transmitters are altered by prenatal exposure to phenobarbital.

NEUROTRANSMITTERS

1395 THE ^{3}H NOREPINEPHRINE UPTAKE AND FATE IN THE ISOLATED CEREBRAL CAPILLARIES. T. Abe*, K. Abe*, M. E. Swink*, I. Klatzo and M. Spatz. Lab. Neuropath. & Neuroanat. Sci., NINCDS, NIH, Bethesda, MD 20014.

In vivo studies had shown that norepinephrine doesn't cross the blood-brain barrier (Weil-Malherbe, Whitby and Axelrod, J. Neurol. 8, 55-64, 1961). In order to elucidate the mechanism responsible for the reported observations the uptake of ^{3}H norepinephrine was investigated in isolated capillaries which were previously proven to be metabolically active and suitable for such studies (Mrsulja, Mrsulja, Fujimoto, Klatzo and Spatz, Brain Res. 110, 361-365, 1976).

The isolated capillaries took up the ^{3}H norepinephrine and the labeled substance increased with the duration of incubation (2-60 minutes). The uptake of ^{3}H norepinephrine in the capillaries was found to be saturable since it was inhibited by increasing concentrations of unlabeled (cold) norepinephrine when it was added to the incubating media containing the labeled substrate. The capillary ^{3}H uptake of norepinephrine was also cross inhibited by addition of cold L-dopa, dopamine, epinephrine and metaraminol but not by normetanephrine or metanephrine in concentrations of 1-2 mM. Pyrogallol, the known inhibitor of catechol-O-methyl transferase competitively inhibited the uptake of ^{3}H norepinephrine in the isolated capillaries. Moreover the preincubation of the capillaries with pargyline, the inhibitor of monoamine oxidase (MAO) led to a decreased level of ^{3}H labeled substance in the capillaries.

Preliminary investigations of the accumulated substances in the capillaries were so far found to be the methylated metabolites of norepinephrine namely normetanephrine and metanephrine.

These results suggest that the uptake of norepinephrine takes place by carrier mediated process (which may be shared by other catecholamines) but the norepinephrine is not accumulated as such since it is metabolized by the catechol-O-methyl transferase and MAO present in the capillaries. These findings also indicate that the capillaries are probably unable to retain the norepinephrine after the inhibition of the enzymes since the inhibition of methyl transferase and MAO inhibited also the "uptake' of norepinephrine. Therefore the cerebral capillaries are the site of enzymatic barrier which prevents the intact norepinephrine to enter or leave the brain.

1396 GABA AND GLYCINE ACTIVATE CHANNELS WITH DIFFERENT PROPERTIES ON CULTURED SPINAL NEURONS. J.L. Barker and R.N. McBurney, LNP, NINCDS, NIH, Bethesda, Md. 20014.

Analysis of conductance fluctuations induced on peripheral vertebrate and central invertebrate post-synaptic membranes by application of putative neurotransmitters has revealed the dimensions of ion channels. We have applied fluctuation (or "noise") analysis to amino acid responses of dissociated spinal neurons derived from mouse embryos and grown in tissue culture. Intracellular recordings with two independent electrodes were made from spinal neurons or dorsal root ganglion (DRG) cells. γ-aminobutyric acid (GABA) and glycine were applied extracellularly by microiontophoresis. $MgCl_2$ was added to reduce spontaneous synaptic activity and allow clearer study of the post-synaptic events. The cells were voltage-clamped and amino acid-induced membrane current responses recorded on magnetic tape for off-line analysis. Both amino acids caused dose-dependent increases in membrane current which were associated with increases in current fluctuations. The fluctuations were analyzed on the assumption that they derive from the statistical variation in the number of open ion channels around a mean level of open channels. The amplitude of the single channel conductance, γ, can be calculated knowing the variance in current, mean current and the driving force. Spectral analysis of the fluctuations gave power density spectra which were generally approximated by a single Lorentzian and allowed estimate of the average channel lifetime, τ. $\bar{\gamma}$ and $\bar{\tau}$ were 18 pS and 20 msec for GABA-activated channels and 30 pS and 5 msec for glycine-activated channels (n= 342 observations on 13 spinal neurons). GABA-activated channels on DRG cells had dimensions similar to those activated by GABA on spinal neurons. The values obtained on spinal neurons are significantly different from each other and indicate that the amino acids activate Cl^- channels with different dimensions.

However, clear interactions between GABA and glycine current responses suggest that the amino acids may utilize the same channel. The amplitudes of glycine responses superimposed on GABA responses which could be desensitized almost completely were only slightly diminished relative to control values, while the amplitudes of GABA responses superimposed on glycine responses which could only be partially desensitized were markedly depressed relative to control. The antagonism was not due to a change in the driving force acting on the Cl^- conductance. One explanation for these results is that desensitization occurs at the receptor step and that GABA and glycine share a common Cl^- conductance mechanism.

1397 LIGHT STIMULATED INCREASE OF CHOLINE UPTAKE AND ACETYLCHOLINE SYNTHESIS IN THE TURTLE RETINA IS ASSOCIATED WITH AN INCREASE IN THE V_{max} OF HIGH-AFFINITY CHOLINE UPTAKE. Robert W. Baughman and Daniel Y. Tso*. Department of Neurobiology, Harvard Medical School, Boston, MA 02115

Acetylcholine (ACh) appears to be a neurotransmitter in the inner plexiform layer of many vertebrate retinas (Masland and Ames, 1976; Baughman and Bader, 1977). The present study concerns the effects of light stimulation on choline transport and ACh synthesis in an isolated, perfused turtle eyecup preparation. The ERG was monitored before and after the period of stimulation to confirm the viability of each eyecup. To control for variability in the perfusion, caused by vitreous remaining in the eyecup, the uptake of ^{3}H choline (1 µM) was measured relative to uptake of ^{14}C leucine (400 µM), which itself was unaffected by stimulation. In constant light the uptake of choline increased slightly, but with flashing light uptake was increased substantially, reaching a level 70% greater than the level seen with constant dark. The increase in choline uptake was accompanied by an increase in ACh synthesis; the ratio of ^{3}H ACh to ^{3}H choline after exposure to flashing light, constant light and constant dark was 0.41, 0.25 and 0.20, respectively. When the flashing light experiment was repeated with 1.8 mM Co^{2+} in the perfusate, which should block synaptic transmission and which in fact eliminated the ERG b-wave, choline uptake and ACh synthesis were no longer enhanced. In a flashing light experiment with 5 µM hemicholinium-3, which should block high-affinity choline uptake and which caused some reduction of the ERG b-wave, choline uptake was reduced to a level below that seen with constant dark, and ACh synthesis was essentially blocked. To determine the changes in kinetic parameters underlying the increased choline uptake, choline uptake was measured in synaptosomal preparations made from retinas previously exposed to either constant dark or flashing light. Relative to values seen after constant dark, with flashing light the low-affinity K_m and V_{max} and the high-affinity K_m were unchanged, but the high-affinity V_{max} was increased more than twofold. Thus the light-stimulated increase in choline uptake, which is accompanied by an increase in ACh synthesis, is associated with an increase in the V_{max} of the high-affinity choline uptake system. (Supported by NIH Grants EY01995 and EY00082.)

1398 IMMUNOCYTOCHEMICAL LOCALIZATION OF L-GLUTAMATE DECARBOXYLASE IN THE RABBIT RETINA. C. Brandon*, J.-Y. Wu and Dominic M. K. Lam* (Spon: G. F. Ayala) Dept. of Cell Biology and Cullen Eye Institute, Baylor College of Medicine, Houston, Texas 77030

Biochemical and physiological studies indicate that GABA is probably a neurotransmitter in the vertebrate retina. The sites of the GABA synapses in mammalian retinas have, however, not been precisely localized. Recent studies by Cadwell and coworkers (J. Physiol. 276, 277) showed that in the rabbit retina, picrotoxin alters certain specific properties of retinal ganglion cells. These findings, together with light microscopic autoradiographic studies of GABA uptake, suggest that some amacrine cells in the rabbit retina may be GABA neurons. With the availability of an antibody against L-glutamate decarboxylase (GAD) from mammalian brains (Wu, J.-Y. "GABA in Nervous System Function", Roberts, E., Chase, T. and Tower, D., ed., Raven Press, NY, 1976), we have begun to precisely localize the GABA synapses and their connections in the rabbit retina by immunocytochemical methods at light and EM levels. Rabbits were perfused through the heart with buffered 4% paraformaldehyde. After enucleation, the anterior chamber and vitreous humor were removed and each eye cup containing the retina was cut radially into strips, embedded in agar and sectioned with a tissue chopper. Sections were incubated in rabbit-anti-mouse GAD serum, washed and treated with a conjugate of horseradish peroxidase (HRP) and protein A (Dubois-Dalcq et al., J Histochem. Cytochem. 25, 1201-1206 (1977)). After washing, the sections were incubated in diaminobenzidine and hydrogen peroxide and the HRP reaction products were visualized by differential interference microscopy. Specific HRP reaction products in the rabbit retina were limited to the half of the inner plexiform layer proximal to the ganglion cell layer cell bodies, and the outer plexiform layer contained little such products. These results indicate that similar to the goldfish retina,(R. Marc et al., J. Comp. Neurol., in press) the GABA synapses in the inner plexiform layer of the rabbit retina may be localized to sublamina b.

1399 SOME ADENOSINE ANTAGONISTS AND ADENYLATE CYCLASE INHIBITORS. Robert F. Bruns* (SPON: C.E. Spooner). Dept. Neurosci. Sch. Med., UC-San Diego, La Jolla, CA 92093.

Adenosine (ado) causes a 50-fold increase in intracellular cyclic AMP in VA13 human fibroblast cells. Studies with analogs of ado show that the structure-activity relationship (SAR) of this response is similar to the SAR reported for a similar response in guinea pig cerebral cortex. VA13 cells may thus provide a simple model for the brain ado receptor and its linkage with adenylate cyclase.

128 nucleosides were tested as ado agonists and antagonists. 11 compounds, all previously unreported, were competitive antagonists. The only commercially available competitive antagonist was 5'-deoxy-5'methylthio-ado, which had a K_i of 8 μM. Results with rigid analogs indicate that ado binds to the receptor in the "anti" conformation. Three nucleosides were noncompetitive antagonists. They blocked responses to isoproterenol and prostaglandin E_1 (PGE_1) as well as to 10 μM and 1 mM ado and were presumably adenylate cyclase inhibitors. The best cyclase inhibitor, 2', 5'-dideoxyadenosine, was a "partial inhibitor", since it only inhibited the response to isoproterenol by 68% even at very high concentrations.

110 purine, pyrimidine, and pteridine bases were tested as ado antagonists. Three distinct classes of competitive antagonists were found: methylxanthines (such as theophylline), benzo[g]pteridines (such as alloxazine), and adenine derivatives (such as 9-methyladenine). None of the bases were cyclase inhibitors. K_i values for some important xanthine derivatives were:

	K_i (μM)
caffeine (1, 3, 7-trimethylxanthine)	13
theophylline (1, 3-dimethylxanthine)	5
3-isobutyl-1-methylxanthine (IBMX)	4
7-(2-chloroethyl)theophylline	1.0
1, 3-dipropylxanthine	.7
8-(p-bromophenyl)theophylline	.05

Theophylline, caffeine, and IBMX were all much better ado blockers than phosphodiesterase (PDE) inhibitors. For this and other reasons the methylxanthines cannot be considered specific PDE inhibitors. Methylxanthines known to be CNS stimulants were good ado blockers, while non-stimulants tended to be poor blockers. This suggests that ado may have a sedative role in vivo.

1400 ACTION OF MICROIONTOPHORETIC ADMINISTRATION OF DOPAMINE ON SUBTHALAMIC NUCLEUS NEURONS IN THE RAT. Gerald A. Campbell* and Forrest F. Weight. Laboratory of Neuropharmacology, NIMH, St. Elizabeths Hosp., Wash., D.C.

In recent investigations using glucose utilization determined by the ^{14}C-deoxy-D-glucose technique as an index of neuronal activity, both apomorphine (L. I. Wolfson and L. Brown, Society for Neuroscience Abstracts, 1976, Vol. II, Pt. I, p510) and d-amphetamine (L. R. Wechler, H. Savaki, C. Kennedy, and L. Sokoloff, Society for Neuroscience Abstracts, 1977, Vol. III, p325 produced greater increases in activity in the subthalamic nucleus than in other areas of the brain. In view of the roles of amphetamine in enhancing release and reuptake of catecholamines at synapses and of apomorphine as a dopamine agonist, these results raised the possibility that there may be dopamine receptors on neurons in this nucleus. The effect of dopamine on the electrical activity of neurons in the subthalamic nucleus was therefore tested using microiontophoretic administration. Sprague Dawley rats weighing 140-160 gm, anesthetized with 25% urethane in saline (6 ml/kg), were used in these experiments. In order to ensure accurate stereotaxic placement of the five-barrel microelectrode, the cortex was sucked away around the horizontal coordinates of the insertion site down to the dorsal surface of the hippocampus, and the depth of penetration was measured from that landmark. Glutamate was used to induce firing in some cells, which were not spontaneously active. One of the side barrels of the five-barrel microelectrode was filled with 3M NaCl and used to pass an automatically generated balance current, equal and opposite in polarity to the sum of the remaining three barrels. At the end of each experiment, horseradish peroxidase (Sigma, Type VI) was microiontophoretically injected from the center, recording barrel to mark the point of maximal penetration. Cell positions were then referenced to the known depth of the injection, visualized in the frozen section by a tetramethylbenzidene reaction. Both increases and decreases in spontaneous firing rates in response to dopamine were observed in the vicinity of the subthalamic nucleus. Responses of both types have been obtained in individual animals with the same microelectrode.

1401 BEHAVIORAL AND BIOCHEMICAL PROPERTIES OF PARA-CHLOROPHENYLETHYLAMINE. Eunyong Chung Hwang* and M.H. Van Woert* (SPON: J. Schwartz). Dept. of Neurol. and Pharmacol., Mt. Sinai Sch. of Med., New York, N.Y. 10029.

p-chlorophenylalanine (pCPA) depletes brain serotonin levels by inhibiting tryptophan hydroxylase. The maximum reduction in brain serotonin occurs between 1 and 3 days after 316 mg/kg of pCPA i.p.. However, several behavioral studies have suggested that pCPA has a serotonin agonist-like action during the first 6 hours after injection. In an attempt to explain these paradoxical observations, behavioral and biochemical actions of pCPA metabolites were investigated.

p-chlorophenylethylamine (pCPEA) (50 mg/kg), a metabolite of pCPA, was found to produce in mice head weaving, tremor, hypertonus, Straub tail, hind leg abduction and salivation; a syndrome characteristic of serotonin receptor stimulation (Jacobs, B.L., Life Sci. 19, 777, 1976). The intensity and duration of this pCPEA-induced "serotonin" syndrome was enhanced by the monoamine oxidase inhibitor, pargyline (75 mg/kg) and partially counteracted by methiothepine (1 mg/kg), a serotonin receptor blocker, pCPA (400 mg/kg, 24 hours prior to pCPEA) and fluoxetine (10 mg/kg) and Org 6582 (10 mg/kg), which are serotonin uptake inhibitors. However, reserpine (10 mg/kg) and alpha-methyl-p-tyrosine (250 mg/kg) had no effect. The same pretreatment with fluoxetine or pCPA entirely prevented p-chloroamphetamine-induced "serotonin" syndrome.

A single injection of pCPEA (50 mg/kg) reduced mouse brain serotonin by 15% ($p < 0.01$) and increased 5-hydroxyindoleacetic acid (5HIAA) by 30% ($p < 0.01$). Pretreatment with fluoxetine (10 mg/kg) completely prevented pCPEA-induced changes in brain serotonin and 5HIAA.

The biochemical data suggest that pCPEA is taken up by the same neuronal transport process as serotonin and causes endogenous serotonin to be released. However, pCPEA is probably also a direct serotonin receptor agonist, since it can produce the "serotonin" syndrome even after pretreatment with fluoxetine, Org 6582 or pCPA. The previously reported paradoxical early effects of pCPA may be due to the action of its metabolite pCPEA.

1402 EFFECTS OF KAINIC ACID ON THE NEURONS RECEIVING OLFACTORY NERVE FIBERS IN THE RAT OLFACTORY BULB. Jody Patricia Corey* and Garl K. Rieke. Department of Anatomy, Hahnemann Medical College, Philadelphia, Pennsylvania 19102.

The collected data on glutamate suggests that this naturally occurring amino acid may be the excitatory neurotransmitter for the main afferent pathways in the central nervous system (Curtis and Johnson, 1974). Schwarcz and Coyle (1977) have demonstrated that microinjection of nanomolar amounts of kainic acid, a potent neuroexcitatory analogue of glutamate, produces selective degeneration of central neurons with glutamate receptors. Most recently, this "excito-toxic" effect of kainic acid has been used by Bird et al. (1978) to demonstrate glutamate's role as a primary afferent neurotransmitter in the rostral AVCN of the cochlear nucleus. It has been suggested by Nicoll (1971) that glutamate and/or aspartate may be excitatory transmitters for certain neurons in the olfactory bulb. To test this possibility, the effects of kainic acid on the neurons of the olfactory bulb were examined.

Two micrograms of kainic acid in 2 microliters of phosphate buffer (pH 7.4) were injected into the olfactory bulb. The bulbs of animals injected 24-48 hours prior to fixation were studied with light microscopy. At 24 hours, selective destruction of those neurons receiving synaptic input from primary olfactory axons, i.e. mitral, tufted, and periglomerular cells, was observed. The remainder of the intrinsic neurons within the bulb were not affected, suggesting that the kainate lesions were specific. Injection of phosphate buffer without kainic acid into the contralateral bulb caused no loss of neurons.

Each of the neuronal types that are sensitive to the toxicity of kainic acid receives synaptic input from primary olfactory nerve fibers; the selective loss of these cells supports the suggestion that glutamate is a primary afferent neurotransmitter in the olfactory bulb.

1403 OPIATE, BENZODIAZEPINE AND MUSCARINIC RECEPTORS IN DIFFERENT AREAS OF THE CEREBRAL CORTEX IN MONKEYS. Ivan Divac and Claus Braestrup*. Institute of Neurophysiology, University of Copenhagen and Skt. Hans Hospital, 4000 Roskilde, Denmark.

Twenty areas were taken from each of six hemispheres of three adolescent specimens of Cercopithecus aetiops. Aliquots of each sample were used to study specific binding of 3H-naloxone, 3H-diazepam and 3H-quinuclidinyl benzilate (QNB). Statistical analysis of results revealed that the studied receptors are distributed independently from one another. The steepest gradient was found for naloxone binding, and the flatest for QNB. The gradient for diazepam binding was in between. The highest values for naloxone binding were found in some limbic areas, the next highest in the medial and orbital prefrontal cortex, and the low values in the parietal, inferotemporal, and particularly visual cortex. Diazepam binding gave the highest values in the visual cortex and the frontal eye field, whereas the lowest values were found in the motor cortex and limbic areas. The only significant difference in QNB binding was between a high value in the visual cortex and a low value in the motor cortex.

1404 PUTATIVE NEUROTRANSMITTERS DECREASE ACTION POTENTIAL DURATION OF EMBRYONIC CHICK DORSAL ROOT GANGLION NEURONS. K. Dunlap* and G.D. Fischbach (SPON: M.L. Karnovsky). Dept. of Pharmacology, Harvard Medical School, Boston, Mass. 02115.

The soma membrane of embryonic dorsal root ganglion neurons in vitro generates both a fast Na spike and a slower Ca spike which produces a prolonged plateau on the falling phase of the action potential (Dichter and Fischbach, J.Physiol., 280:281, 1977). Several putative neurotransmitters were shown to effect a decrease in action potential duration in the absence of changes in resting membrane potential or input conductance. Known concentrations (10^{-7} to 10^{-4} M) of each drug were applied to individual neurons via pressure ejection from a 3-5μ tip micropipet positioned 100-200μ away. The control spike duration in 5.4 mM Ca^{++} was 8 msec. Gamma-aminobutyric acid (CABA), nor-epinephrine, serotonin, and glutamate produce dose-dependent decreases in spike duration with a maximum decrease of ca. 50% at 10^{-4} M. The time course of action was prolonged, lasting several minutes at higher concentrations. Acetylcholine and glycine (10^{-4} M) were without effect. In addition to their action on spike duration, these drugs decreased the rate of rise and peak potential of the Ca spike (recorded in 10^{-7} g/ml TTX) without affecting the Na component of the action potential. The nor-epinephrine response was blocked by the α-adrenergic antagonist phentolamine but not by the β-antagonist propranolol. The non-competitive GABA antagonists, bicuculline and picrotoxin, which block chloride-mediated responses, show no inhibition of the action of GABA on the spike. Several peptides were also tested. Enkephalin and somatostatin decreased spike duration (Mudge, Leeman and Fischbach, ms in prep.) while neurotensin, bradykinin and thyrotropin releasing hormone were without effect at 10^{-5}M. The action potential duration was unaffected by prolonged application of either dibutyryl cGMP or dibutyryl cAMP in bath concentrations as high as 1 mM.

These results imply that the effectors interfere with a voltage-sensitive ion conductance mechanism which ultimately produces a decrease in inward Ca current. Whether this results from a direct action on Ca channels or reflects an increase in outward current is presently unknown. The decrease in rate of rise and peak potential of the Ca spike suggests the former. A voltage clamp analysis to distinguish between these possibilities is in progress. The Ca currents recorded from the DRG soma may provide a useful model both for the study of presynaptic membrane Ca currents involved in transmitter release and ultimately for investigations into the neuromodulatory role of transmitter function. (Supported by USPHS Grant #NS 11160)

1405 MORPHINE SUPPRESSION OF SPONTANEOUS CAUDATE NEURONAL ACTIVITIES IN THE RAT: THE PARTICIPATION OF A CAUDATO-NIGRAL FEEDBACK MECHANISM. Edward P. Finnerty and Samuel H.H. Chan. Dept Life Sci., Indiana State Univ., Terre Haute, IN 47809

Morphine has been reported to inhibit the spontaneous unitary activities in the caudate nucleus (CN). Such suppression has been attributed to a possible direct excitatory action of the opiate on the nigro-striatal neurons in the substantia nigra (SN), and promoting a release of dopamine (DA) at their terminals in the CN (Lee, Wong and Chan, Neuropharmacol. 16:571, 1977). At the same time, a caudato-nigral inhibitory feedback loop has been described neurochemically, which functions to control the DA content in the CN. This study attempts to investigate the role of this loop as another possible mechanism in the morphine suppression of CN units.

Adult male Sprague-Dawley rats (300-800 g) were used in the present study. Under light sodium pentobarbital anesthesia (50mg/kg, i.p.), the trachea and left jugular vein were routinely cannulated. The head of the animal was then placed on a stereotaxic apparatus and appropriate craniotomy was performed to expose the cortex overlying the CN and SN. Spontaneous, single-unit activities from the SN were recorded by means of stereotaxically positioned tungsten microelectrodes which were further advanced by a hydraulic micro-drive. Local injections to the CN at a volume of 1 μl were made by means of a stereotaxically placed 27-gauge syringe needle attached to a microinjection-device. Systemic injections were made via the cannulated jugular vein.

In the first series of experiments, spontaneous SN units were found to respond to a systemic injection of morphine (5 mg/kg) with an almost complete inhibition of activity, lasting beyond 10 min. Subsequent microinjection of DA (50 μg/kg) into the CN resulted in essentially no change in the depressed activity. Naloxone (0.5 mg/kg i.v.), however, was able to reverse the suppression and allow the return of the SN spikes to the control rate.

In the second series of experiments, the SN units responded to the microinjection of DA (50 μg/kg) to the CN with an increase in discharge rate. Subsequent systemic injection of morphine (5 mg/kg) resulted in a twofold effect. There was an initial further enhancement of spike activity lasting 2-3 min, to be followed by a profound suppression of activity. Naloxone (0.5 mg/kg, i.v.) was relatively effective in reversing this depression.

It is concluded that the morphine suppression of caudate spontaneous unit activity may also involve the caudato-nigral feedback mechanism.

(We acknowledge the generous supply of morphine sulfate by Eli Lilly & Co. and Naloxone HCl by Endo Laboratories used in the present study.)

1406 EXCITATORY H1- AND INHIBITORY H2-HISTAMINE RECEPTORS ON NEURONS IN TUBERAL HYPOTHALAMIC TISSUE CULTURES. H.M. Geller. Dept. Pharmacol., Rutgers Med. Sch., Piscataway, NJ 08854.

Histamine was iontophoretically applied to spontaneously active neurons in tissue cultures of new born rat tuberal hypothalamus. Both excitations and depressions of unit activity were observed on different cells. These effects persisted in Ca^{++}-free/4.6 mM Mg^{++} media, suggesting the presence of post-synaptic histamine receptors on tuberal hypothalamic neurons. In order to classify the types of receptors involved, the histamine H1-receptor blocking drugs diphenhydramine and promethazine and the H2-receptor blocking drug metiamide were perfused through the culture chamber during iontophoresis of histamine. Diphenhydramine (10^{-4} M) blocked histamine-elicited excitations, but did so at concentrations at which local anesthetic actions were observed. Promethazine, a phenothiazine antihistamine, (10^{-5} M), also blocked histamine-elicited excitations and had no effect on inhibitions at concentrations below which local anesthetic effects were observed. Metiamide, (10^{-6} M) selectively blocked histamine-elicited depressions of activity, and had no effect on excitations. Further evidence for two independent receptors was obtained with the iontophoretic application of the H1-specific agonist 2-(2-pyridyl) ethylamine (PEA) and the H2-specific agonist S-[3-(n, n-dimethylamino) propyl] isothiourea (Dimaprit). PEA was generally excitatory while Dimaprit was uniformly depressant to unit activity. Evidence that cyclic AMP may be involved in the H2-mediated inhibitions was obtained by perfusing either of the cyclic nucleotide phosphodiesterase inhibitors isobutyl methyl xanthine (IBMX, 10^{-3} M) or RO 20-1724 (3×10^{-5} M). Both of these agents prolonged the depressant actions of H2-agonists.

These results suggest that there exist two populations of histamine receptors on tuberal hypothalamic neurons, with H1-receptors mediating excitatory and H2-receptors mediating depressant actions of histamine. Furthermore, these experiments are consistent with the hypothesis that hypothalamic neurons possess a histamine-sensitive adenylate cyclase coupled to the H2-receptor.

(Supported by NSF grant BNS 77-09241. PEA and Dimaprit were kindly supplied by SKF and RO 20-1724 was supplied by Hoffmann-LaRoche.)

1407 STUDIES OF THE ACETYL-DONOR FOR ACETYLCHOLINE SYNTHESIS. Gary E. Gibson and Adriana Vasil*. Neuropsychiatric Inst., UCLA, Los Angeles, CA 90024.

It is widely accepted that the acetyl-coenzyme A used for acetylcholine synthesis in the cytoplasm is derived from the oxidation of pyruvate or ketones in the intramitochondrial space, but the mechanism of transfer of the active acetyl units across the mitochondrial membranes is a matter of controversy. Quastel (Cholinergic Mechanisms and Psychopharmacology) and Lefresne, et. al. (Biochemie 59, 197) have suggested that the active acetyl groups for acetylcholine synthesis may be generated in the cytoplasm. These suggestions led us to reinvestigate a possible role of acetylphosphate, which is a product of cytoplasmic pyruvate oxidation in bacteria. We have examined its role in acetylcholine synthesis by synaptosomes incubated in a high potassium (31 mM) Krebs-Ringer phosphate buffer with 1.25 mM glucose, 50 μM choline and 40 μM paraoxon.

In the first series of experiments, the mass of acetylcholine and the incorporation of [U-^{14}C]glucose into acetylcholine were determined. Thus, we could determine the specific activity (DPM/nanomole) of the synthesized acetylcholine. Addition of K^+L^+-acetylphosphate (10, 50 or 100 mM) reduced the specific activity of acetylcholine to 82.9 ± 54; 55.6 ± 5.2; and 38.5 ± 3.4 of control, respectively. This is consistent with acetylcholine acting as a donor of acetyl groups for acetylcholine synthesis. Although synthesis of acetylcholine as measured by GC-MS was also inhibited (70.6 ± 2.6; 24.8 ± 1.9; 8.2 ± 1.3 % of control) this was shown to be in part due to the addition of the excess K^+ and L^+ which caused inhibition when added as the chloride salts (31.8 ± 2.2% of control with 100 mM). The specific activity was increased by their addition (128.7 ± 15.2%).

In order to determine if there was a direct transfer of acetyl groups from acetylphosphate to acetylcholine, synaptosomes were incubated with [^{3}H]acetylphosphate synthesized from [^{3}H]acetic anhydride. The purity was determined by enzymatic assay to be 89.9%; IR spectrometry showed it to be identical to commercial acetylphosphate. Although large amounts (38 X 10^6 CPM) of [^{3}H]-acetylphosphate were incubated with synaptosomes, no radioactivity above non-incubated control values were found in acetylcholine (4 counts). The lack of incorporation was not due to hydrolysis of added acetylphosphate, since greater than 90% of the acetylphosphate remained at the end of the incubation. Acetate (10 mM) itself had no effect on acetylcholine specific activity (97.8 ± 2.7% of control). Furthermore, in the absence of glucose, acetylphosphate was unable to stimulate synthesis above non-incubated controls. Thus, acetylphosphate does not appear to be an intermediate in acetylcholine synthesis.

1408 PERMEABILITY OF THE BLOOD-BRAIN BARRIER (BBB) TO NOREPINEPHRINE (NE) IN EXPERIMENTAL CEREBRAL ISCHEMIA. H. Hervonen*, O. Steinwall*, K. Nishimoto*, M. Spatz and I. Klatzo. Lab. Neuropath, & Neuroanat. Sci., NINCDS, NIH, Bethesda, MD 20014.

Observations on the behavior of BBB to NE and other tracers were carried out in Mongolian gerbils subjected for one hour to occlusion of the left common carotid artery and sacrificed at various time intervals following release of the occlusion. Evans blue dye and ^{3}H sucrose served as other than NE tracers. Only symptom-positive animals were used in this study. The abnormal passage of sucrose was observed in the ischemic hemisphere earlier than leakage of other tracers and it persisted for one week. Extravasation of Evans blue was seen only during 10-15 hour interval following release of occlusion. Quantitative measurements of ^{3}H NE and ^{14}C sucrose revealed that abnormally high passage of sucrose into the ischemic hemisphere was evident at all periods studied whereas abnormal elevation of ^{3}H tracer in the ischemic hemisphere was moderate at earlier periods (5 and 12 hours) and it rose to higher levels at 72 hours after release. At that time histofluorescent observations in animals which were also injected with reserpine and pargyline showed in the vicinity of ischemic lesions abnormal noradrenergic structures resembling thickened nerve fibers. The green fluorescence, specific for NE, was also observed in an accentuated fashion in the neurons and arterioles of the basal ganglia. The abnormal passage of NE or its metabolites could be surmised also from the radioautographs showing dark areas in the ischemic hemisphere, especially conspicuous at 72 hour interval following release of occlusion.

1409 TARDIVE DYSKINESIA: SUPPRESSION BY LECITHIN INGESTION. Madelyn J. Hirsch, John H. Growdon* and Richard J. Wurtman. M.I.T., Cambridge, MA 02139 and Tufts Sch. of Med. Boston, MA

We have previously shown that choline consumption raises serum choline (Ch), brain Ch, and brain acetylcholine (ACh) in rats, and serum and CSF Ch levels in humans. Choline has already been used by several investigators to treat a human disease associated with deficient cholinergic tone, tardive dyskinesia (TD); we found it effective in suppressing buccal-lingual dyskinetic movements (TD) that had been refractory to other therapies in 9 of 20 patients (none of whom responded to placebo).

The naturally-occurring dietary Ch source is lecithin (Lec) (phosphatidylcholine). Its ingestion also elevates serum and brain Ch and brain ACh contents in rats; it produces a greater and more prolonged rise in serum choline levels of humans than an equimolar quantity of choline salts. To test lecithin's therapeutic utility in TD, we gave Lec granules (Sigma Chem.Co; approximately 20% pure) to 2 subjects whose abnormal movements had previously responded to Ch therapy, and a partially-purified Lec preparation (Phospholipon-80, Nattermann Co; approx. 80% pure) to 1 additional subject (#3) who had not taken Ch. Lec both increased serum Ch levels and suppressed choreic movements in all 3 subjects (Table 1).

Table 1

Subject	Lecithin Dose (g/day)	Choline Content (g/day)	Movement	Percent Improvement	Serum Choline (nmol/ml) Before	During
1	60	1.8	jaw tremor	90	12.2	21.8
2	80	2.4	facial grimace	75	7.5	29.4
3	40	4.8	tongue twitch	86	10.8	20.0

Lec was as effective as Ch in reducing choreic movements, but, fortunately, did not produce the fishy odor that accompanys Ch ingestion. Lec may be used to treat those diseases where clinicians desire to enhance central cholinergic neurotransmission. (These studies were supported by grants from ADAMHA and NASA.)

1410 DIFFERENTIAL EFFECTS OF DIPROPYLACETATE AND AMINO-OXYACETIC ACID ON GABA LEVELS IN DISCRETE AREAS OF RAT BRAIN. Michael J. Iadarola, Arthur Raines and Karen Gale*. Dept. Pharmacology, Georgetown Univ., Schools of Medicine and Dentistry, Wash., D.C. 20007

The effects of two inhibitors of γ-aminobutyric acid (GABA) transaminase were examined in three regions of rat brain, each of which contained distinctly different concentrations of GABA (nmoles/mg protein); substantia nigra (SN): 102, superior colliculus (SC): 40, frontal cortex (CTX): 18. Brain areas were rapidly dissected out at 4° C and frozen on dry ice; GABA was measured by the method of Odaka, *et al.* (Exp. Br. Res. 13: 514, 1971). Time course of the dipropylacetate (DPA)-induced increase in GABA levels was determined by decapitating animals at 15, 30 and 45 min after i.p. injection of 400 mg/kg. Peak effect in all areas was reached at 30 min and began to decline by 45 min. At 15 min, SC was the only area to show an increase in GABA level (122% of control). When DPA was administered i.p. 30 min prior to sacrifice in doses of 200, 300 and 400 mg/kg, all three areas showed maximum increases with 300 mg/kg. No significant additional increases were achieved with higher doses. Of the three regions examined, SC showed the largest response to DPA and this differential effect was most evident at 200 mg/kg, a dose which produced insignificant increases in GABA levels in CTX and SN (see table). In contrast, amino-oxyacetic acid (AOAA) appeared to affect GABA levels in CTX to a greater degree than in SN or SC. Ninety min after AOAA (40 mg/kg, i.p.), GABA levels in SN and SC were 150% of control, whereas cortical GABA increased to over 250% of control. These results are being verified in rats sacrificed by microwave irradiation. The different GABA profiles may reflect different mechanisms of action of the two compounds, or a difference in ability of the two drugs to interfere with the synthesis of GABA. Further comparisons with other brain regions are currently being made.

% OF SALINE-TREATED CONTROL (CONTROL=100%)

DPA (mg/kg)	SN	SC	CTX
200	109%	143%*	116%
300	151%*	158%*	131%*
400	140%*	157%*	141%*

*Doses where GABA concentration was significantly ($p<0.05$) greater than control.

1411 THE INTERNAL PH OF ISOLATED PLATELET SEROTONIN GRANULES. R.G. Johnson, A. Scarpa, and L. Salganicoff. Dept. Biochem.&Biophys. Sch. Med., University of Pa. 19104 and Dept. Pharm. and Specialized Center Throm. Res., Sch. Med., Temple Univ., Phila., Pa.19140

The internal pH of isolated serotonin granules was measured by [^{14}C]-methylamine distribution. The serotonin granules were isolated from pig platelets by a procedure based upon the incubation of the platelets with a proteolytic enzyme to soften the membrane, cell disruption by a French cell press, and fractionation on a sucrose-Ficoll-D_2O gradient in order to preserve isotonicity. When [^{14}C]-methylamine was added to a granular preparation suspended in 0.3 M sucrose-30 mM Tris-Maleate, a ΔpH of 1.16 was measured with the internal pH being found acidic (pH 5.74). The ΔpH could be predictably perturbed by compounds known to transport H^+ across biological membranes. When nigericin, an ionophore known to exchange K^+ for H^+, was added to a suspension of serotonin granules containing 10 mM K^+, the ΔpH decreased to 0.42 pH units due to the alkalinization of the intragranular space. The addition of 400 µM $CaCl_2$ and A23187, an ionophore which transports Ca^{++} in exchange for protons in a ratio of 1:2, resulted in a ΔpH of o.65. Addition of 30 mM NH_4Cl which is thought to permeate biological membranes as NH_3, resulted in a decrease to 0.35 pH units. The internal pH was found to be independent of the external pH. When the granules were suspended in a medium at pH 5.95, the ΔpH was 0.19. Increasing the external pH resulted in a parallel increase in the pH such that at pH 7.71, the ΔpH was 1.48. The internal pH was also constant when the granules were suspended in media consisting of various ions. Choline chloride, KCl, NaCl, and sucrose media were utilized with the result suggesting the the pH is not due to the establishment of a Donnan equilibrium. The [^{14}C]-methylamine distribution method was also used to monitor the intragranular pH after the addition of various concentrations of serotonin. The addition of 1 mM serotonin decreased the ΔpH from 1.1 to 1.0 pH units; the addition of 10 mM serotonin to 0.6 pH units; and the addition of 33 mM serotonin to 0.25 pH units. When serotonin granule membranes formed by hypoosmotic lysis of the granules were utilized, the ΔpH was found to be o.18 pH units. These results which suggest that a large ΔpH exists across the membrane of the platelet serotonin granule, that the proton permeability of the membrane is low, and that an amine, at least at high concentrations can permeate the membrane in the uncharged form are similar to previous studies of another amine containing subcellular organelle, the chromaffin granule (Johnson and Scarpa J. Gen. Physiol. 68, 601 (1976), Johnson et. al. J. Biol. Chem. 252, 1512 (1978), Casey et. al. Biochem.16, 972 (1977)). The combined study of these two embryologically distinct organelles may provide important insight into the role of the ΔpH in amine homeostasis. (Supported by GM 20246 and AHA 77-675)

1412 IMMUNOHISTOCHEMICAL LOCALIZATION OF CHOLINE ACETYLTRANSFERASE IN THE CEREBELLUM OF NORMAL HUMAN AND HUNTINGTON'S CHOREA BRAINS. K.-S. K. Kan, L.-P. Chao, and L.S. Forno (SPON: A. Yuwiler). Dept. Neuro., Sch. Med., UCLA, Los Angeles, CA 90024 and Stanford U. Sch. Med., Stanford, CA 94305.

Choline acetyltransferase (ChAc) catalyzes the synthesis of the neurotransmitter acetylcholine (AcCh) in the cholinergic neurons. There is no satisfactory histochemical method for the localization of AcCh at the cellular level. The histochemical localization of acetylcholinesterase and the published histochemical methods for the localization of ChAc in terms of free coenzyme A are not very specific for cholinergic neurons. The only alternative is to visualize the highly specific synthesizing enzyme marker, ChAc, by immunohistochemical techniques. ChAc from bovine brain has been purified in our laboratory and antibody has also been produced from guinea pigs. We successfully localized this enzyme in the anterior horn cells of bovine spinal cord which are known to be cholinergic.

Recently, the localization of ChAc in formalin-fixed, paraffin-embedded rabbit brain sections has been accomplished in this laboratory using the peroxidase anti-peroxidase immunohistochemical method and with antibody specific to bovine ChAc. ChAc was found to be localized in the mossy fibers and glomeruli of the rabbit cerebellum (Brain Res. in press). Further study has revealed that the antiserum cross-reacts with human ChAc. The present study is of paraffin sections of normal human cerebellum as well as those from Huntington's Chorea (HC). In the cerebellar folia of both brains there was no peroxidase reaction in the molecular layer, the Purkinje cells, granular cells or Golgi cells. The staining was restricted to the mossy fibers in the medullary layer and extended to the granular layer. Variations in the number of stained mossy fibers in the various folia was observed. No major differences could be observed between the normal and HC cerebellum. These immunohistochemical findings are in agreement with the localization of ChAc in rabbit cerebellum. Additional studies on the localization of ChAc in other areas of normal, HC and other pathological human brains are in progress. Supported by USPH Service Grant No. MS-11087

1413 CONDITIONED EFFECTS OF CHRONICALLY-ADMINISTERED PSYCHOMOTOR STIMULANTS. M. Marlyne Kilbey and Everett H. Ellinwood, Jr. Dept. Psychiat., Behav. Neuropharm. Sect., Duke Univ. Med. Ctr., Durham, NC 27710.

Several sets of data that relate to the question of whether conditioned effects operate in the augmentation of behavioral effects during chronic administration of psychomotor stimulants, as well as when these drugs are re-administered after drug-free periods, will be examined. Behavioral effects measured include: hyperactivity, stereotypy, and amplitude of movement in specific frequency ranges in rats; stereotypies and dysjunctive or dyskinetic postures in cats; and oral buccolingual dyskinesias in monkeys. Data will be discussed in terms of findings consonant with: (1) classical- and operant-conditioning principles; (2) discriminative properties of drugs; and (3) physiological mechanisms acting through specific and non-specific activation. Data addressing the differential contributions of these mechanisms to behavioral augmentation in various species will also be presented.

1414 GLUTAMIC ACID DECARBOXYLASE WITHIN LAMINAE OF THE OLFACTORY TUBERCLE. Neil R. Krieger and John S. Heller (SPON: A.M. Laties). Yale Univ., New Haven, Conn.

We have been interested in the localization of neurotransmitter related enzymes within the rat olfactory tubercle. Here we report on the distribution of glutamic acid decarboxylase (GAD) and gamma amino butyric acid (GABA) in this region of the limbic cortex. Three well-defined histological laminae occupy the 1mm depth of the tubercle: the plexiform, the pyramidal and the polymorphic. Our procedure uses direct enzymatic and chemical assays of homogenates prepared from frozen sections cut parallel to these laminae. The hemisected rat brain was frozen in powdered dry ice, the tubercle trimmed to a pedestal approximately 2mm on each side, and mounted in a cryostat at -15° C. Consecutive tangential 16µ sections were cut. For assays of GAD, groups of six sections (approximately 40µg of protein) were homogenized in a 0.6ml volume. Ten lambda aliquots were assayed using a method similar to that of Albers and Brady (JBC(1959) 234:926) in which enzymatic activity was assessed by the amount of CO_2 released from the substrate glutamic acid in a fixed time interval. GABA and other amino acid levels were determined with the use of a Durrum high pressure D500 amino acid analyzer.

Steep variations in GAD activity were observed as a function of depth in the tubercle. These were accompanied by corresponding but less marked variations in GABA levels. In the posterior medial region of the tubercle, GAD activity varied by as mueh as six fold ranging from 60nmoles of GABA formed hr/mg/protein in the outermost plexiform layer to 400nmoles/hr/mg/protein in the deepest layer of polymorphic cells. Such low activity in the plexiform layer suggests that GAD may play a very limited role in this lamina. In contrast, its high activity in the polymorphic layer rivals the highest known levels in other brain regions and leads to the further question whether this activity is attributable to cells intrinsic to this layer or to entering processes.

1415 NEUROGLIAL DEPOLARIZATION BY INTRACELLULAR INJECTIONS OF MONOAMINES. Y. Lamour*, K. Krnjević, J.F. MacDonald, A. Nistri* . Dept. Anaesthesia Research, McGill Univ., 3655 Drummond St., Montreal, H3G 1Y6.

We have previously reported that intracellular injections of monoamines (catecholamines especially) can have a striking depolarizing action on spinal motoneurons (Nistri et al., 1978, Canada Physiology, 9, 52). During our microiontophoretic studies with multibarrelled electrodes in the spinal cord, we frequently recorded from cells which could be identified as glial cells (high resting membrane potential, and input resistance, and lack of response to dorsal and ventral root or intracellular stimulation). We thus had the opportunity of testing the effects of intracellular injections of catecholamines and 5HT in cells of this type. The amines were injected by push-pull iontophoresis using currents of 5-20 nA for about 1 min. Most cells that were injected in this fashion with noradrenaline, dopamine, isoprenaline or 5HT showed a large fall in input conductance, which usually reversed within a few minutes after the injection was stopped. It was most commonly associated with membrane depolarization; however, the potential changes were sometimes minimal or in a hyperpolarizing direction. The conductance changes appeared to be genuine effects of the monoamines since they could not be produced by similar iontophoretic currents flowing through a barrel containing K-citrate at comparable pH. Moreover, these cells showed no consistent voltage-dependent conductance changes. We therefore conclude that intracellular monoamines appear to cause a marked primary blockade of the ionic conductance of the neuroglial membrane, presumably mainly by occluding potassium channels. Hence, glial depolarization could be a consequence of a rise in neuroglial monamine content, possibly as a result of certain forms of drug administration. This could be of functional significance, for example by slowing down of neurotransmitter uptake.

1416 INHIBITION OF HIGH AFFINITY GLUTAMATE ACCUMULATION BY KAINIC ACID - A KINETIC AND PHARMACOLOGICAL STUDY. John Lehmann, E. G. McGeer and H. C. Fibiger. Div. Neurological Sci., Dept. Psychiatry, University of British Columbia, Vancouver, B.C. V6T 1W5, Canada

Kainic acid (KA) reversibly inhibited the high affinity, sodium-dependent accumulation of labeled glutamate into crude rat striatal synaptosomes. Dixon plots indicated that the K_i was 7.5 x 10^{-4}M and was apparently non-competitive with glutamate In contrast, both glutamate and aspartate were competitive inhibitors, with K_i of 3.7 and 2.3 x 10^{-6}M respectively. KA itself was not taken up into synaptosomes under identical conditions, suggesting that its inhibitory action is mediated at the level of the plasma membrane. The non-competitive nature of the inhibition indicates that kainic acid exerts its action at a site distinct from the glutamate uptake substrate site. Inhibition by KA was not affected by various glutamate receptor-antagonists, tetradotoxin, ouabain, or omission of calcium from the medium. In contrast, agents which disturb structural units of the synaptosome such as neuraminidase, colchicine, and cytochalasin B, reduced control uptake velocity and tended to enhance KA's inhibition. Since KA is not taken up by synaptosomes, it is probably restricted to extracellular space when injected intracerebrally. It is suggested that concentrations of KA equal to those required to inhibit glutamate accumulation are probably attained by intracerebral injections of cytotoxic doses of KA.

1417 OPIATE AND CHOLINERGIC INDUCED CHANGES IN MEMBRANE POTENTIAL MONITORED BIOCHEMICALLY IN NEUROBLASTOMA X GLIOMA HYBRID TISSUE CULTURE CELLS. D. Lichtshtein*, H.R. Kaback* and A.J. Blume, Dept. Phys. Chem. & Pharm. and Dept. Biochem., Roche Institute of Molecular Biology, Nutley, NJ 07110.

Cultured neuroblastoma x glioma hybrid cells NG108-15 have a transmembrane electrical potential ($\Delta\Psi$) of -40 to -60 mV as determined by direct electrophysiological measurements. In an attempt to develop a biochemical method for monitoring changes in $\Delta\Psi$ in populations of cultured neuronal cells, accumulation of the permeant lipophilic cation [^{3}H]tetraphenylphosphonium (TPP^+) [bromide salt] has been studied. TPP^+ is accumulated against a concentration gradient by NG108-15 cells suspended in physiological buffers (high external Na^+) and in buffer containing 135 mM K^+ (high external K^+); however, the concentration gradient is about 9-fold higher in high Na^+. Since high external K^+ is known to collapse $\Delta\Psi$ in NG108-15, the difference in TPP^+ accumulation in high Na^+ versus high K^+ has been taken as an index of $\Delta\Psi$, and using the Nernst equation ($\Delta\Psi = 61 \log [TPP^+]_{in}/[TPP^+]_{out}$), a resting potential of $\sim$ -60 mV has been calculated for NG108-15 cells in suspension. TPP^+ accumulation is time dependent, achieving a steady-state in about 20 min, and is a linear function of cell number and TPP^+ concentration (i.e. $\Delta\Psi$ is independent of TPP^+ concentration up to 26 μM). Moreover, TPP^+ accumulation is decreased or totally abolished by carbonylcyanide m-chlorophenylhydrazone, dinitrophenol or ouabain. In contrast, the ionophore monensin which catalyzes electroneutral transmembrane exchange of Na^+ and H^+ causes an increase in TPP^+ accumulation. Alterations in TPP^+ accumulation are also induced by addition of ligands for certain plasma membrane receptors. Veratridine, a compound which opens a specific Na^+ channel, decreases TPP^+ uptake in high Na^+ to the same level as observed in high K^+. This effect is dependent upon the presence of external Na^+ and is blocked by tetrodotoxin. The cholinergic agonist carbamylcholine and the opiate peptide agonist D-ala^2-met^5-amide (DAMA) induce an increase in TPP^+ accumulation. The carbamylcholine effect is blocked by the specific muscarinic cholinergic antagonist QNB and the DAMA effect is blocked by the specific opiate antagonist naloxone. The data demonstrate clearly that (i) membrane depolarization and hyperpolarization can be monitored biochemically in cultured cell populations; and (ii) in NG108-15 cells, hyperpolarization is induced by agonist occupany of either opiate or cholinergic receptors.

1418 INTERACTION OF GABA MIMETICS WITH CENTRAL DOPAMINE (DA) NEURONS. Kenneth G. Lloyd, Branimir Zivkovic*, Bernard Scatton*, Paul Worms* and Giuseppe Bartholini*. Synthélabo-L.E.R.S., Research Department, 31,Ave Paul-Vaillant Couturier, 92220 BAGNEUX, FRANCE.

The current literature indicates that GABA neurons are involved in the feed-back regulation of DA neurons.In the present study several indirect acting GABA mimetics (e.g. dipropylacetamide, DPA; gamma-acetylenic GABA, GAG; amino-oxyacetic acid, AOAA; pyrrolidinone; gamma-butyro-lactone, GBL) as well as two direct acting GABA mimetics, muscimol (M) and SL 76.002 (SL), were utilized for studying DA neuron function.

Increasing GABA-receptor activity by M or SL (i.p.) did not appear to greatly alter the basal activity of DA neurons as neither drug induced catalepsy, altered apomorphine-induced stereotypies or mesh-climbing, or altered the kinetic state of striatal or limbic tyrosine hydroxylase. M or SL slightly decreased DOPA and DA synthesis in both limbic system and striatum ; DA turnover after α-methyl-p-tyrosine was decreased only in the striatum. After activation of the feed-back circuit by neuroleptics, the DA neurons became much more susceptible to GABA-related drugs. Thus, haloperidol-induced catalepsy was potentiated by M, SL, DPA, GAB, AOAA or pyrrolidinone.Bicuculline blocked the potentiation of catalepsy by M or SL. M, SL and AOAA also potentiated the catalepsy due to thioridazine or chlorpromazine. In correlation with these behavioural findings, M, SL and GBL all blocked the activation of tyrosine hydroxylase induced by haloperidol. M and SL reduced the haloperidol-activated DA turnover to a greater extent in striatum than in the limbic system. These observations indicate that increased GABA receptor activity reduces the feed-back activation of the nigro-striatal DA pathway therefore enhancing the cataleptic action of the neuroleptics. These results also imply that DA neuron function is much more sensitive to modulation by GABAergic mechanisms after activation of the neuronal feed-back loop and enhancement of DA cell firing. The following are consistent with the above conclusions :
i) neither AOAA nor pyrrolidinone induce catalepsy following sulpiride, a neuroleptic with minimal activity in the nigro-striatal DA pathway ; and ii) behavioural effects of direct stimulation of DA receptors by apomorphine are not overcome by SL or M.

1419 POSTSYNAPTIC PHARMACOLOGY OF CEREBELLAR NEURONS IN CELL CULTURE. R. L. Macdonald, G. Moonan*, P. G. Nelson. Laboratory of Developmental Neurobiology, NICHD, NIH, Bethesda, Md. 20014.

Cerebellar neurons grown in cell culture have been examined for responses to amino acid putative neurotransmitters, norepinephrine (NE), dopamine (DA) and 5-hydroxytryptamine (5-HT). Cultures were derived from 17-19 day old fetal rats and were maintained for at least 4 weeks prior to study. Although these cultures contain at least three different cell types, all intracellular recordings were obtained from the largest neurons (soma diameter >15μm). These neurons were polygonal in shape with 1-5 dendritic shafts and fine dentritic arborizations, and appeared, on morphological grounds to be the in vitro equivalent of Purkinje cells. All neurons studied with membrane potentials >25mV and with an action potential (evoked by intracellular stimulation), responded to iontophoretically applied glutamic acid (GLU) (n=20 cells) and γ-amino butyric acid (GABA) (n=30), but few responses were elicited by glycine (2/15 cells), β-alanine (0/10) or taurine (0/6). Aspartic acid (ASP) produced small responses only at high currents (n=15). Responses were also elicited by NE (n=15), DA (n=8) and 5-HT (n=8).

GLU reversibly increased membrane conductance and was depolarizing with reversal potentials between 0 and -10mV (n=4). There was non-uniform sensitivity to GLU with high sensitivity occurring only on the dendrites; little sensitivity to GLU was present on the soma. GABA also reversibly increased membrane conductance but was hyperpolarizing with reversal potentials (n=4) between -50 and -40mV (10 to 15 mV more negative than resting membrane potential). Log-log dose-response curves were linear in the low charge region with GLU having a slope of about 1.0 (n=6) and GABA of about 2.0 (n=7), suggesting that GABA, but not GLU, interacts with its receptor in a cooperative manner. Although having little direct action, ASP was a potent modulator of GLU responses (n=15). ASP at low currents augmented GLU responses and shifted the GLU DR curve to the left while higher currents diminished GLU responses. NE and DA were both inhibitory and decreased or abolished spontaneous spike activity without alteration of membrane potential; at higher currents, depolarization was frequently recorded. 5-HT was excitatory and increased spike activity in all cases.

The results indicate that large cerebellar neurons in cell culture develop considerable neuropharmacological specificity similar to that of Purkinje cells in vivo and suggests that this culture system may be useful in the study of cerebellar neurotransmitter mechanisms.

1420 LOW AFFINITY GABA TRANSPORT BY A HIGH-AFFINITY TAURINE TRANSPORT SYSTEM IN GLIOMA CELLS. D. Martin* and W. Shain Chemistry Dept., University of MD., College Park, MD 20742 and Armed Forces Radiobiology Research Institute, Bethesda, MD 20014.

Transport of GABA, taurine, and β-alanine was studied in a rat glioma cell line cloned from a spinal tumor (LRM55 cells) incubated in HEPES buffered Hank's balanced salt solution. Kinetic analysis of ^{3}H-GABA influx (concentration range 2.5×10^{-8} -2×10^{-3}M) carried out in the presence of 1×10^{-5}M aminooxyacetic acid revealed only a low affinity GABA transport system (K_m=700 μM) whereas analysis of ^{35}S-taurine and ^{3}H-β-alanine influx (1×10^{-6}M to 1×10^{-3}M) showed only high affinity uptake systems with K_m values of 30 μM and 80μ M respectively. Maximum rates of influx were 5.4±1.0, 1.7±0.3, and 4.6±1.4 nmole/min/mg protein for GABA, taurine and β-alanine respectively. The rate of GABA influx at all concentrations was nearly constant for over two hours whereas influxes of β-alanine and taurine were nearly complete after 1 hour of incubation. This difference is attributable chiefly to the differences in kinetic parameters of the uptake systems as shown by numerical integration of the transport rate equation. Net transport of GABA and taurine was demonstrated by direct measurements of the amino acid content of the cells. Influxes of taurine and GABA were both strongly dependent on Na^+. Reduction of (Na^+) to 5 mM by replacement with choline Cl^- reduced the influx of 30 or 300 μM taurine and 70 or 700 μM GABA to less than 5% of control values. GABA, β-alanine and taurine were found to be mutually competitive inhibitors of each other's transport. The inhibition constants for GABA, taurine, or β-alanine when used as inhibitors of the transport of the other two amino acids were similar to their K_m values when used as substrates. Ten compounds including glycine, 2,4-diaminobutyric acid, α-alanine and nipecotic acid were tested as inhibitors and found to have similar effects on GABA, taurine and β-alanine influxes. The results of these experiments suggest that low affinity GABA uptake may be carried out, at least in part, by high affinity taurine or β-alanine transport systems.

1421 GLYCINE, GABA, AND INHIBITORY SYNAPTIC TRANSMISSION ONTO GIANT RETICULOSPINAL NEURONS OF THE LAMPREY. Gary Matthews and Warren O. Wickelgren. Dept. Physiol., Univ. of Colo. Med. Sch., Denver, CO 80262.

Intracellular recordings were made from giant reticulospinal neurons (Müller cells) in the isolated brain of lamprey, and the physiological-pharmacological properties of the inhibitory postsynaptic potential (ipsp) evoked by ipsilateral vestibular nerve stimulation were compared with those of the hyperpolarization resulting from the iontophoretic application of glycine or γ-aminobutyric acid (GABA). The reversal potentials of the ipsp, the glycine response, and the GABA response were identical, averaging -83 mV or about 13 mV negative to the usual -70 mV resting potential of the cells. To determine if a change in Cl conductance was involved in the response, the Cl equilibrium potential was changed either by injecting Cl intracellularly or by lowering extracellular Cl. Both manipulations shifted the reversal potentials for glycine, GABA and the ipsp in a positive direction by identical amounts. Alterations in extracellular K also produced identical changes in the reversal potentials for the drugs and the ipsp, but, although the cell resting potential changed rapidly after a shift in extracellular K, the reversal potentials changed more slowly. This suggests that the effects of K on the reversal potentials were secondary to changes in internal Cl concentration. Picrotoxin or bicuculline at a concentration of 20 μM abolished the response to GABA but had negligible effects on the ipsp or the response to glycine. In contrast, 20 μM strychnine abolished both the ipsp and the glycine response but had little or no effect on the GABA response. For all Müller cells 1 μM strychnine was sufficient to reduce the glycine response by 50% or more within 5 min and, in those Müller cells located in the aqueductal region (the I cells), this was accompanied by a parallel reduction in the amplitude of the ipsp. However, in those Müller cells in the midbrain (the M cells), 1 μM strychnine, although rapidly abolishing the glycine response, had no effect on the ipsp, which required approximately 5 μM strychnine before it was substantially reduced. We conclude that for lamprey Müller cells glycine is a better candidate for the inhibitory transmitter than is GABA, particularly so for those cells (the I cells) in which the sensitivity of the ipsp and the glycine response to strychnine was identical. (Supported by NIH grants NS 09661 and 09660.)

1422 SEROTONERGIC FACILITATION OF FACIAL MOTONEURON EXCITATION: A MODULATORY EFFECT. Robert B. McCall* and George K. Aghajanian (SPON: Michael Davis). Depts. of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06508.

Pharmacological treatments which enhance stimulation of postsynaptic serotonin (5-HT) receptors produce a behavioral syndrome in the rat which includes resting tremor, reciprocal forepaw treading, and lateral head weaving. Although the precise mechanisms underlying this 5-HT motor syndrome have not been elucidated, a direct action of 5-HT on motoneurons is possible since many brain stem and spinal motor nuclei receive a dense 5-HT input. Therefore, the effect of 5-HT on motoneurons located in the facial nucleus of the rat was investigated by single-cell recording. Fluorescence histochemistry revealed the facial nucleus receives a dense 5-HT input as well as a lesser input from norepinephrine (NE)-containing fibers. Microiontophoretic application of 10-200 nA pulses of 5-HT lasting from 1-10 minutes failed to excite facial motoneurons. However, small amounts of 5-HT facilitated the excitation of these cells produced by iontophoretically applied glutamate. The current of glutamate required to produce an activation of facial motoneurons was reduced at least 50% by 5-HT. In addition, 5-HT markedly shifted to the left the cumulative dose-response curve of glutamate-induced excitation of motoneurons. Thus, 5-HT facilitated the excitatory effect of iontophoretically applied glutamate without directly exciting facial motoneurons. The 5-HT releasing agent p-chloroamphetamine (PCA) facilitated the excitatory effect of glutamate on motoneurons in control animals, but not in those pretreated with the 5-HT synthesis inhibitor p-chlorophenylalanine. This indicates the ability of PCA to facilitate motoneuron excitation is secondary to release of endogenous 5-HT.

Microiontophoretic application of large amounts of NE also failed to directly excite motoneurons. However, NE facilitated the excitatory effects of iontophoretically applied glutamate on facial motoneurons. In addition, both 5-HT and NE facilitated the excitation of motoneurons produced by stimulation of the motor cortex and the red nucleus. Thus, 5-HT and NE facilitated synaptically-mediated excitatory inputs as well as the excitation produced by glutamate. The facilitating effect of 5-HT, but not NE, was blocked by methysergide (1 mg/kg, i.v.). On the other hand, piperoxane (2 mg/kg, i.v.) blocked the effect of NE but not 5-HT. Thus the actions of 5-HT and NE appear to be mediated by distinct receptors in the facial nucleus. It is concluded that 5-HT and NE do not produce a direct excitation of facial motoneurons, but rather act as modulating transmitters that enhance the effects of excitatory inputs.

1423 ADENOSINE ACTIVITY IN RAT STRIATUM. Mary L. Michaelis and Elias K. Michaelis. Dept. Human Development, U. of Kansas, Lawrence, Ks. 66044.

Adenosine (Ado) and its non-metabolizable analog 2-Chloro-adenosine (2-Cl-Ado) have been shown to cause large increases in the cAMP content of brain slices and hyperpolarization of cortical and subcortical neurons. We have previously shown that 2-Cl-Ado can stimulate the striatal adenylate cyclases (AC) in broken cell preparations and that it can modulate the dopa-(DA) stimulation of AC activity (Neuroscience Abst. III, 410, 1977). Further pharmacological characterization of the putative Ado receptor which is coupled to a striatal adenylate cyclase has been obtained. The stimulation of the striatal enzyme activity shows excellent correspondence with the physiological activity of adenosine and adenine nucleotides on cortical neurons. Adenosine, AMP-PNP, β, γ-methylene ATP, and 5'-AMP are approximately equipotent in stimulating AC activity but less effective than 2-Cl-Ado. The potent methylxanthine, isobutylmethylxanthine, is a very strong inhibitor of the 2-Cl-Ado stimulation of AC while 2'-deoxyadenosine is essentially inactive. The dependence of 2-Cl-Ado stimulation of striatal AC on various divalent cations and its effects on the enzyme kinetics are currently under investigation.

In addition, we have previously shown that 2-Cl-Ado partially inhibits the release of ^{3}H-DA from preloaded striatal synaptosomes. The magnitude of the inhibition by 2-Cl-Ado of the depolarization (KCl)-induced release of DA is dependent on the strength of the depolarizing stimulus, i.e., KCl concentration, with the greatest effect at low KCl concentrations. 2-Chloroadenosine modulation of DA release is also observed when the releasing stimulus is exposure to various amounts of d-amphetamine. Once again, 2-Cl-Ado decreases the amphetamine-stimulated release of ^{3}H-DA with the greatest effect at the lower amphetamine concentrations. Both the KCl and amphetamine-induced release of synaptosomal ^{3}H-DA is enhanced by pre-incubation of the synaptosomes with the specific Ado metabolizing enzyme adenosine deaminase. These results suggest the presence of endogenous Ado which is continuously controlling DA release from nerve endings. 2-Chloroadenosine has no effect on high affinity synaptosomal DA uptake, thereby ruling out the possibility that the 2-Cl-Ado effects are due to increased uptake activity. It appears, then, that adenosine can have both presynaptic effects on striatal DA nerve endings as well as possible postsynaptic effects on striatal Ac activity.

1424 HIGH AFFINITY UPTAKE SYSTEM FOR CYSTEINE IN SYNAPTOSOMES OF RAT CENTRAL NERVOUS SYSTEM. Chandra H. Misra, Robert C. Smith. Dept. Psychiat., Washington Univ. School of Medicine, St. Louis, Mo. and Tex. Res. Inst. Mental Sciences, Houston, Texas 77030.

The in vitro uptake of [^{35}S]cysteine was studied in synaptosomal preparation of the cerebral cortex of rat brain. The accumulation of cysteine was found to be temperature dependent and very rapid. It was linear at least for 4 minutes at 37^{0} with characteristics of saturable kinetics. This uptake was Na^{+} and K^{+} dependent, but contrary to the Na^{+}, high extracellular concentration of K^{+} has inhibitory effect on cysteine uptake. Cysteine was accumulated against concentration gradients by energy dependent, saturable mechanisms, and the double-reciprocal plot of the cysteine uptake suggests dual affinity system with the Km values for the high affinity uptake of about 16.6 x 10^{-6}M and for the low affinity uptake of about 4.0 x 10^{-4}M. This transport was also found significantly inhibited by oubain, a potent inhibitor of the Na-K dependent ATPase and other metabolic inhibitors.

1425 A COMPARISON OF THE EXCITATORY EFFECTS OF L-ASPARTATE AND L-GLUTAMATE ON PURKINJE CELLS AND OTHER NEURONS IN THE CEREBELLAR CORTEX OF RAT. Sandra L. Morzorati, R.C.A. Frederickson and William J. McBride, Departments of Psychiatry and Biochemistry and Institute of Psychiatric Research, Indiana University School of Medicine, Indianapolis, IN 46202.

L-aspartate (Asp) and L-glutamate (Glu) were administered iontophoretically onto Purkinje cells and other cerebellar neurons of urethane-anesthetized rats. Both Asp (0.5 M, pH 8.5) and Glu (0.5 M, pH 8.5) produced an increase of spike frequency in all cells tested. The excitatory effects of both agents were characterized by a rapid onset (<2 sec), a gradual increase to a maximal firing rate and fast recovery. Depolarization block was seen with large doses of Glu and, to a lesser extent, Asp. In order to compare potencies graded doses of Asp and Glu were ejected onto Purkinje cells and unidentified neurons and dose-response curves were plotted employing percent excitation of maximal firing rate vs. the product of ejection current and time. Potency ratios (at ED_{50}) showed both cell groups, but especially Purkinje cells, to be more sensitive to Glu than Asp. Dose-response curves for Asp and Glu on Purkinje cells were generally non-parallel, implying different mechanisms of action for the two amino acids. Tests for antagonism showed glutamic acid diethylester to be a more effective blocker of Asp than of Glu while DL-α-aminoadipate was equipotent in antagonizing the actions of both agents. These data are compatible with the possibility that both Asp and Glu may be excitatory transmitters in rat cerebellum. (Supported in part by PHS Grants MH10695 from NIMH and NS13925 from NINCDS).

1426 LAMINAR DISTRIBUTIONS OF AMINO COMPOUNDS AND [^{3}H]LIGAND BINDING SITES IN THE DOG OLFACTORY BULB. N.S. Nadi*, J.D. Hirsch* and F.L. Margolis (SPON: C. Zomzely-Neurath). Department of Physiological Chemistry and Pharmacology, Roche Institute of Molecular Biology, Nutley, NJ 07110.

The olfactory bulb was dissected into several discrete layers useful for studying the distribution of amino compounds and [^{3}H] ligand binding sites. Dogs under barbiturate anesthesia were exsanguinated and the olfactory bulbs removed into liquid N_2 within 15 min of the onset of anesthesia. The tissue was warmed to -20°C and 1 mm thick coronal sections were cut and then free-hand dissected into four layers: Fiber layer (F)-fibers arising from the olfactory nerve; glomerular layer (GL)-olfactory nerve endings, the mitral cell dendrites and the periglomerular cells; mitral-granule cell layer (M-G)-mitral cell perikarya, granule cells and tufted cells; and white matter (W)-efferent and afferent axons. Tissue was either deproteinized and analyzed for amino compounds, using Fluram$^{(R)}$, or else membrane fractions were prepared for [^{3}H]ligand binding studies. Levels of several amino compounds and the binding of nine [^{3}H]ligands were measured. Binding of [^{3}H]carnosine (carn) was highest in GL and lower in F, M-G and W. [^{3}H]Dihydromorphine binding was high in both F and M-G, but was much lower in GL and W. [^{3}H]Kainic acid and [^{3}H]spiroperidol (Spi) binding were primarily localized in M-G, while [^{3}H]diazepam (Dz) and [^{3}H]muscimol (Mu) binding were predominant in GL and M-G. [^{3}H]QNB binding was uniformly distributed. α- and β-adrenergic binding was distributed differently with α, lowest in M-G and W, while β was lowest in GL. Carn levels were high in F and GL, low in M-G and non-detectable in W. GABA and tyr levels were high in M-G and low in F, GL and W. The levels of tau, β-ala, glu, asp, ser, gly, ala and phe showed no significant differences among the four layers. The distribution of carn and its binding site support previous reports from this laboratory implicating this dipeptide as a neuroeffector at the glomerular level. While the localization of GABA and Mu binding are consistent with data from other laboratories associating it with granule cell function, the significance of elevated levels of both tyr and Spi binding in M-G remain to be investigated. The generally high level of binding sites in M-G imply that this layer is a major region of physiological and pharmacological interaction in the bulb.

1427 ACETYLCHOLINE INDUCED SLOW-WAVE ACTIVITY IN CAT ESOPHAGEAL SMOOTH MUSCLE. D. O. Nelson and A. W. Mangel*. Dept. of Physiology and Biophysics, Univ. of Illinois, Urbana, IL 61801.

The electrical activity of cat esophageal smooth muscle was investigated with pressure electrodes. Most preparations were quiescent although some gave brief periods of spontaneous slow-waves and spikes. Application of 10^{-5}M acetylcholine induced slow-wave and spike activity to otherwise quiescent preparations. Lower concentrations of acetylcholine induced spike discharge without slow-waves. Continued exposure to acetylcholine for periods greater than 45 minutes caused desensitization which could be reversed by incubation in normal solution. Slow-waves were insensitive to ouabain or TTX application but were eliminated by exposure to low sodium containing solutions. Application of EGTA produced prolonged potentials as demonstrated in other smooth muscle preparations (1). Esophageal slow-waves may result from a sodium requiring, TTX insensitive, process as in the guinea pig ileum (2). Release of Ach from myenteric plexus neurons may be the in vivo correlate of acetylcholine application.

1428 ACETYLCHOLINE SYNTHESIS AND RELEASE BY THE ABDOMINAL GANGLIA OF LIMULUS. Robert F. Newkirk*, M. A. Maleque* and James G. Townsel
Department of Physiology, Meharry Medical College, Nashville, Tennessee 37208

Acetylcholine (ACh) is a neurotransmitter candidate in Limulus (Stephens and Greenburg, 1973, Histochem. Cytochem. 21:923; Townsel et al., 1976, Neurosci. Abs. 2:618). The ventral nerve cord of Limulus has been shown to contain significant levels of choline acetyltransferase (Malthe-Sorenson and Emson, 1976, J. Neurochem. 27:341) and a true acetylcholine esterase (Townsel, Baker and Gray, 1977, Comp. Biochem. Physiol. 58:29). Recent studies have demonstrated the presence of a Na^+ dependent, high affinity choline (Ch) uptake system in Limulus (Maleque and Townsel, 1977, Neurosci. Abs. 3:318). The present study was conducted to evaluate the conversion of Ch to ACh and the mechanism for ACh release by the abdominal ganglia of Limulus.

Isolated ganglia from the ventral nerve cord of the horseshoe crab, Limulus polyphemus were incubated in Chao's solution containing 2μM ^{3}H-choline (0.55μCi). The rate of uptake was linear for 90 min. The uptake was inhibited 73% and 70% by 1mM ACh and 100μM hemicholinium-3 (HC-3), respectively, and stimulated 88% by previous exposure to 90mM K^+. Homogenates of ganglia incubated for 1 hr. in 2μM ^{3}H-Ch were analyzed by high voltage electrophoresis. Analysis showed that the ganglia contained 0.226 ± 0.1 pmole ^{3}H-Ch per mg tissue and 0.109 ± 0.09 pmole ^{3}H-ACh per mg. This represents a conversion to ACh of 25.8% of the Ch taken up. Ganglia labeled with ^{3}H-Ch and perfused with 90mM K^+ released five times the background efflux of radioactivity. The K^+ induced release of radioactivity was found to be Ca^{++} dependent and inhibited by Mg^{++} and Co^{++}. Similarly, 200μM veratridine effected a Ca^{++} dependent release of radioactivity. Analysis of the perfusate revealed that better than 85% of the released radioactivity co-electrophoresed with acetylcholine.

Thus, the abdominal ganglia of Limulus take up Ch via a high affinity Na^+ dependent uptake process, convert substantial amounts of it to ACh and possess a K^+ triggered, Ca^{++} requiring mechanism for the specific release of ACh. These results give further support to the contention that the abdominal ganglia of Limulus contain a population of cholinergic neurons.

1429 DEVELOPMENTAL CHANGES IN BRAIN HISTAMINE: A REASSESSMENT. Edward L. Orr* and Burr Eichelman (SPON: H. Kubinski). Waisman Ctr., Univ. of Wis., Madison, WI 53706; and Wm. S. Middleton VA Hospital, Madison, WI 53705.

We have recently shown that, due to incomplete extraction procedures, previous investigators have underestimated the levels of histamine (Hm) in the adult rat brain by as much as a factor of 10 (Orr & Eichelman, Trans. Am. Soc. Neurochem., Vol. 9, 1978). Since brain levels of Hm in the developing rat brain may have been underestimated as well, we have reinvestigated the developmental changes in rat brain Hm using our modified extraction procedure. Brains from male rats of 1, 10, 25, 40, 53 and 70 days of age (postnatal) were examined. In other reports, "high" concecntrations of whole brain Hm of about 300-350 ηg/g wet wt. were found in rats between 1 and 10 days of age. Brain Hm levels then declined to about 50 ηg/g by 30 days of age, and remained at this low "adult" level for the rest of development. We, too, find high concentrations of brain Hm early in development (466 and 493 ηg/g for 1- and 10-day old rats, respectively), with a subsequent decrease to 338 ηg/g by 25 days of age. However, rather than continuing to decline, brain Hm concentrations remain at this level until the onset of puberty, whereupon Hm concentrations begin to increase, reaching adult levels of about 500 ηg/g between 53 and 70 days of age. Total brain levels (ηg Hm/brain) increased from 1-day postnatal until adulthood. However, between 10 and 40 days of age the rate of increase was much slower than the rates of increase earlier or later in development. In preliminary experiments, the late (pubertal) increase of brain Hm levels in the male rat was prevented by prepubertal castration, indicating a relationship between the hormonal status of the rat and the levels of Hm in the brain.

1430 Voltage-Dependent Excitatory Response to Serotonin in Aplysia. T. C. Pellmar and D. O. Carpenter, AFRRI, NNMC, Bethesda, Maryland 20014.

A slow voltage-dependent excitatory response to iontophoretic application of serotonin has been observed in voltage clamped neurons of Aplysia californica. The response has a time-to-peak of 15 to 30 seconds and a duration of 1 to 3 minutes. At potentials more negative than approximately -40mV, the response is absent. As the cell is depolarized, the serotonin-evoked inward current becomes progressively larger. The potential dependence of the serotonin response is similar to that of delayed rectification. The response is accompanied by an apparent decrease in conductance which can be attributed either to a decrease in conductance to K^+ or to a regenerative inward current. Changes in extracellular potassium concentration up to 30mM have little effect, but higher concentrations reduce the amplitude of the response. The actions of zero sodium solutions depend on the sodium substitute: glucosamine prolongs the response to serotonin; sucrose and mannitol greatly reduce the amplitude. Exposure to lithium-substituted sea water causes a gradual attenuation and subsequent replacement of normal sea water potentiates the response. The serotonin response is minimally affected by alterations in extracellular calcium but is blocked by cobalt and manganese. Observed changes in response amplitude are usually accompanied by consistent changes in delayed rectification.

It is difficult to determine the ionic basis of the serotonin response from these data. A regenerative inward sodium current can be ruled out; but such a current carried by calcium remains a possibility. Alterations of extracellular calcium may not alter the calcium gradient sufficiently to modify such current. The above data seems most consistent with a decrease in a potassium conductance. Yet, it is disturbing that moderate changes in potassium concentration have minimal effects.

1431 EFFECT OF TREATMENT ON CATECHOLAMINE METABOLITES FOLLOWING HEAD TRAUMA. E.W. Pelton, II, Louis R. Nelson, and Robert S. Bourke Dept. Neurol., Albany Med. Coll., Albany, NY 12208.

Head trauma with hypoxia has been shown to alter normal metabolism and inactivation of catecholamines (CA) in cats 1 1/2 hours after insult (Pelton et al., 1977). Injurious trauma is induced by oscillations for one minute with subsequent hypoxia for 60 minutes. As previously reported, early post-injury regional assessment of norepinephrine (NE) and dopamine (DA) and their principal metabolites methoxyhydroxyphenylglycol (MHPG), dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) indicate interference with normal oxidative and energy requiring methods of inactivation of vasoactive catecholamines with no significant changes in levels of CA per se. Recent work assesses the effects of anti-edema agents on morbidity, mortality and monoamines. At the time of insult cats received solumedrol, ethacrynic acid, DCPI, or nothing, and were scored neurologically for 24 hours. CA metabolism was assessed in animals that died during the 60 minute post-shake hypoxia or survived 24 hours. The longer cats survive during the hypoxic period, the lower the concentrations of CA metabolites in certain discrete areas of brain, supporting hypoxia's interference with oxidative degradation. Twenty-four hour survivors showed an inverse correlation between neurologic score and levels of regional DOPAC and HVA, with normal levels in fully recovered animals, and elevations in others. We suggest inability to inactivate vasoactive compounds following hypoxia and/or trauma may affect neurologic recovery, and should be an area of further pharmacologic study of therapy.

1432 SPECIFIC CONDITIONING OF STRIATAL DOPAMINE METABOLISM IN THE RAT WITH METHADONE AS AN UNCONDITIONED STIMULUS. Jorge Perez-Cruet. Dept. Psychiatry at Missouri Institute of Psychiatry, Psychoneuropharmacology Unit, 5400 Arsenal, St. Louis, Missouri 63139.

Methadone is known to produce marked increases in dopamine metabolism and to increase homovanillic acid (HVA) in rat striatum as an unconditioned reflex (Experientia 28: 926, 1972. Previously it has been reported that a conditioned stimulus reinforced with methadone produced increments in HVA and in the synthesis of dopamine as a conditioned reflex with methadone, morphine or bulbocapnine as an unconditioned stimulus (Pavlovian J. Biol. Sc. 11: 237, 1976). The present study was designed to determine if brainstem serotonin metabolism is also conditioned during conditioning of striatal dopamine metabolism with methadone as an unconditioned stimulus. The conditioning experiments included four groups of rats. Group I, was never exposed to a conditioned stimulus or drug treatments with methadone. Group II, was exposed to the conditioned stimulus plus injections of normal saline and never exposed to methadone. Group III, was the conditioned group that was exposed to the conditioned stimulus reinforced with methadone as the unconditioned stimulus for at least 10 trials after which time saline was given instead of methadone. Group IV, was a drug control group receiving methadone injections at random without no association to the conditioned stimulus. The metabolism of serotonin was estimated by measuring the concentration of 5-hydroxyindoleacetic acid (HIAA), the main metabolite of serotonin, in the brainstem. The results showed a conditioned reflex increment in HVA in the striatum tissues to a conditioned stimulus previously reinforced with methadone in trained animals whereas no conditioned reflex changes in the concentration of HIAA were observed in the brainstem of these trained rats. These results suggest that methadone conditioning of striatal HVA was not accompanied by a conditioned reflex change in brainstem HIAA. It is postulated that the conditioning of dopamine metabolism to methadone as an unconditioned stimulus seems to be specific to the dopaminergic system and that brainstem serotonin metabolism was not conditioned.

1433 EFFECTS OF DELETION OF CEREBELLAR GRANULE CELLS ON THE REGIONAL CONTENT, SYNAPTOSOMAL LEVELS, AND HIGH AFFINITY UPTAKE OF GLUTAMATE, ASPARTATE, AND GABA. Michael A. Rea*, Brooks H. Rohde*, Jay R. Simon and William J. McBride. Departments of Psychiatry, Biochemistry and Pharmacology and Institute of Psychiatric Research, Indiana University School of Medicine, Indianapolis, IN 46202.

Exposure of the cerebella of rats to focal low-level x-irradiation treatment at different days following birth can prevent the acquisition of late-forming granule cells (Altman, J., J. Comp. Neurol. 165: 49, 1975). The levels of glutamate (Glu), aspartate (Asp) and GABA were determined in the cortex (where the granule cell bodies and terminals are located), white matter and deep nuclei of the cerebella of control rats and of rats exposed to x-irradiation treatment from day 8 to 15 following birth. Rats were killed at 60 days of age. In the control group, the level of Glu in the cortex was almost twice the values found in the white matter and deep nuclei. Treatment with x-irradiation caused a significant ($P<0.001$) 28% decrease in the level of Glu in the cortex without altering its levels in the other two regions. The levels of Asp did not change in any of the three regions with x-irradiation. Treatment with x-irradiation did not alter the content of GABA in the deep nuclei but it did cause a significant ($P<0.05$) increase in the levels of GABA in the cortex and white matter of approximately 60%. The levels of Glu, Asp and GABA were also determined in a crude synaptosomal fraction (P_2) isolated from the cerebella of adult control animals and rats which had been exposed to x-irradiation treatment on days 12 to 15 following birth. The level of glutamate was significantly ($P<0.005$) reduced by 25% and the level of Asp was decreased ($P<0.02$) by 15% with x-irradiation. The level of GABA in the P_2 fraction was the same for both groups. The uptake of [^{3}H] Glu and [^{3}H]Asp at a concentration of 1 μM was approximately 20% lower in the P_2 fraction from the x-irradiated group than from the control animals whereas the uptake of [^{3}H]GABA was nearly the same in both groups. More detailed kinetic analysis of [^{3}H]Glu uptake revealed that the K_m value was not significantly changed but that the V_{max} value was significantly ($P<0.01$) lower (by 20%) for the x-irradiated animals than for the control group. The data are consistent with the idea that Glu levels are higher in granule cells than in other cells in the cerebellum and that Glu may serve as the excitatory neurotransmitter released from granule cells. Supported in part by Research Grant NS 13925 from the NINCDS .

1434 LOCALIZATION OF TWO GABANERGIC SYSTEMS IN MAMMALIAN RETINA. D. A. Redburn, C. Kyles*, T. Chantenez* and J. Ferkany*. Dept. Neurobiol. & Anat., U. Tex. Med. Sch., Houston, TX 70025.

GABAnergic systems have been identified within two subcellular fractions of rabbit retina. The first is a P_2 synaptosomal fraction containing conventional sized synaptosomes presumably derived from elements of the inner plexiform layer. This fraction demonstrated high affinity uptake and Ca^{++} dependent, K^+ stimulated release of GABA; and the presence of GABA receptors assayed by ^{3}H-GABA binding. The second fraction is a P_1 synaptosomal fraction which contains synaptosomes from photoreceptor terminals. It also demonstrated a high affinity uptake system with a K_m equal to that observed in the P_2 fraction but with a much lower V_{max}. In addition, the P_1 fraction released much less GABA when stimulated by K^+ and Ca^{++}. However, the GABA system in P_1 was stimulated by ACh. Both uptake and release of GABA was stimulated by ACh in P_1; no stimulation by ACh was observed in the P_2 fraction.

In bovine retina, a different distribution was observed, with a much more pronounced GABA system present in bovine P_1 as compared to rabbit P_1. These data are consistant with the suggestion that GABA is a neurotransmitter within both plexiform layers of the retina. Based on the subcellular distribution and species differences reported here and on previously published autoradiography analyses, the GABAnergic system in the inner plexiform layer may be associated with amacrine cells; in the outer plexiform layer it may be associated with horizontal cells which contact cones. In addition these GABAnergic horizontal cells may receive cholinergic input.

1435 SEROTONINERGIC INNERVATION OF RAT AND BOVINE PARENCHYMAL BRAIN BLOOD VESSELS: BIOCHEMICAL AND PHARMACOLOGICAL STUDIES. John F. Reinhard, Jr., Michael A. Moskowitz, Sherman R. Elspas*, and James E. Liebmann.* Laboratory of Neural and Endocrine Regulation, Dept of Nutrition & Food Science, M.I.T., Cambridge, Mass. 02139.

The neurotransmitter serotonin (5-HT) is a potent vasopressor substance whose presence within nerve terminals of brain intraparenchymal blood vessels has been recently suggested by autoradiographic and histofluorescent studies. Serotoninergic nerve terminals, in conjunction with noradrenergic and perhaps other neurons, may participate in the regulation of cerebral blood flow. Present studies provide biochemical evidence that 5-HT is present in nerve endings and not simply within blood of the vessel lumen. Microvessels were isolated from the brains of 450 gm male Sprague Dawley rats by sucrose density centrifugation and microsieving, after meninges and choroid plexi were removed. Blood vessels were examined histologically with H & E and stains for elastin and found not to contain glia, neurons, and myelin. 5-HT was measured by a radioenzymatic assay which converts 5-HT to tritiated melatonin. Tritiated compounds were then resolved by multiply developed unidimensional thin-layer chromatography. Uptake into nerve terminals was measured by a method previously described (J.P.E.T. 181:36, 1972.)

Microvessels were found to contain 15 pmoles of 5-HT per mg protein. The administration of p-chlorophenylalanine (300 mg/kg, I.P.), or p-chloroamphetamine (10 mg/kg, I.P.) 24 hours prior to decapitation reduced the levels of 5-HT in microvessels by 52% and 47% respectively. Levels of 5-HT in cerebral cortex were reduced by 87% in these animals, whereas trunk blood showed no change. Administration of the monoamine oxidase inhibitor, pargyline (75 mg/kg, I.P.) elevated microvessel 5-HT levels to 168% of controls. Saline perfusions of rat brain vessels did not alter microvessel 5-HT levels. Picomole quantities of 5-HT were also measured in microvessels isolated from bovine cerebral cortex: these vessels appear to possess an uptake mechanism for 3H-5HT which can be blocked by the specific inhibitor, fluoxetine, in vitro.

We believe these data provide the first biochemical evidence for the innervation of brain microvessels by serotoninergic neurons.

1436 PROBENECID ENHANCES HALOPERIDOL-INDUCED HVA ACCUMULATION IN CSF AND PLASMA OF MACACCA MULATTA. R. H. Roth, N. G. Bacopoulos*, and G. Heninger (SPON: Jacqueline N. Crawley). Departments of Pharmacology and Psychiatry, Yale Univ. Sch. Med., New Haven, CT 06510

The metabolites of dopamine, 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) were measured in the plasma and CSF of adult male rhesus monkeys by a gas-chromatographic mass fragmentographic method. A 24 hour fast decreased the initially very high levels of DOPAC and HVA in the plasma to stable baseline values (DOPAC = 8.8 ± 3.8 ng/ml, $\bar{x}$ ± S.E.M., N = 5, and HVA = 8.9 ± 1.1 ng/ml) without affecting the concentration of HVA (15.6 ± 7.8 ng/ml) in lumbar CSF. DOPAC was usually not measurable in the CSF of control animals. All subsequent experiments were conducted on animals fasted for 24 hours. Haloperidol, 1.0 mg/kg, i.m., induced variable effects on plasma HVA, doubling the level of this metabolite in 2 out of 4 animals. It was noted that the animals showing large increases in plasma HVA after haloperidol displayed the largest increases in CSF HVA as well.

Probenecid, 25 mg/kg, i.p., produced rapid and prolonged increases in the plasma and CSF concentration of HVA in all animals tested. Haloperidol 1.0 mg/kg, i.m., significantly enhanced the probenecid-induced accumulation of HVA both in plasma and CSF. A significant correlation was observed between plasma and CSF concentrations of HVA within animals, and across the entire group when data from all animals were pooled. The above drug effects and the correlation between plasma and CSF level of HVA did not apply to DOPAC. These results are consistent with the possibility that probenecid, 25 mg/kg, blocked the renal transport of HVA, as evidenced by the accumulation of HVA in the plasma, and only partially blocked HVA egress from the CNS as evidenced by the further increases in plasma HVA in probenecid treated animals induced by haloperidol administration. Application of the above procedure to human patients might expand the usefulness of currently used methods to assess the metabolic state of central dopamine neurons. (Supported in part by USPHS Grant MH-14092 and by postdoctoral fellowship USPHS 1 F32-MH-17146-02 to N.G.B.)

1437 CLASSICAL CONDITIONING USING DRUGS AFFECTING DOPAMINE TURNOVER--BIOCHEMICAL EVIDENCE OF TURNOVER CHANGES ASSOCIATED WITH CONDITIONED STEREOTYPY AND HYPERACTIVITY. Stanley R. Schiff*, Wagner H. Bridger, and Nansie S. Sharpless. Albert Einstein College of Medicine, Departments of Neuroscience and Psychiatry, Bronx, New York, 10461.

We have previously demonstrated that d-amphetamine (amp) induced stereotyped behavior and hyperactivity can be classically conditioned while the similar behaviors induced by apomorphine may not. The conditioned response (CR) to signals (CS) previously associated with amp administration was blocked by a low dose of haloperidol (hal, 0.2 mg/kg)[Fed. Proc. 34(3):860, 1978]. Furthermore, preliminary studies using hal itself as the unconditioned stimulus (UCS) in our conditioning paradigm have demonstrated a CR opposite in direction to the unconditioned behavior (UCR) observed following hal administration. The CR to the CS previously associated with hal injection includes increased sniffing and increased activity measures. Together, these observations suggested that some mechanism of dopamine (DA) release from terminals could be more easily conditioned than direct receptor stimulation or blockade. To determine whether an increased DA turnover was associated with the CR, we measured homovanillic acid (HVA) concentrations in the striatal (caudate) and mesolimbic (nucleus accumbens plus olfactory tubercle) regions of conditioned and control rats. Male hooded rats (N=16) were submitted to 10 daily conditioning trials with amp (2.6 mg free base /kg, i.p.) along with a CS (tone-1 min): then a placebo (saline, i.p.) was paired with the CS. Significant behavioral conditioning was seen in these rats as compared to controls throughout the 30 min interval following the CS - placebo pairing. Control rats (N=16) were pseudo-conditioned by injecting saline with the CS and amp (2.6 mg/kg) after return to the home cage following behavioral testing. Both conditioned and pseudo-conditioned rats were killed by decapitation 30 min after CS-placebo pairing. Caudates from 2-3 rats and mesolimbic areas from 4 rats were pooled and homogenized in 0.1N $HClO_4$. HVA was isolated on small columns of Sephadex G-10 and measured fluorometrically.

In the mesolimbic area, mean (± SE) HVA concentration was significantly higher ($p<0.01$) in the conditioned rats (495 ± 17 ng/gm) than in the pseudo-conditioned rats (421 ± 14) while, in the caudate, the difference was not significant (conditioned: 896 ± 68; pseudo-conditioned: 810 ± 38). The results support the hypothesis that the CR induced by the CS previously paired with amp administration is mediated by increased DA release in the mesolimbic region, the area believed to be most important in the mediation of those behaviors that we have been able to condition.

1438 EFFECT OF OPERANT BEHAVIOR ON THE REGIONAL SYNTHESIS OF ^{3}H-CATECHOLAMINES FROM ^{3}H-TYROSINE IN THE RAT BRAIN. L.S. Seiden and T.G. Heffner*, U. of Chicago, Chicago, IL 60637.

The relative rates of synthesis of norepinephrine (NE) and dopamine (DA) from tyrosine (TYR) in brain regions were compared in rats lever pressing for water and in non-performing control rats. A 10 ul solution of artificial cerebrospinal fluid containing 50 uCi of l-2,6-^{3}H-TYR(42.3 Ci/mmol) was injected into a lateral cerebral ventricle of unanesthetized rats through a chronically-implanted cannula. Rats were killed 5-20 min later, brains were dissected and brain regions analyzed for ^{3}H-NE, ^{3}H-DA and ^{3}H-TYR by alumina and dowex chromatography. Endogenous levels of catecholamines (CA) were determined by radioenzymatic assay while endogenous levels of TYR were determined fluorometrically. The ratio: (nCi ^{3}H-CA)/(nCi ^{3}H-TYR/nmol TYR) was used as an index of conversion of ^{3}H-TYR to ^{3}H-CA and was assumed to reflect the relative rate of CA synthesis from TYR. The conversion index for NE and DA increased linearly in all brain regions between 5 and 15 min after the injection of ^{3}H-TYR. Rats previously trained to perform on a fixed ratio of 5 operant schedule were injected with ^{3}H-TYR and placed in operant test chambers. Control rats not previously exposed to the operant schedule were returned to the home cages after ^{3}H-TYR. After a 1-5 min delay, rats exposed to the operant schedule began lever pressing and continued to do so for the rest of the session. In an initial experiment, all rats were killed 15 min after ^{3}H-TYR. The conversion index for DA in operant rats was 62% higher than in controls in the corpus striatum but unchanged in the mesolimbic area. The conversion index for NE in operant rats was 43% higher than in controls in the hypothalamus, but was unchanged in telencephalon, mesolimbic area and brainstem-mesencephalon. In a second experiment, groups of operant and control rats were killed 5 or 15 min after ^{3}H-TYR in order to better estimate the change in the conversion index with time. In this experiment, performing rats again displayed an increase in the apparent synthesis rate of ^{3}H-DA in the corpus striatum and ^{3}H-NE in the hypothalamus while no changes in the synthesis of either CA were found in other brain regions. These findings suggest that the performance of operant behavior is associated with an increased synthesis of CA from TYR in specific central CA projections. 1439 PURIFICATION OF L-GLUTAMATE DECARBOXYLASE FROM CATFISH BRAIN. Y. Y. Thomas Su*, J.-Y. Wu and Dominic M. K. Lam* (Spon: E. Peck) Cullen Eye Institute and Department of Cell Biology, Baylor College of Medicine, Houston, Texas 77030

L-Glutamate decarboxylase (GAD) has been purified from mouse brains and its properties have been extensively studied (J.-Y. Wu, in "GABA in Nervous System Function", E. Roberts et al. , eds., Raven Press, N.Y., 1976). Unfortunately the antibody against this enzyme does not cross-react with the GAD from neural tissues of fishes. We have therefore begun to purify GAD from catfish brains in an attempt to obtain specific antibodies with a view to localizing GAD in GABAnergic neurons in teleost retinas. GAD was extracted from catfish brains by homogenizing the tissue in water containing 0.1 mM pyridoxal phosphate, 1 mM EDTA, 1 mM AET and 1 mM reduced glutathione, pH 7.2. About 70% of GAD activity was recovered in the supernatent of 100,000 xg. The enzyme was purified to electrophoretic homogeneity by a combination of ammonium sulfate fractionation, gel filtration, calcium phosphate gel and preparative acrylamide gel electrophoresis. The purified protein migrated as a single band on several different polyacrylamide gel systems. Furthermore, the protein band contained all the GAD activity. The enzyme was therefore used as an antigen to produce a specific antibody which will be used for immunochemical and -histochemical studies of the GABA system in teleost retinas.

1440 THE RELATIONSHIP BETWEEN CALCIUM-DEPENDENT AND INDEPENDENT RELEASE OF [^{3}H]GABA FROM CORTICAL SLICES EVOKED BY POTASSIUM, VERATRIDINE AND ELECTRICAL STIMULATION. J.C. Szerb, Dept. Physiology & Biophysics, Dalhousie Univ., Halifax, N.S., Canada B3H 4H7.

Although the transmitter role of GABA in mammalian CNS is supported by extensive evidence, its release from brain slices is not consistently dependent on extracellular Ca^{2+}, raising the possibility that Ca^{2+}-dependent and independent release may occur from two distinct pools. To study this possibility the time course of the evoked release of [^{3}H]GABA was followed during 48 min superfusion with either 50 mM K^+ or 50 µM veratridine in slices which had been incubated for 15 min with 1 µM [^{3}H]GABA and 10 µM aminooxyacetic acid. The latter was also present in the superfusion medium. Both 50 mM K^+ and veratridine caused an initial fast efflux which declined in spite of continuous depolarization and both released about 1.6 nmol.g^{-1} in 48 min. However, while release by K^+ was decreased by 66% when Ca^{2+} was omitted, the release by veratridine was unchanged in the absence of Ca^{2+}. The release caused by both K^+ and veratridine was reduced by about 80% following a 48 min superfusion with 50 mM K^+ but release by both was preserved better if, during the first superfusion with 50 mM K^+, Ca^{2+} was omitted. Omission of Ca^{2+} following the initial superfusion with 50 mM K^+ and Ca^{2+}, reduced further the second release by K^+ but caused a 2.5 fold increase in release induced by veratridine as compared to release in the presence of Ca^{2+}. Release induced by 24 min electrical stimulation (64 Hz, alternating polarity) was delayed by the omission of Ca^{2+}. It was decreased by 80% after 48 minutes superfusion with 50 mM K^+ but this decrease was less if Ca^{2+} was omitted after the superfusion with 50 mM K^+. Results suggest that omission of Ca^{2+} affects little net [^{3}H]GABA release caused by depolarization due to an influx of Na^+ (veratridine or electrical stimulation) because it has two effects: it depresses release from the Ca^{2+}-dependent pool and enhances release from the Ca^{2+}-independent pool, probably by increasing the influx of Na^+. Depolarization by K^+ which causes only a limited influx of Na^+, activates less release from Ca^{2+}-independent pool even in the absence of Ca^{2+} hence the release appears to be largely Ca^{2+}-dependent.

1441 PITFALLS IN THE USE OF THE AUTOMATED AMINO ACID ANALYZER FOR THE QUANTITATION OF SOME ACIDIC AMINO ACIDS IN BRAIN TISSUES. Ken H. Tachiki*, Roger A. Baldwin* and Claude F. Baxter. Neurochemistry Laboratories, V.A. Hospital, Sepulveda, CA 91343, and Dept. of Psychiatry, UCLA School of Medicine, Los Angeles, CA 90024.

The quantitation of amino acids in biological extracts by the use of an automated amino acid analyzer is predicated upon a constancy and uniqueness in retention time of the individual amino acids. Using a Durrum microbore column packed with Durrum DC-4A resin and the Durrum Pico Buffer IV elution system, we found that in amphibian brain tissue, the taurine content appeared to be 1.7 µmoles/gram of tissue. However, as with other automatic amino acid analyzers, the elution peak for taurine was not totally symmetrical. Upon acid hydrolysis of the amphibian brain extract, close to 90% of the "taurine" peak disappeared whereas an authentic sample of taurine was not affected by such treatment. This indicated that extracts of amphibian brain contain two or more compounds with retention times on the column similar to authentic taurine. The unknown compound in the taurine peak was isolated from protein-free extracts of amphibian brain using short columns of Bio-Rad AG50W-X8 resin, AG1-X8 resin and paper chromatographic techniques. In the last system, a butanol/acetic acid/water (12:3:5,v/v/v) solvent separated the unknown compound from taurine. Upon hydrolysis, large amounts of ethanolamine and phosphate were detected. However, the unknown was not phosphoethanolamine. Additional tests have identified the unknown as glycerophosphorylethanolamine. Several investigators have reported a loss of "taurine" upon hydrolysis of mammalian brain preparations (Mussini,E. and Marcucci,F., in Amino Acid Pools, ed. by J.T. Holden, Elsevier Publ. Co., New York, p.486-492, 1962; Lähdesmäki,P., Karppinen,A., Saarni,H. and Winter,R., Brain Res. 138:295-308, 1977). All of these findings reemphasize the tenuous nature of conclusions reached about taurine levels in brain tissues when such conclusions are based exclusively upon the identification of the amino acid by the retention times from an ion-exchange column. An acid labile compound in brain tissues which co-chromatographs with aspartate has also been detected.

Taurine levels in brain tissues have been linked to the containment of convulsive disorders. The function of glycerophosphorylethanolamine in the central nervous system is not well established. Experimental and clinical data for taurine levels often have been determined with the help of an automated amino acid analyzer. Some of this data in the literature deserves to be re-evaluated.

1442 CAGE CONVULSANT DRUGS INHIBIT PICROTOXININ BINDING TO MAMMALIAN BRAIN MEMBRANES. Maharaj K. Ticku and Richard W. Olsen, Depart. of Biochemistry, Univ. of California, Riverside, CA 92521

Bicyclophosphates [P-$(OCH_2)_3$-C-R], bicyclic orthocarboxylic acid esters [R'$(OCH_2)_3$-C-R], silatranes, and tetramine all have a symmetrical caged structure and produce tonic-clonic convulsions and death in mice in a manner similar to picrotoxin (Casida et al., Tox. App. Pharm. 36, 261, 1976). Bowery et al. (Nature 261, 601, 1976) have reported that bicyclophosphates antagonized GABA-induced depolarization (reversed by barbiturates) in a superior cervical ganglion preparation. We have examined the interaction of these 'cage' compounds with [^{3}H]-α dihydropicrotoxinin (DHP) binding sites in rat brain, sites previously shown (Ticku et al., Mol. Pharmacol. in press, 1978) to be related to GABA receptor-ionophores but distinct from the GABA recognition site. Bicyclophosphate esters (up to 100 µM) did not inhibit GABA binding (Na^+-independent) to its receptor sites; however, they did inhibit DHP binding with a potency profile: R = t-C_4H_9 > i-C_3H_7 = C_2H_5 >> CH_3. This agrees with their order of biological activity. t-Butyl bicyclophosphate, the most potent compound of the series, inhibited DHP binding with IC_{50} = 2 ± 1 µM. Orthocarboxylic acid esters [R'$(OCH_2)_3$-C-t-C_4H_9] also inhibited DHP binding in the micromolar concentration range. Compounds with a smaller R' substituent (e.g. -H) were more potent than those with a larger R' substituent (e.g. -C_6H_5). DHP binding was also inhibited by the convulsants tetramine (IC_{50} = 4 ± 2 µM) and p-chlorophenyl silatrane (IC_{50} = 9 ± 3 µM). Our results suggest that 'cage' compounds may produce convulsions by acting via the picrotoxin-sensitive sites at the GABA receptor-ionophores. DHP binding sites are also inhibited by convulsant and depressant barbiturates (Ticku and Olsen, Fed. Proc. 37, 907, 1978), consistent with a common site of action in the CNS for these drugs in modulating inhibitory synaptic transmission.

1443 THE RELATIONSHIP BETWEEN CHOLINE TRANSPORT AND ACETYLCHOLINE RELEASE. Ken Vaca* (SPON: E. Shaskan). Physiology Section, Biological Sciences Group, Univ. of Connecticut, Storrs, CT 06268

The chick ciliary nerve-iris preparation was used to investigate the relationship between sodium-dependent, high affinity choline (Ch) transport and acetylcholine (ACh) release. Depolarization with high potassium was approximately an order of magnitude more effective than electrical stimulation (30 Hz) in releasing newly synthesized ^{3}H-ACh. A 10 min period of depolarization reduced endogenous ACh levels more than 40%. Upon repolarization in the presence of physiological concentrations of Ch (5 mM), the endogenous levels of ACh largely recover to control levels within 10 min. This recovery is dependent on Ch transport and is prevented by hemicholinium-3 or replacement of Na^{+} by Li^{+}. Depolarization in Ca^{++}-free, 10 mM Mg^{++} medium fails to significantly reduce endogenous ACh levels. The conditioning depolarization (in the presence of Ca^{++}) increased the V_{max} for Ch transport approximately 2-fold and ACh synthesis 5-fold after return to normal medium. A conditioning depolarization prior to preloading with ^{3}H-Ch increased the integral of the initial velocity of ^{3}H-ACh release, evaluated over a 2 min interval, several-fold relative to control. After a conditioning depolarization, extended preloading with ^{3}H-Ch resulted in an increase in the initial release of ^{3}H-ACh which maximized at 5-10 min preloading time. Although longer periods of preloading increased the amount of radiolabelled Ch taken up by the tissue, it did not increase the initial rate of release. However, more prolonged preloading with ^{3}H-Ch decreased the rate of decline of ^{3}H-ACh release with successive depolarizations. A comparison of the rate of release of ^{3}H-ACh with the rate of decline of endogenous ACh suggests that newly synthesized (radiolabelled) ACh is preferentially released relative to the older endogenous stores. It is hypothesized that the readily releasable pool of ACh consists of a saturable compartment, which is primarily dependent on Ch transport for its supply. Supported by NIH-NS10338 and the Univ. of Conn. Research Foundation.

1444 DESYNCHRONIZED SLEEP ENHANCEMENT BY BOTH CHOLINERGIC AND ANTIAMINERGIC AGENTS AT THE SAME PONTINE BRAIN STEM SITES. Ennio Vivaldi*, Robert W. McCarley, and J. Allan Hobson. Lab. of Neurophysiology, Harvard Med. School, Boston, Ma. 02115.

We have proposed that desynchronized sleep (D) periodicity results from the interaction between executive cells located in the pontine reticular formation (FTG) and a group of cells in the locus coeruleus (LC). FTG cells are postulated to be cholinergic, self-excitatory and excitatory to LC cells; LC cells are postulated to be noradrenergic, self-inhibitory and inhibitory to FTG cells. From this model one would expect that the administration to a group of FTG cells of either a cholinomimetic agent or an adrenergic blocker would increase their activity, and an increase of D would be observed. Extensive microinjection studies have supported the cholinergic hypothesis but direct injection of adrenergic blockers has not previously been attempted.

Following up on previously reported observations that lowering the volume of vehicle enhanced the cholinergic evocation of D, we have studied the effects of simple diffusion. The mere placement of a 30 ga. cannula stereotaxically aimed at the FTG and containing a 4 g/l solution of carbachol increased D to 63.3% in two hours as compared to 14.3% with a saline containing cannula. Effects were still observable 6 hours later.

Two cats were used to test the effect of propranolol diffusion: at the same sites where carbachol had increased D to 3.53 times control values the placement of a cannula containing 1 g/l of propranolol increased D sleep 2.12 times. The dose-response curve from a 3 dose counter-balanced propranolol microinjection study in two cats showed a graded increase in D from low (0.2µg) through medium (0.6µg) to high (2.0µg) dose levels. The respective D percents were 0.73, 3.04, and 4.05 times saline control values.

The results suggest that D sleep phenomena may be enhanced by either cholinergic stimulation or adrenergic blockade of the pontine reticular formation.

1445 REGIONAL DISTRIBUTION OF ALPHABUNGAROTOXIN RECEPTORS IN NORMAL AND PATHOLOGICAL HUMAN BRAIN. Bruce T. Volpe‡ Andrew Francis‡ Michael S. Gazzaniga, and Nisson Schechter‡(SPON: Fred Plum). Dept. of Neurology, Cornell Medical College, N.Y., N.Y. 10021, Dept. of Psychiatry, S.U.N.Y., Stony Brook, N.Y. 11794

Clinical and pharmacological studies have demonstrated a relation between central cholinergic function and memory processes. Other reports have shown loss of CAT activity in dementia,but no loss of muscarinic receptor activity. Conservation of nicotinic cholinergic receptor also would give further impetus to clinical trials of centrally acting cholinergic drugs. However,the distribution of nicotinic receptors in normal or pathological human brain tissue has not been studied. We have used regional differential binding of radio labelled alphabungarotoxin in human post-mortem brain tissue to identify nicotinic cholinergic receptors. Post-mortem tissue pieces were homogenized (5%w/v) in buffer (10mM sodium phosphate, 0.4mM phenylmethy sulfonyl fluoride, 0.013 mM dimethyl formamide,1mM sodium EDTA,0.02% sodium azide) at pH 7.2 using a teflon glass homogenizer. Aliquots of homogenate were incubated in the presence of excess ^{125}I-alphabungarotoxin (specific activity 10^{6} ci/mole) and counted by liquid scintillation after a centrifuge assay. All counts were corrected for non-specific binding by subtraction of controls obtained in the presence of a several hundred fold excess of native toxin. The demonstrated non-uniform binding of alphabungarotoxin seems unaffected by agonal state. To date, results in the normal human post-mortem brain are similar to other mammals, and reveal the highest activity in the mammillary bodies,hippocampus,amygdala, colliculi, and certain cortical regions; and the lowest levels in the cerebellum,pons,and caudate. Currently, parallel analyses of CAT activity and morphologic studies are in progress.

1446 GLUTAMATE AND EXCITATORY SYNAPTIC TRANSMISSION ONTO GIANT RETICULOSPINAL NEURONS OF THE LAMPREY. Warren O. Wickelgren and Gary Matthews. Dept. Physiol., Univ. of Colo. Med. School, Denver, CO 80262.

Intracellular recordings were made from the cell bodies and axons of giant reticulospinal neurons (Müller cells) in the isolated brain and spinal cord of adult lamprey. Glutamate added to the saline surrounding Müller axons produced a reversible, dose-dependent depolarization of up to 20 mV. However, there was no apparent drug-induced conductance change in the axon when potential-dependent conductance changes were blocked with tetrodotoxin and 4-aminopyridine. This, plus other evidence, including the lack of an axon response to iontophoretically-applied glutamate, suggests that the depolarization to bath application was an indirect effect of the spread of current from other spinal cells depolarized by the glutamate and electrically coupled to Müller axons. On the other hand, glutamate did produce a conductance change when iontophoretically-applied to the Müller cell bodies in the brain. The reversal potential of the glutamate depolarization was compared to that of the excitatory postsynaptic potential (epsp) evoked by electrical stimulation of the contralateral vestibular nerve. In undamaged cells (resting potentials about -70 mV) it was not possible to pass enough current to reverse the epsp or glutamate response, and their reversal potentials were estimated by extrapolation. The values obtained in one such experiment were -28 mV (epsp) & -33 mV (glutamate response). The errors involved in extrapolation were avoided by actually reversing the epsp and glutamate response in cells which had been damaged (resting potentials between -12 & -55 mV) by impalement with a low-resistance micropipette. In these experiments the reversal potentials for the epsp and the glutamate response were essentially identical, the average difference in 12 determinations being 0.54 mV. The absolute value of the epsp-glutamate reversal potential varied from -16 to -33 mV, the more negative values occurring in cells with higher resting potentials. Lowering the extracellular Na concentration to 1/10 normal shifted the glutamate reversal potential by about -14 mV, indicating that an increased Na conductance was involved in the depolarization. Injection of Cl intracellularly had no effect on either the glutamate or epsp reversal potentials. Since the epsp-drug reversal potential was negative to the Na equilibrium potential and Cl was not involved in the response, it appears that there is also an increase in K conductance, although this was not investigated directly. We conclude that glutamate is a candidate for the excitatory transmitter onto Müller cells. (Supported by NIH grants NS 09661 and 09660.)

1447 MODIFICATION OF ACETYLCHOLINE TURNOVER RATE IN SELECTED BRAIN REGIONS: EFFECT OF PARASYMPATHOLYTICS. P.L. Wood* and D.L.Cheney Lab. Preclin. Pharmacol., NIMH, Saint Elizabeths Hosp.,Washington, D.C. 20032

Previous work from this laboratory has examined the actions of benztropine and trihexyphenidyl on cholinergic function in the striatum (Racagni et al., JPET 196: 323, 1976). We now report the effects of these drugs on the turnover rate of acetylcholine in brain areas lacking a dopaminergic/cholinergic interaction. To estimate the turnover rate of acetylcholine, rats were infused with deuterated phosphorylcholine and sacrificed by microwave irradiation. The endogenous and deuterated acetylcholine and choline of specific brain areas were subsequently determined by gas chromatography-mass spectrometry.

Systemic administration of benztropine (20 mg/kg i.p.; 30 min) and trihexyphenidyl (20 mg/kg i.p.; 30 min) produce two types of effects on cholinergic mechanisms in rat brain areas. In hippocampus and thalamus there is an increase in the fractional rate constant for the efflux of acetylcholine, no change in acetylcholine concentration and consequently an increase of the turnover rate of acetylcholine. In frontal cortex, parietal cortex and striatum a decrease in the concentration of acetylcholine compensates for the increase in fractional rate constant for acetylcholine efflux. Thus, the turnover rate of acetylcholine remains unchanged. Disruption of the septal-hippocampal pathway by cutting the fimbria/fornix prevents the alterations of cholinergic parameters elicited by benztropine in either cortex or hippocampus. Moreover, intraseptal injection of phenoxybenzamine (15 nmol; 36 min) does not alter the effects of systemic benztropine. These results suggest that benztropine does not alter cholinergic mechanisms in cortex or hippocampus via an action on presynaptic cholinergic receptors but may produce its effects through a feedback control via the septum.

1448 PURIFICATION AND IMMUNOCHEMICAL STUDIES OF CYSTEIC ACID DECARBOXYLASE AND GLUTAMATE DECARBOXYLASE FROM BOVINE BRAIN. Jang-Yen Wu, M. S. Chen* and W. M. Huang* Department of Cell Biology, Baylor College of Medicine, Houston, Texas 77030

Cysteic acid decarboxylase (CAD) and glutamate decarboxylase (GAD) which catalyze the decarboxylation of cysteic acid and glutamic acid to form taurine and GABA, respectively, have been purified to homogeneity from bovine brain. The purification procedures involved the initial extraction of CAD and GAD from gray matter of bovine brain, followed by ammonium sulfate fractionation, column chromatographies on gel filtration, calcium phosphate gel and DEAE cellulose and finally by preparative polyacrylamide gel electrophoresis. The purified enzyme preparations migrated as a single protein band on 7% polyacrylamide gel electrophoresis and was coincident with the enzyme activities. Previously, we have shown that in partially purified preparations, there were two forms of CAD, one of them, CAD I, contained only CAD activity and was believed to be the synthetic enzyme for taurine and the other one, CAD II, which possessed both CAD and GAD activities and was believed to be responsible for GABA synthesis (Trans. Amer. Soc. Neurochem. 9, 53 (1978)). The same results were also obtained with purified CAD I and CAD II preparations. Using rabbits, we have obtained an antibody specific to CAD II following five biweekly subscapular injections of 10 μg of the purified enzyme in complete Freund's adjuvant. The antisera thus obtained show a single precipitin band on Ouchterlony double diffusion tests against both crude CAD (1% pure) and the purified protein. Rabbits have also been immunized with purified CAD I preparation and the serum will be tested periodically for the production of antibody to CAD I. Using these antibodies, studies on the species and tissue specificity and immunohistochemical localization of CAD and GAD are in progress.

Supported in part by Grant NS 13224-02 from NIH and Grant from Huntington's Chorea Foundation in memory of Mrs. Ruth Berman.

PAIN

1449 Analgesic effect of glutamate injected into the periaqueductal gray (PAG) of the rat: Evidence for excitatory interaction between the PAG and nucleus raphe magnus (nrm).
Michael M. Behbehani and Howard L. Fields. Dept. of Physiology U. of cincinnati, cincinnati ohio and Dept. of Neurology U. of Cal. at San Francisco.

Both the electrical stimulation and injection of morphine into the PAG produces analgesia. It is believed that this analgesic effect is mediated by activating a descending system that involves the NRM. In studies reported here, rats were anesthetized with urethane and after tracheostomy and cannulation of the femoral vein, were stationed in a stereotaxic instrument. Using a microsyringe fitted with a 34 gauge needle, 0.5 µl of monosodium glutamate (50 mM) was injected into the PAG. The analgesic effect of glutamate was measured electromyographically by recording from the flexor muscle of the rigt hind leg and by application of noxious heat to the palm of that foot. Also the the effect of glutamate on the activity of the cells in the NRM was measured using single unit recording techniques. To test the specificity of the effect of glutamate, it was injected 2mm above, in the dorsal part, in the ventral part and 2mm below the PAG. It was shown that only when glutamate was injected into the PAG it caused analgesia and that this analgesic effect was correlated with an increase in the firing rate of the majority of the cells in the NRM. This analgesic effect could be abolished by either lesioning of the NRM and a small area in the reticular formation surrounding this nucleus or by naloxone 20 minutes following its i.v. injection. However, injection of naloxone directly into the NRM had no effect on the analgesia produced by glutamate. It is concluded that there is an excitatory connection between the PAG and the NRM and that activation of this system produces analgesia. Furtheremore it is concluded that this analgesic effect is mediated by a morphine like compound acting at sites other than the nucleus raphe magnus.

1450 ELECTRICAL STIMULATION OF THE MIDBRAIN ANALGESIC SYSTEM: EFFECT ON TRIGEMINAL NEURONS. M.A. Biedenbach. Dept. Physiol., U.T. Health Science Center, San Antonio, TX 78284.

The aim of this study is to identify trigeminal neurons that can be excited by electrical stimulation of the lingual nerve and/or the tooth pulp, and to establish the effect on these neurons of stimulating the midbrain analgesic system. In cats anesthetized with chloralose and paralyzed with Flaxedil, unit potentials were recorded in the part of the trigeminal nucleus that extends from 5 mm rostral to 3 mm caudal to the obex. Bipolar stimulating electrodes were placed on the exposed lingual nerve, into two canine tooth pulps and in the midbrain periaqueductal gray (PAG) at a site from which stimulation inhibited the jaw-opening reflex. PAG-effects were established by conditioning-testing stimulation where a stimulus train to PAG (200 Hz and 200 msec duration) preceded the test shock. Three types of test shocks were used, lingual nerve and tooth pulp stimulation, and, if the neuron was mechanosensitive, nonnoxious and noxious "pinches" were applied to its receptive field. The major PAG-effect was to inhibit responses to the three kinds of stimuli either completely or partially (decreased number of spikes per response). Inhibitory effects after a single PAG-stimulus train lasted in various neurons approximately from 0.1 to 1 second. Nearly all tooth pulp-evoked responses were completely or partially inhibited, only a few were not affected. PAG-effects on lingual nerve responses were less marked, most being only partially inhibited and a somewhat greater fraction was uninfluenced. Partial inhibition of tooth pulp or lingual nerve responses usually blocked the later spikes in a given response. Both lingual nerve and tooth pulp-evoked responses exhibited a considerable range of first-spike latencies. Neurons influenced by PAG spanned the whole latency range but those not influenced exhibited mostly shorter latencies. Among the tested responses to "pinches", a considerable portion was not affected by PAG, but in those which were, responses to both nonnoxious and noxious pinches were inhibited for similar periods. (Supported by Biomed. Res. Supp. Grant RR 05654.)

1451 DIFFERENTIAL ALTERATIONS FOLLOWING HYPOPHYSECTOMY IN ANALGESIA INDUCED BY MORPHINE AND DIFFERENT STRESSORS. Richard J. Bodnar, Murray Glusman, Alfred Mansour* and Dennis D. Kelly. New York State Psychiatric Institute and Columbia University, N.Y.,N.Y. 10032.

Pain threshold elevations in rats occur following acute exposure to such stressors as cold-water swims, inescapable foot shock, food deprivation, rotation and intraperitoneal injections of either hypertonic saline or 2-deoxy-D-glucose, an antimetabolic glucose analogue. The analgesia induced by cold-water swims or by inescapable foot shock is markedly attenuated in hypophysectomized animals, and is only minimally affected by opiate antagonists, which suggests that the analgesic effects of these particular stressors may be mediated by the pituitary and not by opiate-like neural systems. The present study examined the dose-dependent and time-dependent analgesic effects of insulin, 2-deoxy-D-glucose (2-DG) and morphine in three groups (n=6) of normal and three groups (n=6) of hypophysectomized rats. Tail-pinch thresholds were defined by the lowest pressure delivered at a linear increasing rate to a rat's tail which elicited a tail withdrawal response. Threshold determinations were made prior to, and then 30, 60, 120 and 180 min following all injections. Insulin (0, 1, 8, 16, 32, 64 U/kg, sc), 2-DG (0, 100, 200, 400, 600 mg/kg, ip) and morphine (0, 1, 2.5, 5, 10 mg/kg, sc) were administered to separate groups of normal and hypophysectomized animals; a minimum of 96 hrs elapsed between injections. Whereas insulin induced clear dose-dependent and time-dependent tail-pinch elevations in normal rats, the analgesia induced by insulin in hypophysectomized rats was greatly attenuated in terms of both analgesic magnitude and effective dose. By contrast, 2-DG induced greater analgesia in hypophysectomized rats than in normal rats. In addition, morphine-induced analgesia was not affected by hypophysectomy. Thus, insulin-induced analgesia, like that induced by cold-water swims and inescapable foot shock, seems to be dependent upon the integrity of the pituitary, while both 2-DG-induced and morphine-induced analgesia would seem to be mediated by different mechanisms. (Supported by NIH Grant #NS14449 and N.Y.S. Health Research Council Grants #365 and #922.)

1452 DISSOCIATION OF PAIN THRESHOLD AND FOOD INTAKE ALTERATIONS FOLLOWING CHRONIC 2-DEOXY-D-GLUCOSE ADMINISTRATION. Martin Brutus, Richard J. Bodnar and Dennis D. Kelly. New York State Psychiatric Institute and Columbia University, N.Y., N.Y. 10032.

Rats acutely exposed to 2-deoxy-D-glucose (2-DG), an antimetabolic glucose analogue, display dose-dependent and time-dependent elevations in both food intake and pain thresholds. The former seems likely to be mediated by acute cellular glucoprivation and the latter may represent another example of stress-induced analgesia. Since stress-induced analgesia shows adaptation with repeated exposure to the stressors, the present study examined whether chronic 2-DG administration would result in a diminution in either its analgesic or hyperphagic effects. Seven rats were trained on an operant psychophysical procedure in which pulsed foot shocks were presented on discrete trials for 10 sec unless the rat pressed a lever three times to abbreviate the shock train. Each liminal escape session consisted of 100 trials equally distributed over a range of five shock intensities in a randomized-blocks design. On alternate days, 60 minutes prior to liminal escape testing, each rat received in order: seven baseline placebo injections, eight 2-DG (600 mg/kg) injections and seven recovery placebo injections. Food intake was measured for six hours after each injection. The first three 2-DG injections induced profound elevations in liminal escape thresholds and in food intake. However, by the final three injections, 2-DG failed to alter liminal escape thresholds above baseline values, but it continued to induce significant increases in food intake. During recovery pain thresholds remained normal but food intake showed some increases, post-2-DG. Hence, these data demonstrate that the analgesic and hyperphagic properties of 2-DG are experimentally dissociable, and offer further evidence that 2-DG may increase pain thresholds via a stress-induced activation of pain-inhibitory systems. (Supported by NIH Grant #NS 14449 and N.Y.S. Health Research Council Grants #365 and #922.)

1453 LATERAL HYPOTHALAMIC MODULATION OF ESCAPE FROM STIMULATION OF NUCLEUS GIGANTOCELLULARIS IN THE RAT. Kenneth D. Carr* and Edgar E. Coons* (SPON: Samuel M. Feldman). Dept. of Psychology, New York University, New York, N.Y. 10003.

A double-pulse electrical stimulation technique was used to infer neurophysiological interaction between lateral hypothalamus (LH) and pain-associated nucleus gigantocellularis (NGC) of the medullary reticular formation.

Rats were trained to barpress for 3-second escape periods from stimulation of NGC. Trains of .1 msec pulses were delivered through monopolar electrodes. The interval between successive pulses to NGC was fixed at 40 msecs. Once stable escape-responding was established, a concurrent train of pulses was delivered to the ipsilateral LH so that each pulse to NGC was preceded by a pulse to LH. Although all trains were identical with regard to number and frequency of pulses to both sites, the interval by which the LH-pulse preceded the NGC-pulse was varied over trials and ranged from .1 msec to 20 msecs. The purpose of this parametric manipulation was to probe the excitability of the NGC-pain system as a function of time since stimulation of LH. The measure of NGC-pain system excitability was the rate of escape-responding.

When the intensity of LH-pulse trains was above stimulation-bound feeding threshold, escape-responding to concurrent stimulation of NGC was inhibited. Inhibition was greatest (rate of escape was least) at one short (.1 msec) and one long (10-15 msec) LH-NGC inter-pulse interval with less inhibition (high rates) being evidenced at intermediate intervals. Work done previously in our laboratory (Porrino, doctoral dissertation, N.Y.U., 1977) found there to be two separate peaks in the medial hypothalamic inhibition of LH reward. The similarity of the data profile in the present study suggests that here too there operates a biphasic inhibitory mechanism. As in the previous study, it may prove possible to demonstrate neurochemical and/or neuroanatomical dissociation of the two inhibitory peaks.

The modulation of NGC-escape behavior by LH may reflect an inhibition of the ascending aversion-message or competition for use of the final common behavioral pathway. (Supported by NIMH predoctoral fellowship #1 F31 MH07302-01)

1454 MIDBRAIN PROJECTIONS TO THE MEDULLARY RETICULAR FORMATION. J. M. Chung, L. H. Haber, R. F. Martin, and W. D. Willis. Marine Biomedical Inst. and Depts. of Anatomy and Physiology & Biophysics, U. Texas Med. Br., Galveston, TX 77550

Stimulation in the periaqueductal and periventricular gray inhibits reflex reactions to noxious stimulation in rats and cats and pain in humans. This "stimulus produced analgesia" (SPA) is thought to be mediated by descending pathways which relay in the lower brainstem. Part of the relay is probably in the nucleus raphe magnus (NRM). Since stimulation in both the NRM and in the nucleus reticularis gigantocellularis (NGc) can inhibit the activity of spinothalamic tract neurons, it is possible that the NGc may also contribute to SPA. To evaluate this further, we have mapped the cells in the midbrain which project to the NGc and adjacent reticular formation (RF).

Horseradish peroxidase (HRP) was injected into the medullary RF in 3 cats and 4 monkeys (Macaca fascicularis) anesthetized with sodium pentobarbital. A single 0.1-0.2 µl injection of 50% HRP was made in each animal through a glass micropipette. After 3 days, the animals were perfused with Ringers followed by 2.5% glutaraldehyde and 0.5% paraformaldehyde. After soaking in 30% sucrose, frozen sections of the brainstem were cut at 50 µm and reacted with o-dianisidine or tetramethylbenzidine.

The injection was centered over the NGc in 3 cats and 1 monkey. These animals had labelled cells bilaterally in the midbrain RF, periaqueductal gray, and the deeper layers of the superior colliculus. The RF and periaqueductal gray label was heaviest ipsilaterally and the superior colliculus label contralaterally. An injection ventromedial to the NGc in 1 monkey, with spread into the medial inferior olivary nucleus, labelled cells in the same regions and in the ipsilateral red nucleus. Two monkeys had injections centered laterally to the NGc. In an animal with a restricted injection, the labelled areas of the midbrain included the RF, periaqueductal gray, and mesencephalic nucleus of V, but not the superior colliculus. In a monkey with a diffuse injection, with spread to the auditory relay nuclei in the caudal pons, there was label in the inferior colliculus, the nuclei usually labelled from the NGc, and also the red nucleus and mesencephalic nucleus of V.

It is concluded that there are substantial projections to the medullary reticular formation from the midbrain RF and periaqueductal gray. These data are consistent with the hypothesis that stimulation within the periaqueductal and periventricular gray results in an "analgesia" due to activation of a number of pathways descending to the spinal cord from the lower brainstem.

1455 NARCOTIC ANALGESIA: CHANGES IN NEURAL ACTIVITY RECORDED FROM PERIAQUEDUCTAL GRAY MATTER OF RAT BRAIN. Hugh E. Criswell and Frederick B. Rogers*. Dept. Psychol., Williams College, Williamstown, MA 01267.

Multiple unit activity was recorded from the periaqueductal gray matter (PAG) and striatum (CPU) following systemic injections of morphine (20 mg/Kg) and following microinjection of 15 µg of morphine directly into the recording site via hollow electrodes. Animals which received microinjections of morphine were tested for analgesia 1 hour after the injection and were called analgesic if they did not vocalize or struggle following tissue distructive tail pinch. Animals which received systemic morphine were tested for analgesia using the same methodology following electrical stimulation through the recording electrodes. This testing was accomplished at least 48 hours after the last morphine injection. Analgesically active sites in the brain were defined as those where either electrical brain stimulation or microinjection of morphine produced analgesia. Systemic injections or morphine but not saline produced increased multiple unit activity at analgesically active sites within the PAG. No effect was observed at analgesically inactive sites within the PAG or the CPU. Morphine, but not saline microinjected into analgesically active sites within the PAG resulted in increased neural activity at the site of injection. There was no effect when morphine was microinjected into analgesically inactive sites within the PAG or CPU. The increased neural activity seen at analgesically active sites following morphine administration was partly but not completely antagonized by systemic Naloxone (2 mg/Kg). The similarity between systemic and central administration of morphine suggests that systemic morphine may produce analgesia by an action at analgesically active sites within the PAG and that the overall effect of morphine upon neural activity at these sites is an increased rate of neural firing. The overall increase in multiple unit activity in analgesically active sites may result from either a direct excitatory effect of morphine or an indirect effect mediated by small intraneurons.

1456 STIMULATION-PRODUCED ANALGESIA: ASSESSMENT BY DIFFERENT PAIN TESTS AND CORRELATION WITH SELF-STIMULATION. S. G. Dennis and M. Choinière*. Dept. of Psychology, McGill Univ., Montreal, Quebec, Canada H3A 1B1.

Stimulation of certain central grey and raphe regions of the rodent brainstem produces analgesia. The mechanism(s) of stimulation-produced analgesia are apparently related to the mechanisms of morphine analgesia (Mayer & Price, Pain, 2, 1976). Since morphine is known to be more effective on continuous pain of pathological origin than on transient thermal pain (Beecher, in: Soulairac et al., Pain, Academic Press, 1968), we compared, in rats, the analgesic efficacy of central grey stimulation using the formalin test (Dubuisson & Dennis, Pain, 4, 1977), which produces moderate continuous pain, and the tail-flick test, which relies on brief, radiant heat stimulation.

Electrodes were implanted in a region extending from 0-1 mm caudal to the intra-aural line, 0-1.25 mm lateral to the midline, and 0-1.6 mm ventral to the center of the aqueduct. Current thresholds--the amount of current needed to reach a criterion level of analgesia--were determined for each rat on both pain tests. Other stimulus parameters were held constant. 32 rats were used. The data show: 1) that analgesia to the tail-flick stimulus requires significantly more current (~200 µA) than analgesia to the formalin stimulus; and 2) that current thresholds on both tests rise sharply (i.e., less effective analgesia) as the midline dorsal raphe nucleus is approached. These data are not readily explained by known somatotopic organizations, motor deficits, or pain intensity factors. The results are consistent with the hypothesis that the ventrolateral central grey contains analgesia substrates which operate differently on different kinds of pain. It is not as yet clear whether there is a single system common to both kinds of analgesia, or whether separate but spatially mixed systems mediate the effects.

A separate group of rats (n=10) were taught to self-stimulate (bar-pressing) through electrodes implanted in the same vicinity. The current thresholds for self-stimulation were then compared to those for analgesia in the formalin test. A significant correlation was found ($r=0.94$; $p<.005$); the regression line has a slope of 1.2 and passes through the origin. This suggests either a common neural system for analgesia and self-stimulation, or two systems inextricably mixed in this region. Preliminary pharmacological studies suggest a noradrenergic link for both phenomena; no evidence has been found for a serotonergic link. This contrasts with pharmacological studies employing the tail-flick test for measuring analgesia (see Mayer & Price, 1976). Supported by NRC Grant A-7891 to Prof. R. Melzack.

1457 NALOXONE REVERSIBLE ANALGESIA PRODUCED BY D-PHENYLALANINE IN MICE. S. Ehrenpreis, J.E. Comaty* and S.B. Myles*. Dept. of Pharmacology, The Chicago Med. Sch., Chicago, IL 60612.

Two important limitations in using enkephalins or derivatives as analgesics are rapid breakdown by brain enzymes (Hughes, Brain Res. 88: 295, 1975) and development of tolerance to and dependence upon repeated administration (Wei and Loh, Science 193: 1262, 1976). In an attempt to obviate these difficulties, we have utilized the approach of increasing endogenous levels of the peptides by inhibiting the enzyme(s) responsible for their degradation. For this purpose, we have administered D-phenylalanine, an inhibitor of carboxypeptidase A (Delange and Smith, "The Enzymes," 3: 81, 1971) to mice and tested analgesia by the hot plate method. At a dose of 250 mg/kg, i.p., D-phenylalanine produced an increase in jump latency equivalent to 5-10 mg/kg morphine. Naloxone, 20 mg/kg, completely reversed analgesia as did the injection of carboxypeptidase A into the mice. Acutely injected L-phenylalanine was completely devoid of analgesic activity. Non-narcotic analgesics such as indomethacin and other prostaglandin synthetase inhibitors potentiated the effect of D-phenylalanine. Chronic administration of D-phenylalanine for nine days at a dose of 500 mg/kg/day did not result in tolerance to the analgesic effect. In fact, on day 9 the initial baseline analgesic threshold was higher than it had been on day 1. On the 9th day, naloxone reversed analgesia without precipitating any observable signs of withdrawal. These results are further evidence that enkephalins and/or endorphins may be involved in the modulation of pain and demonstrate that it is feasible to develop agents which produce analgesia without tolerance and dependence by preventing breakdown of the peptides at their sites of action in the body. 1458 STIMULATION OF THE PERIAQUEDUCTAL GRAY (PAG) ALTERS THE M PEAKS OF THE THALAMIC PAIN CODE. R. Emmers. Department of Physiology, College of P & S, Columbia University, New York, N. Y. 10032.

As reported in Brain Research 103:425, 1976, thalamic neurons which relay noxious stimulation are excited in a temporal pattern characterized by several activity peaks on spike density histograms. A short-latency I peak codes the intensity of stimulation; late spike potentials form M peaks that are related to the modality of the afferent activity: pain. The M peaks are produced by excitation of a positive feedback loop between the VB complex and the thalamic nuclei CM-Pf. These M peaks can be modified by electrical stimulation of the PAG. In rats given urethane and chloralose, when the first pulse of a pair of electrical stimuli is applied to the sciatic nerve and the second to a site in the PAG, the latter can either fill in the trough between two adjacent M peaks or augment any M peak. Either of these effects can be obtained simply by changing the interstimulus interval. Conversely, when the PAG site is stimulated with a train of pulses immediately preceding a single pulse applied to the sciatic nerve, all M peaks can either be augmented or deranged by changing the parameters of the PAG train (from 0.5 msec pulses at 50/sec for 200 msecs to 0.5 msec pulses at 70/sec for 400 msecs). This suggests that different modes of PAG stimulation could make an animal either more or less susceptible to pain. Moreover, electroanalgesia resulting from prolonged stimulation of the PAG is most likely produced by excitation of axons recently identified as ascending from the PAG to the parafascicular and the VB nuclei (Neurosci. Abstr. 3 # 1215, 1977). These axons, by altering the excitability of the positive feedback loop, could either augment or change the temporal pattern of the M peaks. And since stimulation of the sciatic nerve excites the site of the PAG which influences the feedback loop, electrical stimulation of the PAG simply interferes with the natural regulation of the excitability of this loop and thus modulates the perception of pain (Aided by grant NS-03266 from NINCDS).

1459 SUPERIORITY OF INTERMITTENT VERSUS DIRECT CURRENT ELECTROANALGESIA AT HIGH CURRENT LEVELS. R. Wayne Fields, Robert P. O'Donnell*, Richard B. Tacke* and Patrick J. Reynolds. School of Dentistry, University of Oregon Health Sciences Center, Portland, Oregon, 97201.

Using the monopolar stimulation configuration with a remote cathode and the anode applied to exposed dentin, we have previously demonstrated that direct currents of 70-100 μA block afferent activity from the tooth pulp (Fields et al., Exp. Neurol. 47:229-239, 1975) and that trains of rectangular pulses at 1000 pps having similar peak intensities but with duty cycles as low as 10% are equally efficacious (Fields et al., Exp. Neurol. 53:386-398, 1976). The present experiments were conducted to characterize the absolute and relative effects of monophasic and biphasic intermittent and of constant direct current electroanalgesia (EA) waveforms using intensities of 0-1000 μA, spanning much of the range of electroanalgesia and desensitization procedures reported in the clinical literature. This problem was examined using our previously described methods for recording thresholds of pulp-driven primary afferents in the ipsilateral Gasserian ganglion of cats to electrical stimulation of the test tooth (applied during brief 10 ms "windows" in the EA stimulation). Three EA waveforms were examined a) continuous direct current (dc), b) pulsating direct current of 1000 pps 10% duty cycle (pdc), and c) the pdc waveform capacitively coupled to the animal to effect an alternating current with zero net power transfer (ac). In each experiment, all three waveforms were studied in the order ac-pdc-dc to minimize accumulative effects (Fields et al., Exp. Neurol. 50:293-303, 1976). Each waveform was applied in an ascending series of intensity steps of 10 μA from 0-100 μA and of 200 μA from 200-1000 μA. For the dc and ac waveforms, the threshold of pulp-driven units progressively rose along essentially identical curves with increasing EA intensity, reaching 1000% of control thresholds at 400 μA. Pulpal thresholds also progressivlely rose to 1000% of control using pdc EA but the hypoexcitability was less pronounced than that of the other waveforms for EA intensities above 40 μA. Upon EA cessation, dc recovery was minimal, being 850% of control even after 120 min. The pdc and ac series exhibited recoveries after 30 min. to 350% and 200%, respectively, and the ac record further recovered to reach 150% of control after 120 min. post-EA. These results demonstrate that the ac waveform has equal efficacy to dc over the majority of the clinically significant range and exhibits far superior post-EA recovery properties under conditions of zero electrical power transfer.

1460 ASCENDING PATHWAYS INVOLVED WITH CARDIAC NOCICEPTION GENERATED BY MYOCARDIAL ISCHEMIA. Robert D. Foreman and Carl A. Ohata*. Department of Physiology and Biophysics, University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma 73190.

Studies from this laboratory have shown that myocardial ischemia following coronary artery occlusion (CAO) is an effective stimulus for increasing the discharge rate of spinal neurons responding to viscerosomatic convergence. This study was conducted to determine if the activity from cardiac nociceptors is transmitted by neurons which have axons ascending to higher levels of the central nervous system. The activity of cells in the T_2 to T_3 segments of the spinal cord was recorded extracellularly with a glass microelectrode. These cells were antidromically activated by electrically stimulating their axons in the contralateral, anterolateral quadrant of the C_1 segment of the spinal cord. All of the cells exhibited viscerosomatic convergence which was tested by electrically stimulating the T_2 to T_3 sympathetic chain and by manipulating the somatic fields, respectively. The heart was exposed with a thoracotomy made in the fourth intercostal space. Short segments of the anterior descending branch and the circumflex branch of the left main coronary artery were carefully dissected and ligatures were placed around them for occlusion. Cells increased their discharge rate several seconds following the onset of CAO. The increased activity was usually associated with configurational changes in the ECG suggesting that the heart was becoming ischemic. Cells remained active for a short period following the release of the CAO and then returned to their preocclusion discharge rate. Some cells increased their discharge rate immediately following the onset of CAO and then increased to a higher level of activity several seconds later, usually when changes occurred in the ECG. Not all cells were excited during CAO, even though they discharged following electrical stimulation of the sympathetic chain. Some of the cells had somatic receptive fields similar to the size described for the spinothalamic tract (Hancock et al. Exptl. Neurol. 47, 1975). Another population of cells had large, bilateral somatic fields similar to those observed for the cells of origin of the spinoreticular tract (Fields et al. Brain Res. 120, 1977). All cells responded to a noxious somatic stimulus, however, some cells also responded to touch and increased their discharge rate when a noxious pinch stimulus was applied. The results suggest that the information from cardiac receptors and nociceptors ascends in the anterolateral quadrant of the spinal cord toward suprasegmental levels of the central nervous system. Since these cells exhibit viscerosomatic convergence, they may demonstrate a possible mechanism underlying referred pain associated with coronary artery disease. (Supported by Grant #18728).

1461 THE EFFECT OF AN ACTIVE PLACEBO DRUG AND A NARCOTIC ANALGESIC ON VERBAL DESCRIPTOR SCALES OF THE SENSORY INTENSITY, UNPLEASANTNESS AND PAINFULNESS OF ELECTRICAL TOOTH PULP STIMULI. Richard H. Gracely*, Patricia A. McGrath* and Ronald Dubner. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD. 20014

Eighty subjects used verbal descriptor scales to rate electrical tooth pulp stimuli before and after the IV administration of either the narcotic analgesic fentanyl, the minor tranquilizer diazepam, saline, or fentanyl and diazepam in combination.

Exp I (n=40) used verbal descriptor scales of sensory intensity (e.g., weak, moderate, strong) and unpleasantness (e.g., unpleasant, annoying, distressing) to assess the effects of 0.11 mg/kg diazepam administered to mask the different subjective effects produced by subsequent administration of either 0.66μg/kg fentanyl or saline placebo. The diazepam and fentanyl combination significantly reduced sensory intensity ($F=8.05$, $p<.05$) but not the unpleasantness of the sensations evoked by these stimuli. Diazepam with saline significantly reduced unpleasantness ($F=6.21$, $p<.05$) but not sensory intensity. We have shown previously that fentanyl reduces only sensory intensity ratings and that saline reduces only unpleasantness ratings. Thus diazepam did not influence verbal judgements of the sensory intensity or unpleasantness of painful tooth pulp stimuli and therefore can be treated as an active placebo useful for masking subjective effects of putative pain control agents.

Exp II (n=40) used verbal descriptor scales of painfulness (e.g., slightly painful, moderately painful, very painful) to assess the effects of a diazepam pre-injection on the subsequent administration of either fentanyl or saline. Without a diazepam pre-injection, pain ratings were reduced significantly after the administration of fentanyl ($F=5.56$, $p<.05$), but not after saline. With the addition of a diazepam pre-injection, painfulness was significantly reduced ($F=9.46$, $p<.05$) after the administration of fentanyl, a result consistent with both the effects of fentanyl alone on pain ratings in Exp II and the effects of diazepam with fentanyl on the ratings of sensory intensity in Exp I. Diazepam with saline, however, also significantly reduced painfulness ($F=20.75$, $p<.01$). This result is not consistent with the effects of saline alone on the pain ratings in Exp II but does parallel the effects of diazepam with saline on ratings of unpleasantness in Exp I. This experiment shows that, unlike verbal scales of sensory intensity and unpleasantness, scales of painfulness may not separate the effects of an active placebo and a narcotic analgesic drug.

1462 TOOTH PULP PRIMARY AFFERENT DEPOLARIZATION (PAD) AND NALOXONE: ARE PRESYNAPTIC OPIATE RECEPTORS INVOLVED? J.W. Hu, J.O. Dostrovsky and B.J. Sessle. Fac. of Dentistry and Dept. of Physiology (J.O.D.), Univ. of Toronto, Canada.

Recent studies suggest the existence of opiate receptors on primary afferent terminals. These receptors may be involved in the production of presynaptic inhibition which is generally assumed to result from depolarization of presynaptic terminals (PAD). Because stimuli to the periaqueductal gray (PAG), which has been implicated in opiate-induced analgesia, depress trigeminal (V) brainstem responses to tooth pulp (TP) and noxious facial stimuli (Sessle et al., Can. J. Physiol. Pharmacol. 54: 66, 1976), we tested for a PAD contribution to the depression. The effect of naloxone, 0.4 mg/kg, i.v., was also tested since, if the PAD is mediated by the release of endogenous morphine-like compounds interacting with presynaptic opiate receptors, reversal of the PAD by this opiate antagonist might be expected.

Single unit TP potentials were recorded in the canine TP of chloralose-anesthetized adult cats. Antidromic activity could be evoked by microstimulation in the V nucleus caudalis and/or oralis. Single units displayed clear all-or-none, constant latency responses at threshold intensity and followed high frequency (' 100 Hz) stimulation. Conditioning stimuli were delivered to the PAG, and also to nucleus raphe magnus (NRM), ventroposterior medial nucleus of thalamus (VPM), TP (of other canine teeth), infraorbital nerve, and facial skin. PAD of TP afferents was determined by the increased probability of exciting an antidromic spike following a conditioning stimulus train. We found that all these stimuli could produce PAD which had a peak at 50 ms and lasted for 150-500 ms. Naloxone has been tested on 12 units (7 units antidromically activated from N. caudalis and 5 units from N. oralis), but had no effect on resting excitability and did not reverse PAD produced by PAG, NRM or facial stimuli. Thus this study has shown that the TP endings in N. caudalis and N. oralis are subject to primary afferent depolarization from PAG, NRM, VPM, and oral-facial sites; the ineffectiveness of naloxone to reverse this effect however implies that presynaptic opiate receptors might not be involved in the PAD.
(Supported by the Canadian MRC and NIH grant #1-ROL-DE04786-01).

1463 ANTIBODIES TO G_{M1} GANGLIOSIDE BLOCK MORPHINE ANALGESIA. S. E. Karpiak, R. J. Bodnar, S. Hanson*, M. Glusman, and M. M. Rapport, N. Y. State Psychiatric Inst. and Columbia Univ., Coll. Phys. & Surg., New York, N. Y. 10032.

The region of the periaqueductal gray matter (PAG) in the rat has a high concentration of morphine receptors[1], and it is well established that injection of small amounts of morphine into this region induces analgesia[2]. We have been studying the effects of antibodies to synaptic constituents, in particular G_{M1} ganglioside, in altering CNS functions[3,4], and it was of interest to determine whether these antibodies affect morphine analgesia. An excellent control for evaluating the effects of these antibodies was available by absorbing the specific antibodies from the antiserum with pure G_{M1} ganglioside. Pain threshold was determined by the flinch-jump technique in male Sprague-Dawley rats (250-300 g). The baseline response to an injection of morphine sulfate (10 mg/Kg,I.P.) was determined for each animal. One week later, the animals were injected in the PAG, under stereotaxic control, with 5 μl either of antiserum to total brain ganglioside or absorbed antiserum or saline. No alteration of pain threshold lasting longer than 24 hours was detected by baseline response on the flinch-jump test. Ten to 14 days after intracerebral (PAG) injection of antibodies, the rats were tested again for analgesic response to morphine sulfate (10 mg/Kg,I.P.). Animals injected with anti-ganglioside serum showed a decrease in analgesic response (84% inhibition; $p<.01$). Animals injected with saline or absorbed antiserum did not show differences in analgesic response (from those obtained with the morphine injection 17 to 21 days earlier). These results suggest that G_{M1} gangliosides are involved in the mechanism of action of morphine in the PAG and may be a structural part of the morphine receptor.

1464 STIMULATION-PRODUCED ANALGESIA AND LIMINAL ESCAPE BEHAVIOR: SYNERGY WITH MORPHINE AND REDUCTION BY NALOXONE. Dennis D. Kelly, Shannon K. Such*, Martin Brutus, Murray Glusman, Richard J. Bodnar. New York State Psychiatric Institute and Department of Psychiatry, Columbia University, New York, N.Y. 10032.

Liminal escape (LE) is an operant psychophysical threshold procedure that reflects both an animal's evaluation of the relative aversiveness of a range of shock stimuli and its motivation to terminate their presence. The aim of these experiments was to determine 1) whether intracranial stimulation (ICS) of midline mesencephalic and diencephalic sites previously reported to yield an analgesic depression of pain reflexes in rats would also elevate LE functions in an intensity-dependent manner, 2) whether subanalgesic doses of morphine and low-intensity ICS might interact to produce major LE shifts, and 3) whether opiate receptor blockade by naloxone would alter ICS-induced LE shifts. On each liminal escape trial, pulsed foot shocks (300-msec ON/300-msec OFF) were presented for 10 secs unless the subject pressed a lever three times to abbreviate the shock train. Sessions consisted of 100 trials distributed over five shock intensities (.2, .4, .6, .8, 1.0 ma) in a randomized-blocks design. Biphasic square-wave ICS trains (250-msec ON/400-msec OFF) were superimposed upon 40 preselected trials. Foot shock and ICS were interdigitated and never occurred simultaneously. ICS intensity was varied across sessions in 10-25 μa steps. Of 32 rats implanted with bipolar electrodes, 19 were fully tested in the liminal escape procedure, and only 5 displayed a gradient or family of threshold functions that was dependent upon ICS intensity. There was no evidence in any of these subjects of a post-stimulation time course of analgesia. Both their subsequent intertrial behaviors and their escape thresholds on post-ICS trials were normal. Moreover, these ICS-induced elevations in LE thresholds were significantly reduced by naloxone (1 & 10 mg/kg s.c.), which by itself had no effect upon normal thresholds nor upon the behavior of rats with non-analgesic ICS placements. At all effective analgesic placements, low-level subthreshold electrical stimulation was found to interact synergistically with subanalgesic doses of morphine (2.5 mg/kg, s.c.) so as to produce a profound analgesia. Naloxone at the same doses as above also eliminated the analgesic synergy of morphine and ICS. (Supported by New York State Health Research Council Grants #365 and 922 and by NIH grant #NS 14449.)

1465 SENSITIZATION AND DESENSITIZATION OF THE RESPONSES OF PRIMATE SPINOTHALAMIC NEURONS TO NOXIOUS HEAT STIMULI. D.R. Kenshalo, Jr., R.B. Leonard, J.M. Chung, and W.D. Willis. Marine Biomedical Inst. and Depts. of Physiology & Biophys. and Anatomy, U. Texas Med. Br., Galveston, TX 77550

The spinothalamic tract (STT) is thought to be the chief spinal pathway carrying nociceptive information in primates. Support for this comes from experiments in which the responses of STT cells are studied following stimuli known to activate nociceptors. An easily controlled noxious stimulus is heat.

STT cells were identified by antidromic activation from the contralateral diencephalon in anesthetized monkeys (Macaca fascicularis). A thermal stimulator having a surface area of 14 cm^2 was placed against the glaborous skin in the receptive field on the hindlimb. The stimuli were a series of temperature changes from an adapting level of 35° to 43, 45, 47 and 50°C (rate 2°/s). Stimulus duration was either 30 or 120 s with a 5 min interstimulus interval. The series of heat stimuli was then repeated to determine the effect of prior heating.

There were responses to heating in 40 of 41 STT cells examined. During the first series of stimuli of 30 s duration, there was a monotonic increase in the peak frequency of discharge as the temperature was elevated to progressively higher levels. The baseline discharge during the 30 s preceding each stimulus was also progressively increased. When a second series of identical stimuli was applied, sensitization was evidenced by an increase in the peak frequency and in the baseline discharge preceding the stimulus at each intensity. When 120 s duration changes in temperature were employed, peak frequency was enhanced except when the response to the second 50° heat stimulus was compared to the response to the first 50° stimulus. In this case, there was a desensitization, since the peak frequency was less. Furthermore, the baseline discharge was lowered after the second 45° stimulus.

In addition, to sensitization to repeated heat stimuli, we found evidence for cross-modality sensitization to mechanical and to intense cold stimuli.

It is concluded that the responses of STT neurons in the primate show sensitization and desensitization with characteristics very similar to those of C polymodal nociceptors. It is hypothesized that the responses of STT cells are due largely to the activity of these nociceptive afferents.

1466 EFFECT OF ACUPUNCTURE ON THE EXCRETION OF ADRENALIN, NON-ADRENALIN, 17-HYDROXYCORHCOSTEROID AND VANILLYL MAUDELIC ACID IN URINE. K. C. Kim. Dept. Anat. R. Heimburger. Dept. Neurosur., Sch. Med., IN U, Indpls., IN 46202.

Analgesic effect of acupuncture may explain neurogenic theory or increasing endorphine in brain by acupuncture. However, it is difficult to explain the prolonged improvement of antiinflammatory effect in various pain syndromes.

It has been shown that surgical stimulation increased the excretion of adrenalin (A), non-adrenalin (NA) and 17-hydroxycorticosteroid (17-OHCS) in urine. Many insertions of acupuncture needles may be considered a type of minor surgical stimulation and it may influence A, NA and 17-OHCS level in urine in chronic pain patients.

Chronic intractable low back pain patients, 3 females and 5 males, were admitted to the hospital and A, NA, VMA and 17-OHCS in the urine was measured for 2 days as control before treatment and for 8 days after the treatment.

15 acupuncture needles, made of stainless steel, were inserted on various loci in their back and left for 30 min. Special diet was given for consideration of catecholamine level. Pain was evaluated by patient themself.

Results: A: The mean control value of A was 6.4 ug/L, it was decreased by 21% and 35% on the first and second day respectively. The third day it returned to the control level and after the fourth day A was fluctuating. NA: The mean control value of 27.6 ug/L was decreased by 48% on the first day, the second day it returned to the control value and after the third day it fluctuated. 17-OHCS: The mean control value of 6 ug/L was increased by 44% and 80% on the first and second respectively. It then increased rapidly by 229% by the fourth day, then it decreased to 50% above the control level for the rest of the hospital days. VMA: The first day VMA was decreased by 66% of control, after that it fluctuated, but was significantly lower than the control. PAIN: Pain was relieved significantly in all patients on the first day, thereafter the pain score fluctuated, but was relieved over all.

1467 ANALGESIA INDUCED BY MICROINJECTION OF BACLOFEN AND MORPHINE AT SITES IN THE RAT BRAIN STEM. R. A. Levy and H. K. Proudfit. Dept. of Pharmacol., Univ. of Illinois Med. Center, Chicago, Illinois 60612.

Analgesia induced by both morphine and by the non-narcotic baclofen (β-4-chlorophenyl-GABA) is blocked following transection of the caudal medulla, but not by midcollicular transection (Proudfit and Levy, Eur. J. Pharmacol. 47(1978), 159. This suggests that the analgesia induced by these agents may reflect activation of the same neuronal substrates, albeit by different cellular mechanisms. To test this hypothesis we determined the analgesic capacity of both drugs when microinjected at sites in the periaqueductal gray (PAG) and raphe magnus (RM), brain stem nuclei shown previously to be active areas for morphine analgesia. On separate occasions, equimolar doses of both agents (1.5 µg baclofen, 2.5 µg morphine sulfate) were microinjected, in 0.5 µl saline, into the same site in rats chronically implanted with guide tubes. Sensitivity to pain was assessed with the tail flick assay and expressed as the analgesia index (AI). The AI expresses the drug-induced change in latency as a function of the greatest possible increase (14 sec.); AI = 0, no analgesia; AI = 1, maximum analgesia. AI $\geq$ 0.2 was defined as indicative of analgesic action. Baclofen and morphine were both more effective in producing analgesia when applied at caudal than at rostral PAG sites. Thus, baclofen caused analgesia when microinjected at 10 of 15 PAG sites located caudal to the interaural line, but only at 2 of 16 PAG sites located rostral to this plane. Similiarly, morphine caused naloxone-reversible analgesia when applied at 9 of 9 caudal sites but only at 8 of 12 rostral sites. Analgesia produced by morphine applied at the caudal loci (AI = 0.52 ±0.09) was significantly greater than that caused by morphine applied at active rostral sites (AI = 0.29 ± 0.05). Baclofen and morphine caused analgesia of equal magnitude when injected at their respective active sites in the caudal PAG; however, the relative potency of morphine among caudal PAG sites was poorly correlated with that of baclofen (r^2 = 0.16).

Morphine was more active than baclofen in the RM. Morphine caused a substantial naloxone-reversible analgesia when injected at 7 of 13 RM sites (AI = 0.46 ± 0.08, n = 7); baclofen caused a slight analgesia when applied at only two (AI = 0.2) of 11 RM sites.

Despite the greater potency of both agents at caudal as opposed to rostral PAG sites, the poor correlation in potency of these drugs in caudal PAG and the capacity of morphine but not baclofen to produce analgesia when injected into the RM suggest that different substrates are involved in analgesia induced by systemic administration of these agents. Supported by PHS Grant NS 12649.

1468 ANALGESIA ELICITED BY INTRACEREBRAL MICROINJECTIONS OF BACLOFEN AND MUSCIMOL. Jeffrey M. Liebman and Gary Pastor*. Research Dept., Pharmaceutical Div., CIBA-GEIGY Corp., Summit, NJ 07901.

Baclofen (Lioresal(R)), a muscle relaxant, elicits non-narcotic analgesia when administered systemically. Because analgesia can be elicited by morphine microinjections into caudal ventrolateral mesencephalic central gray, morphine analgesia appears to be at least partly mediated by this region (Yaksh et al., Brain Res. 114:83. 1976). The effects of baclofen (BF) microinjections into this region were, therefore, of interest, particularly as Proudfit and Levy (Eur. J. Pharmacol. 47:159, 1978) have implicated brainstem sites in the analgesic effects of both morphine and BF. Muscimol (MUS), a GABA-mimetic, was also compared to BF, which is a structural analog of GABA but differs from GABA-mimetics in some respects (Naik et al., Neuropharmacol. 15:479, 1976).

Male Wistar rats were stereotaxically implanted in dorsal tegmentum with guide cannulae (0.029" diam.), allowed to recover for at least one week, then injected intracerebrally through a needle protruding 1 mm below the cannula tip. Morphine (5 µg), BF (0.01-2 µg) and MUS (0.001-1 µg) were microinjected in a volume of 0.5 µl. In most cases, the three drugs were injected into a given placement in separate trials at intervals of one week. A pinch test of analgesia was employed, supplemented in some cases by a tail-flick test. Morphine-elicited analgesia was restricted to microinjections in or near ventrolateral caudal mesencephalic central gray, while BF and MUS produced analgesia when microinjected into various tegmental placements including mesencephalic central gray but also extending farther anterior and ventral. Naloxone (1 mg/kg i.p.) reversed the analgesic effects of intracerebral morphine, but not those of BF or MUS. Although ataxia was also noted after some intracerebral microinjections of BF or MUS, it was not invariably present in analgesic rats. MUS was more potent intracerebrally than BF, but further investigations which employed the intraperitoneal route in rats showed, at best, weak analgesic effects of MUS at physically debilitating doses, while BF showed a relatively greater separation between analgesia and obvious physical impairment.

These results indicate that the analgesic effects of BF may be mediated at least partly by central mechanisms. Further, selective activation of central GABA-ergic receptors, as by intracerebral MUS, may suppress nociception directly or indirectly. Because BF is not considered a directly-acting GABA-mimetic, the reason why its effects approximate those of MUS when microinjected intracerebrally remains to be fully elucidated.

1469 EVOKED POTENTIAL CORRELATES OF PAIN RATINGS IN RHESUS MONKEYS. Charles G. Lineberry and Albert T. Kulics*. Dept.Pharmacol., Sch. Med., Univ. of Pittsburgh, Pgh., PA 15261

In previous work, we have used a signal detection theory (SDT) model to assess pain sensitivity and response bias in monkeys responding to terminate trains of noxious electrical cutaneous stimuli. In the present study, we have recorded transcortical field potentials while subjects were performing in the SDT escape task in order to determine whether these potentials were correlated with behavioral responses as predicted from the SDT model. Bipolar, concentric recording electrodes were implanted in the post-central gyrus as well as in more posterior regions of parietal cortex. Subjects received escape trials at each of 5 stimulus intensities in daily sessions. On each trial, monkeys were required to bar-press within 1.5 sec after the presentation of a 20 msec train of electrical stimuli in order to prevent the occurrence of successive trains of identical stimuli. Response probabilities and response latencies were used as intensity ratings of the stimuli. For each stimulus intensity, trials on which escape responses were elicited were then grouped into blocks of 25 on the basis of behavioral response latency, with the first group consisting of the 25 trials having the shortest behavioral response latencies and each succeeding group of 25 trials including those trials with successively longer latencies. The final group for each stimulus consisted of 25 trials randomly selected from the trials on which no escape response occurred. The field potentials associated with each group were then averaged, and determinations were made of the peak to peak amplitude of each wave component.

Certain relatively late components (70 to 150 msec) of the primary somatosensory cortex response correlated well with behavioral response latencies; short latency behavioral responses (sensation rated as intense) were associated with large amplitude potentials, and the no-response groups had the smallest amplitudes. Further, groups of trials with similar response latencies (assumed to represent equal sensation magnitudes) tended to have similar late component amplitudes, regardless of stimulus intensity. Thus, the behavioral intensity rating and not stimulus intensity was best correlated with the amplitude of these later components. For the initial surface positive wave (18 to 20 msec latency), the reverse was true. Potentials recorded from other cortical areas showed little correlation with behavior. These findings indicate that late components of the primary somatosensory evoked potential correlate with behavioral ratings of noxious stimulus intensities and therefore may play a role in the perception of pain.

1470 ACUPUNCTURE AND NALOXONE MODIFICATION OF HUMAN SOMATOSENSORY EVOKED POTENTIALS. P. Maple*, R. Borison, H. Havdala* and B. Diamond. (SPON: C.M. Combs) Mt Sinai Hosp./Rush Med Coll., Chicago, IL.

Since by physiological and/or psychological means, acupuncture as well as naloxone must alter the central nervous system pathways involved in the perception of pain, we have sought to document this by means of measuring somatosensory evoked potentials (SEP) in man. SEP were measured in male and female volunteers free from pain, as well as in patients with pain. The SEP were analyzed by averaging 1000 sweeps of the electroencephalogram by a Computer of Averaged Transients. Acupuncture was performed by placing needles in the Hoku point and other relevant sites for shoulder pain, and needles were twirled every ten minutes. In some subjects naloxone (2 mg, intravenously) was immediately administered after acupuncture was terminated, or in place of acupuncture treatment. In 75% of our subjects the amplitude of the positive peak occurring at 28 msec (P_{28}) decreased and the amplitudes of the later positive peaks, P_{46} and P_{65}, decreased in 83% and 80% of our subjects respectively. We observed a concomitant decrease in latency to the P_{65} wave after acupuncture treatment. Moreover, the early negative peak (N_{18}) amplitude decreased, with the latency to and the amplitude of the late negative wave (N_{120}) decreasing after acupuncture. Furthermore, in studies where naloxone was administered, there appeared to be a noticeable reduction of the P_{46} potential induced by acupuncture. Moreover, when naloxone alone was administered to subjects, the P_{46} potential was markedly increased. Furthermore, in all our subjects there was a noticeable reduction in threshold for stimulation of the evoked potential during and after acupuncture. The early components of the SEP represent conduction of nerve impulses through the spinal cord and medulla to relays in the ventroposteriolateral nucleus of the thalamus, whereas late events indicate the firing of neurons in cortical association areas. Our data, which show dramatic changes in the early events of the SEP induced by either naloxone or acupuncture, would argue in favor of attentuation of stimuli in their conduction to the thalamus, rather than an alteration of perception solely at a cortical level. The action of naloxone on the P_{46} potential in particular shows the presence in man of a naloxone-sensitive pathway, and lends further evidence to an enkephalinergic mechanism mediating the pain response in man. Furthermore, the fact that we observe changes in the late events of the SEP, consistent withour subject's reports of arousal would indicate that acupuncture also produces changes in the supratentorial response to stimuli.

1471 PRIMARY AFFERENT DEPOLARIZATION EVOKED IN IDENTIFIED CUTANEOUS AFFERENTS BY STIMULATION IN THE MEDIAL BRAINSTEM. R.F. Martin, L.H. Haber and W.D. Willis. Marine Biomedical Inst. and Depts. of Physiology & Biophysics and of Anatomy, U. Texas Med. Br., Galveston, TX 77550.

Stimulation in either the nucleus raphe magnus (NRM) or the nucleus reticularis gigantocellularis (NGc) in monkeys (Macaca fascicularis) results in the inhibition of spinothalamic tract neurons. Both background activity and the discharges evoked by stimulation of the skin are inhibited. The possibility that at least a part of the inhibition might be presynaptic was investigated in experiments in which excitability tests were used to determine if primary afferent depolarization (PAD) results from stimulation in these brainstem nuclei.

Cats and monkeys were used. Anesthesia was maintained with either α-chloralose or a combination of this agent and an infusion of sodium pentobarbital (2 mg/kg/h). The spinal cord was exposed by laminectomy and the brainstem by occipital craniectomy and partial cerebellectomy. A freed segment of sural nerve was elevated onto a plastic platform and an incision made through the perineurium. A pair of stimulating electrodes was placed under a second freed segment. Glass microelectrodes (initially about 35 MΩ) filled with 4 M NaCl were used to record from afferent axons. Conduction velocities were determined from the latencies of spikes following stimulation of the nerve. Receptive field properties were determined. The excitability of each afferent was tested by stimulation with a steel microelectrode inserted into the dorsal root entry zone at S1. Firing indices were set at an intermediate value by adjustment of the stimulus strength. Conditioning trains of stimuli were applied through other steel electrodes introduced into the medial brainstem. An increase in the firing index was taken to signify PAD.

Stimulation in the NRM produced PAD in 20 Aδ fibers (12 high threshold and 8 D hair afferents) and 47 Aβ fibers (10 slowly adapting, 9 field and 28 hair follicle afferents). Stimulation in the area of NGc also produced PAD in all of these types of cutaneous afferent fibers. Threshold effects were seen with stimulus strengths as low as 25 μA. The latency of the PAD evoked by stimulation in the NRM was longer than for stimulation in the NGc; bilateral interruption of the dorsolateral fasciculi resulted in a loss of PAD from stimulation of the NRM but not of the NGc.

The results indicate that there are at lease two pathways originating in the medial brainstem in cats and monkeys which produce PAD and presumably presynaptic inhibition of transmission to spinal neurons from afferent fibers carrying information from cutaneous mechanoreceptors and nociceptors.

1472 ANALYSIS OF ENDORPHINS IN CEREBROSPINAL FLUID (CSF) FROM PERSONS WITH LOWER BACK OR LEG PAIN. B.E. Miller, E.E. Codd*, A.L. Ungar* K. Mays*, and W.L. Byrne. Depts. Biochem. & Anesthes., U.T.C.H.S. Memphis, Tennessee 38163.

Since 1975 there have appeared 3 papers each reporting evidence for a functional relationship between CSF-endorphins and pain. The level of endorphin is apparently lower in patients with trigeminal neuralgia (Life Sci. 16: 1759-1764, 1975). Endorphin is elevated in pain patients after stimulation by analgesic electroacupuncture (Acta Physiol Scand. 100: 382-384, 1977). The CSF of persons with headache is lower than those without and these differences are not due to the rate of destruction of met-enkephalin in the CSF (Adv. in Biochem. Psychopharmac. 18: 363-366, 1978).

In the present study, CSF was removed from persons with lower back and/or leg pain while they were undergoing spinal anethesia for pain relief at the U.T. Pain Clinic. The CSF was then frozen. It was thawed and filtered through an Amicon PM-10 filter at 4°C. The filtrate was concentrated to 1/5 the original volume and loaded atop a Sephadex G-10 column and eluted with 0.2 N acetic acid. The column fractions were tested for endorphin activity with an opiate receptor binding assay (described in Prog. Neuro-Psychopharmac. 1: 259-264, 1977). In order to obtain enough material for other tests, several CSF samples were pooled and treated as a single sample. The pooled CSF sample provided enough material to also test the column fractions for endorphin activity with the mouse vas deferens bioassay (similar to: Brain Res. 88: 295-308, 1975). This assay confirmed most of the endorphin peaks indicated by the binding assay.

There is considerable variability in the number and amount of endorphins in the individual CSF samples. Peaks of endorphin activity consistently elute (though not in each sample) in the following positions from the Sephadex G-10 column: Volume(elution)/Volume(void) (Ve/Vo) ± 0.1 = 1.3, 1.7, 2.3, 2.7, 3.0, 3.5, and 4.5. The first four peaks usually account for more than 80% of the endorphin activity. The behaviour of some of these CSF endorphin components in reverse phase high pressure liquid chromatography systems suggests that most of these materials are not identical with as yet structurally identified endorphins.

1473 MEDIATION OF HYPALGESIA AND THALAMOCORTICAL MODULATION BY OPIATE RECEPTORS IN THE PERIAQUEDUCTAL GRAY. William J. Nowack,* Richard N. Johnson, Norman H. Bass and George R. Hanna, Department of Neurology and Clinical Neuroscience Research Center, University of Virginia School of Medicine, Charlottesville, Va. 22901

A major site for the modulation of responses to pain has been demonstrated in the periaqueductal gray (PAG); opiate receptors are found in the PAG. Both electrical stimulation in the PAG and intravenous morphine produce naloxone reversible behavioral hypalgesia. Similar changes in thalamocortical excitability are caused by intravenous morphine and PAG stimulation. We studied the effect of microinjection of morphine in the PAG to determine whether the PAG opiate receptors participate in hypalgesic thalamocortical modulation.

Pairs of pulses were delivered to the ventrolateral thalamus of anesthetized cats and the cortical evoked response following the second stimulus was recorded from ipsilateral sensorimotor cortex; the amplitude of the second stimulus and the interval between the two pulses (PI) were systematically varied by on-line computer. Three dimensional plots of the evoked responses, or evoked response profiles (ERP), were generated and analyzed statistically. Intravenous morphine, electrical stimulation of PAG and microinjection of 5 µg of morphine into PAG all produced similar PI dependent alterations in ERP. These observations suggest that opiate receptors in PAG modulate the thalamocortical processing of information interpreted as pain and presumably the perceptual threshold for pain.

1474 OPTIMUM DUTY CYCLE AND FREQUENCY OF INTERMITTENT ELECTROANALGESIA CURRENT. O'Donnell, Robert P.*, R. Wayne Fields, Richard B. Tacke* and Patrick J. Reynolds. School of Dentistry, University of Oregon Health Sciences Center, Portland, Oregon 97201.

We have been studying the effect of electric current on the excitability of identified primary afferents from tooth pulp. Using the monopolar stimulus configuration with remote cathode and the anode applied to the exposed dentin of the test tooth, we have previously demonstrated that direct currents (DC) in the range of 70 to 100 µA block afferent activity from tooth pulp (Fields et al., Exp. Neurol. 47:229-239, 1975) and that trains of rectangular pulses at 1000 pps having similar peak current but duty cycles as low as 10% are equally effective in blocking pulp afferent activity (Fields et al., Exp. Neurol. 53:386-398, 1976). The present experiments were performed to further examine the range of duty cycle and frequency of pulsed electroanalgesia (EA) current that might produce blockade as effectively as DC. We examined this using our previously described methods for recording thresholds of pulp-driven primary afferents in the ipsilateral Gasserian ganglion of cats to electrical stimulation of the test tooth, applied at intervals during the EA administration. Duty cycles of 1.0, 3.16, and 10.0% were examined at a frequency (based on previous results) of 1000 pps Subsequently, frequencies of 100, 1000, 10,000 and 100,000 pps were studied at the identified optimum duty cycle of 10.0%. In each experiment the monophasic pulsed current waveform was compared to DC, and was applied in increasing steps of peak current from 0 to 100 µA. At effective current levels (70 to 100 µA) there was no difference between DC and the 10% duty cycle waveform, while the 3.16 and 1.0% waveforms were progressively less effective in afferent blockade. Maximal threshold increases for the DC and 10% duty cycle pulsed waveform were in the range of 400 to 500%. Return to within 150% of control excitability (arbitrary index of recovery) occurred in less than ten minutes for all waveforms. For the frequency variable only the 1000 pps waveform compared in effectiveness to DC (maximum threshold elevations of 400%) at similar current levels. The 100 pps waveform was intermediate in effectiveness (maximum 200% threshold elevation) while the 10,000 and 100,000 pps waveforms were totally ineffective. Recovery profiles were similar to those observed in the duty cycle experiments. The results permit identification of 1000 pps, 10% duty cycle as the optimal intermittent current waveform for use in lowering excitability of primary afferents from tooth pulp.

1475 STRESS-INDUCED ANALGESIA: CROSS-TOLERANCE STUDIES OF STRESSORS AND MORPHINE. Angela Spiaggia*, Richard J. Bodnar, Murray Glusman and Dennis D. Kelly. New York State Psychiatric Institute and Columbia University, N.Y., N.Y. 10032.

Rats display elevations in pain thresholds when initially exposed to such stressors as a forced cold-water swim (CWS), inescapable electric shocks, or an injection of 2-deoxy-D-glucose (2-DG), an anti-metabolic glucose analogue. Repeated exposure to each of these stressful situations results in adaptation of the analgesic response in much the same way that repeated administration of morphine results in tolerance. We have previously found that cross-tolerance fails to develop between CWS-induced and morphine-induced analgesia suggesting that the analgesic mechanisms underlying each are not identical. The present study investigated whether cross-tolerance would develop between the analgesia induced by CWS and 2-DG, and between the latter and morphine-induced analgesia. Six separate groups of six rats each were tested over a 22-day paradigm in which flinch-jump thresholds were determined on three pretreatment baseline days, the first of 14 chronic treatment days, the last treatment day, a cross-treatment day and four subsequent posttreatment recovery days. All treatments occurred 30 min prior to flinch-jump testing. Following baseline, the first two groups received 14 daily 2-DG injections (350 mg/kg) followed on the fifteenth, or cross-treatment day by morphine (10 mg/kg) in one group and CWS (2°C for 3.5 min) in the other. The third and fourth groups underwent 14 daily CWS or morphine injections respectively followed by 2-DG injections on the fifteenth day. The fifth group underwent 14 daily warm-water (28°C) control swims followed by 2-DG administration, while the sixth group received 14 placebo injections followed by CWS. Acute exposure to 2-DG, CWS and morphine all produced analgesia; control swims and injections did not. Repeated exposure to the same conditions resulted in adaptation or tolerance. Full development of 2-way cross-tolerance occurred between CWS and 2-DG, in other words, rats chronically treated with either 2-DG or CWS failed to display analgesia when switched to the other. Full cross-tolerance also occurred in chronic morphine-treated rats subsequently exposed to 2-DG, but only partial (50%) cross-tolerance occurred in chronic 2-DG-treated rats subsequently exposed to morphine. Chronic exposure to the warm water control and placebo conditions did not alter the normal analgesic effects of acute exposure to 2-DG and CWS. (Supported by NIH Grant #NS 14449 and N.Y.S. Health Research Council Grants #365 and #922.)

1476 ELECTROPHYSIOLOGIC ANALYSIS OF SYSTEMS SUBSERVING BASAL GANGLIA INHIBITION OF INTRALAMINAR THALAMIC NEURONS. Howard K. Strahlendorf and Charles D. Barnes. Department of Physiology, Texas Tech University School of Medicine, Lubbock, TX 79409.

Intralaminar thalamic nuclei are throught to play an important role in the extralemniscal sensory system since responses in these structures can be evoked by peripheral noxious stimuli. Conditioning electrical stimulation of caudate nucleus (CN) or substantia nigra (SN) evokes long lasting inhibition of driven units in centrum medianum-parafasicular complex of thalamus (CM-Pf) suggesting a modulatory function of the basal ganglia on central nociceptive processing. Latency analyses have suggested CN effects on CM-Pf units are not relayed through SN since onset latencies for both CN and SN are nearly identical.

We have conducted a series of experiments in order to physiologically characterize the neural substrates of CN and SN inhibition on CM-Pf. Units in CM-Pf which responded in a characteristic manner to sural nerve stimulation were recorded with tungsten microelectrodes stereotaxically placed in chloralose anesthetized cats. Discrete conditioning stimuli to CN or SN (200 Hz, 0.2 msec, 2-5 pulses, < 500 µA) produced prolonged inhibition of CM-Pf units with an onset latency of 20-50 msec and a duration of approximately 300-400 msec. Similarly, conditioning stimulation of nucleus accumbens, Fields of Forel (FF), thalamic reticular nucleus (RN), globus pallidus (GP), endopeduncular nucleus (EN), locus coeruleus (LC), periaqueductal gray (PAG), and raphe (R) markedly inhibited firing of sural evoked CM-Pf units. Acute electrolyte lesions were placed in SN, GP, EN, FF, LC and RN. Lesions in EN, FF and LC effectively reduced inhibition from CN while only lesions in SN and FF altered SN induced inhibition.

To investigate the possibility that descending spinal inhibitory mechanisms may have suppressed afferent impulses at sites caudal to the recording electrode in CM-Pf, a stimulating electrode was placed into either PAG or the central tegmental field (FTC). Units in CM-Pf which responded convergently to sural stimulation and single shocks to PAG or FTC (0.1 msec, 0.1 mA to 0.5 mA) were tested by conditioning CN and SN. CN and SN conditioning affected units driven by sural and FTC/PAG indifferently. These data suggest CN and SN induced inhibition of intralaminar thalamic units is mediated via similar but distinct supraspinal neural pathways.

1477 ELECTRICALLY-INDUCED HYPALGESIA OF THE HUMAN DENTAL PULP AND ORO-FACIAL STRUCTURES. Richard B. Tacke*, R. Wayne Fields and Bhim S. Savara*, (SPON: Richard E. Talbott) University of Oregon Health Sciences Center, School of Dentistry, Portland, Oregon 97201

Our laboratory has described the successful induction of hypalgesia in the human dental pulp by electrical stimulation of nearby oral mucosa. (Tacke, Fields, Sakellaris, and Savara, Neurosci. Abst. 1: 119, 1975), and a comparison of the effects of varied waveforms (Tacke, Fields, Sakellaris and Savara, Neurosci. Abst. 2: 921 1976).

The present experiment compares effectiveness of the administration of electro-analgesic (EA) current to the oral mucosa with EA current applied to selected extra-oral anatomic sites on the head and neck. A 'standard' EA waveform composed of a continuous train of bidirectional rectangular pulses @ 100 pps and @ 50% duty cycle, at an intensity 10-20% below perceptual threshold was utilized. The intra-oral sites selected included the buccal oral mucosa near the test tooth and the salivary foramina. The extra-oral sites included areas adjacent to the infraorbital and mental foramina.

Electrode configurations are also compared by evaluation of data recorded when placing electrodes ipsalateral or contralateral to the test tooth. Bilateral active electrode configurations are included. The data from all comparisons will be presented and indicate that EA currents applied to both the buccal oral mucosa and to the mental foramen result in significant EA effects, however, induction time required between the two locations differs significantly.

The application of the 'standard' EA waveform, bilaterally to the mental formina of thirty six patients suffering from chronic head and neck pain has resulted in the following observation: thirty-three percent of the patients treated with EA current show a significant relief from their pain after single sixty minute session, one hundred percent of these subjects have received significant relief after two sixty minute sessions.

The patients treated suffered from chronic pain of the head and neck including trigeminal neuralgia, temporal mandibular joint pain, migraine headache, maxillary and mandibular pain resulting from trauma or surgical intervention. Evaluation of the effectiveness of EA current adminstration is achieved utilizing the model described by Melzack (Pain 1: 277-99 1975).

Preliminary experiments evaluating the efficacy of the use of EA current in operative dentistry will also be discussed.

1478 A NEUROANATOMICAL STUDY OF ANALGESIA AND CATATONIA INDUCED BY ETORPHINE IN THE RAT. B.E. Thorn and R. A. Levitt, Dept Psychol. and Sch. Med., Southern Ill. Univ., Carbondale, IL 62901

Etorphine hydrochloride is a fast-acting narcotic analgesic, several thousand times more potent than morphine. We studied the analgesic and catatonic properties of etorphine when microinjected into one of 7 neuroanatomical sites: periaqueductal gray; cerebellum; caudate putamen; basolateral amygdala; cortico-medial amygdala; hippocampmus; globus pallidus.

The flinch-jump technique was used to assess pain sensitivity and the bar test to study catatonia. Etorphine was administered in either a lug or a 2 ug dose. Each animal was used only once in one experiment and was administered etorphine only one time. The animals received a baseline bar test followed by a flinch-jump test followed by a second bar test (taking 10 min). They were then injected with drug (either water or etorphine in a lul solution) into one neuroanatomical location. All animals received both water and etorphine, presented in a couterbalanced order and separated by a four-day interval.

Neuroanatomical location ranged from AP +3.0 to AP -9.0. The region showing maximum sensitivity to the intracerebral administration of etorphine in the elevation of the nociceptive threshold lay within the periaqueductal gray (N=16). A dose of lug etorphine elicited significant analgesia and catatonia, while 2ug elicited progressively stronger effects. The area showing the least responsivity to etorphine-elicited analgesia or catatonia was the cerebellum (N=8). Neither lug nor 2ug doses elicited analgesia or catatonia. Injections into other areas produced variable results. While lug etorphine had no effect when injected into either the basolat. amygdala (N=8) or cortico-medial amygdala (N=8), 2ug did elicit analgesia and catatonia in the BLA but not in the CMA. Likewise, analgesia and catatonia were elicited in the caudate-putamen (N=8) by a 2ug but not by a lug dose of etorphine. Etorphine injections of 1 or 2ug into the globus pallidus (N=8) or hippocampus (N=8) did not produce reliable analgesia or catatonia. All results were significant at the .01 level. Interesting results due to differences in needle placement will be discussed.

This study suggests that etorphine-elicited analgesia and catatonia seen after injection into the brain is site specific, is related to affinity for the site to bind with etorphine, and is not just a result of diffusion following microinjection of a lipophilic substance into the brain. Moreover, the high correlation between degree of analgesia and presence of catatonia may suggest a common mechanism and substrate for these two actions of the narcotic system.

1479 RECOVERY OF PAIN REACTIVITY FOLLOWING SEQUENTIAL LESIONS TO THE SPINOTHALAMIC TRACT AND OTHER CORD SECTORS OF MONKEYS. Charles J. Vierck, Jr. and Mary Margaret Luck. Dept. Neuroscience and Center Neurobiological Sciences, Univ. of Fla. Col. Med., Gainesville, Fla., 32610.

Cebus albifrons monkeys were trained to escape electrical stimulation of either leg at five intensities, spanning a range from mild tingle to intense but tolerable pain (as judged by human observers). The average duration of shock received by the animals at each intensity was plotted for each leg over the required recovery period following ventrolateral spinal chordotomy. Similarly, recovery of escape responding was observed following subsequent lesions to the spinal cord, in an attempt to define the pathways that subserve pain conduction after readjustment from chordotomies that produced substantial deficits of escape behavior. The most enduring elevations of shock duration by lesion I (left chordotomy) were produced by lesions that involved all of the ventrolateral column and most or all of one or both ventral columns. Secondary lesions of the dorsal columns, Lissauer's tract and the dorsolateral columns, in various combinations, did not produce long term effects on escape responding. In contrast, a complete ventral hemisection produced a pronounced bilateral deficit that did not recover fully over 305 postoperative days. The major conclusions are: (1) that the dorsal pathways do not play a major role in the rostral conduction of information critical for pain perception in monkeys, even though these pathways receive input from high threshold receptors; and (2) in order to produce a lasting decrease of pain sensitivity in primates with spinal surgery, the lesion must be bilateral and must involve both the ventrolateral and ventral columns.

1480 SOME NEURONS OF THE SUBSTANTIA GELATINOSA PROJECT IN THE SPINOTHALAMIC TRACT. W.D. Willis, D.R. Kenshalo, Jr., and R.B. Leonard. Marine Biomedical Inst. and Depts. of Anatomy and of Physiology & Biophysics, U. Texas Med. Br., Galveston, TX 77550.

The substantia gelatinosa (SG) of the spinal cord dorsal horn plays a key role in the processing of information from nociceptors, thermoreceptors and mechanoreceptors. The SG is believed by many investigators to be coincident with both laminae II and III of Rexed. The cell types within the SG include the limitroph and central cells of Cajal. The limitroph cells are in the dorsalmost part of lamina II and have dendrites which project ventrally. The central cells are distributed throughout laminae II and III and have radially oriented dendrites in transverse section and rostrocaudally oriented dendrites in longitudinal section. There are also cells in the ventral part of lamina II with dorsally projecting dendrites, as well as transitional cell types. All of the cells of the SG are thought to have relatively short axons. However, we have found that some neurons of the SG project to the diencephalon.

Horseradish peroxidase (HRP) was injected into the diencephalon in each of 8 monkeys (Macaca fascicularis). The monkeys were anesthetized with sodium pentobarbital. The amount of HRP injected was 0.2-1.0 µl (50% sol'n.) in 1-4 sites. The animals were perfused after 3 days with Ringer's followed by 2.5% glutaraldehyde and 0.5% paraformaldehyde. After further fixation the brain and spinal cord were soaked in 30% sucrose. Frozen sections were made at 50 µm and reacted with either O-dianisidine or tetramethylbenzidine. A total of 4439 cells (average of 555 cells per animal) were identified in the spinal cord at L5 and caudally as belonging to the spinothalamic tract (STT) by the presence of HRP reaction product following retrograde transport. Most of the cells were in laminae I and V when HRP was injected into the lateral thalamus and in laminae VI-VIII when the injection was in the medial thalamus. An unexpected observation was an occasional labelled cell within the SG. To date, 50 such cells (1.1% of the total population of STT cells) have been found, excluding large cells near the boundary between lamina III and IV. Most of the labelled SG cells were contralateral to the side of the thalamic injection, and most could be classified either as limitroph (25) or central cells (17). The labelled cells were found in lamina II (34) and III (16). STT cells were observed in the SG in 6 of the 8 monkeys. In one negative experiment, the injection site was too rostral to label many STT cells in any cord region.

We conclude that the SG contains neurons which contribute to long ascending tracts, and thus the SG is not a completely closed system as is usually assumed.

PLASTICITY

1481 COMPENSATORY CHANGES IN CEREBRAL TYROSINE HYDROXYLASE ACTIVITY FOLLOWING INTRAVENTRICULAR 6-HYDROXYDOPAMINE. Ann L. Acheson* and Michael J. Zigmond. Department of Biological Sciences, University of Pittsburgh, Pittsburgh, PA 15260.

Previous studies have shown that the destruction of sympathetic nerve terminals by the intravenous administration of 6-hydroxydopamine (6-HDA) results in an increase in tyrosine hydroxylase (TH) activity in the adrenal medulla. The present studies were designed to investigate whether a similar increase in TH activity might occur in residual norepinephrine (NE)-containing nerve terminals in brain following intraventricular injection of 6-HDA. Rats were given a single intraventricular injection of 6-HDA (250 µg in 20 µl) or vehicle (0.9% NaCl, 0.1% ascorbic acid) and sacrificed by decapitation 3-21 days later. Cerebellum, hippocampus and the area containing the locus coeruleus were dissected out and frozen. Tissue was homogenized in a Tris-HCl buffer and spun at 49,000 x g for 60 min. Soluble TH activity was then determined in the supernatant by measuring the evolution of $^{14}CO_2$ from carboxyl-labeled ^{14}C-L-tyrosine (75 µM) in the presence of an excess of DOPA decarboxylase and saturating 6MPH$_4$. 6-HDA treatment was found to irreversibly deplete NE in hippocampus and cerebellum by >80% within 3 days, suggesting that no more than 20% of the NE terminals remained. In cerebellum, values for TH activity rose sharply above that predicted by NE levels. By 3 days, TH was 65% of control, where it remained for the duration of the study. Hippocampal TH activity increased from 20% on day 3 to 32% of control on day 12, and reached 66% of control by day 21. In locus coeruleus, an area containing the cell bodies of noradrenergic neurons which terminate in hippocampus and cerebellum, TH activity was 188% of control on day 5, was back down to control values by day 12, and was 75% of control on day 21. These results are consistent with the hypothesis that sub-total destruction of NE terminals induces an increased synthesis of TH in locus coeruleus. TH is then transported to the nerve terminals via a slow axonal transport mechanism, reaching cerebellar terminals, which are in close proximity to the cell bodies, within 3 days, and reaching the more distant hippocampus by 21 days. Similar time courses for the appearance of increased TH activity have been reported following reserpine. Further experiments will determine whether the increased TH activity is actually a result of an increase in the number of TH molecules and whether it is accompanied by an increase in the functional capacity of the remaining terminals for NE release. If so, the observed compensatory increase in TH activity may help explain the lack of behavioral deficits in these lesioned animals.

1482 EFFECTS OF NEONATAL LATERAL HYPOTHALAMIC DAMAGE UPON SENSORIMOTOR, SUCKLING, AND REGULATORY BEHAVIORS. C. Robert Almli, David L. Hill*, Nathaniel T. McMullen, and Robin S. Fisher*. Dept. Psychol., Ohio Univ., Athens, Ohio 45701.

Newborn albino rats (males and females) sustained bilateral destruction of the lateral hypothalamic area (LHA) at one day of age (24 hours ± 12 hours of age, Day-1). Following brain damage, the pups were tested daily for sensorimotor behavioral capacity (e.g. olfactory orientation, vibrisseal placing, activity level), and at 2, 3, and 14 days of age, the pups were tested for suckling-attachment behavior using an anesthetized dam. Body weight was measured daily, and responses to dipsogenic challenges were measured at 50-60 days of age.

Pups sustaining bilateral LHA damage typically lost body weight for no more than one day postlesion. Thereafter, they maintained an attenuated growth curve such that the pups were 20-25% below control body weight at 60 days of age. The suckling-attachment tests revealed deficits in the pups' attachment to the nipples, and these suckling deficits may underlie the attenuated growth displayed by the LHA rats.

The sensorimotor testing and evaluation of clinical signs revealed "no deficits" in the ontogeny of behavioral capacity of the brain-damaged pups. The pups did not display any alteration in orientation to multimodal sensory stimulation, and they failed to display any alteration of motor reflexes or locomotor behaviors.

Regulatory testing revealed that the pups respond to feeding and drinking challenges with intakes that range within the "low normal" level.

Bilateral LHA destruction sustained by neonatal rats failed to produce many of the symptoms of the classical "Lateral Hypothalamic Syndrome". The pups did not cease suckling or become adipsic or aphagic, they did not display significant residual feeding and drinking deficits, and they did not display sensory neglect, motor, postural or activity level deficits. The effects of LHA destruction were dependent upon the age of the rat at the time of brain damage, and early brain damage does not result in deficits as the animal ages.

1483 PROTEIN PHOSPHORYLATION IN REGULATION OF NEUROTRANSMITTER RELEASE; THE BLOOD PLATELET AS A MODEL. W.F. Bennett*, G. Lynch, M.D. Browning*, Dept. of Psychobiol., Univ. Calif., Irvine, CA 92717.

Serotonin release by blood platelets is a process similar in many respects to neurosecretion by synaptic terminals in the brain. Protein phosphorylation has been correlated with aggregation and release in blood platelets just as it has been suggested to control neurosecretion. We have undertaken to characterize the proteins affected during stimulation for 5-HT release, and have found that a basic protein (pI=9.0) of 40K daltons becomes phosphorylated in a manner which correlates with the time course and extent of release. Additionally a 20K dalton protein (pI=4.5-5.0) shows similar effects, but to a lesser degree. We have observed phosphorylation in the absence of release, but not release without phosphorylation, and have concluded that 40K phosphorylation is necessary, although not sufficient in itself, for release. The 40K basic protein has tentatively been identified as troponin-T, and in view of the known role of troponin in regulation of calcium sensitivity in muscle contraction, we propose that the phosphorylation of troponin-T confers calcium sensitivity upon the process of serotonin secretion.

1484 VISUAL CAPACITIES OF ADULT CATS WHICH WERE REARED WITH A LESION IN THE RETINA OF ONE EYE AND THE OTHER OCCLUDED. M. Berkley, S.M. Sherman, D.S. Warmath*, J. Tunkl. Dept. Psychology, Florida State U., Tallahassee, FL 32306; Dept. Physiology, U. Virginia, Charlottesville, VA 22903.

Cats monocularly deprived of form vision during the first few months of life suffer severe visual defects in the deprived eye when tested as adults. Perimetry testing in such animals indicates that they respond only to targets presented in the monocular segment of the visual field of the deprived eye, a region shown by electrophysiological and histological studies of the lateral geniculate nucleus (LGN) and visual cortex to be less affected by monocular deprivation.

These findings led to the suggestion that during development there is competition between the two eyes for control of neurons in those portions of the visual system in which binocular vision is represented. This hypothesis was strengthened by histological and perimetry studies of kittens raised with a lesion in the retina of one eye and the other occluded. In the LGN of these cats, a small segment of normal cells was found corresponding to the locus of the retinal lesion (critical segment), and perimetry tests demonstrated that the cats responded to visual stimuli presented in this region of the visual field.

To determine the visual capacity of the critical segment, in 2 kittens the eyelids of one eye were sutured closed and a lesion made close to the area centralis (AC) of the retina of the other (nondeprived) eye. When tested monocularly with the nondeprived (retinal lesion) eye as adults, the cats performed normally on light vs. dark and 0 vs. + problems. Grating acuity was somewhat low (2.0 c/d) in one cat and normal in the other (4.5 c/d). Reconstruction of the retinal lesions from fundus photographs and whole mounts of the retinae showed that in both cases the lesions were to one side of the AC. In the animal with reduced acuity, the lesion was smaller and medial to the AC, probably interrupting fibers of passage.

Informal perimetry tests of the deprived eye confirmed the presence of a small region of vision in the area of the visual field corresponding to the locus of the lesion in the nondeprived eye. Acquisition of the form and acuity tasks with the deprived eye was extremely poor and similar to that seen in ordinary monocularly deprived (MD) cats. Unlike ordinary MD cats, the critical segment cats reached a high level of performance on the visual tasks on some test days and after binocular training were able to reach criterion performance with the deprived eye. These latter findings suggest that the cats are capable of seeing with a small critical segment but may not learn to utilize it unless they have been given prior binocular training on the discrimination task.

1485 FORELIMB MOVEMENTS AFTER DORSAL RHIZOTOMY WITHOUT VISUAL FEEDBACK DURING TRAINING OR TESTING. D.Berman, A.D.Blau*, J.E.Herskovic* and A.J.Berman. Dept. Neurosurg., V.A.Hosp., Bronx,N.Y. 10468 and Dept. Psychol., Queens College, Flushing, N.Y. 11367.

Previous studies indicate that bilaterally dorsal rhizotomized monkeys can touch targets without visual guidance. These animals however, were permitted vision of their rhizotomized limb position in relation to the target during training. Subsequent performance could therefore be explained on the basis of mechanisms established when visual feedback was available. In the present study, three monkeys were trained to use unilaterally dorsal rhizotomized (C2-T3) forelimbs to touch targets which they were not permitted to see at any time, before or after surgery.

Training and testing were carried out in darkness, utilizing a 3x3 display of touch activated buttons mounted in front of the chaired animal. Initially, the monkey was shaped to touch a sequence of two lit buttons. The first (start) button remained lit until touched, then was turned off and the second (Rf) button lit. Touching the Rf button resulted in delivery of a food pellet. Once these visually guided responses had been trained, the monkey was required to touch intervening (bridge) targets without visual guidance to turn on the Rf light. Bridge positions were visually cued by brief light pulses at an intensity and duration such that the human observer could not see the target or its surround. Repetition rate was slow (0.67/sec) so that monkeys did not keep their hands over the target to obtain visual feedback from subsequent flashes. If the monkey failed to touch the bridge within 15 sec the trial was terminated.

Preoperatively, monkeys reached criterion (bridge touched 9/10 trials without error) with randomly presented single or dual bridges within 7-30 sessions. When tested 14-21 days after surgery, performance with the intact limb was unaffected. Movements of the rhizotomized limb, however, had to be shaped. This was accomplished by covering the response panel, except for the start and Rf buttons, and reinforcing successive approximations to the required movements with the room light on. This required 10-12 sessions, after which testing was continued in darkness and bridges were introduced. Monkeys were successful in touching visually cued targets with their rhizotomized limbs. There was a longer latency, however, more errors and more variability from session to session with the rhizotomized than the intact limb.

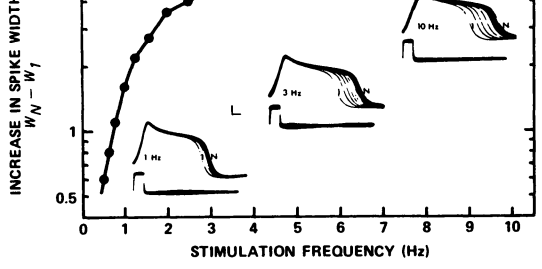
Several alternative explanations for these results are offered. Central representations of relevant movements may be established before surgery. Eye movements to the pulsed bridges may become paired with efferent commands after surgery. Transfer from the intact limb may have facilitated performance. Finally, ventral root afferents may mediate the behavior observed. (Supported by NIH Grant #2RO1-NS 12330-02A1 to AJB)

1486 INFLUENCE OF CATECHOLAMINES ON THE REGULATION BY PATTERNED PREGANGLIONIC NEURAL ACTIVITY OF TRANSMITTER STORES IN A SYMPATHETIC GANGLION. R.I. Birks (SPON: T.L. Sourkes). Dept. Physiol., McGill Univ., Montreal, Canada H3G 1Y6.

The presynaptic stores of acetylcholine in the cat superior cervical ganglion increase by 30-70% during prolonged (30-420 min) preganglionic stimulation with patterns of pulses whose mean frequencies are within physiological limits (0.2-3.0/s). The increases in stores occur when the pulses are grouped into brief (0.05-1.0s) trains at high frequency (10-60/s); but not when they are equally spaced in the patterns. When the mean frequency of the pattern is greater than 5/s the increase occurs only after termination of the stimulation (Birks, R.I., J. Physiol. In Press, 1978). It has now been found that these changes in transmitter stores can be reduced or prevented when patterned stimulation is carried out in the presence of circulating catecholamines at concentrations that are known (Buhler, H.U., Da Prada, M., Haefely, W. and Picotti, G.B. J. Physiol. 276, 311-320, 1978) to occur in animals under stress. The increase in stores was reduced or prevented by arterial infusion of nor-epinephrine or epinephrine at 70-250 ng/kg/min during patterned stimulation in animals that retained their ganglionic circulation intact. Similar depression of the response to patterned stimulation was obtained in ganglia perfused with choline-Locke when the solution contained nor-epinephrine or epinephrine at a concentration of 5 ng/ml. Since the increase in transmitter stores has also been shown to be reflected in a corresponding increase in transmitter output (Birks, R.I. J. Physiol. 271, 847-862, 1977), the present and previous results suggest that transmitter release at ganglionic synapses is subject to modulation both by the form of neural input from the CNS and by the level of hormonal output from the adrenal medulla, acting on the amount of transmitter stored at preganglionic nerve terminals. (Supported by the Muscular Dystrophy Association of Canada).

1487 LOW-FREQUENCY CALCIUM SPIKE BROADENING IN CULTURED MOUSE DORSAL ROOT GANGLION CELLS. Thomas H. Brown, A. Page Chiapella* & John H. Peacock. Department of Neurology, Stanford University Medical School, Stanford, CA 94305

Calcium action potentials recorded from the soma of cultured mouse dorsal root ganglion cells were found to increase in duration during a low-frequency stimulus train. The characteristics of this use-dependent plasticity were studied in 271 cells at 37°C in a defined low NaCl (4 mM) test medium (maintained at 330 mosmols and pH 7.2) which included $MgCl_2$ (2 mM) and either $CaCl_2$ (8 mM) or $BaCl_2$ (0.8 to 8 mM). Cells were impaled with two intracellular microelectrodes, one for passing current and the other for recording voltage. Ca spike broadening and its frequency dependence are illustrated below. Spike broadening in these cells is never accompanied by an increase in the maximum rate of spike rise (dV/dt) or in the spike amplitude; if anything, both decrease during a train. Tetraethylammonium (TEA, 5 to 50 mM), added to test solutions, causes Ca spikes to broaden but it eliminates use-dependent broadening. Barium spikes are also very broad and they sometimes show extreme (> 100-fold) use-dependent broadening. The amount of broadening during a train can be reduced or eliminated by interpolating hyperpolarizing current pulses between Ca spikes. A similar low-frequency Ca spike broadening has also been observed in certain identified molluscan neurons, where it has been hypothesized (Thompson & Getting, Neurosci. Abstr. 3, 189, 1977) to result from cumulative inactivation of a TEA sensitive outward K^+ current rather than augmentation of an inward Ca^{++} current. Our results are consistent with this potassium inactivation hypothesis. (Supported by NIH Grant NS12151).



1488 EVIDENCE FOR AN ORDERLY ARRANGEMENT OF OPTIC AXONS IN THE CENTRAL PATHWAYS OF VERTEBRATES AND ITS IMPLICATIONS FOR THE FORMATION AND REGENERATION OF OPTIC PROJECTIONS. S.M. Bunt*+ and T.J. Horder* (SPON: M. Jacobson) Dept. Anat., South Parks Rd., Oxford, G.B. (+Present address, Dept. Anat., Univ. of Utah, S.L.C., Utah 84132.)

The topographical arrangement of optic fibers within the optic nerve (ON), tracts and tectal bundles was investigated by following to the tectum, using light microscopy of 2μ toluidene blue stained plastic sections, or where necessary, electron microscopy, the degenerating fibers caused by a trans-scleral retinal lesion.

In the fish (Cichlasoma biocellatum), possessing a flattened, ribbon-like ON; the observations confirmed our previous work on the cylindrical ON of the goldfish. (J. Physiol. 171,10-12P (1977)). A dorsal retinal lesion resulted in a line of degeneration along the center of the ON which passed ventrally; a ventral lesion resulted in a strip down each side of the ON that passed dorsally as the degeneration was traced centrally. Thus,as the fibers reach the tectum they are arranged "tectotopically". In 5 day old chicks and the newts Triturus vulgaris, alpestris, and cristatus, the resultant degeneration could be followed as a discrete patch from the fundus to the tectal surface. In adult Xenopus and Rana a concise lesion produced degenerating myelin figures across the ON section. When HRP was applied to the retinal cut it was found that the majority of the tectal bound unmyelinated axons remained segregated in the ON while the few myelinated axons destined for diencephalic nuclei spread at random. When a retinal quadrant was removed from St. 42 Xenopus tadpoles and the ON, (with on av. 250 unmyelinated fibers), observed at St. 45; the resultant degeneration was still limited to 1/2 to 1/3 of the ON cross section. This suggests that the order of the adult ON is not the result of random growth followed by selective death.

These results, together with older reports on the rat, cat, rabbit, oppossum, monkeys and man, suggest that optic fibers reach their termination sites in a topographically ordered array with little intermingling of fibers from different retinal areas at any point along their route. Without evidence for active resorting of fibers, the observed order could be produced during development by new fibers growing alongside the older fibers using only "passive" mechanisms such as contact guidance and fasciculation. The ordered termination pattern on the central nuclei could result from, in development, fibers terminating on the first available tectal cell they encounter and, in regeneration, by the cells they encounter being limited by their position within the fiber array as it crosses the tectal surface. Where the tectum influences the formation of the optic projection, the contribution of the fiber organization to the formation of the nearest neighbor order of the terminations makes it unnecessary to postulate labelling of individual tectal cells. (M.R.C.,G.B., Wellcome trust and NSF #BNS 77-20219).

1489 THE EFFECT OF ALTERED LIMB MOBILITY ON GROUP Ia EPSPs IN DEFINED TYPES OF CAT MEDIAL GASTROCNEMIUS MOTOR UNITS. R. E. Burke, R. F. Mayer, K. Kanda*, B. Walmsley* and J. A. Hodgson*. Lab. of Neural Control, NINCDS, NIH and Dept. Neurol., Univ. of Maryland.

As part of a study of the effect of chronic immobilization on medial gastrocnemius (MG) motor units, we examined the peak amplitude of composite homonymous (MG) and heteronymous (lateral gastrocnemius - soleus, or LGS) group Ia EPSPs in motoneurons of defined motor unit type (Burke et al., J. Physiol. 234,723,1973). The left hindlimb was immobilized in 10 cats by inserting stainless steel pins through bone, spanning knee and ankle joints, under aseptic conditions. After short (3 and 5 weeks in 2 cats) and long (17 - 29 weeks in 8 cats) survival periods, Ia EPSPs and motor unit properties were examined under pentobarbital anesthesia using methods of muscle nerve stimulation and intracellular recording with hyperpolarization block of antidromic spikes as in a previous study of Ia EPSPs in normal cats (Burke et al., J. Neurophysiol. 39,447,1976). Table 1 shows the comparison between Ia EPSPs in normal and immobilized animals.

TABLE 1

Unit Type	EPSP Source	Normal (N=10)	Short Term (N=2)	Long Term (N=8)
FF	MG	4.1 ± 1.5 (58)	2.8 ± 1.3 (14)*	3.0 ± 1.2 (59)*
	LGS	1.2 ± 0.6 (58)	0.6 ± 0.1 (15)*	0.7 ± 0.3 (52)*
FR	MG	7.5 ± 1.9 (23)	4.2 ± 2.4 (7)*	4.4 ± 1.6 (12)*
	LGS	2.0 ± 0.9 (21)	1.1 ± 0.3 (7)	1.1 ± 0.3 (11)
S	MG	9.1 ± 1.8 (27)	6.2 ± 1.5 (3)	5.9 ± 1.5 (24)*
	LGS	2.8 ± 1.1 (26)	1.1 ± 0.5 (4)*	1.6 ± 0.6 (20)*

* = control and experimental means differ with $p < 0.001$

The data in Table 1 show that both homonymous and heteronymous group Ia EPSPs are, on the average, between 25% and 45% smaller in MG motoneurons after chronic hindlimb immobilization in all motor unit types when compared with EPSPs in normal cats. Group Ia EPSPs in MG motor units of cats with paraplegia (complete cord transection at Th12) or monoparesis (cord hemisection at L1) of comparable duration were not different in amplitude from normal. Immobilized ankle extensors were not "disused", since chronic EMG recordings showed appropriate activation patterns during stepping. The many factors that can influence EPSP amplitude were not systematically studied but we assume that immobilization affects (probably decreases) Ia spindle afferent firing and that this causes a net decrease in group Ia synaptic efficacy.

1490 INCREASED DENDRITIC BRANCHING IN HEMISPHERES OPPOSITE EYES EXPOSED TO MAZE TRAINING IN SPLIT-BRAIN RATS. Fen-Lei F. Chang and William T. Greenough. Dept. Psych. and Neural and Behavioral Biology Prog., Univ. IL at Urbana-Champaign, IL 61820

The amount of branching of dendrites is affected by the rearing environment. Preliminary studies also indicated small but consistent differences in dendritic branching between extensively maze-trained adult rats and handled rats. These differences appeared in the upper region of the apical dendrite of layer 5 pyramidal cells of occipital cortex.

To study general stimulation versus specific aspects of the maze training experience, we used a split-brain preparation and a contact eye occluder system to direct visual aspects of the training experience to a single hemisphere. Six groups of 60-70 day old male littermate triplet Long-Evans hooded rats were used (18 animals). The full extent of the corpus callosum was sectioned in a way which did not damage cerebral hemispheres, subcortical structures, or the midsaggital sinus. Two littermates of each set received 25 days training, 25 trials per day, on a series of Hebb-Williams maze problems for water reward. Each animal had an opaque contact lens inserted in one eye during the 2-3 hr. training period. For group T-T, the lens was alternated from one eye to the other on successive days, such that both hemispheres were opposite "trained" eyes. For group T-N, the lens was always placed in the same eye, directing visual training experience to one (T) hemisphere. Group N-N animals had either alternated or unilateral lens placement and were merely handled and given water several times each day.

Ten to 20 Golgi Cox stained layer 5 pyramidal neurons from each hemisphere of each rat were traced and analyzed with computer-aided microscope system by experimenters unaware of individual tratments. Intersections between concentric 20 μm spheres and the 3-dimensional dendritic field were counted. Neurons in hemispheres opposite eyes exposed to the training experience (both T-T group hemispheres and hemisphere T from the T-N group) had significantly more intersections, reflecting dendritic length, in regions of the apical dendrite beyond 200 μm from the cell body than those in hemispheres opposite the occluded eye in group T-N or opposite either eye in group N-N. Of 12 possible within-litter comparisons (T-T vs N-N; T-N (T) vs T-N (N)), 10 favored the T hemispheres or animals. The results indicate that visually-mediated aspects of maze training experiences may alter dendritic branching patterns in young adult rats. Supported by NSF BMS 75-08956 and BNS 77-23660 and PHS RR 07030.

1491 GLUCOCORTICOIDS DECREASE REACTIVE SYNAPTOGENESIS IN THE RAT DENTATE GYRUS. Carl W. Cotman, Stephen W. Scheff and Larry S. Benardo*. Dept. Psychobiology, Univ. Calif., Irvine, CA 92717.

We have investigated whether or not glucocorticoids play a role in modifying reactive synaptogenesis in the hippocampus following lesions of the entorhinal cortex. Corticosteroids are known to control and prevent cerebral edema and are sometimes used clinically following head injury. In previous studies we have shown that the hippocampus displays robust axonal growth and new synapse formation following partial denervation. The hippocampus has also been shown to have specific receptors for cortisol, one of the drugs utilized to control edema. Consequently this area of the brain is well-suited for testing the effects of glucocorticoids on the sprouting reaction. We have examined the response of various hippocampal afferents following a unilateral entorhinal lesion in control animals and those treated with cortisol.

Animals were given daily injections of cortisol six day preoperatively and six or fifteen days post-operatively. Control animals were given cortisol and no lesion and still others were injected with the vehicle only and lesioned. The brains were examined for changes in septal input by means of AChE staining and for changes in the commissural-associational (CA) fiber plexus by means of the Holmes fiber stain. Animals treated with cortisol and lesioned consistently showed a marked decrease in the spread of the CA fiber plexus and in the rate at which the intensification of AChE staining occurs. Additionally the brains were stained for astroglia. In both lesioned and non-lesioned animals treated with cortisol there was a marked hypertrophy of astrocytes, a response which was not present in animals treated with only the vehicle. Thus the administration of glucocorticoids significantly limits reactive synaptogenesis in the hippocampus possibly through an inhibitory action of hypertrophied glial cells.

These findings raise the question of whether corticosteroids administered to treat edema decrease axon sprouting. Moreover, these findings may account in part for the reduction in axon sprouting observed in aged animals. Previously it has been reported that aged animals exhibit both high corticosteroid levels and hypertrophy of astrocytes. Thus altered hormonal levels may be one of the factors responsible for reduced axon sprouting following cell loss in aged animals. (Supported by research grants AG 00538 and NS 08597)

1492 EXPANSION OF RAT CEREBROVASCULAR ANASTOMOSES. Peter Coyle and Pamela G. Brubaker*. Dept. Anat., Univ. Mich. Med. Sch., Ann Arbor, MI 48109.

Anastomoses exist between branches of the three major cerebral arteries in humans and rats. Objectives were to determine if the anastomotic branches could adequately nourish the vascular field of the middle cerebral artery following its interruption near the proximal end and to note chronic size and spatial pattern changes, if any, of the anastomoses.

Wistar rats of each sex ranging from 23-53 days of age were anesthetized with Ketalar 125-200 mg/Kg body weight. Skin over the right zygoma was shaved and a nearly 0.5 cm vertical incision was made extending from the zygomal vibrissa dorsalwards for removal of most of the temporalis muscle and to allow a 2-2.5 mm horizontal by 0.5-1.0 mm vertical trephine hole to be drilled in the squamosal bone extending from the zygomatic point rostralwards. Under stereozoom microscope observation the dura mater was reflected and the major ramus of the middle cerebral artery was transected superior to the rhinal fissure. Bleeding was not a problem. The removed muscle was replaced, the wound sutured with silk, 0.5 ml of 2% Evans Blue made with physiologic saline was injected subcutaneously, and the animal returned to its cage. Of the reported 16 animals, 8 underwent the above procedures, 4 were operated to the point of cutting the dura mater and 4 had minor branches of the middle cerebral vessel transected. All received Evans Blue and 15 were injected with vultex, a latex rubber to demonstrate the cerebral arterial tree at time of sacrifice 5-9,14,19,20 & 27 days later. Of the 12 brains having surgery all showed Evans Blue at the transection site and one brain had ipsilateral leakage concentrated at the occiput. The data suggest an adequate blood supply is usually provided through anastomotic vessels. Only rats with a transected vessel had expanded anastomoses between branches of the ipsilateral anterior, posterior and middle cerebral arteries. No anastomotic changes were observed in the contralateral hemisphere nor in controls. The dorsal expansion was present at 5 days and lateral anastomoses between branches of the supra- and infra-rhinal fissure portions of the middle vessel were evident. The expansion was characterized by greatly increased vessel diameters and a seemingly increased vessel tortuosity. Possibly the number of anastomoses increased. Project received support from the Michigan Heart Association and a Univ. of Mich. Biomedical Research Grant.

1493 CHANGES IN THE ORGANIZATION OF THE LATERAL POSTERIOR NUCLEUS OF THE GOLDEN HAMSTER AFTER NEONATAL SUPERIOR COLLICULUS LESIONS. Barbara J. Crain and William C. Hall, Department of Anatomy, Duke University Medical Center, Durham, N.C. 27710.

The rostrolateral subdivision of the lateral posterior nucleus (LP) in the golden hamster is normally characterized by synaptic clusters in which medium-sized axon terminals synapse around and along a central dendrite. The vast majority of these terminals are contributed by axons from the ipsilateral superior colliculus, although within restricted regions of the subdivision some are contributed by the contralateral superior colliculus and the contralateral retina. In contrast, axons from the ipsilateral posterior neocortex form very large terminals which make numerous synaptic contacts with complex dendritic appendages of a single dendrite. These terminals occasionally extend into the synaptic clusters but they are easily distinguished there from the medium-sized terminals. All four afferent pathways also contribute small terminals to the neuropil outside the synaptic clusters.

When a unilateral lesion of the superior colliculus is made on the day of birth, the ipsilateral LP develops in the absence of the major input to its synaptic clusters. Under these experimental conditions, the retina (Schneider, Brain Behav. Evol. 3:295, 1970) and the remaining colliculus contribute many more terminals to LP than usual. By removing the contralateral colliculus and injecting the contralateral eye with ^{3}H-leucine and then processing adjacent sections for anterograde degeneration and autoradiography, we showed that these two projections to LP expand to share a common border but do not overlap. Typical synaptic clusters are still present in the rostrolateral subdivision of LP under these conditions. Degeneration studies indicate that most of the medium-sized axon terminals in the clusters are now contributed by either the contralateral superior colliculus or by the retina.

These results suggest that the contralateral superior colliculus and retina normally compete with the ipsilateral superior colliculus for postsynaptic sites within the synaptic clusters of LP. In the absence of the ipsilateral tectal pathway, these two inputs form more synaptic terminals but continue to compete with each other for postsynaptic space. Supported by NINCDS Grant #NS-09623 to W. C. Hall.

1494 NORMAL AND ABNORMAL CALLOSAL CONNECTIONS IN THE OCCIPITAL CORTEX OF ALBINO RATS. C. G. Cusick* (SPON: R. D. Lund). Dept. Biol. Struct., Univ. Wash. Sch. Med., Seattle, WA 98195.

The total pattern of callosal projection was studied using tangentially cut sections of flattened hemispheres stained with a bleached Fink-Heimer method and viewed with dark field illumination. Area 17 is outlined by callosal degeneration except anteriorly. The 17/18a border splits anteriorly to form a ring-like pattern of degeneration, a prominent landmark in pigmented as well as albino rats. It is located posterodorsal to the PMBSF which is identified in this material by a callosal projection to the barrel septae. A band of degeneration extends laterally from the ring along the anterior border of 18a and probably marks the position of the region "D" vertical meridian representation of Montero. Area 18b, lying medial to area 17, receives a homotopic callosal input and a previously undescribed heterotopic projection. The region receiving the heterotopic projection is rostromedial to area 17 in the approximate position designated as region "E."

The stability of the pattern of callosal termination was tested in a size disparity experiment. Within 24 hours of birth, rats from several litters received large lateral cortical ablations or slit lesions to block callosal connections to and from the more lateral cortex of one hemisphere. The pattern of callosal connections was tested with Fink-Heimer and autoradiography 5-16 weeks later. In animals in which the 17/18a border remained intact, callosal fibers originating from regions lateral to this border tended not to invade area 17 or the 17/18a border. In animals in which the 17/18a border was removed at birth, callosal axons are found to end on the damaged side in patches situated rostromedially in areas 18b and 17. Double mapping experiments show that the projection to area 17 comes predominantly from around the 17/18a border on the intact side while 18b projections originate more laterally. Reorganization of the total callosal projection was studied in tangential sections after callosal section. In animals in which a large amount of cortex remains, the 17/18a border with its anterior "ring" can be seen and the acallosal area 17 is approximately its normal size. When a small amount of cortex remains, the acallosal region is reduced and the normal terminal pattern is obscured. The 17/18a callosal projection is broader after removal of the ipsilateral thalamus. These results suggest that the reorganization of the callosal projection in the visual area relates to both the boundaries of visual maps and the integrity of the geniculocortical system. (Supported by USPHS Grant GM-07108 from the National Institutes of Health.)

1495 INDEPENDENCE FROM ENVIRONMENTAL INFLUENCE OF THE DEVELOPMENT OF THE CIRCADIAN PACEMAKER OF MICE. Fred C. Davis* and Michael Menaker. Dept. of Zoology, Univ. of Texas, Austin, TX 78712.

The circadian rhythm of running-wheel locomotor activity was measured in *Mus musculus* (C57BL) raised on light cycles with periods (T) different from 24 hours. Parental mice were placed in L:D 11.67:8.33(T=20) or L:D 16.33:11.67(T=28). These cycles have the same ratio of light to dark as a standard cycle of L:D 14:10. The locomotor activity rhythms of all mothers were observed to be entrained prior to mating and were continuously monitored until 3 weeks post weaning. The offspring were weaned at 3 weeks and group housed (by litter) until 7 weeks of age. 15 males and 5 females from each group were then placed in individual running-wheel cages where they remained on T=20 and T=28 for 3 weeks. All of the animals but one were entrained, and at 10 weeks of age were placed into constant darkness (DD). An initial difference in the average free-running periods (τ) of the two groups was measured, but after 50 days (in DD) had disappeared. Similar temporary effects of L:D cycles of T≠24 hours have been shown with adult *Mus musculus* (Pittendrigh and Daan. J. Comp. Physiol. 106: 223, 1976). We have shown that such cycles have no greater effect on the circadian pacemaker of developing animals than they do on adults. Despite long-term entrainment, the period of the circadian pacemaker of mice develops uninfluenced by light/dark and maternal cycles with periods very different from 24 hours. Supported by NIH grant HD-03803.

1496 HETEROSYNAPTIC CONTROL OVER SYNAPTIC MODIFICATION IN THE DENTATE GYRUS. Robert M. Douglas (SPON: G. V. Goddard). Dalhousie Univ., Halifax, N. S. CANADA B3H 4J1

Very long-lasting increases in synaptic efficacy of the perforant path - granule cell synapses (enhancement) can be reliably produced by brief periods of high-frequency activation of the perforant path fibers. The perforant perforant path axons make excitatory synapses in the outer two thirds of the molecular layer. A commissural projection terminates in the inner third of the molecular layer. The predominate effect of stimulation of this input is inhibition of perforant-path-evoked granule cell discharge.

High-frequency trains (eg. 8 pulses at 400 Hz) applied to the commissure had little or no long-term effect on the size of either the commissural or perforant-path-evoked responses. However, when the commissure trains were combined with perforant path trains, enhancement of the perforant path response was greatly reduced. In some cases enhancement was completely blocked. Short-term changes in the perforant path response were largely unaffected. The timing of the onsets of the two trains was critical. The reduction in enhancement was obtained if the start of the commissure train preceded the start of the perforant path train by as little as 2-3 msec, whereas perforant path trains that preceded the commissure trains by the same amount produced almost as much enhancement as normal.

High-frequency activity on the commissure was essential. When the perforant path train was preceded by a single commissure pulse, enhancement was unaffected. Since the single pulse produced considerable inhibition of the perforant-path-evoked population spike, it suggests that the action of the commissure on perforant path plasticity was not mediated via manipulation of post-synaptic discharge.

1497 2-DEOXY-GLUCOSE STUDIES OF MOUSE AND RAT SmI BARREL CORTEX FOLLOWING EARLY LESIONS OF THE VIBRISSAE. D. Durham*, C. Welt and T.A. Woolsey. Dept. Anat. and Neurobiol., Washington U. Sch. Med., St. Louis, MO 63110 and Res. Dept. Central Wisconsin Center for the Developmentally Disabled, Madison, WI 53704.

Early lesions to the vibrissae have been shown to alter the normal arrangement of both barrels and the specific thalamocortical afferents in the mouse and the rat SmI cortex. It is of interest to know what functional changes, if any, accompany the morphological ones. These changes have been assessed in the rat by electrophysiological methods (Welt, 1977). Another way to determine the functional properties of the cortex in these animals is to use radioactive 2-deoxy-glucose (^{14}C-2-DG), which is a marker for functionally active brain regions. In this study, various combinations of vibrissae were lesioned in newborn rats and in mice of various postnatal ages. Thirty to sixty days after birth, the animals were examined with the 2-DG technique (Durham and Woolsey, 1978). To stimulate selectively particular groups of cortical cells, various combinations of vibrissae were left intact and the remainder clipped prior to injection of the 2-DG. For example, animals in which Row-C vibrissae were lesioned were divided into two groups: i) all whiskers clipped except those that had regrown in Row-C, and ii) all whiskers clipped except those in the adjacent Rows B and D. The former were used to test whether the regrown vibrissae were capable of driving cortical cells and the latter to determine whether the adjacent vibrissae could activate neurons in the cytoarchitectonically altered regions. All tissue was processed for film autoradiography and subsequently stained with thionin as described previously. In addition, similarly lesioned littermates were examined using the SDH histochemical method to demonstrate thalamocortical afferents.

We found that: 1) The patterns of thalamocortical terminals as seen with SDH match the cytoarchitectonics seen in the Nissl stained material; 2) In cases where the cortical anatomy was most severely disrupted, there was no evidence that regrown whiskers could drive cortical cells. If only the whiskers in adjoining rows were left intact, they activated only the appropriate barrels. There was no spread of activity into the altered zones; 3) In cases where the cortical alterations were less severe there was evidence that regrown whiskers activated the cells in the altered zone. The whiskers in the adjacent rows did not drive the barrels associated with the damaged whiskers, and 4) the results were similar for mouse and rat. The extent of cortical damage produced by vibrissal lesions in newborn rats varied considerably. This presumably is related to differences in gestational age of the animals at birth.

1498 ASYMMETRICAL DENDRITIC DEVELOPMENT OF NEURONS IN THE ACCESSORY SUPERIOR OLIVARY NUCLEI OF ALBINO RATS RAISED UNDER MONAURAL "DEPRIVATION".* Albert S. Feng. Department of Physiology and Biophysics, University of Illinois, Urbana, IL 61801.

Neurons in the mammalian accessory superior olivary nucleus receive inputs from the ventral cochlear nuclei at the two sides of the brain. Their dendrites extend primarily laterally and medially. Those dendritic branches oriented medially receive input from the contralateral cochlear nucleus and those oriented laterally from the ipsilateral cochlear nucleus (Stotler, 1953; Liu and Liu, 1971). These neurons serve as an excellent model system in the present investigation for studying the plasticity of dendritic development. Monaural "deprivation" during the early stage of development of the albino rats resulted in asymmetrical dendritic development, i.e., the dendritic branches that normally receive input from the "deprived" ear were poorly developed in comparison to branches that receive input from the intact ear. This pattern is reflected in the accessory superior olivary neurons at both hemispheres, i.e., the lateral dendritic branches of neurons ipsilateral to the deprived ear and the medial dendritic branches of neurons contralateral to the deprived ear developed relatively poorly. Ontogenetical developmental patterns of these neurons were also examined and were found to follow a certain time course. These results demonstrate the environmental effect on the development of dendritic processes.

1499 CEREBELLAR PLASTICITY: MODIFICATION OF DENDRITIC BRANCHING BY DIFFERENTIAL REARING IN MONKEYS. M. K. Floeter*, W. T. Greenough. Dept. Psych. and Neural and Behavioral Biology Prog., Univ. IL., Champaign, IL 61820 and G. P. Sackett* . Dept. Psych and Regional Primate Res. Ctr., Univ. Washington, Seattle, WA 98195.

Eight newborn monkeys, Macaca fascicularis, were reared in one of three environments for the first six months after birth. Isolation reared monkeys (I) were reared in small cages, providing limited environmental stimulation and no social contact. Socially reared monkeys (S) were kept individually in small, adjacent cages and allowed to play in pairs for four hours each day. Semi-naturalistically reared monkeys (N) were raised in large colony rooms with several other monkeys and with fixed structures and objects for play. Monkeys were killed at eight months and the uvulae were stained with a nissl stain. Measurements were made of the diameter of 100-200 Purkinje cell bodies for each animal. N monkeys averaged significantly larger soma diameters than S and I monkeys. The paraflocculi were stained by the Golgi-Cox method and computer tracings were made of portions of the Purkinje cell spiny branchlet dendritic tree, twenty for each animal. A Sholl analysis in which intersections between dendrites and a series of concentric spheres were recorded, showed that N monkeys had significantly more intersections, per spiny branchlet unit, indicating more dendritic material, than S monkeys. Computer tracings of granule cell dendrites from the paraflocculus, thirty per animal, showed no group differences with a Sholl analysis. The results indicate that experience can selectively modify the morphology of certain cerebellar cell populations in monkeys. Studies are presently underway to determine the effects of experience on other cerebellar areas.

1500 ALTERED PATTERN OF ASSOCIATIONAL HIPPOCAMPO-DENTATE CONNECTIVITY FOLLOWING LESIONS IN THE NEONATAL RAT. Russell A. Fricke, Dept. Biol. Sciences, Stanford University, Stanford, CA 94305.

Extrinsic afferents to the molecular layer of the rat dentate gyrus have the ability to expand into neighboring deafferented areas. For example, extensive lesions of the entorhinal cortex result in the spread of hippocampal afferents into the adjacent entorhinal terminal fields of the molecular layer (Lynch et al., Br. Res., 50:174, 1973). Similarly, when both the commissural and associational components of the hippocampo-dentate (H→D) projection are eliminated, neighboring entorhinal afferents appear to fill in the vacated hippocampal synaptic zone (Zimmer, Br. Res., 72:137, 1974). If, on the other hand, only the commissural afferents are disconnected, no such entorhinal expansion occurs. This is presumably due to the selective growth of associational afferents; however, this idea is difficult to test, since commissural and associational H→D afferents are co-extensive in the molecular layer of the dentate gyrus.

To address this exclusion hypothesis directly the hippocampal commissures and rostral hippocampus of one side were ablated in rat pups before the third postnatal day. Three to six months after surgery the same animals were stereotaxically injected with ^{3}H-proline (0.1-0.5μCi) at sites within the intact hippocampus. Injections into subfields CA_{3C} and CA_4 located approximately halfway between the septal and temporal poles of the hippocampus, always give rise to a band of silver grains in the proximal 3rd of the molecular layer of the dentate gyrus. In normal animals, the number of grains appearing over the external blade of the ipsilateral dentate exceeds the number found over the internal blade on the same side by a margin of at least 2-3:1 (Gottlieb & Cowan, Br. Res., 41:452, 1972). Early surgical elimination of commissural H→D afferents results in the disappearance of this particular quantitative asymmetry. Since the commissural projection has approximately the opposite quantitative pattern as the associational in normal animals, these results suggest that: (i) the total number of potential synaptic sites in both blades of the dentate gyrus is approximately equal; (ii) associational fibers occupy postsynaptic space vacated by the commissural afferents; and (iii) the amount of expansion is determined by the amount of degeneration.

It appears that following lesions which eliminate commissural hippocampal afferents, non-hippocampal classes of afferents are excluded from the hippocampal zone in the dentate gyrus by preferential growth of the intact associational hippocampal fibers. It remains uncertain, however, whether this is merely due to a spatial advantage or involves some residual, perhaps cytochemical, features which serve to distinguish the different extrinsic classes of afferents from each other during development.

1501 AGE-DEPENDENT REACTIONS OF OLFACTORY CORTEX TO DEAFFERENTATION. B. Friedman and J.L. Price, Dept. Anat. & Neurobiol., Wash. Univ. Sch. of Med., St. Louis, MO 63110.

The reaction of piriform cortex to deafferentation has been studied in rats using the Timm stain (Haug, 1973) and the autoradiographic method (Cowan et al., 1972) following ablation of the olfactory bulb in developing and mature rats. The Timm method stains heavy metals in axons, and in normal animals it reveals a striking bilaminar pattern in layer I of piriform cortex. The superficial lamina (Ia) is very pale while the deep lamina (Ib) shows a dark rust colored reaction. In addition, layer Ib and to a lesser extent Ia contain a granular reaction which is most prominent at the outer edge of Ib. The pale and colored laminae correspond precisely to the layers of termination of axons from the olfactory bulb (in Ia) and of the association fibers from the olfactory cortex (in Ib) (Price, 1973), but the granular reaction does not correspond to any known extrinsic fiber system. Some indication of a bilaminar Timm reaction in layer I is seen by the first day after birth (P-1) but the fully mature pattern does not develop until 17-18 days of age.

Following ablation of the olfactory bulb on P-1 (2-12 weeks survival) layer I develops to its normal thickness but the granular and rust colored reactions are found throughout this layer. This corresponds to an extension of the association fibers into the superficial part of layer I, demonstrated in parallel autoradiographic experiments.

In contrast, following ablation in adult rats (2-8 months survival) layer I is reduced in width by about 25%, probably due to dendritic degeneration. The normal color reaction in Ib is preserved but there is a profusion of the granular reaction in Ia which becomes much more intense with longer survivals. The association system, demonstrated autoradiographically, is largely confined to Ib, in correspondence to the color reaction.

Following ablations at ages 4-14 days (2 month survival) there is a reduction in the width of layer I (20%) which is almost comparable to that seen after ablations made in adult animals. However, the staining pattern is similar to that after P-1 ablations; the density of the stain is fairly homogeneous throughout layer I although the rust colored reaction tends to be concentrated deeply and the granular reaction superficially. Autoradiographic experiments show that the association fibers extend throughout layer I but are concentrated in its deeper part. Supported by NIH Grants NS09518 and NS07057.

1502 ROLE OF EARLY EXPERIENCES IN BEHAVIORAL ASYMMETRY IN THE RAT. J. Garbanati*, G. Sherman*, G. Rosen*, D. Yutzey*, and V. H. Denenberg. Depts. Biobehav. Sci. & Psychology, Univ. of Conn. Storrs, CT. 06268.

The human right hemisphere has been implicated as having a major role for affective processing. This phenomenon is not restricted to humans since rats which are handled in infancy and raised in complex environments exhibit differential involvement of the cerebral hemispheres in emotionality as measured by activity in the open-field test (Denenberg et al., Neurosci. Abs., 1977). A right cortical ablation produced a large decrement in activity in contrast to scores of left lesion and control animals.

Another major function of the right cerebrum is to monitor the spatial environment. Since the open-field test also involves locomotion through space, this test was used to assess the effects of early experience to induce a spatial bias. Spatial asymmetry was measured by observing the direction (left-right) of initial movements of rats in the open field. As in the previous study, we attempted to induce brain asymmetry by variation of early experience. This consisted of handling or not handling litters of pups during the first 20 days of life. At 105 days, 4 male littermates were given: a) a right neocortical ablation, b) a left ablation, c) a sham operation or d) no surgery. After a 30-day recovery period, all animals were tested in the open field for activity and wall-hugging behavior. One directionality score was computed for each animal using the responses which were recorded from 4 successive days of testing. The means of these scores for each group are presented in Table 1. Unilateral lesions resulted in the expected bias of movement along the wall ipsilateral to the side of lesion. Nonhandled sham and control rats showed no behavioral asymmetry. However, handled sham and control rats exhibited a behavioral bias in the left direction. These results provide evidence consistent with the hypothesis that early experience induces a spatial bias as well as the central asymmetry of affective processing found by Denenberg et al. (1977). These findings may reflect: a) the simultaneous inducement of two independent functions of affective and spatial processing, or b) the manifestation of a spatial bias which is due to a central asymmetry evoked during an emotional task.

Table 1. Group means for directionality scores[a]

	Right	Left	Sham	Control
Nonhandled	.509(34)[b]	-1.028(31)	.113(33)	-.047(30)
Handled	.329(31)	- .739(27)	-.530(24)	-.285(34)

[a]Directionality scores for individual animals were derived by the following formula (D.S. = R-L/ R+L); a negative score indicates a left bias, and a positive score indicates a right bias.

[b]( ) = n.

1503 ANOMALOUS CROSSED CORTICO-CAUDATE PROJECTIONS IN THE POSTNATAL MONKEY INDUCED BY PRENATAL RESECTION OF FRONTAL NEOCORTEX. Patricia S. Goldman, NIMH, Bethesda, Md. 20014

Primates, including man, exhibit remarkable sparing of behavioral performance following circumscribed brain injury that occurs early in life. It is not known, however, to what degree primates exhibit a capacity to respond to such injury by reorganization of axonal connections. To examine this issue, the prospective dorsolateral prefrontal cortex was resected in one hemisphere of a fetal rhesus monkey 6 weeks prior to birth. Following surgery, the fetus was returned to the uterus and subsequently delivered near term. On the 5th postnatal day, the homotopic region of the dorsolateral cortex contralateral to the cortex that was resected prenatally was injected with microquantities of ^{3}H-leucine and ^{3}H-proline. The monkey was sacrificed one week later and its brain processed for autoradiography. Autoradiograms from normal 5-day old monkeys that had been injected with the same quantities of tritated amino acids into the same cortical location were used to determine the normal projections from prefrontal cortex in neonates.

In the postnatal monkey whose prefrontal cortex was resected before birth, the projection to the ipsilateral caudate nucleus is similar in topography and configuration to that observed in normal monkeys of the same age. However, the projection to the contralateral caudate nucleus differs markedly from the controls. Whereas in normal monkeys, the contralateral nucleus contains grains which only barely exceed background level, in the prenatally operated case, dense concentrations of label can be traced in consecutive serial sections throughout the entire extent of the head of the nucleus. Significantly, the projection is greatly expanded in that portion of the nucleus that would normally receive ipsilateral projections from the prefrontal area that was removed. Further, the pattern of grain distribution is reminiscent of the intricate patches found normally on the ipsilateral side, indicating further that the anomalous projections have a predilection for deafferented areas.

The axonal rearrangement reported here is comparable to that described so far in other species. It is probably significant that a considerable degree of plasticity can be induced in the primate by a lesion performed prior to birth when major developmental events such as neuron genesis, cell migrations and elaboration of basic connections are occurring at a rapid rate. Mechanisms proposed for other systems may account for neuronal reorganization in the primate, among them, that cortico-striate projections expand their terminal fields to occupy vacated synaptic spaces made available by loss of input from the ipsilateral cortex.

1504 DIFFERENTIAL RESPONSE OF MOTOR AND SENSORY FIBERS TO LIGATION OF CAT HINDLIMB PERIPHERAL NERVES. T.Gordon, J.A.Hoffer and R.B.Stein. Physiol. Dept., Univ. of Alberta, Edmonton T6G 2H7, Canada.

Last year we reported that in cats with implanted neural recording electrodes, neural signals generated during locomotion declined after nerve section and resuture, but recovered following reinnervation (Hoffer et al, Neurosci.Abstr.3:863,1977). Motor signals recovered to near-control levels, while sensory signals did not. One reason could be that sensory fibers atrophied more severely than motor fibers following section. Such a differential effect could not be ascertained from our chronic recordings of evoked compound action potentials from whole nerves. We therefore have developed a method based on measurements of compound action potentials recorded at spinal roots when individual peripheral nerves are stimulated electrically, that has allowed us to measure changes separately in sensory and motor fiber populations.

Under sterile conditions we sectioned and ligated the lateral gastrocnemius-soleus and tibial nerve branches in one hindlimb and the medial gastrocnemius, common peroneal, and sural branches in the other hindlimb of cats. In acute experiments 45 or 150 days later we exposed the ligated nerves and contralateral controls, and also the spinal roots L6, L7 and S1 bilaterally. As each nerve was stimulated we measured amplitude and area of compound action potentials evoked at corresponding cut dorsal and ventral roots. We also measured the electrical impedance of each spinal root, to control for variations in compound action potential amplitude due to filament size. From these parameters we calculated the total electrical charge delivered by fibers mapping from each nerve onto each root, and added separately the contributions of the dorsal root and of the ventral root subpopulations. The ratio of these quantities, when compared with the ratio for each intact contralateral nerve, gave a measure of the relative shrinkage of each fiber subpopulation due to previous nerve ligation.

Root ratios were not significantly different from control values 45 days after ligation, but dorsal root fiber contributions were significantly more reduced than ventral root fiber contributions 150 days after ligation.

Our results indicate that sensory fibers are more affected by interruption of their peripheral processes than motor fibers. The reason for this differential effect is obscure. It could be due to the greater dependence of sensory fibers on trophic factors from the periphery, or to the electrical silencing of sensory, but not motor fibers, following ligation.
(Supported by MDA and MRC of Canada).

1505 SUB-SYNAPTIC PLATE PERFORATIONS: A NEW FORM OF SYNAPTIC PLASTICITY? William T. Greenough, Roger W. West, Timothy J. DeVoogd, and Janice M. Juraska. Dept. Psych. and Neural and Behavioral Biology Prog., Univ. IL at Urbana-Champaign, IL 61820 and Dept. Psych., Memorial Univ., St. Johns, Newfoundland, Canada.

Several forms of potential plasticity at the synaptic level have been described following exposure to differential rearing conditions. In studies of differential postnatal and postweaning experience upon synapses, we have examined interruptions in the darkly staining region underlying the post-synaptic membrane. Peters and Kaiserman-Abramof (Z. Zellforsch., 1969, 100: 487) demonstrated through serial sectioning that these interruptions represented perforations in a sub-synaptic plate. We have found that the relative frequency of these sub-synaptic plate perforations (SSPP's) varies with age and experience in the occipital cortex of rats.

In one experiment, one member of each of 11 male littermate triplet sets of Long-Evans hooded rats was reared from weaning in a toy-filled complex environment with other rats, a second littermate was reared with one other rat in a standard laboratory cage, and the third littermate was reared alone in a standard laboratory cage. At 55 days of age, occipital cortical tissue was studied electron microscopically at 41,800x. The percentage of asymmetric round vesicle synapses in which there was an interruption of .05 μm or greater in the post-synaptic opaque region was determined in layers 1, 3 and 4 (as determined from adjacent light microscopic sections). Across layers, complexity-reared rats had 25% more synapses with SSPP's ($p<.05$) than the isolates in the 5,537 synapses examined. Socially reared rats were intermediate. While percentages differed, the effect was seen in all 3 layers.

A second experiment compared male littermates housed either in pairs or in isolation for 130 days following weaning. The socially-housed rats' synapses had a 45% higher frequency of occurrence of SSPP's than those from isolates ($p<.05$).

Additional experiments have shown that extensive sensory stimulation shortly after birth can increase the relative frequency of SSPP's by more than 200% at 10 days of age and that the relative frequency of SSPP's increases by an equivalent amount from 10 to 60 days of age in isolation housed rats. Studies of the relationships of SSPP's to presynaptic anatomy are in progress. These studies suggest a change in post-synaptic anatomy in response to experience which could underlie functional changes in synaptic efficacy or permanence.

1506 TWO-DIMENSIONAL MAPPING OF PROTEINS FROM RAT SYMPATHETIC GANGLIA: CHANGES IN SYNTHESIS RATES FOLLOWING DEAFFERENTATION AND AXOTOMY. Michael E. Hall and David L. Wilson. Dept. of Physiology and Biophysics. Univ. of Miami Sch. of Med., Miami, FL 33152

Superior cervical sympathetic ganglion (SCSG) cells respond to nerve section (axotomy) with a number of morphological, electrophysiological and biochemical changes. Section of the preganglionic axons (deafferentation) induces some of the same changes, such as separation of pre- and post-synaptic elements. Both treatments lead to changes in protein synthesis. By analyzing these changes in protein synthesis, using two-dimensional gel electrophoresis for protein mapping, we hope to gain insight into the regulatory mechanisms underlying gene expression in SCSG neurons.

Rat SCSG were deafferented by section of the pre-ganglionic sympathetic trunk. Three days later, SCSG were removed, desheathed, and incubated in the presence of ^{14}C-leucine for 1 hr. Labeled SCSG were then homogenized and subjected to two-dimensional gel electrophoresis as previously described (Anal. Bio., 83, 33, 1977).

A number of the more abundantly synthesized SCSG proteins exhibited significant changes in relative synthesis rates (RSR) following deafferentation. When these results were compared to the results of a previous analysis of changes in RSR after axotomy (SN abstr., 3, 426, 1977), it was observed that, of the 36 sample protein spots analyzed in detail following both deafferentation and axotomy, 16 protein spots exhibited changes in RSR of the same magnitude and direction after both treatments. Of the remaining sample proteins, one changed RSR only after deafferentation, five changed RSR after axotomy only and 14 did not change with either treatment. Furthermore, there were no protein spots that completely disappeared with either treatment, nor did any new protein spots appear. The RSRs of actin and tubulin were unchanged by deafferentation.

These results will be discussed in terms of what they indicate about the complexity of gene expression in SCSG neurons.

1507 SPROUTING OF CORTICORUBRAL TERMINALS IN THE CEREBELLAR DEAFFERENTED CAT RED NUCLEUS. Joseph Hanaway and Jeanne Smith. Dept. Neurol., Wash. U. Sch. Med., St. Louis, MO 63110.

We have investigated collateral sprouting or reactive synaptogenesis in the mammalian motor system using the cat red nucleus as a paradigm because of the distinct terminal fields of its two major afferent projections. Ultrastructural studies of normal corticorubral terminals have shown them to be exclusively on distal dendrites mostly in the rostral quadrants of the nucleus with a few found caudally. Cerebellorubral endings were found on somata, dendritic shafts and on distal dendrites mostly in the caudal quadrants of the nucleus but also rostrally. Cerebellar afferents were contralateral and cortical afferents ipsilateral.

To produce the environment for collateral sprouting from corticorubral terminals, lesions were placed in the nucleus interpositus and superior cerebellar peduncle in 4 cats and we waited one month for the degenerated endings to disappear. Ipsilateral corticorubral fibers were then transected in the hemisphere and after 3 days animals were sacrificed and perfused slowly(hours) with 3L of 1% paraformaldehyde and 1.5% glutaraldehyde. The red nucleus was identified on 250 um sections of the midbrain and was quartered into rostral(medial and lateral) and caudal(medial and lateral) blocks which were prepared for electron microscopy. One control cat with only cerebellar lesions was sacrificed at 37 days to see if any degenerated terminals persisted that could be misinterpreted in our double lesion series. 3.2% endings on the somata and 2.4% on dendritic shafts had not been phagocytosed, to our surprise, and were considered artifacts that were subtracted from our final counts. We found, after the double lesions, that corticorubral endings, normally found on distal dendrites, were now in greatly increased numbers on somata, dendritic shafts and distal dendrites and that the concentration was greater in the caudal "cerebellar quadrants" of the nucleus than in the rostral quadrants. We concluded that considerable collateral sprouting from corticorubral terminals had occurred into vacated postsynaptic sites and new ones.

1508 SEIZURES EVOKED BY FIBERS FROM THE CONTRALATERAL ENTORHINAL CORTEX WHICH REINNERVATE THE DENTATE GYRUS AFTER KINDLING AND ABLATION OF THE IPSILATERAL ENTORHINAL CORTEX. E.W.Harris*, J.Messenheimer and O.Steward,Depts. Physiology and Neurosurgery, Univ. of Va Sch Med,Charlottesville,VA 22901 (SPON:E.W RUBEL)

Unilateral stimulation of the entorhinal cortex (EC) leads to the gradual development of seizures in response to the stimulation (kindling), which may result from transynaptic changes in the targets of the kindled structure (Goddard et al.,Exp.Neurol. 25,1969). A major target of the EC is the ipsilateral dentate gyrus (DG). Because unilateral EC lesions result in the reinnervation of the DG by the contralateral EC, we tested whether these sprouting connections gain access to circuitry which when activated could evoke seizures. Chronic stimulating electrodes were implanted bilaterally in the EC of rats and daily stimulation was delivered to one EC until 5 seizures had been evoked. The kindled EC (EC1) was then ablated, and after 2 weeks (sufficient time to permit sprouting), kindling of the contralateral EC (EC2) was begun. An average of 24.3 trials preceded the first seizure for kindling of EC1 while an average of only 2.0 trials were required to evoke the first seizure from EC2. We have tested the hypothesis that the more rapid kindling of EC2 results from sprouting connections which gain access to structures transynaptically altered by the initial kindling, by using 3 treatments: 1)By omitting the lesion we examine the effects of primary kindling alone on the rate of EC2 kindling. In this group where the primary site of kindling was not destroyed, kindling of EC2 required an average of 6.1 trials, a rate significantly slower than that for kindling following destruction of EC1; 2)By omitting the initial kindling prior to ablation we examined whether post-lesion sprouting would increase the rate of kindling. This group required an average of 23.5 trials for kindling, which was not significantly faster than the initial kindling rate in normal animals; 3)By beginning EC2 kindling on day 1 rather than day 14 post-lesion, we examinedwhether the enhanced transfer can take place before sprouting has occurred. EC2 kindling required an average of 10.3 trials in this group, which was not significantly faster than the rate of secondary kindling observed in animals with no lesion. These results are consistent with the hypothesis that reinnervation of the DG by fibers from contralateral EC after kindling of the ipsilateral EC results in the sprouting fibers gaining access to circuitry which has been transynaptically altered by the kindling stimulation.

1509 MORPHOLOGY OF GOLGI-IMPREGNATED NEURONS IN MOUSE CORTICAL BARRELS FOLLOWING VIBRISSAE DAMAGE AT DIFFERENT POSTNATAL AGES. R.M. Harris* and T.A. Woolsey (SPON: R. Grubb). Dept. Anat. & Neurobiol., Washington U. Med. Sch., St. Louis, MO 63110.

The cytoarchitectonic appearance of and the pattern of thalamocortical afferents to the barrels in mouse SmI cortex can be altered by lesions to the contralateral vibrissae in the early postnatal period. Damage to the middle row of vibrissae (row C) prior to the sixth day of life (PND-6) prevents the formation of the middle row of barrels (row C) (Woolsey and Wann, '76). The earlier the vibrissae are damaged, the smaller the resultant row C zone becomes; the adjacent row B and D barrels enlarge as if to "compensate" for areal losses in row C.

To study the effects of vibrissae damage on the morphology of individual barrel neurons, the vibrissae in row C of mice were cauterized on PND's 1,2,3,4, or 5. The animals were sacrificed on PND-60. The brains were processed by the Golgi-Cox method, sectioned serially at 100 µm parallel to the plane of layer IV, and counterstained with thionin. The barrel fields were reconstructed, the position and extent of dendritic fields of impregnated neurons plotted, and their somata drawn using a camera lucida.

The findings are: 1) The altered cytoarchitectonic patterns of the barrels in these specimans are comparable to those previously described. Typically there were from 20-30 impregnated neurons in the altered C zones. 2) Impregnated neurons of both Class I and Class II (Woolsey et al., '75) were found in the C-zones and in the enlarged barrels in the adjacent rows B and D. Computer-based quantitative measures of somal area, three-dimensional distance to dendritic branches and to dendritic ends were similar for cells in the C-zones and in the expanded barrels in adjacent rows; they are comparable to like measures of barrel neurons in normal animals. 3) However, the spatial distribution of dendritic fields with respect to the barrel or zone boundaries showed that the earlier the vibrissal damage, the larger the fraction of C-zone cell dendritic fields extending out of the C-zone became. From PND-2 on, a majority of C-zone cells had their dendrites confined to that zone. The spatial distribution of processes of cells in the enlarged B and D barrels was the same as in normal animals.

These data suggest that a number of important structural properties of barrel neurons are determined intrinsically, but that the spatial orientation of the processes is largely determined by extrinsic influences, in particular the specific thalamocortical afferents.

1510 NOREPINEPHRINE LEVELS IN VARIOUS BRAIN AREAS, WITH FLUORESCENCE MICROSCOPIC CORRELATIONS, AFTER 6-HYDROXYDOPAMINE LESIONS OF THE LOCUS COERULEUS. Dennis P. Healy*, Jean Jew, and Asa C. Black, Jr. Dept. Anatomy, Univ. Iowa Coll. Med., Iowa City 52242.

Reis and Ross (1973) have shown that the closer a lesion is placed to the cell body of a noradrenergic neuron, the greater the neuronal degeneration, resulting in a diminished regenerative response. While electrolytic lesions have been shown to destroy central noradrenergic neurons (thus eliminating any regenerative response), the effect of 6-hydroxydopamine (6-OHDA) on central noradrenergic cell bodies is less well understood. We wished to determine what the effects of injection of 6-OHDA into the locus coeruleus (LC) itself would have on the morphology and catecholamine levels of this homogeneous population of noradrenergic cells. We have assessed the long-term effects of lesions of the LC on norepinephrine (NE) levels in selected areas of rat brain known to receive LC projections. We have also sought to determine whether the prolonged time course of anterograde degeneration in central noradrenergic systems produced by axonal injury is also seen following lesions of the cell body. A stereotaxic technique was used to inject 1 µl of a 2 µgm/µl solution of 6-OHDA into the LC of male Sprague-Dawley rats (150-160 gm body weight). Control animals received 1 µl of a physiological salt solution (McIlwain's solution). Animals were sacrificed at 1,2,4 and 8 weeks after lesion. Lesion placement was checked using a glyoxylic acid fluorescence microscopic technique. Portions of brain from the ipsilateral frontal cortex, parietal cortex, hippocampus, hypothalamus, and cerebellum were removed and assayed for NE using a radioenzymatic technique.

Brain Area	1 week†	2 weeks†	4 weeks†	8 weeks†
Frontal Cortex	85%(5)	40%(6)*	35%(6)*	35%(5)*
Parietal Cortex	76%(5)	52%(6)*	46%(4)*	67%(2)
Hippocampus	86%(5)	42%(6)*	36%(6)*	47%(6)*
Cerebellum	55%(4)*	30%(6)*	18%(3)*	22%(3)*
Hypothalamus	67%(4)	25%(6)*	71%(5)	47%(4)*

†Percentage control value. Number of samples in parenthesis.
*P<0.01, Student's "t" test.

Significant reductions of NE levels were found in all brain areas. These were followed by a levelling off within 2 weeks after lesioning. No increases were noted (with possible exception of the hypothalamus at 4 weeks). Morphological studies of terminal areas are under way at this time to determine the extent of damage produced by 6-OHDA. (Supported in part by NS-11650 to T.H. Williams from the N.I.H.).

1511 NEONATAL HAMSTER EYE ENUCLEATION AND TECTAL MIDLINE DAMAGE: EFFECTS OF PARTIAL COLLICULAR ABLATION ON RETINOTECTAL PROJECTIONS. K.K.-J. Hsiao and G.E. Schneider. (SPON: S. Corkin). Dept. Psychol., M.I.T., Cambridge, MA 02139.

The following three surgical procedures were performed on eight newborn hamster pups: a) right-eye enucleation; b) 1.5-mm deep slit made through the skull along the midline between the superior colliculi; and c) ablation of part of the lateral right superior colliculus (SC) made by heat applied to varying proportions of the overlying skull. When the pups were six-weeks old, the remaining left eye was enucleated, and the brains were processed two days later using the Fink-Heimer method for visualizing degenerating terminals and fibers. Each case was charted so that both the surface area and volume of the terminal region could be measured.

The inter-collicular slit impeded the formation of the normal midline tissue, and in five cases resulted in partial fusion of superficial gray on the left and right sides. In all cases, fibers from the left eye crossed the tectal midline and innervated the medial portions of the intact left SC, as well as the entire remaining right SC. This occurred even when the right SC was entirely undamaged, showing that retinotectal fibers can project to a supernormal tectal area. Preliminary electrophysiological work indicates that fibers which recross at the midline terminate in the left SC in a mirror image fashion (G. Sachs and K.K.-J. Hsiao)

Both the thickness of the brachium of the SC and the total retinotectal terminal volume decreased as the damage to the right SC increased, suggesting that direct axonal damage during neonatal collicular ablation, or some indirect post-ablative effect which leads to axonal degeneration, compromises the viability of retinotectal fibers.

When the entire right SC was ablated, the entire left collicular surface was innervated. On the other hand, when none of the right SC was ablated, only the medial third of the left SC was innervated. In either case, however, the recrossed terminal volume in the left SC was the same. Despite a constant recrossed terminal volume, the surface areal distribution of the fibers in the left SC increased and spread laterally in proportion to the damage done in the right SC. Current studies are focussed on an analysis of retinotopic organization in both the partially ablated right SC and in the intact left SC in similarly prepared cases.

1512 PROLONGED CHANGES IN BRAINSTEM TYROSINE HYDROXYLASE ACTIVITY FOLLOWING NEONATAL CEREBELLECTOMY, L. Iacovitti, T.H. Joh, D.J. Reis. Laboratory of Neurobiology, Cornell Univ. Medical College, 1300 York Ave., New York, NY 10021.

Treatment of neonatal rats by systemic administration of the catecholamine (CA) neurotoxin 6-hydroxydopamine produces in the pons-medulla (p-m) an apparent increase in: the number of CA containing fibers as visualized by histofluorescence, the content of norepinephrine (NE), and the activity of CA biosynthetic enzyme tyrosine hydroxylase (TH) (Jonsson and Sachs, Med Biol 54:286,1976). These results have been attributed to a "pruning effect" whereby widespread destruction of distal collaterals of immature NE neurons of the nucleus locus coeruleus (LC) stimulates compensatory growth of sprouts from uninjured branches. We sought to establish in developing rats whether: (a) a lesion restricted to a single projection of LC, either that projecting to cerebellum or that projecting through the median forebrain bundle (MFB) to innervate forebrain and hippocampus would also stimulate increased TH activity in p-m and LC; (b) such changes depend upon the postnatal age at the time of the lesion; (c) damage to one projection will elicit changes in TH in remote uninjured collaterals; and, (d) such lesions will alter developing cholinergic and gabergic neurons as reflected by changes in the activities of choline acetyltransferase (CAT) and glutamic acid decarboxylase (GAD), respectively. The cerebellum was totally ablated in rat pups on postnatal days (d) 3,6,9, or 18, and the rats killed 30-40 d thereafter. TH, CAT and GAD were assayed in LC, p-m and hippocampus. In other rats the MFB was transected on d 3, and 30 d later TH, CAT and GAD were measured in LC, p-m, and cerebellum. Controls were age matched, unoperated, or sham operated rats. Cerebellectomy performed on d 3 resulted in a 30-60% increase in TH in p-m and LC ($P<0.001$); a smaller but significant difference when performed on d 6 and 9; but no change when performed on d 18. These brainstem changes were unaccompanied by TH changes in the hippocampus. Cerebellectomy on d 3 did not alter the number of LC neurons (1466 ± 32 vs 1501 ± 109; $n=4$) 30 d later, nor did it increase the number nor distribution of TH containing fibers visualized by immunocytochemical staining with a specific antibody to TH. MFB lesions placed on d 3 resulted in no changes in TH activity in LC, p-m, or cerebellum 30 d later. Changes in CAT and GAD were not observed in any region following either lesion. We conclude that neonatal cerebellectomy results in an age-dependent and prolonged increase in TH activity in LC and adjacent brainstem, which is not reflected in uninjured collaterals, and without evident changes in the number of TH containing fibers. Cerebellectomy in early development may produce profound but restricted changes in CA synthesizing capacity in rat brain. (Supported by NIH grants HL 18974 and NS 03346.)

1513 VISUAL EXPERIENCE AND THE DEVELOPMENT OF THE EFFERENT SYSTEM TO THE CORPUS CALLOSUM; G.M. Innocenti and D.O. Frost. Institut d'Anatomie, Université de Lausanne, Lausanne, Switzerland.

In normal adult cats, neurons projecting through the corpus callosum (callosal neurons) are located within a limited region (callosal zone; CZ) spanning the area 17/18 boundary. At birth, however, the CZ is much wider. It extends throughout all of areas 17 and 18 and its medial limit reaches the fundus of the splenial sulcus. The CZ shrinks gradually and is almost adult-like by the end of the first postnatal month. The rules guiding this process and the fate of the callosal neurons lost are unknown. We have investigated whether visual experience is i) necessary for, or ii) can modify, the normal development of callosal connections. Three different experiments were performed: a) two kittens were deprived of pattern vision in both eyes and b) two in one eye, by eyelid suture maintained from postnatal day 6 or 7 (prior to spontaneous eye opening) on. Two days before sacrifice, (4th - 5th postnatal month) all these animals received unilateral multiple injections of horseradish peroxidase (HRP) alone or combined with radioactive leucine/proline, in their visual cortices (contralateral to the open eye for monocularly deprived cats). The postlateral and lateral gyri were completely filled by the injections. c) Convergent strabismus was provoked in two kittens and divergent strabismus in one, by bilateral section of either the lateral or medial recti muscles. At 7-8 months of age, these animals could perform standard visual reaching and placing tasks with either eye. At 8 or 9 months of age they received cortical injections as in a and b. They were sacrificed two to three days later at the end of an experiment in which microelectrode penetrations aimed at assessing the degree of binocularity of cortical neurons were performed in area 17, 18 or both. Thirty six to 44 single units were recorded in each animal. The overwhelming majority had strictly monocular receptive fields (groups 1, 2, 6 and 7 of Hubel and Wiesel). The degree of squint estimated in paralyzed animals from the projection of the retinal landmarks was 26-39 deg. Coronal sections from each brain were processed for HRP (with diaminobenzidine or o-dianisidine), autoradiography or both. Only the HRP results are reported here. The distribution of callosal neurons in each brain was determined from computer aided reconstructions. In all the animals, as in normal cats, the heaviest packing density of callosal neurons in areas 17 and 18 was found near the 17/18 boundary. The medial edge of the CZ appeared in the binocularly deprived animals in its normal adult position. From caudal to rostral it moved gradually from the crown of the postlateral gyrus onto the medial bank of the hemisphere. It reached the fundus of the suprasplenial sulcus only at its most rostral levels. In the three squinted and in one of the monocularly deprived cats, callosal neurons extended further medially. They reached the fundus of the suprasplenial sulcus or, posteriorly (where this sulcus is not yet apparent), comparable distances from the crown of the postlateral gyrus. A few were also found below the suprasplenial sulcus. Assuming unaltered cortical retinotopy, the CZ in these cats can be estimated to extend to regions in area 17 representing 7-12 degrees (depending on vertical excentricities from area centralis) from the vertical meridian, against 1-5 deg in the normal. Radial location and morphology of callosal neurons are not obviously affected. Thus, normal vision does not appear to be necessary to the development of the main morphological features of the CZ. However, the outcome of the developmental process can, to some extent, be modified by manipulations affecting the animal's visual experience.

1514 CATECHOLAMINERGIC TERMINALS IN KITTEN VISUAL CORTEX: THE NORMAL DISTRIBUTION AND ITS CHANGES FOLLOWING THE LOCAL MICROPERFUSION OF 6-HYDROXYDOPAMINE. Toru Itakura*, Takuji Kasamatsu and John D. Pettigrew*. Div. Biol., Calif. Inst. Tech.,Pasadena CA 91125

We have presented physiological evidence that the local availability of catecholamine (CA) is necessary for maintaining the high level of the synaptic plasticity in the developing visual cortex which can be demonstrated during the early postnatal life (Science, 194, 1976; Nature, 271, 1978). In the present study we present the morphological evidence that the cortical CA had been depleted locally in the cortical area from which our samples of single neurons were collected for the physiological assay of plasticity.

First, the normal distribution pattern of CA fibers was studied by a modified fluorescence histochemistry. The animals (4-8 weeks of age) were perfused with a mixture of glyoxylic acid and paraformaldehyde in a buffer solution which was rich in magnesium. Frozen sections were cut with a cryostat. The preterminal CA fibers are parallel to the cortical surface in the white matter and they give off perpendicularly collateral branches toward the deep layers in the gray matter. Some of these collaterals appear to be the stem CA fibers judged on their strength of fluorescence. In the course of their extension, perpendicularly or obliquely, toward the cortical surface, there are found many short and long collaterals in various directions. Giving off these fine branches, the stem fibers continue to stretch up to the molecular layer where they start to run horizontally as fine terminal fibers. The density of CA terminal fibers (with varicosities) seems to be highest in the superficial layers (layer II + III) but not in the molecular layer. The dense plexus formation in layer II + III) is the most characteristic pattern of the CA innervation in kitten visual cortex.

When the visual cortex was depleted of its CA by a week-long microperfusion of 6-hydroxydopamine (6-OHDA) (4.0 mM-40 μM) the yellowish-green fluorescence disappeared completely from the area near the perfusion site. The extent of lesion in which no CA fibers were found varied in the proportion of the concentration of 6-OHDA. Next to this primary lesion area, fragmented CA fibers appeared in the background of autofluorescence and those fibers were thicker in size and brighter in their intensity than the normal, suggesting the accumulation of CA at the sites proximal to the lesioned terminal fibers. When we moved further away from the perfusion site finally we started to see nearly normal patterns of fiber distribution. But the intensity seemed still lower than that at the corresponding site in the opposite hemisphere of the same animals. Work supported by the Spencer Foundation, and by MH25852 and NSF-BNS77-19433.

1515 APPARENT "CRITICAL PERIOD" AND DOMAIN CHARACTER OF NERVE SPROUTING IN MAMMALS. Patrick C. Jackson and Jack Diamond. Dept. of Neurosciences, McMaster University, Hamilton, Ontario, Canada, L8S 4J9.

We have examined the ability of cutaneous nerves in the mammal to enlarge their peripheral fields by collateral sprouting into adjacent denervated skin. Mechanosensory nerve fields were mapped by recording afferent impulses in whole nerve trunks during mechanical stimulation of the skin with a fine bristle. Surprisingly, we found no enlargement of a remaining mechanosensory skin field either in the adult rabbit or adult rat during periods up to 90 days after denervation of adjacent skin. In the neonatal rat however the situation is quite different.

In the rat the dorsal portion of each trunk dermatome is supplied by a dorsal cutaneous nerve (D.C.N.), the medial branch of which serves an area of skin bordering the midline, the lateral a comparable area within the dermatome, immediately lateral to the first. Consequently an "island" of innervated skin is left by cutting all cutaneous nerves supplying a region of the back except for the medial branch of one D.C.N. Nerve fields normally enlarge in proportion to the skin area as an animal grows in size. However, remaining "islands" produced in 10 day old rat pups, by 20 days had increased to an area almost double that of controls. This "extra" sprouting of intact nerves resulted only when adjacent denervations were carried out within the first 20 days after birth, and seemed to cease at about 20 days of age, irrespective of when it was elicited.

It seems then that, in the rat at least, there is a "critical period" for collateral sprouting of intact cutaneous nerves into denervated skin, which ends about 20 days postnatally. The sprouting which can be evoked before this time however does not occur uniformly from the still-innervated field. The remaining branch of a D.C.N. showed a distinct preference for the denervated skin of its "parent" dermatome, rather than an adjacent one. When an entire dermatome was left with its innervation intact, but the adjacent dermatomal nerves were cut at 10 days of age, we detected no sprouting, i.e. there was no significant extension of the dermatomal field into the adjacent denervated skin. It seems then that the "domain" character of peripheral nerve fields suggested by previous findings in the salamander (Diamond et al., 1976, Science 193: 371-377) may apply in the mammal too. In contrast, regenerating axons appear to be unaffected by these spatial restrictions, and even in the adult rat will readily invade "foreign" nerve territories.

1516 VISUAL CAPACITIES OF MONOCULARLY DEPRIVED CATS AFTER REVERSE LID SUTURE AND ENUCLEATION OF THE NON-DEPRIVED EYE. K.R. Jones*, M. Berkley, P. Spear, L. Tong. Depts. Psychol., Florida State U., Tallahassee, FL 32306; U. of Wisconsin, Madison, WI 53706.

Behavioral studies of mature cats after monocular occlusion during the first few months of life have shown that vision through the deprived eye is very poor. These results are consistent with electrophysiological studies of visual cortex of such animals which have shown that few neurons (<11%) can be activated via the deprived eye.

More recent studies of the cat have suggested that the number of neurons activated via stimulation of the deprived eye may be increased (e.g., to a maximum of 40%) after enucleation of the nondeprived eye. The degree to which this procedure affects the visual capacities of the deprived eye, however, is not known.

To determine if there is a behavioral correlate of the reported electrophysiological changes after enucleation, kittens were monocularly deprived by lid suture starting at 7-11 days of age. Ten to fourteen months later, the lid-sutured eye was opened and the animals permitted another 6-9 months of normal binocular visual experience before behavioral testing began. All cats were tested monocularly on light-dark, 0 vs. + and grating acuity tasks.

The cats learned all the tasks easily with the nondeprived eye and showed little, if any, transfer to the deprived eye. Acquisition of the discriminations using the deprived eye was very poor. Only two of the four monocularly deprived cats were able to give a grating acuity estimate and they were far below normal (<1.0 c/d). The other two cats never achieved a sufficiently high level of performance when tested with the deprived eye to yield an acuity estimate.

When stable performance levels were reached in each eye, the eyelids of the nondeprived eye were sutured closed and testing of the deprived eye continued. Some small improvements in performance were noted in all four cats but no change in the acuity thresholds for the two animals which yielded acuity estimates. After 3 weeks of testing, the nondeprived, now lid-sutured, eye was removed and testing continued. Another small performance increment at low spatial frequencies was noted but again no change in the grating acuity estimates. At the conclusion of the behavioral testing, single unit studies of visual cortex confirmed earlier reports of an increase in the number of driveable neurons after enucleation when compared to nonenucleated monocularly deprived cats.

These results suggest that while enucleation of the experienced eye increases the number of neurons driveable through the deprived eye, it produces only a small performance improvement and little, if any, change in the acuity threshold of the deprived eye.

1517 PLASTICITY IN THE CORTICOSPINAL TRACT AFTER EARLY LESIONS OF THE MEDULLARY PYRAMID. K. Kalil and T. Reh*. Dept. of Anatomy and Neurosciences Training Program, Univ. of Wis., Madison, WI 53706.

In the newborn hamster the pyramidal tract is still in the process of descending through the medulla and into the spinal cord. Thus, plasticity in this pathway at early postnatal ages can be studied by interrupting the corticospinal fibers in the medulla before they have established connections in the spinal cord.

In normal animals, the growth of the corticospinal pathway was plotted by injecting [^{3}H] poline unilaterally into the sensorimotor cortex of 1 to 8 day old hamsters. Autoradiographs showed few labeled fibers in the medullary pyramid at 2 days of age. By 5 days labeled fibers could be traced in the white matter to thoracic levels of the spinal cord but the dorsal horn of the cord was labeled only at cervical levels. At day 8 the pyramidal tract had reached lumbar levels but had invaded the dorsal horn only as low as the mid-thoracic cord.

In another series of experiments, animals ranging from 2 to 14 days of age received discrete unilateral lesions of the medullary pyramid several mm. rostral to the decussation of the tract. After survival times of 2 to 12 weeks, the sensorimotor cortex ipsilateral to the lesion was injected with [^{3}H] proline and the brains processed for autoradiography. Our results show no labeled axons below and ipsilateral to the lesion, but instead reveal a massive and abnormal decussation of the pyramidal tract several mm. rostral to the lesion. These aberrant fibers follow an abnormal course medial to the spinal trigeminal nucleus and descend through the brainstem to terminate in the dorsal column nuclei, the spinal trigeminal nucleus and in the dorsal horn of the cervical spinal cord. These terminations occur in precisely the same pattern observed in normal animals and in the correct side of the brain. This new pathway develops in animals in which the pyramidal tract was transsected as late as 8 days. Since results in the normal animal show that the pyramidal tract is fully developed at medullary levels by this age, it seems likely that the aberrant fibers represent new growth of the severed pyramidal tract fibers rather than redirection of later arriving corticospinal axons. Further, although the trajectory of the pathway is completely abnormal, the fibers are able to establish their normal pattern of terminations.

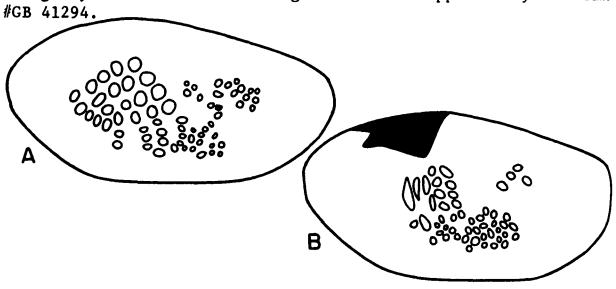
1518 EFFECT OF NEOCORTICAL DAMAGE ON THE ORGANIZATION OF THALAMIC PROJECTIONS. H. Killackey, J. Dames* and R. M. Akers. Dept. Psychobio., Univ. of Calif., Irvine, CA 92717.

Previous work in our laboratory has demonstrated that the thalamocortical projections to the rat somatosensory cortex exhibit considerable plasticity. Cauterization of vibrissal follicles at birth results in the development of aberrant projections associated with the damaged vibrissae. In the present experiment we have examined the possibility that the organization of thalamocortical projections may be altered by central, as well as by peripheral damage.

Newborn rats received electrolytic lesions of the posterior somatosensory cortex on the day of birth or on postnatal day 5 and were allowed to survive until at least two weeks of age. Following perfusion with 10% glycerol, their brains were removed, sectioned at 30 µm in a plane tangential to the neocortical surface, and processed for localization of succinic dehydrogenase activity.

Comparison of the reconstructed pattern of thalamocortical afferents in an undamaged hemisphere (A) and an experimental hemisphere (B) reveals that lesions of somatosensory cortex on the day of birth produce marked alterations in the pattern of thalamocortical afferents. First, the area occupied by the projections associated with the mystacial vibrissae is reduced. Second, discrete clusters within a given row tend to be fused. Finally, when individual clusters of afferents are present, they are reduced in size as compared with those in normal animals. Neocortical lesions on postnatal day 5 do not have the same effects. In such cases the organization of thalamocortical projections not directly damaged by the lesion is essentially normal. The present results suggest that the development of thalamocortical afferents may be influenced both by the state of the periphery and the integrity of their central target tissue. Supported by NSF Grant #GB 41294.



1519 EARLY POSTNATAL DEVELOPMENT OF NORMAL AND ABNORMAL UNCROSSED OPTIC PATHWAYS IN ALBINO RATS. Peter Land and R. D. Lund. Dept. of Biol. Struct. and Neurol. Surgery, Univ. Wash., Sch. Med. Seattle, WA 98195.

After unilateral enucleation of newborn rats, the uncrossed optic pathway from the remaining eye exhibits an expanded distribution throughout subcortical visual centers. In this study, we removed one eye from albino rats within 2 hours after birth. The remaining eye was injected with ^{3}H-proline 0 hours to 9 days after enucleation. A comparable series of unoperated littermates received uniocular isotope injections. The animals were perfused after 24 hours and the brains were sectioned and processed for autoradiography.

A substantial crossed projection to thalamic and midbrain visual centers is detectable at 1 day postnatal in both groups of animals, although the projection to the medial portion of the dorsal lateral geniculate nucleus (dLGN) is quite sparse. In day 1 control animals, there is a diffuse uncrossed projection to dLGN, which primarily is distributed in the anterolateral part of the nucleus. The uncrossed projection to the superior colliculus (SC) is close to background at this time. Between 6 and 9 days postnatal, the normal uncrossed projection to dLGN becomes localized much as in adult animals and the projection to SC is more clearly focused anteromedially in the stratum opticum.

The uncrossed projection to SC in enucleated animals is already distinct from controls by 2 days, with grain levels above background throughout the stratum griseum superficiale. However, the ipsilateral projection to dLGN cannot be distinguished from normal until day 4. The density of the abnormal projections appears to increase throughout the time period studied. The rapid appearance of the abnormal ipsilateral projection in SC suggests that at least some of the fibers contributing to it must arise from axons already present ipsilaterally at birth rather than solely from aberrant axons which have grown from the optic chiasm after enucleation. (Supported by USPHS Grants EY-05185 and EY-00596.)

1520 RIGHT HEMISPHERE SPEECH FOLLOWING CALLOSOTOMY. Joseph E. LeDoux,* Bruce T. Volpe,*Charlotte S. Smylie,*Donald H. Wilson,*Michael S. Gazzaniga. Dept. of Neurology, Cornell Medical College, NYC 10021

Language and speech are typically located in the left cerebral hemisphere. Under certain conditions, however, all or part of these processes appear in the right hemisphere. We have been studying case P.S., who was observed to have bilateral comprehension skills, but only left hemisphere speech immediately after section of the corpus callosum. Now,two and one-half years postoperatively,his right hemisphere is acquiring the capacity to speak. The patient can verbally describe visual information exclusively presented to his right hemisphere. This recently acquired ability to verbally describe left visual field stimuli is not attributable to the reinstatement of interhemispheric visual transfer. This is demonstrated through several control tests. First,while he was able to name objects and words presented to either visual field,he was unable to state whether two simultaneously presented stimuli,one in each field,were the same or different. Second,when line drawings of finger postures were presented to one visual field,only the contralateral hand was able to mimic the postures. Third,when one of a pair of homonyms was presented to either hemisphere,for example "coat" or "cote," he could name appropriately. Subsequent to each naming trial he was asked to spell the articulated word;following left hemisphere naming,the words were correctly spelled. Yet,following right hemisphere naming of "cote" he spelled "c-o-a-t." Presumably the right hemisphere said "cote" and on the basis of this information,the more robust and competent left hemisphere speech system took over and spelled "c-o-a-t." If his capacity to name left field objects were attributable to visual transfer from the right hemisphere to the left,he should have performed differently in the above conditions. Further,he performed above chance when asked to name objects in his left hand and,in addition,on certain trials,in which he was seemingly unable to name the object,correct naming was detected through a sensitive microphone. After naming the object at a level that was undectable by the unaided ear,he was unable to respond to the question,"What is in your hand?" Presumably the right hemisphere had named the object and the left hemisphere, which did not have access to the amplified vocalization,had responded to the probe. These observations, which clearly suggest, for the first time,the unequivocal presence of expressive speech in the right hemisphere of a split-brain patient,have implications for notions of neural plasticity and volitional control of conscious activities in man.

1521 QUANTITATIVE DEMONSTRATION OF AXOSOMATIC SYNAPSE SPROUTING IN THE NEONATAL RAT INDUCED BY DENDRITIC DEAFFERENTATION. Nicholas J. Lenn, Viviana Wong* and Geoffrey Hamill*. Depts. Neurol. and Ped., Carnegie Labs. of Embryol., Sch. Med., UCD, Davis, CA 95616.

When one or both habenulae are removed from a rat in the first days following birth, several changes in the synaptology of the interpeduncular nucleus result (Lenn, J. Comp. Neurol., 1978). One of these changes, based on these qualitative observations, was an increase in the number of axosomatic synapses from their low normal number. This increase was evident in axosomatic synapses containing spherical and flattened vesicles.

We have reassessed this phenomenon quantitatively by preparing 10 normal and sham-operated animals and 5 lesioned animals with uni- and bilateral habenula lesions. Neuronal perikarya were randomly selected from the central portion of the interpeduncular nucleus on low power electron micrograph maps (x100). These perikarya were then photographed at moderate magnification (x16,000), and each apparent synapse was photographed at high magnification (x30,000). The only selection made was an attempt to approximately equalize the numbers of large and small perikarya included in the sample as judged by their size on the microscope screen at low magnification. Axosomatic synapses were then recognized in the photographs and counted. The perimeter of each perikaryon was measured. The results were expressed by several statistics of which the most meaningful appears to be synapse number per 100 microns of neuron circumference.

In the control animals the range of synapses per 100 microns of neuron circumference was 6.38 to 10.35, with a mean of 7.99. In the operated animals the range of this statistic was 8.72 to 16.67, with a mean of 12.63. This 50% increase was significant as judged by a two-tailed Student t test ($p < .001$). The endings forming the synapses contained pleomorphic vesicles including at most one or two true flattening vesicles in almost all cases. Occasional endings had all spherical vesicles, or prominent numbers of flattened or large granular vesicles. The synaptic contacts were more asymmetrical with more spherical vesicles, varying to symmetrical for endings with prominent flattened vesicles.

It is concluded that the qualitative observation was correct although the magnitude of the effect is much smaller than had been apparent from the qualitative study. These observations confirm this unusual example of synaptic plasticity, namely an increase in axosomatic synapses following deafferentation of the dendritic portion of the neurons in the interpeduncular nucleus.

1522 REGENERATION OF PRIMARY OLFACTORY NEURONS AND "GLOMERULARIZATION" WITHIN THE FOREBRAIN OF NEONATALLY BULBECTOMIZED MICE. R. R. Levine*, G. A. Monti Graziadei* and P. P. C. Graziadei. Dept. Biol. Sci., Unit 1, Florida St. Univ., Tallahassee, FL 32306.

After sectioning the olfactory nerve, olfactory neurons undergo retrograde degeneration. Stem cells within the olfactory neuroepithelium exhibit increased mitotic activity, differentiate into mature receptor neurons and replace the degenerated receptor units (Graziadei and Monti Graziadei, in Neuronal Plasticity, Raven Press, 1978). Fibers from the reconstituted olfactory neurons reinnervate the olfactory bulb where they reform functional synaptic relationships in the glomerular neuropil. This study was designed to determine the extent of the plasticity of the olfactory neurons and their ability to regenerate in the absence of their primary neural target, namely the post-synaptic processes within the glomerular layer of the olfactory bulb.

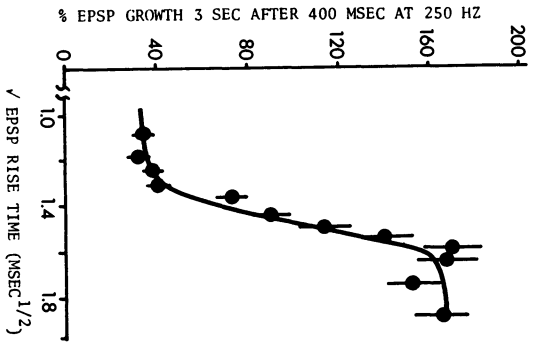
Neonatal (1 - 6 days) mice were subjected to complete unilateral bulbectomy (including accessory olfactory bulb and anterior olfactory nucleus) and sacrificed after periods ranging from 1 - 120 days. Material was processed routinely for light and electron microscopy and several results were noted. By 30 days following surgery, reconstituted olfactory nerve fibers were observed crossing the cribriform plate into the cranial cavity where they ended in glomerular-like formations in close proximity to cerebral tissue. The cerebrum itself appeared to migrate forward to fill the gap created by bulbectomy. In many cases there was a proliferation of cells from the ependymal lining of the cerebral vesicle that surrounded the new fibers and glomeruli. Most striking, however, were our observations of "glomeruli" directly enmeshed within populations of large cell-bodied neurons within the protruding cerebrum. Longer term survivals indicate that this "glomerularization" persists and that there may be a relationship between the length of survival and degree of glomerularization in the forebrain. EM analyses revealed clearly recognizable pre- and postsynaptic elements and synaptic contacts within these forebrain glomeruli, reminiscent of those seen in the in tact olfactory bulb. Thus, despite the loss of its primary target, olfactory axons penetrate an "unfamiliar" cellular matrix and form new synaptic relationships. (Supported by NSF Grant BNS 77/16737 to P.P.C. Graziadei and by NIH Training Grant 5-T-32 NS 07010).

1523 SHORT-TERM SYNAPTIC MODULATION IN THE MEDIAL AND LATERAL COMPONENTS OF THE PERFORANT PATHWAY. Bruce L. McNaughton. Dept. of Psychology, Dalhousie Univ., Halifax, N. S. CANADA B3H 4J1.

As indicated by their discrete pattern of heavy metal accumulation (e.g., Zimmer & Hjorth-Simonsen, J.Comp.Neur. 1975, 161, 71-102), the terminals of the medial and lateral perforant pathways to the fascia dentata appear to represent two biochemically distinct populations. This evidence is not necessarily incompatible with the evidence (Steward, J.Comp.Neur. 1976, 167, 285-314) that there may be a continuously ordered mapping from the medio-lateral axis of the entorhinal cortex onto the proximo-distal axis of the granule cell dendrites.

It was shown previously (McNaughton and Barnes, J.Comp.Neur. 1977, 175, 439-454) that the extracellularly recorded synaptic responses of these two components could be differentiated on the basis of waveform, the more laterally elicited responses having a slower rise time.

The present experiments show that while a continuous range of EPSP rise times can be recorded with varying stimulus locations in the angular bundle, the magnitude of short-term synaptic modulations following either single pulses or brief high-frequency trains, differs in a discontinuous fashion when plotted as a function of EPSP rise time. This result indicates that the two components are physiologically discrete. Under pentobarbital anaesthesia, the lateral pathway shows a dynamic range of synaptic efficacy of at least 170% of baseline whereas the medial pathway has a range of less than 40% for the equivalent conditioning input.



1524 AUTORADIOGRAPHIC MAPPING OF RETINOTECTAL FIBERS IN NORMAL GOLDFISH AND AFTER REGENERATION FOLLOWING NERVE CRUSH. Ronald L. Meyer* (SPON: C. R. Hamilton). Division of Biology, California Institute of Technology, Pasadena, CA 91125.

The distribution of optic terminals was mapped in normal fish and in fish after regeneration of the optic nerve. In both groups, the nasal or temporal hemiretina was lesioned just prior to injection of ^{3}H-proline into the vitreous. Autoradiography on normal fish showed label only in tectal regions appropriate to the intact retina. In fish labeled after optic nerve crush and regeneration, the distribution of terminals was found to be orderly after long recovery periods, but diffuse at early stages. At 1 mo, the label was found over nearly the entire tectum, whereas at 4 mos, grains were restricted to topographic regions similar to that in normal fish. In another study, a mediolateral mid-dorsal incision through the tectum in normal fish disrupted all fibers coursing to dorsal tectum posterior to the lesion, so that label was found only in lateral regions of the posterior tectum. After regeneration of the optic nerve, however, a similar incision failed to produce such a well defined zone of denervation even after long recovery, although there was a marked lateral to medial decrease in the gradient in the posterior tectum. Apparently, the accuracy of termination improves with time, but pathway errors remain. (Supported by the Caltech Hixon Fund and USPHS grant MH-03372 to R. W. Sperry.)

1525 CHANGES IN Ia FIBER PROJECTION TO MOTONEURONS IMMEDIATELY FOLLOWING SPINAL CORD TRANSECTION. S.G. Nelson, T.C. Collatos*, A. Niechaj* and L.M. Mendell, Dept. Physiol., Duke Univ. Med. Ctr., Durham, NC 27710

In previous experiments we have shown that transection of the spinal cord at T13 or L5 6 to 8 hours before recording resulted in enhancement of Ia evoked individual EPSPs recorded in homonymous motoneurons. These data were obtained in anesthetized cats using the spike triggered averaging technique in medial gastrocnemius (MG) motoneurons with comparison made to similar data in intact anesthetized preparations. In the present experiments done using identical techniques, EPSPs were recorded in several MG motoneurons prior to spinal cord transection at either T13 or L5. Following transection uncommonly large EPSPs (> 400 μV) were observed but only after several hours had elapsed. EPSPs exhibiting the largest amplitude increases had brief rise times; the Ia terminals producing them may be located proximally on the motoneuron. Procaine block followed by transection at that level resulted in no change in EPSPs in cells recorded continuously throughout this procedure. We conclude that enlargement of EPSP amplitude is not an immediate consequence of loss of descending input.

The large EPSPs in these preparations were observed both in slow and in fast motoneurons. Their rise times and half widths clustered near the origin of the shape index curve (half width vs. rise time), suggesting a selective enlargement of EPSPs produced by Ia terminals synapsing proximally on the motoneuron. Input resistance of these motoneurons was within normal limits.

Immediately following transection, single Ia fibers evoked EPSPs in virtually all homonymous motoneurons in contrast to the projection frequency of 78% previously reported by Scott and Mendell (J. Neurophysiol. 33, 679-692, 1976) in cats with intact spinal cords. No lower projecting type Y afferents (Scott and Mendell, ibid) were observed following transection in contrast to cats with intact spinal cords in which about 1/3 of all Ia fibers were type Y. Furthermore, a Ia fiber classified as type Y before transection exhibited the characteristics of a type X fiber (projecting to virtually all motoneurons) following transection. Subject to uncertainty due to sampling, we speculate that the increased connectivity (which can occur without increases in amplitude) may be immediate. It could represent either increased invasion of Ia terminal branches or perhaps activity of hitherto "silent" synapses. The link between cord transection and these increases is not presently known.

(Supported by NIH.)

1526 REVERSIBLE REDUCTION IN THE ACTIVITY AND AMOUNT OF CHOLINE ACETYLTRANSFERASE IN HYPOGLOSSAL NEURONS DURING THE RETROGRADE (AXON) REACTION. D.H. Park, G.F. Wooten, T.H.Joh and D.J. Reis, Laboratory of Neurobiology, Cornell Univ. Med. College, New York, NY 10021; and (GFW) Dept. of Neurology, Univ. of Washington, St. Louis, MO

A reversible reduction in the activity and amount of the neurotransmitter synthesizing enzymes, tyrosine hydroxylase (TH) and dopamine-β-hydroxylase, probably a consequence of reduced enzyme biosynthesis (Ross et al, Neuroscience Abstr. 3, 431, 1977) characterizes the response of central dopaminergic and noradrenergic neurons to axonal injury. We sought in this study to establish if lesions of cholinergic neurons will also reduce reversibly in the parent cell body the activity and amount of the specific enzyme required for acetylcholine biosyntnesis, choline acetyltransferase (CAT). The cholinergic hypoglossal nerve was transected unilaterally distal to the cricoid cartilage in anesthetized rats. At various days thereafter the animals were killed and the hypoglossal nucleus assayed for CAT and also for acetylcholinesterase (AChE), the enzyme degrading the transmitter, and compared with unoperated controls. Between 24-72 hours after surgery, CAT activity fell to 52% of control, recovering to prelesion levels 4-5 weeks later at a time of reinnervation of the tongue. The activity of AChE was reduced in parallel but with a smaller magnitude (to 80% of control). Immunotitration with a specific antibody to CAT prepared from rat caudate nucleus demonstrated the reduction in CAT activity was entirely due to reduced accumulation of enzyme molecules. Morphologically, signs of chromatolysis in hypoglossal neurons was minimal. These results further support the view that a reduction in neurotransmitter biosynthetic enzymes may be a hallmark of the retrograde reaction in all neurons. Since the retrograde reaction in hypoglossal neurons is associated with a net increase in protein biosynthesis (Watson, J. Physiol. (Lond.), 180, 741, 1965), the reduced accumulation of CAT protein may reflect reordering of patterns of protein biosynthesis favoring production of proteins for reconstitution of regenerating axons at the expense of those required for the function of the cell in neurotransmission. (Supported by NIH grants HL 18974 and MH 24285.)

1527 ABNORMAL AXONAL GROWTH IN THE DORSAL LATERAL GENICULATE NUCLEUS. J.A. Robson and C.A. Mason, Dept. of Pharmacological and Physiological Sciences, University of Chicago, Chicago, Illinois 60637.

Dorsal lateral geniculate laminae A and A1 of the cat normally receive inputs from different eyes. However, removal of one eye during the first postnatal week induces growth of axons from the intact eye into the denervated laminae. This abnormal growth has been shown to occur predictably in the binocular segment of the nucleus and the region of these translaminar sprouts contains large cells that have not undergone denervation atrophy. Sprouting has also been shown in monocular regions of denervated lamina A, but this does not occur in all experimental animals nor is there evidence that it is associated with surviving large cells. To determine if the abnormal retino-geniculate axons invading the region of large cells differ from those invading the region lacking large cells, the structure of these axons in the binocular and monocular regions of the nucleus has been studied light and electron microscopically. To reveal the axons we filled them with horseradish peroxidase using a method described previously (Science, 1978). There, we demonstrated that translaminar sprouts between laminae A and A1 arise as preterminal and ultraterminal branches of axons that also contribute to their normal target laminae. These sprouted branches give rise to terminals that in all respects resemble those of normal retino-geniculate axon terminals. In comparison, axonal sprouts in the monocular segment of lamina A are not translaminar; they arise directly from the optic tract or as branches of axons in the optic tract. Some have terminals similar to those of normal retino-geniculate axons. That is, many terminals have a crenulated appearance and occur singly or in clusters (Fig. 1). Ultrastructurally these terminals also resemble normal retino-geniculate axon terminals and they form similar patterns of synaptic contacts. However, other sprouted axons in the monocular segment are different (Fig. 2); they branch profusely and give rise to many terminals, most of which have smooth contours and a spherical appearance. Furthermore, these terminals are typically surrounded by glia; make few synaptic contacts; and contain few, if any, synaptic vesicles.

1528 LESIONS IN OCCIPITAL CORTEX OF RAT LEAD TO SECONDARY LOSS OF CELLS IN OTHER CORTICAL REGIONS. Mark R. Rosenzweig, Edward L. Bennett, Hiromi Morimoto* and Marie Hebert *. Dept. Psych. and Laboratory of Chemical Biodynamics, UC-Berkeley, Berkeley, CA 94720.

We reported previously that lesions confined to occipital cortex result in significant loss of weight and DNA in other intact regions of cerebral cortex (Will et al., J. comp. physiol. Psychol., 1977, 91, 33-50). In subsequent experiments involving about 400 rats we have investigated how magnitude of remote loss varied with (a) cortical region, (b) size of lesion, (c) time elapsed between lesion and sacrifice, and (d) post-operative environment, either enriched (EC) or impoverished (IC). Somesthetic cortex, although adjacent to the occipital area, showed only about 2% loss of DNA while remaining dorsal cortex and ventral cortex lost 6-8%; hippocampus showed no change. Magnitude of remote loss increased directly with size of lesion. There was not a consistent difference between losses in DNA of EC rats (EC-lesion vs EC-sham) and IC rats (IC-lesion vs IC-sham), so post-lesion enriched experience did not help to protect against secondary loss contrary to a hypothesis suggested in Will et al. The secondary loss was somewhat greater in rats sacrificed 95 days after lesion than in rats sacrificed 35 days post-lesion. This apparent progressive loss is being investigated in further experiments; it may provide a model for studying progressive loss that has been reported in some clinical cases. Although the EC experience did not protect against remote loss of cells, it did improve subsequent learning behavior. Furthermore, social grouping did not have this effect, so inanimate features of the enriched environment are important in recovery of function.

This research was supported by grants from the Easter Seal Foundation and ADAMHA grant R01 MH26704. It also received support from the Division of Biomedical and Environmental Research of the U.S. Department of Energy through the Lawrence Berkeley Laboratory.

1529 NEURONAL GROWTH IN ADULT NEOCORTEX INDUCED BY STIMULATION AND CONDITIONING. L. T. Rutledge, Mary Ann Werz* and Marilyn E. Conlon*. Dept. of Physiol., Univ. of Mich., Ann Arbor, Mi. 48109

Neuronal ultrastructure was studied following long-term unilateral electrical stimulation of a suprasylvian gyrus in adult cats. For one group (conditioned), brain stimulation (CS) was paired with foreleg shock (US). For another group (unconditioned), brain stimulation was unpaired with foreleg shock. Daily brain stimulation via indwelling cortical electrodes consisted of 20 2-sec trains of 0.5 msec biphasic pulses at 50 Hz. Constant current levels were 0.4 to 1.1 mA. Unstimulated cats served as controls. Bilateral tissue samples from homotopic cortical areas of the suprasylvian gyri of each cat were prepared for electron microscopy.

Brain stimulation, with and without conditioning, produced neuronal growth in both the stimulated and contralateral cortex as indicated by the presence of axonal and dendritic growth cones and filopodia. Qualitatively, growth cones and filopodia were more numerous on the side contralateral to stimulation. Systematic measurements of various dendritic and axonal processes were made. In cortical layer I, cross-sectional areas of dendrites, on both sides of the brain, were larger in the two stimulated groups compared with normals. The two sides of the brain in the unconditioned group did not differ. However, for the conditioned group, dendritic cross-sectional areas were larger on the side contralateral to stimulation. Preliminary data from one animal show that conditioning produced localized changes within the cortical layers. Axonal terminals containing round vesicles were more numerous, but smaller, in layer I, and more numerous in the upper part of layer II, contralateral to stimulation. These data indicate the development of new axonal terminals. Other data indicate the formation of new synaptic contacts. In layer I, the number of symmetric and asymmetric contacts on dendritic shafts was greater contralateral to stimulation. Furthermore, the number of spines and asymmetric contacts on spines was greater in the upper part of layer II, contralaterally.

In these experiments stimulation induced the growth of both dendritic and axonal processes in the adult central nervous system. Cortical stimulation combined with a conditioning paradigm produced more neuronal growth contralaterally than did stimulation alone. Marked growth restricted to certain portions of the cortical layers argues for specificity of plasticity in these experiments.

1530 EXCITATORY AND INHIBITORY POSTSYNAPTIC POTENTIALS DURING HETEROSYNAPTIC POST-ACTIVATION POTENTIATION IN HIPPOCAMPUS. John M. Servey, Ulrich Misgeld* and Manfred R. Klee*. Dept. of Neurobiology, Max Planck Institute for Brain Research, Frankfurt am Main, F.R.G.

In the pyramidal layer of field CA3 of guinea pig hippocampal slices (300-400 µm thick, 37°C) the orthodromic extracellular population spike from single shocks (0.1 to 0.5 cps) to both mossy fiber (mf) and Schaffer collateral (Sch) regions was potentiated, sometimes for more than 3 hr, after tetanic stimulation (usually 20 cps for 10 sec) to either region. Potentiation was usually enhanced by a second tetanus.

During intracellular recording from pyramidal cells orthodromic stimulation elicited only rarely "pure" excitatory postsynaptic potentials (EPSP; 5%) or inhibitory postsynaptic potentials (IPSP; 25%) but mostly mixed EPSP/IPSP (70%). If potentiation means an increase in orthodromic population spike, the question arose, what changes occur in the IPSP? In most cells with mixed EPSP/IPSP, after tetanus the EPSP progressively increased and the IPSP decreased, while the resting membrane potential remained unchanged. In contrast, in other cells with mixed EPSP/IPSP or apparently pure IPSP, the IPSP increased, while the EPSP remained unchanged. But we observed that, if we repeated the tetanic stimulation, after the second tetanus the EPSP increased (or even developed in cells formerly showing no EPSP), while the IPSP was drastically reduced.

A possible explanation for these data is that after the first tetanus the impaled cell and its synapses are not changed, while the response of most neighboring cells is potentiated. The resulting increased recurrent inhibition, through common inhibitory interneurons, would increase the recorded IPSP. After the second tetanus the impaled cell and/or its synapses are also altered, so that the recorded EPSP increases and the IPSP decreases. This would account for both types of post-tetanic response seen in different cells. Finally, the idea that the potentiation is heterosynaptic (i.e., not restricted to the tetanized synaptic input) is strengthened by the observation that any change in PSPs which occurs after tetanus to one input is seen in response to both inputs.

1531 SPECIFIC NEURITIC PATHWAYS AND ARBORIZATIONS FORMED BY FETAL MOUSE DORSAL ROOT GANGLION CELLS WITHIN ORGANIZED SPINAL CORD EXPLANTS IN VITRO. Neil R. Smalheiser, Edith R. Peterson* and Stanley M. Crain. Dept. of Neuroscience, Albert Einstein College of Medicine, Bronx, New York 10461.

In cultures of fetal mouse spinal cord cross-sectional explants with attached, NGF-enhanced, dorsal root ganglia (DRGs), focal DRG or dorsal cord stimuli evoked characteristic 'PAD'-like synaptic network responses restricted to dorsal horn regions (Cr. & Pet., Br. Res. 79,'74). Stimuli to nearby ventral cord regions, on the other hand, failed to evoke these dorsal horn responses, indicating that few stray collaterals of the primary afferent DRG input were present in the ventral cord. To trace these DRG fibers directly, orthograde horseradish peroxidase, Golgi-like labeling of DRG cells was carried out (at 0.5-5 wks in vitro) in over 60 co-cultures with: attached cord cross-sections, separate longitudinal cord strips, isolated explants of dorsal and ventral regions, and superior colliculus explants. HRP (Type II, 20% in saline) was iontophoresed extracellularly into DRGs via two-four 8 µm pipettes, with 100 msec pulses, 2/sec (~ 3 µa) for 4-12 hrs, then incubated for 0.5-5 hrs, fixed, and processed with Hanker-Yates reagent (modified from Hanker et al., Histochem. J. 9,'77). Scores of fibers (~ 0.3µ-3µ) were filled, up to 3 mm. Fiber growth, ramification, and arborization types in cross-sectional cord explants with attached DRGs resembled those seen in situ (e.g. Proshansky and Eggar, Neurosci. Lett. 5,'77). Similar preferential invasion and ramification of dorsal cord regions was observed in co-cultures with isolated dorsal and/or ventral cord explants. In longitudinal cord strips, HRP-labeling confirmed electrophysiologic evidence (Cr. & Pet., Soc. Neurosci. Abstr. 1,'75) that DRG fibers entered directly into dorsal regions and not via the adjacent ventral regions on the same facing edge; this was observed even within a day or two after arrival of DRG neurites at the cord explant. In repeated attempts with a truly inappropriate target, superior colliculus explants, we have observed only rare, sparse DRG arborizations, in contrast to those seen in nearby cord targets in the same culture. This was not due to deficits in the collicular tissue in vitro; for example, preliminary HRP injections of retino-collicular co-cultures have shown elaborate arborizations in the tectal explants. These studies set limits to the extent of aberrant DRG growth and terminal arborizations within the developing CNS, and they provide a baseline for exploring underlying specificity mechanisms in vitro. (Supported by grants 5T5 GM 1674 from NIH, NS-12405 from NINCDS, BMS75-03728 from NSF; N.R.S. is in the Medical Scientist Training Program at Einstein.)

1532 MONOAMINE INVOLVEMENT IN THE DEVELOPMENT OF THE POST-DECAPITATION REFLEX IN RATS. Sonya K. Sobrian, Martin A. Rogers* and Byron A. Campbell. Dept. Pharmacol., Sch. Med., Howard University, Washington, D.C. 20059 and Dept. Psych., Princeton University. Princeton, N.J. 08540.

The post-decapitation reflex (PDR) is a series of coordinated movements which follows decapitation in the cervical region. Selective depletion of brain and spinal cord norepinephrine (NE) by 6-hydroxydopamine (6-OHDA) treatment altered the development of this reflex in Sprague-Dawley rat pups. Subcutaneous injections of 50 ug/g of 6-OHDA on postnatal Days 0-3 significantly reduced cortical and cerebellar NE concentrations 67% and 57%, respectively, while brain stem NE was increased 55%. In the spinal cord the reduction in NE was 30% of control values, while dopamine levels remained unchanged. This injection schedule also increased the latency and decreased the duration and intensity (bilateral kick frequency) of the PDR in 10-25 day old pups. The incidence of pups exhibiting the reflex was 100% in both groups at each of these ages. However, at 30 days of age, the PDR was abolished in 6-OHDA treated pups; recovery was not evident at 90 days of age. Moreover, the PDR was absent only in pups receiving 6-OHDA during the first 2 or 4 postpartum days (Day 0 = birth). Injections of 6-OHDA on Days 4 and 5 or Days 8 and 9 significantly altered the latency, duration and intensity without reducing the incidence of the PDR in 15 and 30 day old rats. Further evidence for the involvement of NE in the PDR was indicated by the reinstatement of the reflex in 6-OHDA pups by acute treatment of 30 day old animals with clonidine (2 mg/kg, i.p.). The latency, duration and intensity of the response, however, were still significantly different from controls. Amphetamine (4 mg/kg) and l-DOPA (100 mg/kg) were ineffective, while apomorphine (8mg/kg) produced an attenuated PDR in 42% of the rats tested. Depletion of central serotonin concentrations by neonatal 5,7-dihydroxytryptamine treatment reduced the intensity of the PDR without significantly altering the other parameters in 30 day old rats.

Several tasks of motor coordination were also affected by neonatal lesions of NE terminals. 6-OHDA treated pups, 30-35 days of age, failed on a task of hind limb support when suspended, took significantly longer to cross balance beams of various widths and to remount a moving treadmill.

These data indicate that NE neurons of descending bulbospinal pathways are essential for the development and maintanence of the PDR and that dopamine and serotomin may influence several aspects of this reflex.

1533 THE DEVELOPMENT OF PLASTICITY IN THE HIPPOCAMPUS. Timothy J. Teyler and Charles Duffy*. Neurobiology Program, Northeastern Ohio Universities College of Medicine, Rootstown, Ohio 44272.

It has been well established that environmental influences can have a marked effect on the development of structure and function in the nervous system. These influences are also reflected in the plasticity exhibited by the developing brain. The normal development of neuronal response plasticity has, however, been neglected. In this experiment we have examined the development of several forms of monosynaptic response plasticity in the normally developing rat hippocampus, using a combination of electrophysiological and light microscopic techniques.

Four types of plastic change in electrophysiological response properties were examined in the dentate gyrus of rats as a function of development. Animals of 7, 14, 30, 60 and 210 days of age were used.

The monosynaptic junction between the perforant path fibers and dentate granule cells was examined at each age for frequency potentiation, post-tetanic potentiation, long-term potentiation and habituation. Electrophysiological measures were taken from the in vitro hippocampal slice preparation. The electrophysiological development of plastic processes was compared to the morphological development of dentate granule cells at each age, using rapid Golgi techniques.

Frequency potentiation and long-term potentiation exhibited a developmental progression between 7 and 210 days postnatal. Post-tetanic potentiation remained constant across this period. Except for the youngest group, the degree of habituation increased as a function of age. Thus, most forms of plastic response processes followed a developmental time course.

The anatomical data indicate that the dendritic field of the rat dentate gyrus granule cell layer is not fully mature until well into the first year of life. Four stages of dendritic development are described: (1) The establishment of primary dendrites, (2) The formation of dendritic spines, (3) The elaboration of the dendritic arborization, and (4) The reintensification of spine density.

These results may indicate that the mechanism(s) underlying post-tetanic potentiation is different from that underlying the other forms of response plasticity in that it does not show a developmental time course. These results do not allow us to draw conclusions regarding the neuronal mechanisms underlying response plasticity. The development of response plasticity was seen to be correlated with synaptogensis, spine formation, dendritic arborization and the reorganization of dendritic input patterns.

1534 THE STIMULUS FOR COLLATERAL NERVE SPROUTING IN SKELETAL MUSCLE. C. D. Tweedle and J. J. Kabara*. Dept. Anat. and *Biomech., MSU, E. Lansing, MI 48824.

It is known that, following partial denervation of skeletal muscle, collateral sprouting of the remaining nerve supply occurs. Therefore, there must be a stimulus from the denervated muscle fibers or degenerating nerve to elicit the neuronal outgrowth. Our experiments indicate that lipid extracts of rat gastrocnemius muscle that has been denervated for nine days will elicit histological evidence of significant nerve sprouting when injected into normal rat muscle (tongue). Control muscle lipid extracts or lipid extracts from normal or degenerating nerve have no such activity, indicating that the stimulus for sprouting is from the denervated muscle and is lipophilic in nature. Analysis of the denervated gastrocnemius muscle shows increases in both non-polar and polar lipids. Biological activity was found in the glycolipid and phospholipid fractions.

Preliminary evidence also indicates that extracts from the endplate region of denervated muscle have more biological activity than extracts from the non-endplate region. Data to date indicate that at least two lipophilic substances isolated from denervated muscle can elicit nerve sprouting.

1535 CYTOARCHITECTONIC ALTERATIONS IN MOUSE CORTICAL BARRELS FOLLOWING DIFFERENT PATTERNS OF EARLY VIBRISSAL DAMAGE. K.L. Valentino*, T.A. Woolsey and A.J. Wilson*. (SPON: W.M. Landau). Dept. of Anat. and Neurobiol., Washington U. Sch. Med., St. Louis, MO 63110.

In mice the large vibrissae on the face project to the posteromedial barrel subfield (PMBSF) in the contralateral SmI cortex. The vibrissae and PMBSF barrels are arranged in 5 rows labeled A-E. Within each row the vibrissae and barrels are numbered from 1 up to 8. Barrels or vibrissae in different rows having the same number are described as arcs. If the vibrissae are lesioned, the PMBSF barrels can be altered. When Row-C vibrissae are lesioned on different postnatal days (PND), there is a "critical period" after which the peripheral damage does not alter the cortex. Areal losses in Row-C barrels are "compensated" for by enlargement of barrels in Rows B and D, and there is a caudal to rostral gradient in the cortex for this compensation (Woolsey and Wann, '76).

The present experiments were designed to examine this gradient of "compensation". Vibrissae in Row B or D, arcs 2 or 5 and other combinations including all vibrissae were lesioned in animals on PND's 1-6. On PND-30 the animals were sacrificed, the brain embedded, sectioned serially at 75 µm tangential to the pia stained with thionin, the PMBSF's drawn using a camera lucida and the areas of each barrel measured with a computer.

The results are: (1) Lesions of Row B or Row D produced the most severe cortical alterations when the vibrissae were damaged on PDN's 1 and 2. There is a critical period on PND-5 after which no cortical changes are produced by the peripheral damage. The row zones did not show evidence of segregation into barrels until PND-4, and there was "compensation" by the adjacent rows. (2) Animals with lesions of vibrissae in arcs 2 or 5 show the same "critical period", but the arc zones become segregated into barrels earlier-on PND-2. In several cases, there was a clear indication of the caudal to rostral gradient in that across an arc the Row-E barrel was more severely effected than the Row-A barrel. In all cases, there was areal "compensation" within the barrel row by the more medially placed barrels.

These data confirm our earlier observations with respect to a "critical period" and provide direct evidence for a caudal to rostral gradient of "compensation" in the cortex. There is a second lateral to medial gradient of compensation within PMBSF barrel rows. The organization of barrel neurons into rows, presumably by segregation of the thalamo-cortical afferents, dominates over the segregation of neurons within a row into single barrels. This finding agrees with single unit studies in which neurons in the supragranular layers have been shown to respond to several vibrissae which are commonly within a particular row.

1536 SOME BEHAVIORAL CONSEQUENCES OF NEURAL TRANSPLANTS IN THE RAT BRAIN. Robert B. Wallace, Gopal D. Das*, Joanne Bell* and David Maheux*. Dept. of Psych., Univ. of Hartford, West Hartford, Ct. and Dept. of Biol. Sci. Purdue Univ., West Lafayette, Ind.

Embryonic neural tissue obtained from the forebrain of 17 day rat embryos was transplanted into the midline cerebellum of 10 day old Long-Evans hooded rats. The animals were allowed to survive for behavioral testing and were then sacrificed and the brains processed for Nissl stain and Golgi-Cox impregnation.

These heterotopic transplants had displaced much of the host cerebellar tissue and in terms of cytology and cytoarchitecture, had retained the characteristics of their region of origin. Anatomically all transplants were continuous with the host brain tissue.

These animals were tested on a series of behavioral tasks and compared with normal animals of the same age and strain. There were no differences between the groups in emotionality as assessed by the King Emotionality Scale. General activity, ataxia, tremor, dysmetria, and rearing behavior were measured in an open field situation. There were no differences between the two groups on the first four measures but the transplant animals did have more abnormal rears than the control subjects.

Results on an elevated runway revealed no substantial differences between the groups.

Activity as measured in activity wheels did reveal differences with the transplant animals being significantly more active than the control subjects.

These data were then contrasted with results from a previous study (Wallace and Altman, 1969) where two groups of Long-Evans hooded rats received neonatally 8 or 10 x 200r of x-irradiation focally delivered to the cerebellum. This experimental treatment reduced by approximately 80% the number of granule cells in the internal granular layer. These animals were tested at ages comparable to the subjects in the present investigation.

In terms of emotionality and the measures assessed in the open field, the x-ray animals were in all instances more impaired than the control and transplant material from the present study. Only with regard to rearing behavior did we note any comparability between the transplant and the x-ray animals. Activity as assessed in the wheels with the x-ray subjects showed them to be significantly less active than the control subjects of the present study.

Although our results are tentative at this point and it is clear that much additional work has to be done, it is suggested that heterotopic tissue transplants might well possess some capacity to maintain reasonably normal levels of function. It is further suggested that transplanted tissue might produce a juvenilization effect in the host animals.

1537 SYNAPTOGENESIS IN RAT LUMBAR SPINAL CORD AND RECOVERY OF FUNCTION. Eric D. Weber* and Dennis J. Stelzner (SPON: James A. Horel). Dept. of Anatomy, S.U.N.Y. Upstate Medical Center, Syracuse, N.Y.

Mid-thoracic spinal cord transection produces dramatically different behavioral results which depend upon a rat's age at the time of surgery. If complete spinal transection occurs on or prior to the twelfth postnatal day, spinal shock is minimal and recovery maximal. If the lesion is produced at 15 days of age or later in development little recovery occurs and the classical picture of paraplegia is observed. (Brain Research 125:241-255; 1977). The present study was initiated to determine whether the synaptic development in the gray matter of the normal, developing spinal cord differs before and after this critical period for behavioral recovery.

The L6 segments from ten groups of animals, 0 - 30 days of age, taken at three day intervals (four animals/group) were studied by light microscopy. Areal measurements of the gray matter were made using an integrating X - Y tablet interfaced to a computer. Cell size, cell density, and area of neuropil were evaluated in the lateral portions of the intermediate gray matter, laminae VI and VII. This region was selected for study since it is an interneuron pool which matures relatively late in ontogeny. (Exp. Neurol. 31: 337-357; 1971). Electron microscopic analyses of synaptogenesis were performed on material from the same region in animals 3, 12, 15, 21, and 30 days old using similar morphometric methods while taking note of vesicle, junctional, and mitochondrial morphology.

A 60% increase in area of neuropil paralleled a linear increase of comparable magnitude, in area of the gray matter until 15 days of age when both curves reached a plateau. Cell size remained constant ($\approx$20 μm^2 in plane of nucleolus) throughout development so could not have contributed to the increase in area of gray matter. Areal measurements of the size and counts of the number of vesicle containing profiles demonstrated a 50% increase in density of axon terminals between 3 and 12 days of age and a steady decline thereafter. The size of vesicle containing profiles in laminae VI and VII remained constant at a small value ($\approx$0.37 μm^2) until 12 days of age, showed rapid growth to 0.55 μm^2 between 12 and 15 days of age, followed by a more moderate increase in sectional area after 15 days. This may indicate that the addition of new vesicle containing profiles ceases at about the time a growth in their size commences. These results suggest that synaptogenesis in this region of the lumbar spinal cord proceeds rapidly between birth and 15 days of age but only very slowly thereafter.

We interpret our results to indicate that recovery is maximal after spinal cord injury if the damage occurs before synaptogenesis is complete. If synaptic development is complete at the time of injury, little recovery of function results.

1538 THE EFFECT OF ENVIRONMENTAL DEPRIVATION ON THE GROWTH OF THE MOUSE PURKINJE CELL DENDRITIC TREE: A MORPHOMETRIC GOLGI ANALYSIS. Gary M. Weiss* and J.J. Pysh. Dept. Anat. Northwestern Univ. McGaw Med. Ctr., Chicago, IL 60611.

Previous studies of the effects of functional deprivation on neuronal development have been largely confined to the visual system. Since the isoplanar nature of the dendritic tree makes the cerebellar Purkinje cell uniquely suited for morphometric analysis, we chose to investigate in Golgi-Kopsch preparations the effect of environmental deprivation on the late postnatal development of the Purkinje cell dendritic tree.

Littermates of C57/DBA hybrid mice were placed in either a deprived or enriched environment after weaning at 18 days of age until sacrifice at 35 days of age. Deprived animals were kept together in a small cage, where their movements were severely restricted, allowing them to move about only enough to gain free access to food and water. In contrast, enriched animals were raised in a large Habitrail cage with exercise toys which allowed running and climbing ad lib. In addition, on a daily basis, enriched animals were trained to swim and walk a tight wire and encouraged to exercise.

Body and brain weights were reduced significantly 15.5 and 3.0% in the deprived group. Histometric analysis of sagittal sections of the vermis revealed a significant reduction of 10.7% in the molecular area in deprived animals and no change in the area of the granular layer. Morphometric analysis of Golgi sections revealed a significant reduction in deprived animals of 9.6% in dendritic field areas and 9.2% in total dendritic length of Purkinje cells. This reduction was consistent in all lobules of the vermis.

Purkinje cells of deprived mice did not appear to be merely immature cells reflecting a slower rate of development because they had a normal branching density for their age. The above environmental effects on cerebellar development might result from a decrease in the length of parallel fibers and/or the amount of glia which could reduce the thickness of the molecular layer and hence the area available for Purkinje cell dendritic growth.

These data offer the first evidence that the development of the Purkinje cell dendritic tree may be alterable by environmental manipulation.

1539 LONG TERM POTENTIATION IN THE LESION-INDUCED CROSSED TEMPORO-DENTATE PATHWAY OF THE RAT. R. Wilson* and O. Steward. Depts. of Neurosurgery and Physiology. University of Virginia School of Medicine, Charlottesville, VA 22901

Unilateral entorhinal cortical lesions disrupt the normal ipsilateral entorhinal cortical (IEC) projection to the dentate gyrus (DG) of the rat hippocampal formation and induce marked alterations in the terminal organization of surviving afferents to the partially denervated DG (sprouting). Among these changes is a proliferation of terminals of the normally sparse crossed temporo-dentate pathway originating in the contralateral entorhinal cortex (CEC). As part of an effort to ascertain the extent to which this lesion-induced crossed pathway reproduces the electrophysiological properties characteristic of the normal IEC projection, we compared their capacities for long term potentiation (LTP). Stimulation of the IEC with short, high frequency (8-12 pulses, 400 Hz) stimulus trains induces dramatic, long lasting increases in the amplitudes of the DG population EPSP (a measure of summed synaptic currents) and population spike (a measure of DG granule cell discharge). Comparison of population EPSP amplitudes to population spike amplitudes at several stimulus intensities previous and subsequent to delivery of the potentiating trains indicated that the two parameters increased in parallel during LTP such that the increased synaptic drive induced greater granule cell discharge. In experiments in animals with long-standing IEC lesions, delivery of identical short, high frequency stimulus trains to the CEC likewise produced LTP of the synaptic response elicited via the sprouted crossed temporo-dentate connections. No evidence of potentiation of the contralaterally elicited population spike was obtained, however, indicating the increased synaptic drive associated with LTP in the lesion-induced crossed temporo-dentate pathway did not, in contrast with LTP in the normal ipsilateral pathway, result in an enhancement of granule cell discharge. The results suggest that the lesion-induced and normal connections possess similar synaptic capacities, but that the enhanced synaptic input has different consequences for granule cell discharge in the case of the lesion-induced crossed pathway. (Supported by USPHS RESEARCH GRANT #1 ROl NS12333 to O. Steward).

1540 MORPHOLOGICAL AND ELECTROPHYSIOLOGICAL STABILITY OF THE MAUTHNER CELL FOLLOWING AXOTOMY BY SPINAL CORD TRANSECTION. Steven J. Zottoli and Donald S. Faber. N.Y.S. Res. Inst. on Alcoholism, 1021 Main Street and Dept. Physiol., SUNY at Buffalo, Buffalo, N.Y. 14203, U.S.A.

In order to explore the potential of the Mauthner cell (M-cell) system for studies of neuronal plasticity, we have analyzed its behavioral, morphological and electrophysiological responses to axotomy performed by spinal cord or bulbar transections at different levels rostral to the anterior edge of the dorsal fin. M-cell function was evaluated by the presence or absence and extent of the sound-evoked startle response it initiates. There were no such responses involving distal trunk and tail musculature in 171 trials conducted from 1-232 days postoperatively (n= 16; prior to axotomy the same fish had a response rate of 80%) although the characteristic movements of the jaw, operculi, fins and eyes were present. In contrast, in most fish examined coordinated swimming behavior returned within 2-7 months. Another 30 experimental fish were sacrificed at different postoperative times for morphological investigations. In no case was there definitive light microscopic evidence of M-cell chromatolysis or other retrograde reactions. Furthermore the Mauthner axon maintained a "normal" appearance 3-4 mm rostral to the level of transection while in the immediate region of the cut abnormal myelin profiles were generally observed for up to 8 months after transection. More caudally this myelin became fragmented and gradually disappeared. These findings indicate a lack of functional and morphological M-axon regeneration and further suggest a maintenance of normal M-cell function proximal to the cut. Electrophysiological experiments on similarly axotomized fish (1 day to 1 yr postoperatively) confirmed that the M-cell retains a high degree of stability in its membrane properties and input connectivity despite an appreciable axonal truncation and the consequent loss of output connections. Specifically, the cell could be activated orthodromically by ipsilateral VIIIth nerve stimulation and antidromically by spinal cord stimulation above but not below the level of transection, and no physiological signs typical of other axotomized neurons (e.g., dendritic spikes or selective deafferentation) were found. The hypotheses that this apparent lack of an axon reaction is due to a minimal trophic influence exerted upon the M-cell by the efferent connections removed by axotomy and/or a stabilizing influence of the predominantly electrotonic afferent inputs to this neuron are presently being studied further. (Supported in part by NIH Grant No. NS-12132)

PSYCHO-PHARMACOLOGY

1541 EFFECTS OF INTRACRANIALLY ADMINISTERED PENTYLENETETRAZOL ON ELECTROCORTICOGRAM AND CONCOMITANT MOTOR ACTIVITY IN THE FREELY MOVING RAT. Bruce J. Albala and Tibor Palfai*
Skytop Labs. Division of Biopsychology, Syracuse Univ. Syracuse, New York 13210.

Pentylenetetrazol (PTZ) is often utilized as both a diagnostic as well as a research tool in clinical or model epilepsy. A number of publications indicate that when applied intracranially the drug induces epileptogenic foci with charateristics comparable to grand mal seizures. However, because most intracranial animal preparations are anesthetized or restrained during electrical recording, no data are available on the effects of intracranially administered PTZ on concomitant motor behavior.

Work in our laboratory indicates that PTZ, (in concentrations up to 50 %) fails to elicit overt motor convulsions when administered intraventricularly in freely moving rats. That the absence of convulsions are not due to faulty injection procedures is suggested by the fact that while the distribution of ^{3}H-PTZ in the brain following intracranial (I.C.) or intraperitoneal (I.P.) injections are comparable, the amount of ^{3}H-PTZ is significantly lower following the I.P. administration. Electrocorticograms (ECoG) recorded following I.P. or I.C. injection of PTZ indicate brain seizures that are similar qualitatively on a number of measures. Overt convulsions however occur only after I.P. but not after I.C. infusion. These data suggest a dissociation between neural activity measued by ECoG and motor behavior following the intraventricular administration of PTZ.

1542 ANTAGONISM OF ETHANOL NARCOSIS IN MICE BY LOW LEVEL HYPERBARIC TREATMENT WITH HELIUM-OXYGEN. R. L. Alkana and R. D. Malcolm, School of Pharmacy, University of Southern California, Los Angeles, CA 90033.

Preliminary studies in this laboratory suggest that hyperbaric treatment with pure oxygen or 20% oxygen-80% helium at 3-6 atmospheres absolute (ATA) antagonizes ethanol depression without accelerating ethanol metabolism. The present experiments further investigated the effects of low level helium-oxygen hyperbaric treatment on ethanol sleep-time in mice. Drug naive, C57 Bl/6j mice were injected i.p. with 3.2 g/kg ethanol (20% v/v). Upon loss of their righting reflex, animals were placed in a hyperbaric chamber and the atmospheric pressure was brought to 1, 6, 8, or 10 ATA with helium-oxygen mixtures adjusted to maintain an oxygen partial pressure approximating 0.20 ATA. Control animals were treated similarly and exposed to air (1 ATA) or 20% oxygen-80% helium (1 or 6 ATA). Immediately after return of their righting reflex and decompression of the chamber, 20 µl blood samples were obtained from the tail vein for gas chromatographic ethanol determination. Mean ± S.E. sleep-times in minutes or blood ethanol concentrations upon awakening in mg/deciliters are shown in parenthesis with the respective oxygen content of the mixture. Hyperbaric helium-oxygen significantly reduced sleep-time at 6 ATA ($\bar{X}_{3.41\%O_2}$ = 8.2±0.8; $\bar{X}_{20\%O_2}$ = 10.3±2.6) and 8 ATA ($\bar{X}_{2.60\%O_2}$ = 8.8±2.3) when compared to 1 ATA controls ($\bar{X}_{air}$ = 18.0±3.0; $\bar{X}_{20\%O_2}$ = 17.7±2.9) ($p<0.05$; 1-tailed t-test). The 10 ATA treatment did not significantly reduce sleep-time ($\bar{X}_{2.05\%O_2}$ = 17.2±3.6). Blood ethanol concentrations were significantly higher at 6 ATA ($\bar{X}_{3.41\%O_2}$ = 388±12) and 8 ATA ($\bar{X}_{2.60\%O_2}$ = 381±10) when compared to 1 ATA controls ($\bar{X}_{air}$ = 350±7; $\bar{X}_{20\%O_2}$ = 334±8) ($p<0.05$; 2-tailed t-test). No significant difference was seen at 6 ATA ($\bar{X}_{20\%O_2}$ = 342±11) or 10 ATA ($\bar{X}_{2.05\%O_2}$ = 360±8). The present findings replicate the ethanol antagonism demonstrated in previous hyperbaric studies with pure oxygen and 20% oxygen-80% helium. Furthermore, these results indicate that antagonism occurs at elevated atmospheric pressures even when the oxygen partial pressure is not raised above normal (0.20 ATA). Although the mechanism of hyperbaric-induced ethanol antagonism remains unknown, these and previous results suggest that the antagonism is not due to elevated partial pressures of oxygen, nor to enhanced ethanol metabolism. Further studies are necessary to clarify the mechanism of the hyperbaric antagonism and to assess its potential in the treatment of acute ethanol overdose.

1543 ESCAPE DEFICITS AFTER INESCAPABLE SHOCK: NEUROCHEMICAL CONDITIONING OR SENSITIZATION. H. Anisman*and L.S. Sklar* (SPON: Jane Stewart). Department of Psychology, Carleton University, Ottawa, Ontario.

Exposure to inescapable shock produces deficits of subsequent escape performance. These deficits are thought to be due to difficulties in maintaining sustained vigorous responding owing to depletion of norepinephrine and dopamine. However, the escape deficits have been found to be long lasting, whereas the stress-induced amine changes are relatively transient. It is suggested that the neurochemical changes induced by stress are subject to conditioning or sensitization. Thus, upon reexposure to stress the extent and rapidity of the amine reduction is accentuated. In support of this notion it was observed that L-Dopa (400-600 mg/kg) administered prior to either inescapable shock or testing, eliminated the escape deficits otherwise observed. Moreover, pairing α-methyl-p-tyrosine (125 mg/kg) or bis (4-methyl-1-homopiperazinylthiocarbonyl) disulphide (FLA-63)(40 mg/kg) with as few as 1 or 5 shocks,which have no effect on their own, disrupted performance 24 hours later. The drug plus 5 shock combination had effects which persisted for 7 days. These effects could not be attributed to long term effects of the drug treatments on catecholamine levels or turnover. It is posited that pairing of catecholamine depletion with stress results in the augmentation of subsequent stress elicited amine changes. The relevance of these data to "learned helplessness" are critically discussed.

1544 LONG-LASTING INFLUENCE OF STRESS ON THE BEHAVIORAL EFFECTS OF AMPHETAMINE AND HALOPERIDOL. S.M. Antelman*, A.J. Eichler*, C.A. Black* and G. McCloskey* (SPON: D.J. Edwards). Dept. of Psychiatry and Psychobiology Program, School of Medicine, University of Pittsburgh, Pittsburgh, PA 15260.

We have recently begun to investigate the related questions of whether moderate stress can produce effects similar to those observed following repeated treatment with amphetamine (AM) and whether such effects might be long-lasting. Since repeated AM treatment is known to produce a progressive augmentation of stereotypy, we first examined whether chronic administration of a moderate tail-pressure (TP) stress to adult male rats could likewise enhance the stereotypy seen following a subsequent dose of AM. We now report that when TP sufficient to induce eating (approximately 80-100 psi) was applied daily for a total of 56 mins. spread over a 15 day period it markedly enhanced AM induced sniffing (3 mg/kg) when this was examined 24 hrs after TP had been discontinued.

In order to determine whether the effects of stress persisted we also conducted tests two weeks after discontinuation of our stressor. This time a 72 hr period of food deprivation was used as the stressor. It's effects were measured 15 days later (at which time body weights and food intake were no different from controls) on both AM (4 mg/kg)-induced sniffing and the ability of haloperidol (0.8 mg/kg) to attenuate TP induced eating. Animals that had received the food-deprivation stress 15 days earlier showed significant enhancement of AM stereotypy and a marked (significant) diminution in the ability of haloperidol to reduce eating precipitated by TP.

These results indicate that moderate stress can produce effects similar to those obtained with AM. By inference they also suggest that many of the effects of AM (and presumably other stimulants as well) may be attributable to its capacity to mimic the influence of stress on the organism. The ability of our stressors to enhance the effect of a dopamine (DA) agonist such as AM while retarding the influence of the DA antagonist, haloperidol, suggests that moderate stress can have a long-lasting, sensitizing influence on DA function. Such an influence could be of considerable importance in a stress-related progressive disorder such as schizophrenia.

1545 LACK OF EFFECT OF SELECTIVE SEROTONIN DEPLETION ON BODY WEIGHT AND AMPHETAMINE ANOREXIA. L. A. Baez, R. A. Browning and M. Cusatis. Department of Psychology and School of Medicine, Southern Illinois University, Carbondale, Ill. 62901.

Intraventricular administration of 5,7-dihydroxytryptamine (5, 7-DHT) in rats has been reported to enhance the intake of food and water and to increase body weight (Saller & Stricker, Science, 192, 385, 1976). Moreover, the intraventricular administration of parachlorophenylalanine (PCPA) was reported to produce hyperphagia and elevated body weight (Breisch, et al., Science, 192, 382, 1976). These findings have suggested an inhibitory role for serotonin (5-HT) neurons in regulatory functions. In the present study this question has been examined further by assessing the influence of chronic serotonin depletion on body weight and ingestive behavior in both Long-Evans and Sprague-Dawley rats. Animals were treated with protriptyline (20mg/kg; i.p.) followed two hours later by an intraventricular injection of 5,7-DHT (200 µg) or vehicle. After behavioral testing was completed, all animals were sacrificed and forebrains were assayed for norepinephrine (NE) and 5-HT content. Body weight data from four separate groups of animals are presented below in table form. Numbers in parentheses indicate the number of animals in each group.

	Time after	Weight ± S.E.M.	
Strain	Treatment	5,7-DHT	Vehicle
Long-Evans	24 days	376±9(6)	363±6(10)
Long-Evans	24 days	359±12(10)	377±10(10)
Sprague-Dawley	30 days	326±8(7)	337±5(7)
Long-Evans	1 year	580±19(6)	578±17(7)

In addition, body weight data were obtained for eight weeks, at weekly intervals, in both male and female Long-Evans rats. Again, there were no significant differences between the treated and untreated rats within each sex category. 5,7-DHT treatment also failed to alter the anorexigenic properties of (+)-amphetamine. Forebrain 5-HT was depleted in all groups of treated animals, with values ranging from 66% to 85% depletion relative to vehicle-injected animals. NE was not affected significantly in any group. The present study, then, failed to produce any evidence of increased body weight in animals chronically depleted of brain 5-HT with 5,7-DHT. The lack of a body weight effect in animals at a broad range of post-treatment intervals as well as the lack of change in (+)-amphetamine-induced anorexia, casts serious doubt on the hypothesis that 5-HT neurons exert a major inhibitory influence on ingestive behavior and body weight regulation.

1546 EFFECTS OF NALOXONE ON ACTIVITY AND REACTIVITY IN THE RAT. Gary G. Berntson, Timothy C. Champney*, Thomas S. Paulucci*, and J. Michael Walker. Dept. Psychol., Ohio State University, Columbus, Ohio 43212.

The exogenous administration of the opioid peptides, enkephalins and endorphins, can induce a variety of behavioral effects. The role of these peptides in natural behavioral regulation, however, is not well understood. While stress has been shown to elevate brain levels of opioid peptides and to produce parallel increases in pain thresholds, the tonic activity of these peptide systems is less clear. We have previously shown that naloxone (an opiate receptor blocker) administered to rats in a non-stressful situation decreases pain thresholds as measured by the tail flick test, suggesting some degree of tonic activity in these systems. To further examine the potential tonic behavioral effects of the opioid peptides, we examined the effects of naloxone on a number of measures of activity and reactivity in the rat. We found that naloxone (2mg/kg SC) significantly reduced activity, as measured by an electronic activity counter, for a period of at least one hour after injection. Comparable decreases in activity were seen when naloxone was preceeded by 1) no treatment, 2) a 3 min. warm water (25°C) swim, and 3) a stressful 3 min. cold water (0°) swim. There was no interaction between the stress condition and the decline in activity. In a second set of experiments, naloxone was found to have no effect on the magnitude of the acoustic startle reflex, while it decreased inter-stimulus activity in the same experiment. These data provide further evidence that tonic activity exists in opioid peptide systems, and that these systems may participate in natural behavioral regulation.

1547 A COMPARISON OF THREE ANIMAL MODELS FOR SCHIZOPHRENIA. R.L. Borison, H.S. Havdala* and B.I. Diamond. Ill. St. Psych. Inst. and Anesthes. Dept., Mt. Sinai Hospital, Chicago, IL 60612 & 60608

Amphetamine-induced stereotyped behavior is the well accepted animal model for schizophrenia because it can be blocked by antipsychotic agents and amphetamine abuse in man produces a schizophreniform-like paranoid psychosis. Amphetamine is not alone in these properties, as we have proposed that another central nervous system (CNS) stimulant, phenylethylamine, may actually provide a more accurate model for schizophrenia (Life Science 21: 117, 1977). We now report a comparison of the behavioral effects in rats of amphetamine and phenylethylamine with another CNS stimulant, cocaine. The repeated daily administration of either of these three agents, in a dose which is per se subthreshold for eliciting stereotypy, produces stereotyped behavior which increases in intensity until plateauing after approximately 3 - 5 weeks. This stereotypy is characterized by head-swaying, forepaw treading and stereotyped sniffing in animals. In animals receiving cocaine a significant amount of locomotor activity is also present. The latency to onset of these behaviors was from 2 to five minutes after injection and the duration of phenylethylamine stereotypy was 30 minutes, whereas that for cocaine and amphetamine was over two hours. The administration of the potent dopamine blockers haloperidol or pimozide completely block stereotypy induced by either phenylethylamine or d-amphetamine, while markedly antagonizing the actions of cocaine. Clozapine, a dopamine blocker with few extrapyramidal effects, selectively blocked phenylethylamine and cocaine behavior, while having no significant action upon d-amphetamine. Thioridazine, another antipsychotic agent with a low index of extrapyramidal side-effects, selectively blocked only phenylethylamine stereotypy. Two alpha-adrenergic blocking agents, phentolamine and phenoxybenzamine, antagonize phenylethylamine stereotypy, whereas only phentolamine antagonizes cocaine and neither affects d-amphetamine behavior. A serotonin blocker, methysergide, selectively blocks only phenylethylamine stereotypy. Although all three compounds, phenylethylamine, d-amphetamine and cocaine can precipitate toxic paranoid schizophrenic-like syndromes in man, only phenylethylamine-induced behavior, as shown in our animal model, can be effectively blocked by a range of antipsychotic agents.

1548 OPIOIDS AND PRESSING FOR HYPOTHALAMIC INTRACRANIAL STIMULATION (ICS) IN RATS. Michael A. Bozarth and Larry D. Reid, Depts. of Psychol., Concordia University, Montreal, Quebec, Canada, and Rensselaer Polytechnic Institute, Troy, NY, USA, 12181.

This presentation summarizes the results of several studies testing the effects of various opioids on pressing for ICS. Rats were prepared with a chronically indwelling bipolar electrode. Histological analyses, after behavioral testing, have confirmed that sites of ICS were in the lateral hypothalamic region, e.g., medial forebrain bundle, Forel's fields, zona incerta.

After at least 5 days post surgery, each rat was trained to press a lever to obtain ICS in a typical ICS-apparatus where each lever depression resulted in a single train of ICS (60 Hz sine waves; .3 sec duration; individualized intensities, but always less than 50 µA, rms).

After stable pressing for ICS was established (2 trials/day), 65 rats were given morphine (10 mg/kg/day, s.c.) for 9 days and tested 2 and 4 hr later. After 6 days of tests without drugs, one group was again tested with morphine (10 mg/kg/day) across 13 days while other groups received equianalgesic doses of other opioids: leverphanol (2 mg/kg), methadone (8 mg/kg), codeine (120 mg/kg), and nalorphine (10 mg/kg). These multiple tests provide an opportunity for a drug to produce an increment in pressing if the drug has that capability. Additionally, there have been tests with pentazocine (40 mg/kg), naloxone (1 and 10 mg/kg), and nalorphine (10 mg/kg) before and after opioid administration.

Morphine in a variety of doses (including the standard 10 mg/kg dose), levorphanol, and methadone produced reliable increments in pressing. Neither nalorphine, pentazocine, nor naloxone led to reliable increments in pressing following initial injections of these agents. Pentazocine did, however, lead to reliable increases in pressing among rats that had previously received considerable quantities of either morphine or pentazocine. Nalorphine produced only slight increments in pressing even subsequent to considerable exposure to opioids. Naloxone has not reliably modified pressing for hypothalamic ICS among opioid-free subjects, but did decrease the pressing of those rats whose pressing rates were augmented by opioid administration. Because the drugs that human beings are apt to abuse are those that increased pressing for ICS in rats and because previous opioid-use seems to potentiate human abuse of pentazocine as well as increasing pressing for ICS under pentazocine in rats, it is suggested that drugs which increase pressing for ICS have a high abuse potential.

1549 TAIL PINCH-STRESS ACTIVATES NIGROSTRIATAL DA NEURONS AND BEHAVIOR: THE REVERSAL OF BOTH EFFECTS BY CERVICAL PROBING. A.R. Caggiula*, L.A. Chiodo*, S.M. Antelman* and C.G. Lineberry* (SPON: C. Malsbury). Departments of Psychology, Psychiatry and Pharmacology. University of Pittsburgh, Pittsburgh, PA 15260.

Non-painful tail pinch and related manipulations can reliably induce or potentiate a variety of biologically significant, active motor responses, including eating, gnawing, maternal behavior and male copulatory behavior in rats. Comprehensive pharmacological analyses strongly suggest that tail pinch-induced behavior is critically dependent on unimpaired function of nigrostriatal dopamine (NSDA) neurons (Antelman & Caggiula, 1977).

We now report evidence for a direct relationship between tail-pinch and NSDA function. That is, mild, undulating pressure (1-2 min.), when applied to the tail of urethane anesthetized female rats in a manner which almost invariably induces behavior in awake animals, increased, and often doubled the firing rate of extracellularly recorded units in the zona compacta of the substantia nigra, the origin of the NSDA pathway. In addition to confirming York's (1976) recent report that tail pinch increases cell discharge in the pars compacta, our data more clearly implicate the NSDA in this effect since cells responding to tail pinch exhibited spontaneous firing rates (1-7 Hz) within the range reported by Bunney and Aghajanian as characteristic of this system, and their baseline activity could be suppressed by i.v. amphetamine (1-2 mg/kg) and subsequently reinstated by haloperidol (.1-.2 mg/kg).

We have also obtained evidence which suggests that tail pinch-activation of NSDA neurons is directly related to its behavioral effects, by showing that a stimulus which suppresses tail pinch-induced behavior also blocks its effect on NSDA activity. The stimulus used was vaginal-cervical pressure, since this stimulus inhibits active motor responses (Komisaruk, 1974), and blocks tail pinch-induced feeding in awake animals (Naggar and Szechtman, in preparation and our own unpublished observations). A reciprocal relationship between tail pinch and cervical probing is further supported by the finding that, just as tail pinch-behavior is reduced by drugs which block DA function, the same drugs potentiate some of the behavioral effects of cervical stimulation (Crowley et al., 1977).

In the present study, pressure against the cervix, induced by a glass rod, completely blocked the activation of presumed NSDA neurons if applied concurrently with tail pinch, or brought their firing rates back to baseline if applied after the onset of tail pinch. Continuation of the tail pinch after removal of the rod again activated the cell whereas cervical stimulation, by itself, had little effect.

This study appears to represent the first demonstration that stress can increase the firing of verified NSDA neurons.

1550 BLOCKADE OF INTRACRANIAL SELF-STIMULATION BY HIGH DOSES OF AMPHETAMINE IS LINKED TO THE OCCURRENCE OF HYPERTHERMIA. Robert J. Carey. VAH at Syracuse, Syracuse, NY 13210 USA

Many studies have shown that low doses of d-amphetamine facilitate but high doses suppress responding for rewarding brain stimulation. The low dose facilitative effects of amphetamine are generally considered supportive of, and consistent with, a large body of evidence which implicates brain catecholamines in the mediation of brain stimulation reward. While high doses of amphetamine have a predominant dopaminergic action any attempt to relate this dopaminergic effect to brain stimulation reward is obscured by the disruptive response stereotypy syndrome evoked by a high dose of amphetamine. Interestingly, recent studies on the thermoregulatory dysfunction produced by a high dose of amphetamine indicate that it may be possible to administer a high dose of amphetamine without eliciting the stereotypy syndrome since the stereotypy syndrome emerges only when the ambient temperature is sufficiently high to trigger a hyperthermic response. Accordingly, the present study compares the effect on brain stimulation reward of d-amphetamine when testing is conducted under a normal versus a cooled laboratory environment. Seven rats with medial forebrain bundle electrode implants which supported self-stimulation were administered high (5-10 mg/kg) doses of d-amphetamine. In one set of tests the chamber temperature was cooled to 12° C. in order to prevent hyperthermia. In other tests, however, the chamber temperature was at the normal laboratory temperature of 24° C. which was conducive to an amphetamine-induced hyperthermic reaction. When hyperthermia was prevented by chamber cooling the rats given amphetamine not only responded for brain stimulation but also acquired differential response rates to stimuli which signalled stimulation versus non-stimulation. In contrast, when tested at 24° C. hyperthermia invariably developed and the rats failed to respond differentially to the presence or absence of brain stimulation. Also, the response rates of the hyperthermic rats particularly at the 10 mg. dose level became erratic and unreliable. Thus, the interference with intracranial self-stimulation by high doses of amphetamine appears to be closely linked to the occurrence of hyperthermia.

1551 STIMULUS-ELICITED INVESTIGATION IN THE AMPHETAMINE-TREATED GERBIL AS A MODEL SYSTEM FOR PSYCHOTIC DISORDERS. MaryLou Cheal. Neuropsychology Lab., McLean Hospital, Belmont, MA 02178.

Amphetamine-induced stereotypies reported in the gerbil (Cheal et al., Behav. Biol., in press) are analogous to stereotypic behaviors emitted in human amphetamine psychotics and schizophrenics. Following injections of large doses of d-amphetamine, gerbils (like other species) develop repetitive motor patterns and social behavior ceases. Another analogy to schizophrenic behavior would be the demonstration of "passive" attention. In spite of a lack of overt interest in surroundings, schizophrenics may later report events to which they had appeared oblivious at the time. Bleuler (Dementia Praecox, Internat. U. Press, 1950) called this behavior "passive" attention in contrast to active attention, or seeking of stimuli. An analogous test for "passive" attention was made in amphetamine-treated gerbils using stimulus-elicited investigation. In this paradigm, a novel stimulus elicits investigatory behavior in a series of one minute trials. Following the initial response on the first trial, the investigation habituates on the second trial. Habituation on the second trial has been exhibited with intervals between the two trials from 60 sec to 2 weeks indicating a long-term memory process (Cheal, J. Biol. Psychol., in press). Gerbils were given single injections of d-amphetamine (4.0-6.0 mg/kg) and were observed 45 min later during one trial with a novel object. Due to competing stereotypies, on this trial an average of less than 2 sec was spent investigating the stimulus. Twenty four hours later, when given a second trial, little responding occurred, indicative of habituation. The effect was not due to residual effects of amphetamine as gerbils treated on Day 1 with amphetamine, but not exposed to the novel stimulus, showed normal investigation on Day 2.

This model system was used to study the gerbils' gradient of response to the location of an object following a low dose of amphetamine (1.0 mg/kg) that did not elicit stereotypies. Normally, when the gerbil has habituated to the novel object, investigation can be renewed, or dishabituated, by moving the object 45° or 90°. The amphetamine-treated gerbils demonstrated dishabituation only if the object was moved 90°, not 45°.

The data indicate that an amphetamine-treated gerbil displays behaviors analogous to those observed in human amphetamine psychotics and schizophrenics and that the neurochemical changes caused by the drug treatment result in a broadened generalization gradient of localization of an object.

1552 ESTROGEN MODULATION OF SPIROPERIDOL-INDUCED CATALEPSY AND AMPHETAMINE STEREOTYPY IN THE RAT. L.A. Chiodo* and A.R. Caggiula* (SPON: D. Asdourian). Psychobiology Program, Depts. of Psychology and Pharmacology, Univ. of Pittsburgh, Pittsburgh, PA 15260.

Evidence from both the clinical and experimental animal literature suggests that sex and/or hormonal condition can significantly influence the behavioral consequences of drug-induced alterations of brain DA activity. For example, women have been reported to show a greater degree of motor disturbances after antipsychotic drugs. The possible role of gonadal hormones in this difference is suggested by the finding that the higher incidence of chlorpromazine-induced catalepsy displayed by female, when compared to male rats, was abolished by ovariectomy (Mislow and Fridhoff, 1973).

In the present study, the potentiating influence of estrogen on neuroleptic-induced catalepsy in female rats was confirmed under conditions in which both drug and hormonal effects were clearly specified. That is, ovariectomized (OVX) female rats that received estradiol benzoate (EB) (100 ug/kg s.c.) 48 h before the test showed significantly longer durations of catalepsy than OVX/oil controls in response to 250 ug/kg of the specific DA receptor blocker, spiroperidol. Catalepsy was tested at 14 time points (7 hours) by measuring the step-down latency after the animal's hind quarters were placed on an elevated, wooden block.

Although these results suggest that estrogen may exert a behaviorally relevant influence on DA function, its effects are likely to be neither simple nor direct. That is, EB's potentiation of catalepsy, obtained at some doses of spiroperidol, was actually reversed at others. While it is possible that hormone-induced alterations in peripheral drug metabolism may have contributed to some of these changes, the additional finding that EB drastically altered the short-term (5-10 min.) development of catalepsy in response to intraventricularly administered spiroperidol (20 ug/25 ul) suggests a central mechanism as well.

The foregoing suggests that estrogen's effect on spiroperidol-induced catalepsy is critically dependent on the dose of the drug. An additional study indicates that the type of drug, and perhaps the topography of the behavior being tested, are also decisive factors. That is, the same EB treatment greatly increased the intensity of amphetamine (3 mg/kg)-induced stereotypy, when compared to OVX/oil treated controls.

These results point to the importance of taking hormonal conditions into account when assessing drug effects on DA function and behavior, and suggest a potentially fruitful new direction of research into endocrine modulation of neurotransmitter function.

1553 ACTIVITY OF Δ^9-THC SIDE CHAIN ANALOGUES. H. Dix Christensen, W. C. Goad*, M. Perez-Reyes* and M. E. Wall*, Dept. Pharm., OUHSC, Okla. City, OK 73190, Dept. Psych. UNC, Chapel Hill, N.C. 27514 and RTI, Research Triangle Park, N.C. 27709.

The relative potency, any unusual physiological or behavioral effects, and an estimate of relative safety were determined for a series of Δ^9-THC analogues with side chain hydroxylation. The profile of activity was determined using 130 CF-1 male mice, 29.2 ± 0.3 gms, by a slight simplification of Irwin's procedure (Psycho pharm. 13, 222, 1968). In addition, rectal temperature was recorded at the end of each observational period of control, 10, 20, 30, 45, 60, 90 and 120 minutes post administration intravenously through a tail vein. The vehicle consisted of 5% ethanol, 5% Emulphor EL620 and water, which was inactive at 0.3 ml/10 gms, with 0.1 ml/10 gms the normal injection volume. The relative potency was determined by the minimum dose that would cause a significant decrease in spontaneous activity with marked depression.

Compound	Decrease in activity with depression				Relative Potency	Minimum Lethal Dose
	Dose mg/kg	Onset	Peak Minutes	Duration		mg/kg
Δ^9-THC	4.0	1	15	100	1.0	24
11-OH-Δ^9-THC	2.0	1	8	60	2.0	>48
1'a-OH-Δ^9-THC	24.0	5	15	20	0.17	?
1'b-OH-Δ^9-THC	64.0	10	45	80	0.06	?
2'-OH-Δ^9-THC	16.0	0.5	10	45	0.25	32
3'-OH-Δ^9-THC	0.4	0.5	10	60	10.0	16
4'-OH-Δ^9-THC	16.0	0.5	10	60	0.25	48
5'-OH-Δ^9-THC	24.0	1.5	10	45	0.17	64

The relative potency varied slightly if hypersensitivity to tactile stimuli, crouched posture and gait, a sensorimotor response such as visual placing or coordination, or respiratory arrest were compared. At the depression dose, all of the compounds had a maximum decrease of about 4° in rectal temperature. This occurred at 25-30 minutes with essentially normal temperature for all except Δ^9-THC at 120 minutes. If death occurred it was within the first 30 min. by respiratory arrest. No long term behavioral effects were observed from a single dose. The hydroxylated side-chain Δ^9-THC analogues did not form a progressive series of responses. The two 1'epimers were relatively inactive with a slow onset, the 4'OH and 5'OH analogues had a change in their properties having an ataxia gait rather than the Δ^9-THC narcotic type gait. 2'OH Δ^9-THC was the most similar to Δ^9-THC. The potency of the 3'OH analogue may be due to an extra ring created by hydrogen bonding of the 3'OH to the 5 oxygen. Pathological examination indicated no gross or significant light microscopic findings. Supported in part by Medsera Inc. C7704.

1554 EVIDENCE FOR PHARMACOKINETIC AND PHARMACODYNAMIC TOLERANCE TO PENTOBARBITAL FOLLOWING BRIEF CHRONIC PENTOBARBITAL ADMINISTRATION TO RATS. R.L. Commissaris* and R.H. Rech. Dept. of Pharmacol., Mich. State Univ., East Lansing, Mich. 48824

Female Sprague-Dawley rats, trained on the rotarod (RR), were fed ground chow containing pentobarbital (PB; 2.0 mg/g chow) and were given twice-daily i.p. injections (30 mg/kg PB) for 6 days. Controls were given ground chow and distilled water injections. On day 7 the animals were injected i.p. with various test doses of PB and tested on the RR 5, 15, 30, 60 and every 30 minutes thereafter until recovery (180 seconds on RR) or sacrificed at various times post-injection by decapitation and assayed for PB in brains and sera by gas chromatography. Chronic PB treatment significantly reduced the duration of RR disruption following all i.p. test doses of PB as compared to controls. Using the time to 50% recovery of RR, we found that chronic PB treatment resulted in a significant shift to the right of the dose-response curve for PB-induced RR disruption. Body levels of PB 35 minutes after administration of 30 mg/kg PB (time to 50% recovery in chronic rats) were lower in the chronic PB-treated animals than in controls, indicating an enhanced removal of the drug due to the chronic treatment. Measuring the body levels of PB in these groups at their respective times to 50% recovery of RR following 20 mg/kg PB, we found that chronic PB-treated rats had significantly higher levels of PB in brains and sera as compared to controls (time to 50% recovery in controls = 330 minutes). This data indicates a decrease in central sensitivity to PB following chronic PB treatment. Thus, there is evidence for both pharmacokinetic and pharmacodynamic tolerance to PB following brief chronic PB administration. (Supported by NIDA Contract ADM-45-74-146.)

1555 Reversal and Prevention of Acute Morphine Induced Catalepsy by Phenytoin in Naive Rats. Susan L. Cookson* and J. Douglas Mann. Department of Neurology, University of North Carolina, 27514

Catalepsy is a state of prolonged motor immobility, waxy rigidity, and an apparent increase in alertness despite reduced responsiveness to stimuli. Morphine induced catalepsy in rats has been well described, though the neurochemical basis of this phenomenon is poorly understood. Chronic administration of morphine results in depletion of calcium in brain, possibly producing instability of endplate regions and increased neurotransmitter release. To determine if altered calcium metabolism is important in acutely induced morphine catalepsy, phenytoin, an agent known to decrease calcium conductance and increase membrane stability was administered to rats prior to, or following, intravenous morphine sulfate.

A chronic indwelling venous catheter was placed in adult albino rats, not previously exposed to morphine, two days prior to experimentation. Groups consisting of six animals were tested for catalepsy using a standard foot/bar test (Kuschinsky and Hornykiewicz, Eur. J. Pharmacol. 19: 119-122, 1972), a test for duration of sustained motor immobility. Experimental protocol consisted of the intravenous administration of: 1. morphine sulfate in saline, 1 mg/kg (a dose adequate to produce catalepsy for more than two hours); 2. phenytoin 35 mg/kg (all phenytoin was administered in a carrier of 40% propylene glycol and 10% ethanol); 3. morphine followed fifteen minutes later by phenytoin; 4. phenytoin followed fifteen minutes later by morphine; 5. saline alone; 6. phenytoin carrier alone; 7. phenytoin carrier followed by morphine; and 8. morphine followed by phenytoin carrier. Within fifteen minutes of administration, phenytoin was markedly effective in reversing morphine induced catalepsy ($p < .001$). Phenytoin also prevented the appearance of catalepsy when given fifteen minutes prior to morphine ($p < .001$). Administration of phenytoin, carrier alone, or saline alone did not produce significant changes in motor activity. Additionally, phenytoin carrier or saline had no effect on the expected cataleptic response when given in combination with morphine.

Morphine induced catalepsy in rats is both prevented and reversed by phenytoin. Morphine and phenytoin may have opposing effects on calcium linked neurotransmitter release at the presynaptic membrane. While phenytoin reduces membrane calcium conductance, morphine may produce increased calcium flux with each depolarization, resulting in enhanced release of neurotransmitter. This view is consistent with the previously reported increased turnover of dopamine in association with morphine catalepsy.

1556 EFFECT OF CHRONIC LOW LEAD EXPOSURE ON THE DEVELOPMENT OF EXPLORATORY BEHAVIOR IN RAT PUPS. Kevin M. Crofton*, Douglas H. Taylor*[1], and Richard J. Bull. U.S. E.P.A., Cincinnati, OH 45268; [1]Miami Univ., Oxford, OH 45056

Exploration away from the mother was studied in male offspring of female rats which had been administered lead (200 mg/l) via their drinking water from two weeks prior to breeding until their pups were weaned. The mean blood lead levels of the lead exposed pups at 21 days of age was 36 ug/100 ml ± 3.4 S.E. Pup exploration away from the dams was monitored continuously (see figure below), beginning when the pups were 10 days old and ending when they were 21 days old. No significant differences were noted in the time of eye opening between the control and experimental groups. A statistically significant delay in the development of exploratory behavior was noted between the lead treated and the control animals. Additionally, the activity levels of lead treated pups were depressed, and significantly different, from the control pups from day 14 through day 19. By day 20, and through day 21, the activity levels of the treated and untreated pups were no longer significantly different. The lead induced modification in behavior noted in this experiment correlates temporally with biochemical and morphological indications of delayed cerebral cortical development as evidenced by delayed increases in cytochrome content and synaptic development (McCauley and Bull, Fed. Proc. 37:2764, 1978).

1557 ANTAGONISM OF METHYLPHENIDATE-INDUCED STIMULATION BY SPIROPERIDOL. Michele A. Cusatis and Luis A. Baez. Dept. Psych., S. Ill. U., Carbondale, IL 62901

It has been reported that methylphenidate-induced stimulation can be effectively antagonized by pretreatment with reserpine but not by AMPT pretreatment; the reverse is true of arousal behavior produced by amphetamine (Scheel-Kruger, Psychiat. Neurol. Neurochi., 1972). These findings have been taken to reflect differential release of stored versus newly-synthesized catecholamines, respectively. This apparent difference in mechanism of action led us to investigate the possible existence of other dissimilarities in the neurochemical actions of these stimulants.

Previous research in our laboratory has demonstrated that a very low dose of the dopamine receptor blocking agent, spiroperidol, can prevent the development of amphetamine-induced locomotion and stereotypy (Baez, Kerns & Smith, Eur. J. Pharm., 1977). These data are consistent with other evidence suggesting that amphetamine influences behavior primarily through an interaction with dopamine neurons. The present study was designed to determine whether spiroperidol would also block the development of the behaviors generally elicited by methylphenidate.

Adult male Long-Evans rats were placed in stabilimeters and allowed to habituate for 30 minutes. Following habituation, animals were injected with a dose of spiroperidol (0.0, 0.03125, 0.25 or 1.0 mg./kg. i.p.). Thirty minutes later methylphenidate was administered (0.0, 5.0, 10.0 or 30.0 mg./kg. i.p.). A total of eight animals received each spiroperidol-methylphenidate combination, and animals were used only once.

Locomotion and stereotypic behaviors were observed for 2 hours after methylphenidate injection; observations were made of each animal during a one minute period every five minutes for a total of 24 such periods in a two hour session. Within these one minute periods, observations were scored at 10 second intervals in a dichotomous presence/absence fashion. The behaviors observed were: walking, rearing, sniffing, licking, nosing, head nodding, gnawing, grooming and jaw opening. Locomotion was scored as stabilimeter crossings.

Scores were subjected to factor analysis and the resulting factors were used as input data for analysis of variance tests. Both the intermediate and high doses of spiroperidol were effective in preventing the appearance of methylphenidate-induced locomotion and stereotypy, even with the highest dose of methylphenidate examined. These data suggest that methylphenidate produces its behavioral stimulation via an enhancement of dopaminergic synaptic transmission. In this respect, methylphenidate and amphetamine appear to be functionally similar.

1558 GABA BLOCKADE: THE EFFECTS OF PICROTOXIN ON BIDIRECTIONAL ACTIVE AVOIDANCE, LOCOMOTOR ACTIVITY AND STRAIGHT ALLEY PERFORMANCE Robert E. Davis, David Wirtshafter, Karen Asin and Ernest Kent Dept. of Psych., Univ. of Ill. at Chicago Circle, Chicago, Ill.

Picrotoxin (Pic), a putative GABA antagonist, has been previously reported to depress bar pressing for electrical stimulation of the lateral hypothalamus (ESB-LH). To determine if this deficit was specific to ESB-LH, we examined the effects of this compound on bidirectional active avoidance (BAA), locomotor (LA) activity in the jiggle cage (JC), open field (OF), and closed field (CF), and straight alley performance (SA, after 8 and 24 hrs deprivation, early and late in training). Additionally, we studied the effects of prior amphetamine (Amph, 2 mg/kg),lysergic acid diethylamide (LSD, 10 ug/kg), diazepam (Diaz, 10 mg/kg), methysergide (MS, 10 mg/kg) and cinanserin (Cin, 10 mg/kg) administration on Pic-induced behavioral changes.

BAA acquisition was impaired by pretreatment with picrotoxin (.75 and 1.4 mg/kg: 50 trials/day, 200 trials over 16 days). However, this appears to be a performance deficit since animals trained under Pic immediately performed at control levels when switched to saline. BAA performance was maximally depressed by 1.5 mg/kg Pic. This deficit could be reversed by prior administration of Ampt, LSD or Diaz, but was unaffected by MS or Cin.

Locomotor activity was also depressed by picrotoxin in a dose dependent manner. The three testing environments yielded different dose-response relationships. LA exhibited in the OF or CF was more sensitive to the depressant effects of Pic than was activity in the JC. Rearing in the open field was also severely reduced reduced. Amph reversed the activity activity decreases in the JC but was not tested in the other environments. Both LSD and MS did not influence the Pic induced LA deficit.

Picrotoxin (up to 2 mg/kg) was not effective in depressing well trained approach responses in the SA under 24 hour food deprivation conditions. Yet, if the deprivation level was lowered or if animals were tested during the early trials of training, running speed was decreased in a dose dependent manner.

This evidence suggests that Pic produces a general behavioral depression which is reversed by environmental and pharmacological manipulations resulting in increased arousal. These picrotoxin-induced behavioral changes are similar to those seen after antagonism of dopamine systems by haloperidol and may be mediated through similar biochemical mechanisms. However, distinct functional mechanisms can not be clearly established, since Pic may be simultaneously influencing a number of diverse behavioral and biochemical systems.

1559 CAUDATE LESIONS CHANGE THE BEHAVIORAL EFFECTS OF MORPHINE IN CATS. I. de Andrés*,J.R.Villablanca and Ch.E.Olmstead. Depts. Psychiat., Anat. and MRRC, UCLA, CA. 90024

The behavioral effects of low doses(1-3mg/kg,i.p.) of morphine SO_4(MS)were evaluated on cats with bilateral caudate aspirations (BAc N:8)and intact controls(N:6). Comparisons were made with cats with removals of both cerebral hemispheres(diencephalic,N:4),the caudate unilaterally(UAc N:2),frontal cortices(BFr N:3)or the septum (SEp N:2). MS was administered 2-6 times per animal at at least 15 day intervals.Observations were made via a one-way mirror in a sound attenuated chamber for 1 hr prior and 5 hrs after MS. Two min samples were videotaped every 15 min and selected items(i.e., basic postures and discrete behaviors)were later quantified using an event recorder.Intact animals showed a 3-phase response: I)2-4 min after MS they had licking and swallowing which usually ended in retching and vomiting; II)For the next 10-20 min depending on the dose, they adopted a sitting posture or, less frequently,they crouched or laid down attentively with fixed gaze and pinna movements,Mydriasis was present; III)Usually without changing their posture they began to look around,both laterally and up and down with intervals of fixed gaze,pinna movements and vocalizations as if they were exploring or tracking imaginary objects.After the first hour, with doses larger than 1 mg/kg,they showed lateral and forward forepaw and back and forth body movements.The head movements peaked between 2-3 hrs and the amount was dose dependent.These events had clearly attenuated after 4 hrs when cats usually laid down but remained alert.UAc,BFr, and SEp cats showed,with slight differences,similar behavior patterns.BAc cats were indistinguishable for the I and II stages.However, stage III was different.They showed increased unspecific motor activity.Most started walking incessantly and occassionally stopped briefly and looked around or exhibited fixed gaze.Upon stopping some were extremely restless with head and body movements.Panting was frequent.Both the latency to onset of locomotor activity and its duration were dose dependent.Compared to intacts the BAc had a significant decrease in the frequency of head movements, the duration of fixed gaze episodes and total sitting time.Although histological studies are not completed,a direct correlation appears to exist between amount of"looking around"and the amount of remaining caudate tissue.Diencephalic cats did not show these head movements. In conclusion:1)we saw no feline"morphine mania";2)caudatectomy seems to eliminate the marked apparently visually determined behavior of intacts;3)the results suggest that the forebrain and, particularly, the striatum mediates these morphine behavioral effects. This contrasts with our findings relative to the action of amphetamine following similar brain lesions.A 16 mm film will be presented. (USPHS grants HD-05958, MH-07097, HD-94612 and Fellowship of MEC, Spain)

1560 DIFFERENTIAL EFFECTS OF METHYLPHENIDATE AND AMPHETAMINE ON THE ORIENTING BEHAVIOR OF GERBILS. J. Diaz,R. Bien* and A. McClelland*; Depts of Neurology and Psychiatry,NPI,Sch Med,UCLA,LA,CA 90024.

Numerous studies indicate that stimulants improve attention in hyperactive children as well as in normal children (Rapoport et al, Science,199,560,1978) and adults (Sroufe and Stewart, N Eng J Med, 289,407,1973). This increase in attention span can be produced by various stimulants in spite of the different central pharmacological actions of these drugs. The purpose of the present study is to examine the effects of low doses of two stimulants on the orienting behavior of an active animal--the Mongolian gerbil (Meriones Unguiculatus).

Twenty-three adult gerbils were divided into three groups: a vehicle group (n=8), a methylphenidate group (n=8), and an amphetamine group (n=7). Each animal was tested once a week for six weeks in a plexiglass shuttle box. For each 15 minute session the number of crossings, as well as the number of rears and the time spent rearing, was recorded by trained observers. For the fifth session, the animals were injected thirty minutes prior to the testing with either saline, or methylphenidate (1 mg/kg, ip), or d-1 amphetamine (1 mg/kg, ip).

Prior to drug administration, there were no differences between the groups. The administration of either amphetamine or methylphenidate just before testing produced opposite effects on orienting behavior. The gerbils which received methylphenidate consistently spent more time rearing than the vehicle treated animals ($t=5.52$, $p<.001$): whereas, the gerbils which received amphetamine consistently spent less time rearing than the control animals ($t=10.75$, $p<.001$). In addition, during minutes four through seven of the testing session, animals given methylphenidate reared more often than the control animals ($t=3.36$, $p<.001$) and animals given amphetamine reared less often than control animals ($t=8.06$,$p<.001$). In contrast to orienting behavior, the number of crossings for the two drug groups was not different than that for the control group. There were no differences between the groups one week after drug administration.

There is mounting evidence that the attentional improvements produced by small doses of stimulants, once thought to be a peculiarity of a hyperactive organism, may instead be a general characteristic of normal central arousal and inhibitory systems. Even though this may be the case, the effects of methlyphenidate and amphetamines on the orienting behavior of gerbils are different than those observed in the orienting behavior of the rats given the same drug treatments (Bryan and Ellison, Psychopharm,43,1975). Since rats have a much lower activity level than gerbils, these data suggest there may be fundamental differences in central systems between animals that have normally high activity levels compared with those that do not.

1561 HUMAN FEMALE CHRONIC MARIJUANA USE AND ENDOCRINE FUNCTIONING. Rhea L. Dornbush, Robert C. Kolodny,* Joan E. Bauman,* and Sandra K. Webster.* Reproductive Biology Research Foundation, St. Louis, MO 63108.

The relationship between chronic marijuana use ($\bar{x}$ = 4x/week) and reproductive hormones was evaluated by comparing 26 women (18-30 years of age) who used marijuana with 16 age-matched controls. All subjects were in good general health, did not use oral contraceptives, and were not using other drugs. Subjects were evaluated by physical examination, personal interview, daily written self-reports of drug use, mood, sexual activity, and intercurrent health problems; and blood samples obtained on cycle days 1, 5, 11-19, 25, and 30 (analyzed for estrone, estradiol, progesterone, testosterone, luteinizing hormone (LH), follicle-stimulating hormone, and prolactin). Most subjects (37 of 42) were studied for two complete menstrual cycles. Cycle length was significantly shorter for marijuana-using women (26.8 ± 2.3 days vs. 28.8 ± 2.3 days). Prolactin levels were consistently and significantly lower and testosterone was consistently and significantly higher in marijuana users on all sampled days during the menstrual cycle. There were no significant differences in other hormone measurements. These data do not support the female animal data, which -- although sparse -- suggest depressed fertility via the mechanism of suppression of ovulation. In the current study there were no statistically significant differences in the number of anovulatory cycles or LH peaks.

1562 CHANGES IN TELENCEPHALIC SELF-STIMULATION RATE RESULTING FROM PRIOR SELF-STIMULATION EXPERIENCE AND FROM CHRONIC HALOPERIDOL. David C. Douglin* and Robert B. Glassman, Dept. Psychol., Lake Forest College, Lake Forest, IL 60045

Demonstrations of neuroplasticity may shed light on phenomena of drug tolerance or on dyskinesias that arise spontaneously or as a result of long term drug treatments. Nine rats were prepared with intracranial self-stimulation (ICSS) electrodes at telencephalic (TEL) points (medial frontal cortex, MFC, or caudate nucleus, CN) and 7 of these animals also had successful placements in more caudal (CDL) points (lateral hypothalamus, LH, substantia nigra, SN, midbrain reticular formation, RF). Daily 10-minute sessions were carried out with TEL ICSS either immediately before or after a 10-minute session of CDL ICSS. Parameters were: 0.1 msec negative pulses at monopolar electrode; 100 pulses/sec; 0.2 sec train; TEL current 0.55 ma or 0.74 ma in different rats; CDL 0.2 or 0.45 ma. TEL ICSS was initially slow and steady (138 barpresses/10 min, average of first 5 sessions over all rats) and, in each animal, gradually rose during about 15 daily sessions, leveling off at 453 barpresses/10 min. CDL ICSS showed no such changeability. The longterm increase of TEL ICSS appeared associated (a) with a phase, occurring approximately days 7-12, when cumulative records showed an upturn within a session and (b) with an increased tendency for behavioral seizures, following TEL ICSS, suggesting kindling. Changes in reward value of hippocampal stimulation have previously been attributed to kindling (Campbell et al, Neurosci Abs 535, 1976).

Administration of haloperidol in the drinking water of these rats for a month (0.013 mg/ml) caused a sharp drop in TEL ICSS; following withdrawal, ICSS recovered to predrug level in 3 cases, to 50% above predrug level in one case, and to below (half) predrug rate in 5 cases (3MFC, 2CN). In four of these last cases, reduction of current intensity on 1-3 occasions led to a clear rise in ICSS rate. Since similar probes were not run before drug it is hard to say yet whether this represents a drug-induced heightened sensitivity of the stimulated points. We have a small amount of data for the CDL points during and after drug treatment. Of 5 rats, all showed less decrease in CDL ICSS than TEL ICSS during drug; 4 returned to predrug ICSS rate the day after withdrawal. The rat that had shown the most barpresses during drug pressed at greater than the predrug rate after withdrawal. Eichler et al (Neurosci Abs 1225, 1976; 1400 1977) have reported increased ICSS, following chronic spiroperidol, for points in frontal cortex, SN, and far--but not near--LH.

Supported by the Illinois Department of Mental Health and Developmental Disabilities.

1563 PLATELETS-PROTEIN PHOSPHORYLATION IN SCHIZOPHRENICS WITH AND WITHOUT TARDIVE DYSKINESIA. Y. H. Ehrlich, I. Jackson*, M. V. Reddy*, L. G. Davis and E. G. Brunngraber. Univ. of Mo.-Columbia, Sch. Med. at The Missouri Inst. Psychiatry, St. Louis, Mo. 63139

Several lines of investigation indicate that long-term treatment with neuroleptic drugs results in the development of receptor supersensitivity in the central nervous system. Our animal studies have indicated that the latter may involve alterations in the phosphorylation of membrane-bound proteins, presumably of synaptic origin (Life Sci. in-press). Such changes may occur, therefore, in the brain of chronic schizophrenics in-general, and in patients demonstrating symptoms of tardive dyskinesia, in-particular.

Human platelets and lymphocytes have cyclic AMP-generating systems as well as protein kinases that phosphorylate membrane proteins in a cyclic AMP-regulated fashion. These cells may serve, therefore, as a model for investigating the possible involvement of these enzymatic systems in mechanisms underlying certain mental disorders. We have found that membrane fractions of platelets, RBC and leukocytes prepared from as little as 7 ml of blood are sufficient for examining phosphorylative activity and obtaining the pattern of endogenously phosphorylated proteins (Reddy et al, in-prep.). In the assay, membranes are incubated with radioactive ATP in the presence and absence of cyclic AMP. The reaction products are separated by SDS-gel electrophoresis and specific phosphoproteins are identified by autoradiography of dried gel-slabs (Ehrlich et al, Nature 265: 238, 1977; Neurochem. Res. 2: 533, 1977). In a preliminary study, membrane preparations from platelets of nine female schizophrenic patients, 5 with and 4 without symptoms of tardive dyskinesia, were examined. Endogenous phosphorylative activity directed towards specific proteins in the preparations was found to be greater in 4 of these samples than in the other five. These 4 were then identified as patients with tardive dyskinesia. Quantitative analysis of the phosphorylation of a specific band, indicated that in spite of great variability in the pattern of protein and protein phosphorylation of individual samples, the difference between patients with and without tardive dyskinesia was statistically significant. It should be emphasized, however, that further research is required to determine whether protein phosphorylation systems are involved in mechanisms related to the development of this syndrome. Supported by intramural funds from the Missouri Institute of Psychiatry.

1564 CHRONIC AMPHETAMINE ADMINISTRATION PRODUCES A SENSITIZATION OF SNIFFING AND A TOLERANCE FOLLOWED BY A RETURN OF LICKING BEHAVIOR. A.J. Eichler*, S.M. Antelman* and C.A. Black* (SPON: G. Werner). Psychobiology Program and Dept. of Psychiatry, School of Medicine, University of Pittsburgh, Pittsburgh, PA 15260.

Although chronic administration of amphetamine is known to produce a progressive sensitization of the drug's ability to induce stereotypy, individual components of the stereotypy syndrome (e.g., licking and sniffing) have not been studied in this way. Since it has been suggested that amphetamine-induced licking and sniffing are subserved by different brain dopamine (DA) pathways, this hypothesis was tested in the present studies by examining the profile of these behaviors during chronic amphetamine administration.

Rats were injected i.p. daily for 65 days with amphetamine sulfate (2,4,8 or 12 mg/kg), and both stereotyped licking and sniffing were rated twice weekly. Licking behavior, which was seen following acute injection of the 8 and 12 mg/kg doses, virtually disappeared by the 14th injection day. This tolerance persisted until the 24th injection day when licking behavior gradually began to return. At about this same time, licking also started to occur to doses which failed to elicit this behavior acutely (i.e., 2 and 4 mg/kg).

Stereotyped sniffing displayed a considerably different pattern than licking. No tolerance occurred at any time. Rather, sensitization became apparent beginning on the 17th day of amphetamine injection. Sniffing intensity increased until day 35, whereupon it stabilized until drug treatment was discontinued. This enhanced response to amphetamine involved both the maximum sniffing intensity as well as the duration of the behavior.

The dissimilar profiles of licking and sniffing to chronic amphetamine support the notion that these behaviors involve different brain DA systems. The return of licking behavior following tolerance may also reflect an interaction with norepinephrine (NE) systems since: (1) assays of brain catecholamines one day following termination of amphetamine treatment revealed a significant depletion (approximately 20%) of cortical NE at all doses of the drug and (2) at a point where tolerance to licking had occurred, this behavior could be reinstated by administration of beta NE receptor blockers (propanolol or alprenolol; 6 mg/kg).

1565 SILASTIC TUBING SYSTEMS FOR CONTINUOUS DRUG ADMINISTRATION: CONSTRUCTION AND APPLICATIONS. Michael S. Eison, Gaylord Ellison, and Harris H. Huberman*. Dept. Psychology, UCLA, Los Angeles, CA 90024

Simply constructed, inexpensive, and easily implanted continuous slow-release systems for drug administration can add a much needed dimension to the study of drug effects upon brain biochemistry and behavior. We have developed two such systems based upon the passive diffusion of drug across the semipermeable walls of silastic tubing reservoirs and have used these systems in our research on the effects of continuous amphetamine intoxication on rat behavior and neurochemistry.

One such system is a non-refillable silicone pellet that when filled with 50 mg d-amphetamine base in polyethylene glycol vehicle releases drug for at least 10 days. We recently reported a reliable behavioral syndrome observed in rats implanted with these pellets: initial hyperactivity followed by prolonged stereotypy lasting 48-72 hrs,followed by a late phase of exaggerated social behaviors. We have suggested that the late phase may serve as an animal model of amphetamine psychosis. Implantation of this pellet also induces progressive catecholamine (CA) depletion and alterations in tyrosine hydroxylase (TH) activity. Two days after implant (during maximum stereotypy), brainstem and diencephalic norepinephrine (NE) and striatal dopamine (DA) are significantly depleted; brainstem DA is significantly elevated at this time. Changes in CA levels are paralleled by similar trends in TH activity in these regions;the most pronounced change in TH occurred in the caudate nucleus (48% of control values). Five days after implant (when stereotypies break and animals exhibit exaggerated social behavior), NE is depleted in the brainstem, diencephalon, caudate, and frontal cortex; DA is depleted in the caudate and frontal cortex but remains elevated in the brainstem. Striatal TH remains at 50% of control values. In assays done 110 days after a 7 day period of implantation, CA levels return to control values while caudate TH remains uniquely depressed.

A second silastic system used in the course of our research is a refillable loop with which one can maintain desired levels of drug available for release over longer periods of time; such implants have proven viable for 30 days. Although the time course of behavioral changes observed in loop animals (11 mg/kg/loop twice daily) is somewhat different from that seen in pellet rats, the sequence of changes is remarkablely similar. Brain amphetamine levels of approximately 3.0 ug/g were found after 2 days and 5 days of loop administered drug. Construction of these systems will be discussed more fully at this poster session.

1566 ALTERATION IN STIMULANT-INDUCED MOTOR FREQUENCIES BY CLOZAPINE. Everett H. Ellinwood, Jr., and M. Marlyne Kilbey. Dept. Psychiat. Behav. Neuropharm. Sect., Duke Univ. Med. Ctr., Durham, NC 27710.

Use of a new sensitive motility transducer, which allows reduction of movement to power spectrums, has demonstrated a number of drug-induced changes which cannot be quantified will less sensitive observation methods. Pimozide, a neuroleptic which has little presynaptic activity, blocks 6 mg/kg amphetamine effects in a linear dose-response curve. Clozapine induces a biphasic response potentiation at lower doses and suppression at higher doses. At the same 20 mg/kg dose that maximally potentiates amphetamine stereotyped motility, clozapine blocks direct dopamine agonists and stimulants that act through "reserpine-dependent" storage pools of dopamine (e.g., 40 mg/kg cocaine and 12 mg/kg methylphenidate). The data are consistent with a strong presynaptic (synthesis activation) and moderate postsynaptic activity of clozapine. Examination of the more unique features of the pharmacologic profile of clozapine may provide important clues as to the nature of certain psychotic processes.

1567 EVIDENCE OF DOPAMINERGIC SUBSENSITIVITY AND HALLUCINATORY BEHAVIORS DURING THE LATE STAGES OF CONTINUOUS AMPHETAMINE INTOXICATION. Gaylord Ellison, Michael Eison, Melvin Lyons*, Linda Nelson, and Erik Nielsen*. Dept. Psychology, UCLA, Los Angeles, CA 90024 and University of Copenhagen, Denmark.

Following 4-5 days of continuous amphetamine intoxication produced by implantation of slow-release silicone pellets rats and monkeys enter a late stage characterized by heightened startle responses, socially abberant behaviors (in rats) and hallucinatory episodes (in monkeys) involving distress vocalizations, parasitosis, fleeing responses, and frequent orienting responses. At about the same time fluorescence studies of dopamine fibers in the caudate of rats reveal swollen axons. Rats show a subsensitivity to the motor stereotypies evoked by amphetamine or apomorphine injections just after amphetamine pellet removal, whereas daily injections of the same amount of amphetamine produce heightened stereotypies. Thus, continuous amphetamine intoxication both evokes hallucinatory episodes and has a selective neurotoxic effect on caudate dopamine fibers.

1568 DIFFERENTIAL EFFECTS OF NALOXONE, PENTAZOCINE, CYCLAZOCINE, NALORPHINE, AND MORPHINE ON INTRACRANIAL SELF-STIMULATION IN THE RAT. R.U. Esposito, J.O. Jacobson*, S. McLean* and C. Kornetsky, Boston University School of Medicine, Boston, MA. 02118

Previous research in our laboratory has demonstrated that drugs known for their ability to produce euphoria in man (e.g. morphine, cocaine, amphetamine) will cause a significant lowering of the reinforcing threshold for self-stimulation behavior in rats. (Esposito & Kornetsky, Science, 195:189, 1977; Esposito, Motola & Kornetsky, Pharmac. Biochem.& Behav., in press, 1978). The present report represents an attempt to determine if our method for assessing self-stimulation thresholds could differentiate between opioid drugs with varying capability for producing morphine-like subjective effects. Accordingly, the effects of pentazocine (5-30 mg/kg), cyclazocine (0.01-1.0 mg/kg), and nalorphine (4-16 mg/kg), on self-stimulation thresholds to the medial forebrain bundle were measured. The effects of morphine (1-8 mg/kg) and the narcotic antagonist naloxone (1-4 mg/kg) were also assessed on the same procedure.

Morphine, as reported previously, caused a marked lowering of the threshold, while naloxone had no significant effect. Pentazocine yielded significant threshold reductions which were, however, not as large as those produced by morphine. Nalorphine and cyclazocine generally yielded modest reductions at low doses, and threshold increases or response suppression at higher doses. These results are discussed within the context of the subjective effects and abuse liability associated with these agents.

1569 GENETIC DIFFERENCES IN DOPAMINE-MEDIATED SPONTANEOUS AND DRUG-ELICITED BEHAVIORS IN INBRED MOUSE STRAINS WITH DIFFERENT NUMBERS OF MIDBRAIN DOPAMINE NEURONS J. S. Fink, T. H. Joh and D. J. Reis, Laboratory of Neurobiology, Dept. Neurology, Cornell Univ. Medical College, New York, N.Y. 10021

Mice of the BALB/cJ strain have 25% more midbrain dopamine (DA) cells than mice of the CBA/J strain. This difference is reflected in a correspondingly higher activity of tyrosine hydroxylase (TH), the rate-limiting enzyme for dopamine (DA) biosynthesis, in the major terminal field of this DA cell group, the caudate nucleus (Nature 264:654, 1976). We sought to determine if these strains also differ in: (a) TH activity in the mesolimbic and mesocortical terminal fields, (b) a spontaneous behavior (investigatory exploration) which is dependent on DA release in these terminal fields, and (c) the behavioral responses to the presynaptic DA agonist d-amphetamine (AMPH) and the postsynaptic DA agonist apomorphine (APO). TH activity was measured in the frontal and parietal cortices and in micropunches of the nuc. accumbens and olfactory tubercle. TH activity was also measured in the region of the A10 perikarya, the source of DA afferents to the mesocorticolimbic terminal fields. BALB/cJ mice had 64%, 62%, 115% and 23% (all $p < 0.05$) greater TH activity in the nuc. accumbens, olfactory tubercle, frontal cortex and A10 area, respectively, than CBA/J mice. TH activity in the predominantly noradrenergic parietal cortex was the same in the two strains. In the exploration test, mice of the BALB/cJ strain showed more investigation of a novel object than CBA/J mice. AMPH produced locomotion (2.0-5.0 mg/kg) and stereotypy (5.0-20.0 mg/kg) at lower doses in BALB/cJ mice than in CBA/J mice. In contrast, APO (2.0-10.0 mg/kg) produced stereotypy at lower doses in CBA/J than in BALB/cJ mice. A greater number of midbrain DA neurons and higher TH activity in forebrain DA terminal fields in BALB/cJ mice correlates with greater exploratory behavior, increased responsiveness to a presnaptic DA agonist and decreased responsiveness to a postsynaptic DA agonist. Genetically-determined differences in the number of midbrain DA neurons are reflected in differences in spontaneous and drug-induced behaviors which are dependent on DA release or receptor activation in these terminal fields. (Suported by grants NS 03346, NS 06911 and MH 24285).

1570 THE ROLE OF CATECHOLAMINERGIC RECEPTORS IN THE HYPOTHALAMIC CONTROL OF LORDOTIC BEHAVIOR IN THE OVARIECTOMIZED-ESTROGEN PRIMED RAT. Mark M. Foreman* and Robert L. Moss. Dept. of Physiol. and Obst.-Gyn., Univ. Tex. Health Science Center, Dallas, Texas, 75235.

Catecholaminergic effects upon lordosis behavior were studied in ovariectomized(OVX)-estrone primed rats by infusing dopaminergic, α- and β-adrenergic receptor stimulants and blockers via unilateral, 23 gauge stainless steel cannulae implanted into either the medial preoptic area(MPOA,N=44), arcuate-ventromedial area(ARC-VM,N=44) or lateral hypothalamic area(LHA,N=13). In the first experiment, OVX rats were primed with 100-250μg of estrone 48 hrs prior to testing to maintain low preinfusion receptivity(mean lordosis to mount ratio, L/M=.164). The infusion of 200 or 800ng/0.5μl doses of dopamine; norepinephrine; epinephrine; dopaminergic receptor stimulant, apomorphine; α-adrenergic receptor blockers, phentolamine or phenoxybenzamine; and β-adrenergic receptor stimulant, isoproterenol significantly increased lordotic behavior compared to vehicle($p < .005$). Conversely, infusions of dopaminergic and β-adrenergic receptor blockers, haloperidol and propranolol, as well as α-adrenergic receptor stimulant, methoxamine in identical dosages depressed lordotic reflex. None of these agents had any effect when infused into the LHA.

A second experiment evaluated catecholaminergic effects on sexual behavior in OVX rats primed with a 350μg of estrone to maintain high preinfusion receptivity(mean L/M=.884). MPOA or ARC-VM infusions of dopaminergic receptor blockers, haloperidol and α-flupenthixol; βadrenergic receptor blocker, propranolol; or α-adrenergic receptor stimulant, methoxamine(1.0μg/0.5μl) significantly depressed mating behavior compared to vehicle response($p < .001$). However, MPOA or ARC-VM infusions of apomorphine, isoproterenol, phentolamine, or phenoxybenzamine had no significant effect.

A third experiment evaluated the hypothalamic interactions between catecholamines and luteinizing hormone-releasing hormone(LRH) upon lordotic behavior. Comparisons were made among lordotic responses to 0.5μl MPOA and ARC-VM infusions of LRH(50ng); LRH(50ng)-haloperidol(1.0μg); LRH(50ng)-propranolol(1.0μg); LRH(50ng)-methoxamine(1.0μg) and vehicle in OVX rats primed with 100-250μg estrone. Infusions of LRH into either area significantly increased lordotic behavior($p < .001$); whereas the addition of haloperidol, propranolol or methoxamine abolished this response.

These results suggest that MPOA and ARC-VM areas contain neurons which contribute to the efferent pathway mediating lordotic responses and can amplify sexual behavior in response to dopaminergic, β-adrenergic and LRH receptor stimulation and α-receptor blockade. The dopaminergic and β-adrenergic blockade or α-adrenergic stimulation can depress either estrogen- or LRH-facilitated mating behavior. Supported by NSF Grant PCM76-10015.

1571 PIMOZIDE-INDUCED EXTINCTION OF SELF-STIMULATION: A REWARD DEFICIT. K.B.J. Franklin* and S.N. McCoy* (SPON: R. Hirsh). Dept. Psych., McGill Univ., 1205 McGregor, Montreal, PQ, Canada H3A 1B1.

When a rat pretreated with the DA antagonist pimozide is given an opportunity to self-stimulate it commences responding in its usual manner but ceases responding after a few minutes. This cessation of responding is thought to represent extinction through loss of the rewarding properties of brain stimulation but a similar behavior pattern might be the result of excessive fatiguability or some other non-motivational deficit.

It was reasoned that if the pimozide-induced loss of responding were due to loss of reward, it should be possible to bring responding under stimulus control, while if the extinction-like responding were due to a non-motivational deficit, stimulus control should be lost.

Two groups of rats were trained on a schedule brain stimulation reward in which 6 min of VI 15 sec alternated with 6 min of FR 4. After 5 sessions of training the schedule was changed so that the last 3 min of each component was unreinforced. For 1 group the FR 4 component was always signalled by a flashing light (correlated group) and for the other group the flashing light was presented independently of the VI-FR schedule (uncorrelated group). Thus in the correlated condition, after a period of no-light (VI), the flashing light signalled the recommencement of reward on FR 4. In the uncorrelated condition the flashing light had no consequences. After 6, 30-min sessions on the VI, EXTN, FR, EXTN schedule all animals were run to extinction in the absence of the light signal. For half the animals in each group, 'extinction' was produced by pimozide (.25 mg/kg, 4h), for the other half by reduced brain stimulation.

When the flashing light was introduced animals in the correlated group immediately recommenced responding at a high rate and then again extinguished. Animals in the uncorrelated group emitted small bursts of responding at various times following light onset. The same pattern of responding was seen when extinction was induced by pimozide as when induced by vehicle and reduced brain stimulation. It was concluded that responding under pimozide was under stimulus control and that pimozide blocks the rewarding effect of brain stimulation.

1572 EFFECTS OF HALOTHANE ON SCHEDULE-INDUCED BEHAVIOR IN THE RAT. Joseph Garfield* and Ennio Vivaldi* (SPON: R.W. McCarley) Dept. of Anesthesia, Peter Bent Brigham Hosp., and Dept. of Psychiatry Harvard Medical School, Boston, Ma. 02115

Potency of inhalational anesthetic agents is generally expressed as an ED_{50} for not withdrawing from a painful stimulus. This quantal measure neglects the continuum of behavioral effects from the awake state to onset of Stage III (surgical) anesthesia. Hence, comparisons based on the ED_{50} alone can be misleading.

We sought a measure of graded behavioral effect that would obviate this problem by quantitating the degree of narcosis.

Four Long-Evans rats were trained to bar-press for evaporated milk on a fixed-ratio-10 schedule (FR-10). Dose-response curves were obtained in each animal by measuring response rates at several ascending subanesthetic halothane concentrations (0.10-0.34%v/v) until responding ceased. Halothane was chosen because it is a widely used inhalational anesthetic agent, with potent effects on performance at sub-anesthetic concentrations (Cook et al., ASA Abstracts, 625, 1977). Sub-anesthetic concentrations were administered by incremental liquid injection, with gas chromatographic monitoring. Each rat was studied three times, at one-week intervals, to determine whether tolerance developed.

Results: No order effect was seen, indicating that no tolerance occured. On the other hand, the dose-response curves revealed a clear-cut rate-dependency effect. Two animals, with low control rates, had initial depression of response rates at low concentrations, elevations approaching control at mid-range, and, at higher concentrations, depression again until responding ceased. This effect was much less pronounced in those animals with higher control rates. Rate-dependency occurs with "excitatory" agents (amphetamines) as well as "depressants" (barbiturates), but has not been reported with an inhalational anesthetic agent. We postulate that the rate increases we observed in our animals may reflect second-stage anesthetic excitement owing to depression of inhibitory control centers. This is supported by the observation in man that Babinski responses appear during the excitement stage of general anesthesia. We plan further study of this phenomenon using fixed-interval schedules, a more sensitive measure of rate-dependency. Schedule-induced behavior using positive reinforcement is a sensitive index of graded anesthetic effect.

Supported in part by GM 23794, NIGMS.

1573 SEROTONERGIC MECHANISMS IN AGGRESSION. Judith L. Gibbons, Murray Glusman, Gordon A. Barr, Wagner H. Bridger, and Sarah F. Leibowitz. Dept. Psychiatr. Columbia Univ. Col. of Physicians & Surgeons, New York, NY 10032 and Dept. Psychiatr. Albert Einstein Col. Med., Bronx, NY 10461.

Several neurotransmitters appear to be involved in the regulation of aggressive behavior. Among these is serotonin (5-hydroxytryptamine, 5-HT) which may be inhibitory to certain types of aggressive behavior, including predatory aggression. Consistent with this hypothesis are studies indicating that reduction of brain 5-HT activity via tryptophan hydroxylase inhibition, destruction of the dorsal and median raphe nuclei of the brainstem, or a tryptophan-free diet, induces or facilitates muricidal behavior (mouse killing) in rats. In the present investigation further pharmacological manipulation of serotonergic mechanisms were carried out and their effects on muricidal behavior in the rat were determined. Injections of l-tryptophan (25, 50, and 100 mg/kg) inhibited muricide in killer rats in a dose related manner, and at the highest dose significantly elevated whole brain 5-HT and 5-HIAA levels. Similarly, the serotonin reuptake inhibitor, fluoxetine (3.3, 10, and 30 mg/kg) and the 5-HT receptor agonist, quipazine (3, 6, and 12 mg/kg) also inhibited muricide by significantly increasing latencies to attack and kill mice. Conversely, fenfluramine, which is neurotoxic to cells of the raphe nuclei and decreases brain 5-HT (Harvey et al, J. Pharm. exp. Ther., 202, 1977, 581-589) induced mouse killing behavior in nonkiller rats tested 3 days after a single injection of 27 mg/kg fenfluramine. These results provide further evidence for an inhibitory role of 5-hydroxytryptamine in aggressive behavior.

This investigation was supported in part by training grants 1 T32 MH 15174-01 (JLG) and MH 06418 (JLG and GAB) from the National Institute of Mental Health, by an NIH Research Grant MH 22879 and an Alfred P. Sloan Fellowship to SFL, and by funds from the Whitehall Foundation (SFL).

1574 ASSOCIATIVE AND NONASSOCIATIVE EFFECTS OF D-LYSERGIC ACID DIETHYLAMIDE (LSD) ON PAVLOVIAN AVERSIVE AND APPETATIVE CONDITIONING IN THE RABBIT. I. Gormezano* and J. A. Harvey. Dept. of Psychology, University of Iowa, Iowa City, Iowa 52242.

Previous investigations from our laboratories, employing Pavlovian aversive conditioning of the rabbit nictitating membrane response, revealed that LSD produced enhanced acquisition of conditioned responses (CRs). Maximal enhancement occurred at 30 nmol/kg LSD. This study examined whether LSD would also produce enhancement in Pavlovian appetative conditioning of the rabbit jaw movement response. For purposes of contrast two experiments were conducted each involving 10 days of acquisition training to tone and light conditioned stimuli (CSs) at a CS-UCS interval of 800 msec. For one experiment, involving conditioning of the jaw movement response the unconditioned stimulus (UCS) consisted of a 1 cc injection of water over a 300 msec interval into the oral cavity via a permanently indwelling cheek fistula. Sinusoidal jaw movement responses, representing components of the swallowing reflex, were recorded as CRs when they occurred during the 800 msec CS-UCS interval. The second experiment involving conditioning of the nictitating membrane response, utilized a 3 ma, a.c. shock of 100 msec duration as the UCS. Extension of the membrane was recorded as a CR when it occurred during the CS-UCS interval. Animals were injected intravenously with equal volumes (0.4 ml/kg) of vehicle or LSD (30 nmol/kg) thirty minutes before each daily conditioning session. Under these experimental conditions LSD produced a significant enhancement in rate of acquisition of both the conditioned jaw movement and nictitating membrane response relative to vehicle controls. Enhanced acquisition occurred to both the auditory and visual CSs. Moreover, the enhancement in rate of acquisition produced by LSD was reflected not only in the greater overall level of conditioned responding to the CSs but also in a fewer number of trials required to initiate the first CR and to reach a criterion performance of 10 successive CRs. To control for possible nonassociative effects of LSD on the acquisition of CRs, separate groups of rabbits received explicitly unpaired presentations of CSs and UCSs under vehicle and LSD injections. These latter experiments revealed that LSD did not alter nonassociative responding to tones and lights, nor did it alter the base-rate of responding. In summary, LSD produces enhanced acquisition of CRs in both appetative and aversive Pavlovian conditioning preparations, which cannot be attributed to nonassociative effects such as sensitization, pseudoconditioning or altered base rate of responding. This study was supported by USPHS, NIDA, Grant Number DA01759.

1575 TRANSMITTER GATING, ADAPTATION, AND REBOUND IN EXAMPLES OF SENSORY PROCESSING, REINFORCEMENT, AND MOTOR CONTROL. Stephen Grossberg. Dept. Math., Boston Univ., Boston, MA 02215.

Competition between parallel channels whose signals are gated by chemical transducers occurs in cortical sensory processing, motor agonist-antagonist commands, and the control of net incentive motivation, among other topics. This talk discusses a physiological mechanism that can be derived from behavioral considerations, in which intracellular habituation and adaptation, antagonistic rebound in response to novel arousal increments, underaroused and overaroused motivational syndromes, and analgesic effects occur, among others. For example, the mechanism suggests why reducing J units of shock to J/2 units of shock is less rewarding than reducing J/2 units of shock to 0 units, and generalizes this result to predict when reducing J_1 units to K_1 units will be less rewarding than reducing J_2 units to K_2 units. It also suggests how a mismatch between actual and expected sensory data can generate short term memory reset across a field of cortical feature detectors to begin a search for a correct sensory code of the data. The model suggests that a sudden increment in nonspecific arousal, gated by a catecholaminergic transmitter, can do this by driving an antagonistic rebound that causes STM reset. The transmitter model appeared in J. Theoret. Biol., 1969, 22, 325 and is reviewed in Prog. in Theoret. Biol., 1974; the rebound mechanism is derived and applied to problems about reinforcement in Math. Biosci., 1972, 15, 253; about attention and discrimination learning in Internatl. Review of Neurobiol., 1975; and about cortical reset and parallel code search in Biol. Cybernetics, 1976, 23, 187.

1576 MATERNAL CONSUMPTION OF ETHANOL, BARBITAL OR CHLORDIAZEPOXIDE: EFFECTS ON THE BEHAVIOR OF THE OFFSPRING. R. Adron Harris and Jeff Case* (SPON: D. Easton). Dept. of Pharmacol., Univ. of Missouri School of Med., Columbia, MO 65212.

Female Long-Evans rats were given solutions of barbital (1 mg/ml) or chlordiazepoxide HCl (CDP, 1 mg/ml) as their sole drinking fluid. Neither of these treatments reduced fluid consumption as compared to the control rats receiving tap water (H_2O group). Another group was given 5.5% v/v ethanol in a liquid diet; the control group was pair-fed with a diet in which sucrose was substituted isocalorically for ethanol (sucrose group). All treatments were begun 1 week before breeding and were continued until the pups were weaned at 28 days of age. At 21 days of age pups were trained to avoid footshock in a one-way shuttlebox avoidance test and were retested at 28 days of age. At 90 days of age, the male offspring from each litter were trained to press a bar 20 times (FR20) in order to receive a food pellet and their response rates during 20 min. daily sessions were recorded for 15 days (see Pharmacol. Biochem. Behav. 6:371, 1977). Data are summarized:

		Body Weights			
Treatment	Litter Size	7 days	14 days	21 days	28 days
Barbital (vs. H_2O)	NC	↓*	↓*	NC	NC
CDP (vs. H_2O)	NC	NC	NC	NC	NC
Ethanol (vs. Sucrose)	NC	↓*	↓**	↓**	NC
Sucrose (vs. H_2O)	NC	↓**	↓**	↓**	↓**

	Avoidance Latencies		FR20 Rates
	Acquisition	Retest	
Barbital (vs. H_2O)	↑**	↑**	↓**
CDP (vs. H_2O)	↓**	NC	↓**
Ethanol (vs. Sucrose)	↓**	NC	NC
Sucrose (vs. H_2O)	NC	NC	↑ *

*, $p<0.05$; **, $p<0.01$; NC, no significant change

The effects of ethanol on avoidance behavior resembled those of CDP but not those produced by barbital. These alterations in avoidance responding may be due to effects of the drugs on development or to direct effects of the drugs on behavior since the pups were ingesting the drug (from the milk and/or from the drinking solution) when these tests were conducted. The suppression of FR20 responding in the barbital and CDP groups must be attributed to long-lasting developmental effects of the drugs as the drug solutions were removed about 70 days before these tests. These results indicate that exposure to ethanol, barbital or CDP (in utero and post partum) alters the ability of pups to perform certain behavioral tests. These experiments demonstrate the usefulness of shock-avoidance and food-reinforced behaviors in the study of behavioral teratology. Supported in part by grants from the Pharmaceutical Manufacturers Association Foundation to R.A. Harris.

1577 IPRINDOLE IS A POTENT ENHANCER OF SPONTANEOUS AND KCl-INDUCED EFFLUX OF NOREPINEPHIRINE FROM RAT BRAIN SLICES. Edith D. Hendley. Dept. Physiol. & Biophys., Univ. Vermont, Burlington, VT 05401.

Iprindole is an atypical tricyclic antidepressant whose clinical efficacy has heretofore not been attributable to inhibition of amine uptake, nor to enhancement of amine metabolism in the brain. This lack of effect of iprindole on amine mechanisms has seriously questioned the amine hypothesis of affective disorders. We have confirmed that iprindole is not a very potent inhibitor of ^{3}H-l-norepinephrine (^{3}H-l-NE) uptake in slices or homogenates of rat cerebral cortex (ID_{50} = 3.8 uM). However, we also found that this agent enhanced spontaneous as well as KCl-induced efflux of ^{3}H-l-NE from rat cerebral cortical slices, at doses of iprindole as low as 10 picomolar.

McIlwain slices (0.4 x 0.2 x 0.2 mm) of rat cerebral cortex were preloaded in vitro with ^{3}H-l-NE in the presence of nialamide (10 uM) and tropolone (10 uM), inhibitors of the enzymatic degradation of NE, then rinsed thoroughly with warm fresh Ringer. Efflux was determined by incubating, at 37°C for 5 to 15 min, 10 mg of washed slices in 10 ml of Krebs HCO_3 Ringer containing nialamide and tropolone, and varying doses of iprindole from 1 picomolar to 10 micromolar. The small amount of tissue in a large volume of incubating medium minimized the effects of reuptake on the measurement of efflux. The radioactivity remaining in the slices after incubation at 37°C was compared with that in the slices incubated at 0°C, and the difference was used as an estimate of the efflux. The effects of iprindole were determined by comparison with no-iprindole controls.

Efflux under the conditions described above was essentially totally dependent on temperature. As high as 50 mM KCl caused a loss of only 4% of the radioactivity in the slices at 0°C as compared with 70% loss at 37° (maximal efflux in this system). Iprindole increased spontaneous efflux as well as efflux induced by the addition of KCl (6.25 to 25 mM) as long as control efflux (no iprindole present) was not maximal. The shape of the dose-response curves was biphasic over the wide range of doses of iprindole used, both with respect to spontaneous efflux and to KCl-induced efflux. Significant increases in both types of efflux (20-30% above controls) were noted at 10 picomolar iprindole, and maximal enhancement (140% above controls) was observed at 10 uM iprindole. These findings emphasize that although iprindole is not as potent as the other tricyclic antidepressants in inhibiting NE uptake, its marked potency in enhancing NE efflux would increase the availability of NE during nerve transmission, in accordance with the amine theory of affective disorders.
Supported by USPHS grant MH 25811.

1578 TREATMENT OF TARDIVE DYSKINESIA AND ITS UNDERLYING MECHANISM. Chuong C. Huang, Richard I.H. Wang* and Luca Alverno*. Wood VA Center and Dept. of Psychiatry, Medical College of Wisconsin, Milwaukee, WI. 53193.

The population of Tardive Dyskinesia (T.D.) patients has increased as the long term neuroleptic chemotherapy is continued. We have seen the development of new cases. In a sample survey at this VA Center, 75 chronic schizophrenia patients who had been on antipsychotic medication for years were interviewed. 21 of them shown evidence of Tardive Dyskinesia symptoms. (28%) 18 T.D. patients were studied on inpatients on the clinical pharmacology ward with double-blind controlled method. They were randomly assigned to 3 treatment groups receiving different medications--placebo, alpha-methyldopa and reserpine. The T.D. movements of each patient were evaluated every day by the same observer. They were also videotaped once before medication and once while on medication. Those patients who received alpha-methyldopa or reserpine shown reduction of T.D. symptoms. Severe rebound phenomenon were observed after the discontinuation of alpha-methyldopa medication. No placebo effect was seen. Reserpine is considered as a dopamine depleting agent and alpha-methyldopa is considered as false transmitter. The results of this study are consistent with the hypothesis that the T.D. symptom is a receptor hypersensitive phenomena to dopamine. Gradual desensitization phenomenon were seen in 5 cases after the discontinuation of antipsychotic medication despite of the fact that they have T.D. symptoms for many years. It is concluded that the T.D. symptom is not an irreversible phenomena, its underlying cause is the receptor hypersensitivity to dopamine caused by many years use of antipsychotic medication. The treatment of T.D. depends on desensitization processes. Reserpine appears to be helpful in receptor desensitization processes. Alpha-methyldopa does not appears to be an useful agent for the treatment of T.D. because its effects are the same as the increase of antipsychotic medication.
The authors would like to express their gratitude to Dr. Leitschuh, his colleague and many others who made this study possible.

1579 EFFECTS OF DIAZEPAM ON THE SUPPRESSION OF SCHEDULE-CONTROLLED AND SCHEDULE-INDUCED BEHAVIOR DURING SIGNALLED AND UNSIGNALLED SHOCK. N. Hymowitz* (SPON: B. Natelson). New Jersey Medical School, Newark, NJ 07103.

The effects of diazepam on the suppression of food-maintained leverpressing and schedule-induced licking during signalled and unsignalled response-independent electric-shock delivery were studied in the rat. For each behavior, two measures of response suppression were obtained; (1) the suppression of responding during the preshock stimulus (conditioned suppression) and (2) the suppression of the total number of responses emitted in the components of a multiple schedule associated with signalled and unsignalled shock (differential suppression). Differential suppression was influenced by the intensity of shock and the dose of diazepam. Depending upon the intensity of shock, some doses of diazepam "released" from suppression responses which were emitted primarily during signalled shock; other doses primarily influenced responding during unsignalled shock. The intraperitoneal injections of diazepam (1.00 mg./kg-10.00 mg./kg.) had no effect upon the conditioned suppression of schedule-controlled and induced responding. Responding remained suppressed during the preshock stimulus throughout the study. The data fail to support findings which suggest that benzodiazepines further enhance the suppression of responding due to response-independent shock. The data also do not lend themselves to analysis according to the rate-dependent effects of drugs. There did not seem to be a consistent relationship between the control rates of pressing and licking and the effects of the drug on the enhancement of schedule-controlled and-induced responding during signalled and unsignalled shock. Rather, the findings support a safety signal analysis of response suppression and suggest that diazepam primarily affects that aspect of response suppression due to the failure to discriminate when the noxious event is not available.

1580 EEG AND BEHAVIORAL EFFECTS OF BUPRENORPHINE, A NEW NARCOTIC AGONIST-ANTAGONIST, IN THE RAT. Sarala Kareti* and J. Edward Moreton. Dept. Pharmacol. and Toxicol., Univ. of Maryland Sch. of Pharm., Baltimore, MD 21201.

Rats were prepared with chronic cortical and temporalis muscle electrodes for continuous recording of the electroencephalogram (EEG) and electromyogram (EMG) and intermittent observations of overt behavior for two days before and two days after acute intravenous administration of physiological saline or buprenorphine hydrochloride at doses of 0.3, 1.0, 3.0, 10, and 30 mg/kg. Generally, narcotic agonists such as morphine produce a biphasic behavioral and EEG response of an initial phase of behavioral stupor associated with high-voltage EEG slow-wave activity (slow bursts) followed by a secondary phase of behavioral arousal and low-voltage EEG activity. Sleep and REM sleep then reappear. These agonistic effects can be prevented by administration of the pure narcotic antagonist, naloxone. In the case of morphine (10 mg/kg) each of these phases lasts about 1-1½ hours with the appearance of REM sleep at about 3-4 hours. It might be expected that partial agonists would have either agonist or antagonist effects depending upon the dose used. The present study investigated the agonist-antagonist effects of buprenorphine with respect to duration of stupor, duration of arousal, latency to REM sleep and increase in EEG spectral power during behavioral stupor. The duration of the stuporous behavior was an inverted U-shaped function of the doses from 0.3 to 10 mg/kg. 0.3 mg/kg produced EEG and behavioral stupor lasting about 15 minutes; increasing the dose to 1 mg/kg produced effects lasting from 2-3 hours while further increases in dose to 3 or 10 mg/kg decreased the duration of stupor to less than 30 minutes. The duration of the secondary phase of behavioral arousal was 3-4 hours at the 0.3 mg/kg dose and 15-20 hours at 3 to 10 mg/kg. On the other hand, a high dose of 30 mg/kg produced only about 2 hours of arousal. The latency to REM sleep showed a similar dose-effect curve with a latency of about 5 hours at 0.3 mg/kg and 25 hours at 10 mg/kg. In contrast, REM sleep appeared within 3-4 hours after 30 mg/kg. Computer derived EEG spectral power between 0-10 Hz also showed an inverted U-shaped relation to doses from 0.3 to 10 mg/kg. Maximal power output corresponding to maximal EEG synchrony and intensity of behavioral stupor occurred at 1 mg/kg. These findings demonstrate a dose-dependent interaction of the agonist and antagonist effect of buprenorphine; it has narcotic agonist action at low to intermediate doses while it manifests antagonists action, blocking its own agonist effects, at higher doses. (Supported by NIDA Grant DA 01050)

1581 EFFECTS OF DRUGS ON RESPONSE RATE AND "REWARD VALUE" IN CAUDATE AND HYPOTHALAMIC SELF-STIMULATION. Ernest W. Kent Dept. Psychol. U. of Illinois at Chicago Circle, Box 4348, Chicago, Ill. 60680.

Rats working for electrical stimulation of the lateral hypothalamus or caudate were trained to a two-lever titration paradigm which provided measures of response rate and "reward value" (intensity at reset) of the stimulus. When stimulus intensity is manipulated, lateral hypothalamic animals show high and variable response rates which, together with reward values, follow changes in stimulus intensity in the expected manner. Caudate animals, in contrast, show low and extremely stable response rates which are relatively independant of stimulus intensity above a minimum threshold for responding. Their reset intensity choices however indicate that reward value follows stimulus intensity in the usual fashion, and their response rate may be raised with drugs, indicating it is not physicaly limited.

When stimulus intensity is held constant, the effects of drugs on response rate and reward value may be observed. Hypothalamic animals in our sample showed a characteristic pattern of response to a variety of drugs. Among these effects were increases in response rate with amphetamine, and decreases with haloperidol, apomorphine, and picrotoxin. Reward value was increased by amphetamine (but the effect was not time-locked to the effect on rate), and picrotoxin, and decreased by apomorphine. Caudate animals on the other hand appeared to fall along a continuum with drug response type "A" at one end having a response profile very similar to the hypothalamic animals, and type "B" at the other end which showed no effect of amphetamine, haloperidol or picrotoxin on response rate. Type "B" animals show increases in reward value with apomorphine and haloperidol. Animals falling between these extremes show smaller effects, in one direction or the other, even with large doses. The only drug which was found to affect both response rate and reward value in the same fashion in all animals was Lioresal (Baclofen) which depressed rate and enhanced reward value.

It is not excluded that more than one type of hypothalamic animal may be encountered as coordinates are varied, and our sample to date may represent nigro-striatal bundle (NSB) stimulation at the hypothalamic level. It is tempting to speculate that the "A" and "B" drug response profiles in caudate animals may represent varying degrees of driving in elements pre- and post-synaptic to the NSB. In many cases, a depression in rate together with a rise in reward value appeared to represent a loss of contingency between response and reward effect rather than a physical incapacitation. An interpretation of these results will be presented.

1582 HALOPERIDOL CLASSICAL CONDITIONING - PARADOXICAL RESULTS. James J. King*, Stanley R. Schiff* and Wagner H. Bridger, Albert Einstein College of Medicine, Department of Neuroscience, Bronx, New York, 10461.

Male Long-Evans hooded rats were randomly assigned to conditioning groups (haloperidol 0.1, 0.2, or 0.6 mg/kg as treatment for experimental session) and pseudo-conditioning control groups (saline as treatment for experimental session, followed by drug injection 45 min to 1½ hr after animal has been returned to its home cage-one group for each drug dose).

The experimental sessions were conducted each day and consisted of (1) transfer rat to injection cage, (2) expose to tone (CS) for one min while scoring activity by observing the number of crossings (forepaws crossing into separate quandrants of injection cage), (3) inject i.p. with treatment (UCS) and immediately place into observation cage, (4) quantify behavior (UCR) for 90 sec intervals at 3 min, 7 min, 11 min, and 41 min post injection and (5) return rat to home cage. The behaviors sniffing, staring (rat immobile with fixed gaze), rearing (both forepaws leaving the floor-time and frequency), crossing and grooming were rated blind using microswitches and automatic counters through a two-way mirror from a sound-proof room.

The animals received 10 days of drug treatment while the 11th day was a saline test day during which conditioning was assessed. Behavioral scores for conditioning and pseudoconditioning control groups were compared using two-tailed tests, with $p < 0.05$ accepted as significant.

Results show significant conditioning of behaviors paradoxical (opposite) to the behavioral effects of haloperidol itself. These include decreased staring, increased crossing, increased rearing, increased sniffing and increased preinjection crossing (as recorded during the 1 min CS presentation). Conditioning seemed to take from 6 to 8 days as evidenced by significant differences in preinjection crossings. Thus, the paradoxical response to haloperidol conditioning suggests there is no significant conditioning of post-synaptic blockade. Rather, the conditioning appears to involve increased pre-synaptic activity.

1583 ROTATIONAL BEHAVIOR AFTER ACUTE AND CHRONIC SYSTEMIC AMPHETAMINE TREATMENT. L. Kokkinidis* (SPON: W.G. Webster). Department of Psychology, University of Saskatchewan, Saskatoon, Sask.,

Circling behaviour elicited by acute and chronic d-amphetamine administration was evaluated in a series of five experiments. Acute systemic treatment with d-amphetamine was found to produce a dose dependent increase in locomotor activity, direction changes as well as circling behaviour in a circular alleyway. Reduction of whole brain dopamine (DA) and norepinephrine (NE) by α-methyl-para-tyrosine (α-MpT) antagonized both the locomotor and circling effects elicited by amphetamine. Potential involvement of NE in mediating the circling response to amphetamine was suggested by the findings that a 50% reduction of whole brain NE by bis (4-methyl-1-homopiperazinylthiocarbonyl) disulphide (FLA-63) successfully attenuated the drug-induced circling, without altering the locomotor excitation. Pretreatment with propranalol, a B-adrenergic receptor blocker, decreased the circling behaviour induced by amphetamine, whereas phenoxybenzamine, an α-adrenergic blocker, had no effect in this respect. Following chronic d-amphetamine treatment the circling elicited by acute drug treatment was abolished. Moreover, as found with FLA-63 and propranalol the number of direction changes were increased. Since tolerance was not observed to the locomotor effects of amphetamine, a behaviour primarily mediated by dopamine activity, the results of the present study are consistent with earlier reports suggesting that tolerance is observed to develop to behaviours which involve a noradrenergic component. The data were also discussed in terms of the relationship between circling and perseverative behaviour, as well as changes in selective attention elicited by acute and chronic amphetamine treatment.

1584 EFFECTS OF ETHANOL ON PUNISHED RESPONDING. G.F. Koob, S.L. Foote and F. E. Bloom. A.V. Davis Center for Behavioral Neurobiology, The Salk Institute, La Jolla, CA 92037.

Rats were trained on a three component multiple schedule consisting of reward, time out and conflict. Responses during the reward component (10 min. period) were reinforced on a random interval (RI) schedule - 25 sec; responses during the time out component (4 min. period) were never reinforced; and responses during the conflict component (4 min. period) were reinforced on a RI-25 sec. with both food and foot shock. Following training each rat received chlordiazepoxide (10 mg/kg) and five doses of ethanol (glucose, 0.5, 1.0, 1.5 and 2.0 g/kg). As already reported by others, chlordiazepoxide produced a significant increase in responding during both the time out and conflict components of the schedule, but no change in the rate of responding during the reward component. Ethanol also produced a dose-dependent increase in responding during the time out and conflict components at low doses (maximum effect: 1.0 g/kg), and significant decreases in responding during the reward component at the higher doses. This decreased responding at 1.5 and 2.0 g/kg was accompanied by signs of motor incoordination.

Pretreatment with 5 and 10 mg/kg of naloxone significantly reversed the release of punished responding observed with 10 mg/kg of chlordiazepoxide and 1.0 g/kg of ethanol. Naloxone by itself (10 mg/kg) failed to alter responding in any of the components of the schedule. These results suggest that ethanol possesses anxiolytic properties similar to the benzodiazepines and that both drugs interact with a naloxone sensitive substrate.

Supported by grant AA 03504.

1585 SERUM PROLACTIN AND CLINICAL STATE IN PATIENTS DURING NEUROLEPTIC TREATMENT AND WITHDRAWAL. Thomas P. Laughren*, Walter Armin Brown
Dept. Psychiat., VA Hosp., Brown Univ., Providence, RI 02908.

Serum prolactin is elevated both acutely and chronically by a variety of neuroleptics. There is little evidence regarding the development of tolerance to the prolactin-elevating effect of neuroleptics or relating prolactin to clinical response. Subjects were 11 male outpatients taking thioridazine (mean dose:212mg/day) or haloperidol (mean dose:17 mg/day) for a mean duration of 4.4 years. Patients continued their usual dose for a 2 week baseline period (chronic), took matched placebos for 4 weeks (placebo), and returned to baseline dose for 4 weeks (acute). An AM fasting blood sample was obtained at each weekly visit along with a Brief Psychiatric Rating Scale (BPRS) and a Profile of Mood States (POMS). Samples from the same subject were measured in the same radioimmunoassay.

The mean prolactin during placebo was 5.8 $\pm$ 0.5 ng/ml and differed from the chronic (13.2 $\pm$ 2.2 ng/ml) and acute (14.8 $\pm$ 2.1 ng/ml) prolactins ($F = 6.8$, $p < .01$). Nine patients had higher mean prolactins during the acute than chronic period (Sign Test, $p < .05$). The percent increases in prolactin from chronic to acute period ranged from 4 to 120 percent (Mean = 42%).

Although mean BPRS and POMS scores did not change across treatment periods, individual patients varied considerably. Chronic prolactin levels did not relate to chronic clinical state, but 3 patients with the lowest chronic prolactins (<6 ng/ml) did show the greatest change in POMS scores ($>50\%$) after drug withdrawal (Fisher Exact Test, $p = .006$). There was a trend for lower prolactins during placebo to be associated with clinical worsening during placebo (BPRS:$p = .067$; POMS:$p = .067$). The 3 patients with lowest prolactins chronically also had lowest prolactins during placebo (<4 ng/ml) and showed the greatest improvement in POMS scores after drug resumption ($p = .006$). Patients showing tolerance effects (i.e., greater serum prolactin levels acutely than chronically) tended to be the same patients who showed clinical worsening after drug withdrawal (BPRS:$p = .067$; POMS: $p = .013$) and greater improvement after drug resumption (BPRS: $p = .013$; POMS:$p = .006$). Prolactin levels, tolerance and clinical state were not related to dose or duration of drug treatment.

Either dopaminergic receptor sensitization or increased drug metabolism could explain the tolerance finding. Alternatively, noncompliance during chronic treatment could have occurred. In either case, lower prolactin levels predicted greater susceptibility to clinical change with either drug withdrawal or resumption.

1586 ENHANCED ^{3}H-NEUROLEPTIC BINDING IN POST-MORTEM SCHIZOPHRENIC BRAINS. Tyrone Lee and Philip Seeman. Pharmacology Department, University of Toronto, Toronto, Canada.

It has been reported in a previous communication (Lee and Seeman, Proc. Neurosci. Soc. 3:443, 1977) that ^{3}H-haloperidol receptors in the caudate nucleus, putamen and nucleus accumbens was significantly higher in post-mortem brains from schizophrenic patients when compared to normal controls. The present report extends the study to incorporate 24 schizophrenic brains and 32 neurologically normal human brains.

Post-mortem normal human brains were obtained through hospital pathologists from people who had died from sudden deaths of non-neurological origin. Schizophrenic brain tissues were contributed by Dr. W.W. Tourtellotte (NINCDS/NIMH Human Neurospecimen Bank, Los Angeles, California), Dr. E.D. Bird (MRC Human Brain Bank, Cambridge, England) and Dr. O. Hornykiewicz (Vienna, Austria). Tissues were homogenized in Tris-buffer, incubated with ^{3}H-apomorphine, ^{3}H-haloperidol or ^{3}H-spiroperidol and the mixture was rapidly filtered through GF/B filters and washed. Specific binding of the radioligand was defined as that amount bound in buffer minus the amount bound in the presence of (+)-butaclamol.

The specific binding of ^{3}H-haloperidol, ^{3}H-spiroperidol and ^{3}H-apomorphine (femtomoles/mg protein) to normal and schizophrenic brain tissues were as follows:

	^{3}H-HALOPERIDOL	^{3}H-SPIROPERIDOL	^{3}H-APOMORPHINE
NORMAL			
CAUDATE	44.4±1.9 (21)	89.1±7.0 (14)	28.7±2.8 (13)
PUTAMEN	49.8±3.3 (21)	87.6±4.1 (12)	26.3±2.7 (13)
N. ACCUM.	37.5 (2)	51.7 (2)	30.5±3.1 (4)
SCHIZOPHRENIC			
CAUDATE	76.8±2.9* (18)	150.2±10.6*(16)	27.7±3.3ΨΨ (7)
PUTAMEN	75.3±4.1* (18)	157.5±13.8*(17)	27.6±2.3ΨΨ (7)
N. ACCUM.	65.5 (2)	117.0±18.6 (4)	20.0±4.6ΨΨ (3)

* $P<0.001$; ΨΨ non-significant.
(Number in parentheses denotes number of human brains assayed, each with 5-20 replicate determinations).

The present data indicate that specific binding of both ^{3}H-haloperidol and ^{3}H-spiroperidol were significantly higher in schizophrenic brains whereas no difference was found for specific ^{3}H-apomorphine binding.

Although most patients had been on long-term neuroleptic therapy, the untreated patients also exhibited significantly higher binding of ^{3}H-neuroleptics.
(Supported by the Ontario Mental Health Foundation and the Medical Research Council of Canada).

1587 EFFECTS OF APOMORPHINE ON AVOIDANCE PERFORMANCE AND ACTIVITY IN DEVELOPING RAT PUPS TREATED WITH 6-HYDROXYDOPAMINE (6-OHDA). Susan V. Lipton* and Bennett A. Shaywitz. Lab. Dev. Neurobiol. Yale Univ. Sch. of Med., New Haven, CT. 06510

The selective depletion of brain dopamine (DA) by intracisternal administration of 6-OHDA in the 5 day old rat pup results in a spectrum of behaviors including hyperactive motor activity between the 2-3 weeks of life, inability to habituate to a novel environment, and impairment of avoidance performance in both T-maze and shuttle box tasks. Administration of d-amphetamine or methylphenidate reduces the hyperactive motor behavior and decreases the prolonged latency of avoidance tasks characteristic of the 6-OHDA treated animal. In order to further explore the effects of selective DA depletion during maturation we have administered the DA receptor agonist apomorphine (APO 0.1 and 1.0 mg/kg) to developing rat pups treated with 6-OHDA at 5 days of age. Such treatment resulted in a marked reduction of brain DA by more than 90% ($p < 0.001$) while norepinephrine concentrations were not significantly altered. APO produced an increase in escape latency at 20 days of age (T-maze) of 158% in normal animals but reduced escape latency by 44% in 6-OHDA treated rat pups ($p < 0.001$). At 26 days of age, APO increased escape latency (shuttle box) by 92% at the low dose and by more than 500% at the high dose in normal animals, but in 6-OHDA treated rat pups APO at both dosages reduced escape latency by 16% ($p < 0.001$). In both normal and 6-OHDA treated pups APO increased activity in a dose dependent fashion and these effects were more pronounced as maturation progressed. Thus APO increased activity by only 40% at 13 days but by 200% at 19 and 26 days ($p < 0.001$). At 19 days of age this effect was more pronounced in normal pups. Exploratory activity as measured in a hole box at 30 days was reduced by APO in both normal and 6-OHDA pups. The effects on stereotyped activity were more complex. High doses of APO produced a six fold increase in rotary activity in both treated and normal pups at 26 days; the low dose was ineffective in normals but 0.1 mg/kg APO produced a marked increase in 6-OHDA pups. At 19 days the low dose APO produced increases in both groups, significantly greater than that observed after high doses. No significant effects were evident at 13 days. Sniffing behavior was increased moderately in treated pups at 19 days and to a lesser extent at 26 days. Our results support the notion that both the decrease in escape latency and the increase in stereotyped activity observed in 6-OHDA rat pups after APO are most parsimoniously explained on the basis of denervation supersensitivity of damaged DA receptors.

1588 THE EFFECTS OF IMIPRAMINE ON SCHEDULE INDUCED AND SCHEDULE DEPENDENT BEHAVIOR. Costas C. Loullis and Matthew J. Wayner. Brain Res. Lab., Syracuse Univ., Syracuse, NY 13210.

Rats were reduced to 80 percent body weight and were exposed to an FI 1 min food reinforcement schedule for 60 min daily until lever presses, licks and water consumption stabilized for at least ten days. During the acute phase, animals were injected with 0.9 percent saline, 2, 4, 8 and 16 mg/kg of imipramine in a counterbalanced design. Following return of all three measures to pre-injection baseline, the same animals were injected with 16 mg/kg of imipramine daily for 8 days. Results of the acute phase revealed a significant decrease in lever presses at 8 mg/kg and a decrease in lever presses and water consumption at 16 mg/kg. Licks were not significantly different from saline baseline at any of the doses used. During chronic administration of imipramine lever presses and water consumption were both significantly depressed from baseline on all 8 days. Licks, however, were not significantly different from saline baseline. These data indicate that imipramine produces differential and dose dependent effects on schedule induced and schedule dependent behavior.

1589 DEGRADATION AND BRAIN PENETRATION OF ^{3}H-MUSCIMOL AFTER SYSTEMIC ADMINISTRATION. A. Maggi* and S.J. Enna. Depts. Pharmacol. and of Neurobiol. and Anat., Univ. Texas Med. Sch., Houston, TX. 77025.

In vitro, muscimol is a potent GABA receptor agonist and, after systemic administration, it induces behavioral changes in laboratory animals and man. These findings have led to the hypothesis that muscimol may be clinically useful as a GABA agonist agent. However, little is known about the metabolism of muscimol and the extent to which it penetrates into the brain after systemic administration. In the present investigation, ^{3}H-muscimol was injected systemically into mice and the amount of tritium in the brain was analyzed both quantitatively and qualitatively. For the study, two types of ^{3}H-muscimol were utilized, methylene side chain ^{3}H (12.1 Ci/mmole, mus-A) and muscimol having a ^{3}H on the 4 position of the isoxazole ring (10.35 Ci/mmole, mus-B). Administration (5 μCi,i.v.) of either mus-A or mus-B into mice results in the accumulation of measurable amounts of tritium in the brain for up to 3 hr after injection. Chromatographic analysis of the brain tritium revealed that 90% of the brain tritium after mus-A and 10-30% after mus-B is volatile. TLC analysis indicates that all of the nonvolatile tritium migrates as authentic muscimol. Coadministration of a high dose of unlabeled muscimol (24 μmoles/kg) or bicuculline (0.75 μmoles/kg) did not affect the accumulation of nonvolatile tritium in the brain. Intravenous administration of ^{3}H-GABA, ^{3}H-mus-A or ^{3}H-phenobarbital indicated that, in terms of the percent of dose administered, muscimol accumulates in the brain no better than ^{3}H-GABA, which is more than an order of magnitude less than ^{3}H-phenobarbital. Determination of chloroform/water partition coefficients revealed that muscimol and GABA have similar coefficients and that they are some 300 times less lipid soluble than phenobarbital. These results suggest that muscimol is rapidly degraded after systemic administration by at least two processes, side chain oxidation and ring cleavage. Furthermore, these findings indicate that very little, if any, unchanged muscimol gains access to brain GABA receptors after systemic administration. Thus, the behavioral and biochemical effects evoked by this agent may be due to some derivative formed after administration. 1590 OUABAIN-INDUCED CHANGES OF IN VITRO TRANSMEMBRANE LITHIUM DISTRIBUTION IN ERYTHROCYTES FROM DEPRESSED PATIENTS. Alan G. Mallinger, Joan Mallinger,* Jonathan M. Himmelhoch,* John F. Neil* and Israel Hanin. University of Pittsburgh School of Medicine, Western Psychiatric Institute and Clinic, Pittsburgh, PA. 15261.

Lithium (Li^+) was used in this investigation to study cell membrane cation transport in erythrocytes (RBCs) from depressed patients. The transmembrane distribution of this ion was studied both in vivo and in vitro in 13 patients. Interindividual differences of transmembrane Li^+ distribution found during lithium carbonate treatment in vivo were replicated in vitro when RBCs were incubated with Li^+, so that there was a significant correlation between the in vivo and in vitro measures of this parameter ($r = 0.80$, $p<0.001$). However, when in vitro incubations were conducted with the addition of 0.1mM ouabain, the correlation between the in vivo and in vitro measures of transmembrane Li^+ distribution was abolished ($r=0.32$, $p>0.1$). Moreover, ouabain reduced differences in transmembrane Li^+ distribution between individual subjects, thereby causing a significant decrease in the variance of this parameter ($r_{DS} = 0.79$, $p<0.001$).

In order to investigate potential relationships between transmembrane Li^+ distribution and specific clinical features of depression, RBCs from 20 drug-free depressed patients and 14 non-depressed control subjects were incubated with Li^+ in vitro. We found that transmembrane Li^+ distribution values were more homogeneous among bipolar (manic-depressive) patients than among patients with recurrent unipolar depression ($F = 15$, $p<0.01$), patients with secondary depression ($F = 17$, $p<0.01$), or non-depressed control subjects ($F = 19$, $p<0.01$). Moreover, although ouabain substantially reduced the range of transmembrane Li^+ distribution values in both control subjects ($r_{DS} = 0.80$, $p<0.05$) and in patients with unipolar and secondary depression ($r_{DS} = 0.91$, $p<0.001$), it had no overall effect on this parameter in the bipolar patient group ($r_{DS} = 0.24$, $p>0.1$). These findings provide evidence that, with respect to Li^+ transport, the membrane characteristics of cells from bipolar patients may differ from those of other depressed patients or control subjects. Because Li^+ is effective for the treatment of bipolar mood disorders, such a difference in membrane transport characteristics could be an important factor in the action of this drug.

1591 EVIDENCE AGAINST THE CURRENTLY HELD VIEWS ON THE MODE OF ACTION OF LYSERGIC ACID DIETHYLAMIDE. M. K. Menon* and W. G. Clark. Psychopharmacol. Res. Lab., V. A. Hospital, Sepulveda, CA 91343

Using an electromyographic method of Bieger et al (Eur. J. Pharmacol., 18, 128, 1972), LSD in low doses was shown to produce a central antiserotonin effect and a serotonin (5-HT) receptor stimulant effect in higher doses. It also produced hyperactivity in reserpinized mice. This may indicate a dopaminergic activity. Lisurid, a nonhallucinogenic lysergic acid derivative, which is structurally closely related to LSD, also showed all the above effects in similar dose ranges. Hence the hallucinogenic effect of LSD may not be dependent on its effects on 5-HT and/or dopamine (DA) systems alone.

Experiments were performed in mice to bring to light the differences in the central effects of these two drugs. Lisurid, but not LSD, produced a dose-dependent hypothermic response. This effect of lisurid was blocked by haloperidol. LSD, but not lisurid blocked the apomorphine-induced hypothermia. Lisurid, but not LSD, inhibited the alpha-methyl-p-tyrosine-induced depletion of brain DA. The hyperactivity produced by lisurid in reserpinized mice was more effectively blocked by haloperidol than that of LSD. These and other differences in the effects of LSD and lisurid may help one to obtain new insight into the mode of action of LSD.

1592 A NEW TEST FOR AGGRESSION IN RATS: DIFFERENTIAL EFFECTS OF d-AMPHETAMINE AND COCAINE. Klaus A. Miczek. Dept. Psychol., Carnegie-Mellon Univ., Pittsburgh, PA 15213.

Psychopharmacological and neurochemical studies of aggression in the laboratory are frequently confronted with the problem of investigating animals that are subjected to very stressful procedures such as isolated housing, food deprivation, conditioning procedures and electric shock applications evoking mostly defensive reactions. A simple test situation has been developed which does not require stressful manipulations in order to generate the species-specific repertoire of agonistic behavior, including attacks, threats, defensive, submissive and flight reactions, in common laboratory rats. The alpha male of 4-member colonies of rats attacks reliably intruder rats. Either resident alpha or intruder rat were injected i.p. with d-amphetamine or cocaine 30 or 10 min before the test. Two observers recorded frequency and duration of agonistic and non-agonistic acts and postures for 5 min after the initial attack. Administration of d-amphetamine to resident alpha rats increased their attacks, threats and pursuits at a very low dose (0.063 mg/kg, i.p.) and decreased them at higher doses (0.5, 1.0 mg/kg), whereas cocaine (0.5-32.0 mg/kg) only decreased these behaviors in a dose-dependent linear manner. At the highest dose of cocaine (32 mg/kg) and d-amphetamine (1 mg/kg), alpha rats also showed more non-agonistic motor activity. Intruder rats, when administered with d-amphetamine, but not with cocaine, were attacked, groomed, and investigated more often by non-treated alpha rats. The defensive upright posture was shown less by amphetamine-treated intruders, but more by those given cocaine. Amphetamine also impaired the immobility reaction and submissive-supine posture and decreased ultrasonic vocalizations in intruder rats. The pattern of drug effects indicates that (1) cocaine selectively decreases the attack component of agonistic behavior, (2) d-amphetamine enhances several aspects of the attack pattern at very low doses, and at higher doses disrupts many elements of attack and defensive behavior and increases escapes, (3) non-treated resident rats alter their behavior as a function of the intruder's drug state, i.e. amphetamine-treated intruders. The resident-intruder situation appears to be a reliable, easy-to-use, and drug-sensitive procedure avoiding the confounding influence of aversive stimulation typically associated with aggression tests in the laboratory.

1593 EFFECT OF FOREBRAIN NOREPINEPHRINE DEPLETION ON THE EXTINCTION-RELEASING EFFECTS OF CHLORDIAZEPOXIDE. Michael D. Morris*, Frederick Tremmel* and Gerald F. Gebhart. Dept. Pharmacol., U. of Iowa, College of Med., Iowa City, Iowa 52242.

Forebrain norepinephrine (NE) was reduced to 35% of control values by means of bilateral radiofrequency lesions of the noradrenergic dorsal tegmental bundle (DTB). Hypothalamic NE was unaffected and dopamine levels in both hypothalamus and cortex were also unchanged. Both DTB lesion rats (n=21) and sham controls (n=21) were then trained on a straight alley runway task for food reward. Training continued for eight days; six trials were given each day. On the last two days of acquisition, all rats received chlordiazepoxide (CDP; 10 mg/kg as base) so that when CDP was administered during extinction it would not produce dissociation. Following acquisition, eleven of the lesion animals and eleven of the sham animals received CDP on each of four days in which food was no longer given for the runway response (i.e., extinction). The remaining animals (10/group) received vehicle injections at the same 30 min interval prior to each session. The following results were obtained: 1. During acquisition of responding, animals with DTB lesions were retarded in acquiring the running response. This deficit disappeared by the end of acquisition. 2. In the two groups which received vehicle, DTB lesion animals did not perseverate more in extinction than sham animals. This result is contrary to the perseveration of responding during extinction previously reported following selective reduction of forebrain NE (e.g., Tremmel et al., Brain Res. 126: 185, 1977). 3. The finding that CDP elevates extinction-response speeds was replicated for the sham groups. 4. Depletion of forebrain NE attenuated the anti-extinction effect of CDP.

The present results, in combination with previous reports, are interpreted as suggesting that (1) the DTB carries information about frustration and fear to a limbic response-suppression system, (2) that incomplete depletion of forebrain NE (i.e., 65%) leads to compensatory functional reorganization which, under certain circumstances, may lead to increased suppression of ongoing behavior, and (3) that CDP produces its anti-extinction effects by indirectly inhibiting the response-suppression system. Supported by USPHS Grant NS12114 to GFG.

1594 DOSE RESPONSE EFFECTS OF PHENCYCLIDINE ON STEREOTYPED BEHAVIOR IN RATS. Thomas F. Murray* and Akira Horita* (SPON: Lawrence M. Halpern). Dept. Pharmacol., Sch. Med., Univ. of Washington, Seattle, WA 98195.

Phencyclidine (PCD) is a psychotomimetic drug of abuse which has recently been implicated in the production of a schizophreniform psychosis in some users. Because of current interest in the role of dopamine in the pathogenesis of psychotic symptomatology, we investigated the ability of PCD to induce stereotyped behavior in rats. All subjects were observed individually for 1 minute epochs every 5 minutes for a period of 2 hours following i.p. injections of PCD. During each observation period the presence of any of 3 stereotyped behaviors was recorded in an all or none manner. The 3 stereotyped behaviors that were evaluated were backward locomotion, circling, and head swaying. This scoring system has been employed by other authors in the study of amphetamine-induced stereotyped behavior (Psychopharmacology 40:249, 1974). PCD treatment (4-16 mg/kg) induced dose-dependent increases in the mean stereotypy scores for all 3 behaviors. The predominant behavior elicited by low doses was head swaying, while with higher doses circling and backward walking were observed in addition to the head swaying. Pretreatment with either chlorpromazine (2.5, 5.0, and 10.0 mg/kg) or haloperidol (0.25, 0.5, and 1.0 mg/kg) antagonized the PCD-induced (4 mg/kg) stereotyped behavior in a dose-dependent manner. These results indicate that at least some of the behavioral effects of PCD appear to be mediated by dopaminergic systems.

1595 NEUROLEPTIC/DOPAMINE RECEPTORS: BIOCHEMICAL AND AUTORADIOGRAPHIC STUDIES. L. Charles Murrin*, Nikolai Klemm*, and Michael J. Kuhar, Dept. Pharmacology & Exp. Ther., Johns Hopkins Univ. Sch. Med., Baltimore, MD 21205.

We have carried out in vivo studies of dopamine (DA) receptors in the rat brain using ^{3}H-spiroperidol (^{3}H-SP) as a ligand (Life Sciences 22: 203, 1978). There was a regional distribution of stereospecifically bound ^{3}H-SP consistent with in vitro studies and with known DA innervation of brain regions. The in vivo binding was saturable and was blocked by DA agonists and antagonists, such as (+)butaclamol. Compounds inactive at DA receptors, such as (-)butaclamol, were ineffective in blocking ^{3}H-SP binding. These data suggested that autoradiographic studies of the DA receptor were feasible. In the present work male rats were administered 100 µCi (biochemical studies) or 125 µCi (autoradiographic studies) of ^{3}H-SP via tail vein, were decapitated two hours later and various brain regions were either analyzed for radioactivity or were prepared for autoradiography. Autoradiographic grains were found to be highly localized in specific brain regions. The olfactory tubercles and the nucleus accumbens were heavily labeled, consistent with their innervation by the mesolimbic DA system. The striatum had the greatest grain density of any region studied, as would be expected from its dense dopaminergic innervation. In the striatum the grains were found to be localized over the neuropil rather than over cell bodies with a ratio greater than 2:1. Other areas found to accumulate ^{3}H-SP as reflected in autoradiographic grain densities were parts of the frontal cortex, the claustrum, the nucleus of the stria terminalis, the lateral septum, the central nucleus of the amygdala, the ventral hypothalamus, the nucleus subthalamicus and the substantia nigra (particularly the zona compacta). The accumulation of grains in all of these areas was blocked by prior treatment with (+)butaclamol. Treatment with 1 mg/kg of either d-LSD or pipamperone (a serotonin receptor antagonist) one hour after injection of ^{3}H-SP resulted in a significant decrease in the accumulation of radioactivity in the frontal cortex, but not in the striatum, olfactory tubercles, nucleus accumbens or cerebellum. This confirms the work of others (Nature 272: 168, 1978) and suggests that in the frontal cortex ^{3}H-SP is binding to a significant degree to serotonin receptors. The effects of d-LSD and pipamerone treatments on the distribution of autoradiographic grains in the frontal cortex will be presented. The effects of kainic acid and 6-OHDA lesions of the striatum and the substantia nigra and of electrolytic lesions of the nigro-striatal and strio-nigral pathways on DA receptors will also be presented. Supported by MH 25951, RCDA MH 00053 and Deutsche Forschungsgemeinschaft.

1596 **INDUCTION OF PHYSICAL DEPENDENCE UPON ETHANOL IN RATS USING INTRAVENOUS INFUSION.** **Robert Numan and Anne M. Gilroy*. Dept. Psychol., Univ. Santa Clara, Santa Clara, CA 95053.**

The intravenous (i.v.) method of drug administration, while successfully employed to study many dependence producing substances, has not been adequately investigated for use in animal studies on alcoholism. The present research shows that the i.v. procedure can be safely used to rapidly induce physical dependence upon ethanol in rats.

Male hooded rats were implanted with chronic jugular cannulae and housed in sound attenuating chambers with food and water freely available. During the immediate postoperative period rats were infused with saline (3 ml every 4 hr at rate of 0.3ml/min) until food and water intake stabilized. Following this habituation period ethanol infusions were initiated in experimental rats (n=11) and saline infusions were continued in control subjects (n=6). Ethanol (30% v/v) was administered over a 7-day period (inter-animal range 5-10 days). The mean daily dose ranged from 10g/Kg/day to 14g/Kg/day. This dose was administered in 4-5 fractional doses over each 24-hr period (infusion rate: 0.3ml/min). Following this intoxication phase ethanol infusions were discontinued and rats were observed hourly for 20-hr and thereafter at 8-hr intervals for signs of physical dependence.

All ethanol treated rats showed withdrawal symptoms (moderate to severe, n=9; mild, n=2). Saline treated controls did not show these symptoms. Five days of intoxication was sufficient to produce these effects. The most reliable symptoms are listed below. Parenthetically we include the number of animals showing the symptom, the mean hr of onset during the withdrawal, and the mean hr of peak intensity onset during withdrawal respectively. The symptoms include: spontaneous seizures (n=7, 13.6 hr, 14.0 hr), audiogenic seizures (n=7, 10.9 hr, 11.1 hr), tremors (n=6, 10.2 hr, 11.5 hr), tail stiffening (n=10, 7.3 hr, 10.7 hr), and body rigidity (n=9, 4.8 hr, 12.0 hr). Other symptoms were also observed (e.g., aggression, body shakes, stereotypy, teeth chattering) but were less reliable. All symptoms were greatly reduced by 36 hr of withdrawal. (Supported by NIAAA Grant 1 R03 AA 03451-01)

1597 DIFFERENTIAL TOLERANCE TO EFFECTS OF CHRONIC d-AMPHETAMINE ON AGONISTIC AND NONAGONISTIC BEHAVIOR IN MICE. James M. O'Donnell* and Klaus A. Miczek. (SPON: H. Barry III). Dept. Psychol., Carnegie-Mellon Univ., Pittsburgh, PA 15213.

Assessing tolerance or sensitization to the effects of amphetamine is problematic when a single behavioral parameter is measured. The effects of amphetamine on locomotion and stereotypies illustrate that many elements of an animal's repertoire are interdependent, i.e. amphetamine-induced stereotypies prevent further stimulation of locomotor activity. We investigated the possibility that tolerance or sensitization may develop differentially to the effects of d-amphetamine on various components of an animal's behavioral repertoire. The ethological analysis of agonistic and nonagonistic behavioral elements permitted a comprehensive assessment of the behavioral effects of d-amphetamine during a nine week chronic treatment period in mice that were subjected to periodic resident-intruder tests. Agonistic behavior such as attack bites, threats, pursuits, and tail rattles as well as nonagonistic behavior such as anogenital investigation, walking, rearing, and self-grooming were recorded in male resident mice confronting an intruder mouse. Resident-intruder tests, conducted twice per week, were recorded on videotape for five minutes after the first attack. After an initial dose-response determination of d-amphetamine's effects on agonistic and nonagonistic behavior, mice were injected i.p. daily for four weeks with either d-amphetamine (n=15) or saline (n=15). While maintaining the animals on their respective chronic treatments for five more weeks, the dose-dependent effects of d-amphetamine were redetermined and also, the effects of cocaine were assessed. Our results indicate that (1) tolerance does not develop to the antiaggressive effects of d-amphetamine, (2) d-amphetamine-maintained mice show tolerance to the locomotion stimulating effect of the drug, (3) amphetamine induces stereotypies at a lower dose and to a greater degree in mice maintained on amphetamine than in those maintained on saline, and (4) there was no difference in the behavioral effects of cocaine in animals maintained on d-amphetamine and those maintained on saline. We also observed changes in fighting behavior of saline control animals during the course of the chronic treatment. This emphasizes the necessity of dose-response determinations before and after chronic treatment in order to guard against invalid conclusions about tolerance or sensitization to the effects of d-amphetamine.

1598 EFFECT OF IPRINDOLE ON MOUSE BRAIN SEROTONIN METABOLISM. Bertha G. Ortega-Corona, José Carranza-Acevedo, Patricia Guzmán-Amaya*, Nora Esparza-Avalos*, and Guadalupe Castro-Osuna*. Subjefatura de Investigación Básica, Instituto Mexicano del Seguro Social, Po. Box 73-032, Mexico City, 73, D.F., MEXICO.

Tricyclic antidepressant drugs (TAD) were found to block transmitter uptake. This finding inspired the older and now classic hypothesis about their mode of action. However, accumulating evidence about the actions of TAD on serotonin (5-HT), norepinephrine(NE) and dopamine (DA) in the brain make natural to consider other hypothesis. In order to shed some light into the mechanisms of action of these TAD, it was investigated the chronic administration of iprindole upon NE, DA 5-HT and monoamine-oxidase (MAO) in the midbrain, cerebral cortex, and cerebellum of the mouse Four groups of 40 animals were administered intraperitoneally with 0, 0.5, 1.0, 2.0 mg/kg/day respectively, during 120 days. Monoamines levels were determinated by Welch and Welch's method and MAO activity was measured by Wurtman's method. Independently of the doses chronic administration of iprindole induced remarkable increase in serotonin levels ($p < 0.001$) in the regions studied. It is important to point out that no changes were observed in DA and NE levels. MAO activity showed a significant inhibition ($p < 0.01$) at the doses used in all the regions. The inhibition showed a direct dose-response relationship in the midbrain. The specific changes observed in 5-HT, in its degradation product and in MAO activity, as well as, in the absence of catecholamine changes, permit us speculate a direct and specific action of iprindole on the serotonin metabolism.

1599 DEVELOPMENT OF IMPROVED TRAINING PROCEDURES FOR THE TWO-BAR DRUG DISCRIMINATION TASK. Donald A. Overton. Dept. Psychiatry, Temple Med. Sch., EPPI, Phila., Pa. 19129.

Many investigators use a drug discrimination (DD) task in which rats must press one lever when drugged and a second lever when not drugged in order to obtain food or water reinforcement. However, as usually implemented, this task has several unfortunate properties--prolonged training is required, asymptotic accuracy of discrimination is low, and no index of the degree of discriminability of a drug is provided. In an attempt to find solutions to these problems, a series of experiments was conducted in which rats discriminated phenobarbital 50 mg/kg ip from saline injections, as follows:

(1) Variations in training compartment design were tested to see if they would increase DD accuracy above that obtained in the usual box in which two bars are mounted side-by-side on one wall. They did not.

(2) Various schedules of reinforcement were used. Markedly different asymptotic accuracies were observed under these schedules. Fixed ratio schedules yielded highest DD accuracies, DRL, tandem VI-FR and VI-approach/avoidance schedules yielded intermediate DD accuracy, and variable interval schedules yielded lowest accuracy.

(3) Several methods of accomplishing the early stages of operant training were compared. Accurate discrimination was much more rapidly achieved if drug was used during early shaping sessions on the 'drug' bar than if shaping was completed without drug. When response-appropriate drugs were used during initial training, many rats showed state dependent learning and pressed the state-appropriate lever from the very beginning of DD training.

(4) DD training using the FR schedule was performed with several doses of phenobarbital in order to develop an index that would reflect the relative degree of discriminability of various training drugs.

The combined use of a ratio schedule and response-appropriate drugs during shaping allowed us to train DDs to asymptotic accuracy in less than 10 training sessions which is considerably faster than previously reported.

1600 RESPONSE TO PENTOBARBITAL IN ALBINO AND PIGMENTED MICE: A WITHIN STRAIN COMPARISON. Regina Pakalnis* and I.S. Westenberg (SPON: A.S. Schwartz). ASU, Tempe, AZ 85281 & VA Hosp., Phoenix AZ 85012.

Albino strains of rodents differ from pigmented strains in their responses to drugs; e.g. when compared with pigmented strains of rats, albinos had lower LD50's and increased sleep-time to pentobarbital (Shearer et al.,1973). Their study was a "between strains" comparison; thus the genetic variable of albinism was confounded with other genetic variables. To eliminate this confounding, we used a "within strain" design comparing albino and pigmented mice of the same inbred strain; animals differed in 1 gene at the C locus but were otherwise genetically identical. We used 7 littermate pairs of coisogenic C57BL/6J-c^{2J} male mice 137-162 days of age (mean = 146) at the start of the experiment. Each pair was from a different litter and consisted of an albino, c^{2J}/c^{2J}, and a pigmented, $+/c^{2J}$, matched for weight. In some litters additional male mice were available and used as controls (4 albino, 2 pigmented). All mice were food deprived 3-4 hours prior to injection. Mice were weighed on the morning of the injection and 3 days after. Experimental animals were injected weekly i.p. with sodium pentobarbital(Nembutal); dosage increased 10 mg/kg/week (to 150 mg/kg as of 5-5-78). Controls were injected i.p. with saline 2 µl/g. After injection littermates were placed together in observation cages. Controls were removed upon experimental animals' loss of righting reflexes (LRR). Frequent checks assured accurate timing of the return of the righting reflexes(RRR). Experimental animals were returned to their home cages after RRR. Between experimental sessions littermates were housed together in the mouse colony.

Median sleep-time (interval from LRR to RRR) was consistently greater for albinos at dosages greater than 50 mg/kg. Sleep-time differences were significant ($p \leq .05$, Mann-Whitney U) at 70,100,110,120,130, and 150 mg/kg and approached significance at 80 mg/kg. The LD50 was 140 mg/kg for both albino and pigmented mice. No significant differences were found for time to LRR. Sleep-time results are consistent with the findings of Shearer et al.(1973), but LD50 data are not. However, their study involved comparisons across several strains of rats while ours was a within strain comparison of mice.

1601 AN OPIATE EXCESS MODEL OF CHILDHOOD AUTISM. Jaak Panksepp, Barbara Herman*, and Tom Vilberg*. Dept. Psych., Bowling Green State University, Bowling Green, OH 43403

Early childhood autism has several distinct behavioral characteristics which are amenable to being modelled in animals--a low incidence of crying during infancy, a failure to cling to parents, a low desire for social companionship, and a variety of learning abnormalities characterized by unusual strength or persistence. From the assumption that a primary disorder in autism is a deficit in the elaboration of social affect, and from our theoretical perspective that social affect in mammals may be controlled by brain opiates, we have hypothesized that autistic symptoms may be precipitated by excessive activity of endogenous brain opiate systems. Accordingly, we have attempted to generate the above-mentioned behavioral symptoms of autism in animals with injections of low doses of the opiate agonist morphine sulfate. We have found that morphine at doses of 0.25-1.0 mg/kg can markedly reduce acute isolation-induced crying in young puppies, guinea pigs, and chickens in dose-dependent fashion. For instance, in 8-16 day old guinea pigs, .25 and 1.0 mg/kg morphine reduced crying to 65% and 25% of placebo levels respectively. At the same dose levels, morphine reliably reduced clinging behavior of 12-18 day old rat pups, and the desire for social companionship (as measured by proximity maintenance time) in adult rats and adolescent guinea pigs. Finally, in a T-maze learning situation motivated by either the reward of food or return to home, morphine (1 mg/kg) led to marked persistence of behavior during extinction in 20-40 day old rat pups. Control animals extinguished within 3-6 daily sessions, while morphine treated animals continued to run without diminished speed for up to two weeks of testing. These results suggest that morphine has a very powerful capacity to modulate social affect, and are consistent with the possibility that autistic symptoms in human children may be due to endogenous overactivity of brain opiate systems. If so, a rational pharmacologic adjunct to psycho- or behavior-therapy may be the administration of relatively pure opiate antagonists such as naloxone or naltrexone.

1602 STIMULANT DRUGS ENHANCE EFFECTS OF PUNISHMENT IN NORMAL AND CHLORDIAZEPOXIDE TREATED RATS. B.A. Pappas, R.A. Vogel, G.D. Frye, G.R. Breese and R.A. Mueller. Biol. Sci. Res. Ctr., UNC Sch. Med., Chapel Hill, NC 27514.

Animal models of minimal brain dysfunction (MBD) have focused upon reproducing the hyperkinetic aspects of this syndrome. There has been scant attention paid towards models for the attenuated impulse control which is a major symptom (Wender, Life Sci. 14, 1974). To this end we assessed the effects of stimulant drugs in a conflict procedure in which water-deprived rats, previously trained to drink in the apparatus, were briefly exposed to electric shock delivered through the water spout. The number of shocks received can be argued to reflect the capacity of the rat for inhibitory control of the drinking impulse when the latter leads to punishment. As previously reported (Vogel et al., Psychopharmacol. 21:1, 1971) prior injection of the anxiolytic chlordiazepoxide (8 mg/kg) more than doubled the number of shocks that the rats received. This disinhibition of punished behavior was counteracted by the stimulants d-amphetamine (0.5-4.0 mg/kg) and methylphenidate (0.75-6.0 mg/kg) in a dose related manner. Imipramine (4.0-32 mg/kg) and buproprion (2.5-40 mg/kg) were similarly effective. Imipramine and buproprion have not previously been reported to affect punished responding in other paradigms, such as the operant Geller conflict. These drugs, except methylphenidate, also reduced the number of punishments received by saline control rats in a dose related fashion.

The disinhibition caused by chlordiazepoxide in this procedure may be analagous to the weak impulse control displayed by children diagnosed as minimal brain damaged. Future research should further assess the possibility that antagonism of this disinhibition by drugs reflects their clinical efficacy for symptomatic treatment of MBD. (Supported by HD-10570, AA-02334 and MH-00013.)

1603 AMITRIPTYLINE INDUCED ALTERATIONS IN CEREBRAL CAPILLARY PERMEABILITY. S.H. Preskorn*, H.B. Clark*, B.K. Hartman, and M. Raichle (SPON: D.R. Justesen). Depts. of Psychiatry and Neurology, Washington University School of Medicine, St. Louis, MO 63110.

Intraperitoneal (i.p.) administration of amitriptyline (AMT) has been shown to profoundly alter cerebral capillary permeability to water (P_W). This has been studied using a modication of the indicator-dilution technique in rats (Oldendorf, et al., Am. J. Physiol. 229:1110, 1975) and a single injection, external registration technique in monkeys employing $H_2{}^{15}O$ as the tracer (Raichle, et al., Am. Physiol. 220:543, 1976). AMT at blood levels under 800ng/ml in rats induced an increase in extraction fraction of ^{3}H-water (E_W) from control values of 0.67 to 0.90 ($p < .001$) within five minutes of administration. Ethanol which normally has an extraction fraction (E_e) of 0.80 in rats becomes freely permeable (i.e. $E_e = 1.00$) under this treatment. Changes in E_W are a function of cerebral blood flow (CBF) as well as P_W. However, AMT at blood levels between 150-200ng/ml in monkeys caused a significant increase in the permeability of ^{15}O-water without altering CBF. Thus, AMT appears to specifically alter brain P_W in both rats and monkeys. The AMT effect was not blocked by phenoxybenzamine administered i.p. 24 hours before AMT treatment. Lidocaine administered i.p. at the same dose produced a comparable increase in water permeability. The relative potency of tricyclic antidepressants in producing this permeability alteration is: amitriptyline $\geq$ nortriptyline > imipramine > protriptyline. This is the same order as their relative local anesthetic effects. The AMT effect is thus compatible with the potent local anesthetic properties of AMT. The presumed psychopharmacology of tricyclic antidepressants has not previously considered such microculatory effects.

1604 PERSISTENCE OF CHOLERA TOXIN-INDUCED STIMULATION OF ADENYLATE CYCLASE AND BEHAVIORAL CHANGES. Linda F. Quenzer* and Linda G. Dusek*, (SPON: R.L. Volle). Dept. Pharmacol., U. Conn. Health Ctr., Farmington, CT 06032.

We have previously shown that stereotaxic injection of cholera enterotoxin (1 µg in 1 µl) unilaterally into the substantia nigra produces a 2-fold increase in basal adenylate cyclase activity in the ipsilateral caudate nucleus 24 hours after the injection (Quenzer et al., Sci. 195: 78, 1977). We now find that adenylate cyclase activation, beginning at 6 hrs after toxin treatment, occurs in homogenates of both substantia nigra and the ipsilateral caudate after a single cholera toxin injection into the substantia nigra. Basal activity in the caudate on the toxin side increases significantly ($p<.005$) from 42.7 pmol cAMP formed/mg wet weight/3 min to 110.1 pmol/mg tissue/3 min at 24 hrs and is maintained at that level for the duration of time tested (3 wks). Basal adenylate cyclase activity in substantia nigra (23.4 pmol cAMP/mg tissue/3 min) is much lower than that in caudate but it too is increased (46.9 pmol/mg tissue/3 min) 24 hrs after intranigral cholera toxin. Although the basal adenylate cyclase activity is increased 2-3 fold, the ability of 100 µM dopamine to further stimulate the enzyme is apparently unchanged. No change occurs in the activity of cAMP phosphodiesterase when measured using 1 µM and 100 µM substrate concentrations. The prolonged increase in adenylate cyclase activity in combination with unchanged phosphodiesterase metabolism of cAMP suggests that endogenous levels of cAMP are elevated on the toxin treated side of the brain for at least 3 weeks.

A 3.5-fold increase in motor activity also appears within 24 hrs after an intranigral injection of cholera toxin. The increased activity is characterized by spontaneous rotation contralateral to the toxin-treated side. Spontaneous rotation persists in most animals for at least 3 days but is entirely lost within 1 week of the toxin injection. At that time no direction bias is evident even in animals stimulated with tail pinch. Increased motor activity also diminishes by one week but is more persistent than the rotation. The difference in time course of neurochemical changes and behavioral changes following cholera toxin injection suggests that the toxin-induced increase in cAMP formation is unrelated to the increase in activity or spontaneous rotation.

1605 ONTOGENY OF AMPHETAMINE ANOREXIA: EFFECTS OF AMPHETAMINE ON NIPPLE ATTACHMENT. Lisa A. Raskin* and Mark J. Dollinger* (SPON: B. A. Campbell). Princeton University, Princeton, N.J. 08540

The psychomotor stimulant properties of amphetamine are evident in the rat as early as one day of age, but amphetamine anorexia is not observed until approximately 15 days of age. Prior to that age amphetamine appears to potentiate feeding (Lytle, Moorcroft & Campbell, JCPP, 1971, 77, 388-393). The following experiments examined this transition in the effects of amphetamine from facilitation to disruption of feeding in the developing rat. This was accomplished by using three tests of nipple attachment.

In the first test pups were placed near the ventrum of an anesthetized dam which made it necessary for them to move about in order to attach to the nipple. Consistant with the effects on feeding, amphetamine produced an increase in attachment in 5-day-olds but decreased it in 15-day-olds. In the second test 5- and 15-day-old pups were held at the nipple of an anesthetized lactator and nipple attachment was observed. In this test pups did not nave to locomote to the nipple before attaching. Amphetamine neither disrupted nor facilitated nipple attachment in 5-day-olds but markedly disrupted it at 15 days of age. Our third test was designed to dissociate the psychomotor stimulant properties of amphetamine from its direct effect on attachment. Latency to approach an anesthetized lactator was measured in 2-, 5-, 10-, and 15-day-old pups using a runway apparatus with the anesthetized lactator at one end. After the pup had reached or was placed at the ventrum, latency to attach was also recorded. Amphetamine facilitated approach to the mother at all ages but slowed attachment in 15-day-old pups. As in the second test, amphetamine did not effect speed of attachment in the younger pups.

These results demonstrate that amphetamine facilitates feeding in the young pup by enhancing the locomotor activity required to approach the nipple. In the older pup amphetamine disrupts feeding due to its anorexigenic properties.

1606 SMALL DOSES OF MORPHINE SULFATE AND PRESSING FOR HYPOTHALAMIC INTRACRANIAL STIMULATION (ICS) IN RATS. Larry D. Reid, Marcia D. Lind*, Michael A. Bozarth, Vicki J. Merriman*, and June M. Stapleton*. Dept. of Psychol., Rensselaer Polytechnic Institute, Troy, NY, USA, 12181.

There has been considerable exploration of the effects of larger doses of morphine (e.g., 10 mg/kg) on pressing for hypothalamic ICS. These doses are larger than those a rat might self-administer. We tested, therefore, for the effects of smaller doses on pressing for ICS (.125, .25, .5, 1.0, and 2.0 mg/kg, ip).

Rats were each fixed with a chronically indwelling bipolar electrode. The lateral hypothalamic sites of ICS were confirmed histologically after behavioral testing. After recovery from surgery, rats were trained to press a lever for a single train of ICS (60 Hz sine waves of .3 sec). Intensities of ICS differed for each rat, being selected during initial testing to produce stable, sustained pressing, and ranged from 15 to 40 μA. Doses of morphine or placebo were then given immediately before each 1-hr test session.

Doses of .125 and .25 mg/kg occasionally led to increased pressing for ICS, but overall increments in pressing were not reliably different from those following placebos. Doses of .5, 1.0, and 2.0 mg/kg did produce reliable increments in pressing.

A second study tested whether the doses of 0, .5, and 10 mg/kg of morphine produced a conditioned preference for the place where a rat had experienced morphine's effects. The testing procedure was nearly identical to the one used by Rossi and Reid (1976, Physiol. Psychol., 4, 269-274). Results indicated that the doses of .5 and 10 mg/kg lead rats to spend more time in the place of their morphine-experience compared to results from placebo-injected controls.

Small doses of morphine, therefore, (a) lead to increments in pressing for hypothalamic ICS and (b) induce a state that leads rats to go to the place where they experienced that state (i.e., the morphine produced a positive affective state). These observations (as well as others with larger doses) are concordant with the idea that morphine is self-administered for its positive affective effects. Such positivity might be due to morphine's ability to increase activity in the tissue of intracranial self-stimulation.

1607 NICOTINE AS A DISCRIMINATIVE CUE IN RATS: ISOMERIC SPECIFICITY. Carmelo Romano* and Avram Goldstein. Dept. Pharmacology, Stanford Univ. Sch. Med., and Addiction Research Foundation, Palo Alto, CA 94305

Rats were trained to discriminate (-)-3-nicotine (0.4 or 1.0 mg/kg, base) from saline, utilizing a T-maze-shock escape paradigm similar to Overton's (Psychopharm. 10:6, 1966). Training sessions (5 days per week) lasted a period of months so that consistent and reliable performance was maintained (91% mean correct responding for 0.4 mg/kg group, N = 3; 97% for 1.0 mg/kg group, N = 7; for most animals, this represents performance maintained for most than 90 sessions). A 10-session performance test preceded each test drug session to allow statistical analysis.

We report here responses of the animals to (+)-3-nicotine, (±)-2-nicotine, (±)-4-nicotine, and lobeline. Also included are the pooled data from tests with (-)-3-nicotine and saline administered blind. The fraction shows the number of animals giving a nicotine response (i.e., turning in their nicotine direction) and the total number of animals tested.

Drug and dose (mg/kg base)	Training dose 0.4	1.0
(-)-3-nicotine training dose	6/6*	11/11*
saline	2/6*	0/9*
(+)-3-nicotine 1.0	0/3	0/7
10.0		0/3
(±)-2-nicotine 1.0	0/3	1/4
10.0	0/3	0/4
(±)-4-nicotine 1.0	0/1	0/4
10.0	1/3	0/3
lobeline 10.0	0/3	0/4

*multiple tests on same animals.

We conclude that the receptor mediating the discriminative cueing property of nicotine possess a high degree of geometrical specificity.

1608 THE EFFECTS OF A LOW-TRYPTOPHAN DIET ON APOMORPHINE-INDUCED STEREOTYPED BEHAVIOR IN RATS. B. J. Sahakian, R. J. Wurtman, J. K. Barr*, and W. R. Millington. Lab. Neuroendocrine Regulation, Dept. Nutrition and Food Science, M.I.T., Cambridge, MA 02139.

Psychomotor stimulant drug-induced stereotyped behavior is thought to be mediated primarily by dopaminergic mechanisms. However, other neurotransmitter systems, such as the cholinergic, noradrenergic, and serotonergic (5-HT), are known to exert modulatory control over this behavior. Therefore, we examined the effects of decreased levels of brain 5-HT, produced by dietary manipulation, on apomorphine-induced stereotypy in rats. Rats on a low-tryptophan diet showed significantly shorter durations of stereotyped behavior as compared with rats on a control diet in response to most doses of apomorphine. In addition, low-tryptophan-diet rats showed significantly less intense stereotypy induced by 0.2 mg/kg apomorphine. The differences between the two groups in stereotypy were abolished by pretreatment with 50.0 mg/kg L-tryptophan. It was later confirmed that the rats on a low-tryptophan diet had decreased levels of brain 5-HT. In other experiments, it was found that pretreatment with MK-212, a novel 5-HT agonist, or with quipazine also was able to restore the apomorphine-induced stereotypy to control levels among low-tryptophan-diet rats. Results are discussed in terms of the role of the serotonergic system in the modulation of psychomotor stimulant drug-induced stereotypy, and the inverse relationship between amount of locomotor activity and the amount of stereotyped behavior.

Supported by grants from NIH (AM-14228) and NASA (NGR-22-009-627).

1609 EFFECTS OF MORPHINE ON ESCAPE FROM HYPOTHALAMIC STIMULATION IN THE RAT. Susan Schenk*, Terrence Williams* and Peter Shizgal. Cen. Res. Drug Depen., Dept. of Psychology, Concordia University, Montreal, Quebec, Canada, H3G 1M8.

The modulation by morphine of the aversive properties of electrical brain stimulation has been studied less extensively than the drug's interaction with rewarding effects of stimulation. The present study was undertaken in order to extend previous findings in several ways. First, we used a frequency threshold measure of stimulation-escape in an attempt to reduce the contribution of performance effects that often bias response rate measures. Second, we attempted to establish time- and dose-response relationships that could be compared with those describing the effects of morphine on brain stimulation reward. We also administered a given dose repeatedly to observe tolerance effects.

Rats were trained to press a lever in order to obtain a 1 second interruption of lateral hypothalamic stimulation. If the rat failed to respond, the train of 0.1 msec. monophasic, cathodal pulses was automatically terminated after 10 seconds and then reinstated 1 second later. The rectangular, constant current pulses were delivered through monopolar electrodes. Frequency thresholds were determined by decreasing the stimulation frequency in 0.1 $\log_{10}$ steps. Subjects were tested for 2.5 minutes at each step. Optimal current intensities were selected for each rat and then fixed for the duration of the experiment. After stabilization of baseline performance, a series of daily morphine HCl injections was begun. An initial dose of 20 mg/kg (i.p.) was incremented in 0.1 $\log_{10}$ steps until a dose of 320 mg/kg was achieved.

Morphine reliably produced a monophasic increase in threshold for stimulation escape. No consistent tolerance effects were observed; escape thresholds were unaltered during withdrawal. There were large individual differences in the magnitude of the drug's effect which may be related to the ratio of thresholds for self-stimulation and escape at each placement.

Experiments are now in progress to determine concurrent changes in self-stimulation and stimulation-escape from the same stimulating electrode. Initial findings suggest that changes in the aversive properties of stimulation are not due to the effects of the drug on the substrate underlying reward. This work was supported by Canadian NRC Grant A0308.

1610 CHRONIC ADMINISTRATION OF d-AMPHETAMINE TO SELECTED MEMBERS OF PRIMATE SOCIAL COLONIES AS AN ANIMAL MODEL OF PSYCHOSIS. R.F. Schlemmer, Jr., D.L. Garver, N. Narasimhachari, J.M. Davis. Illinois State Psychiatric Institute, Chicago, Illinois 60612

Chronic administration of large doses of amphetamine to human volunteers results in a syndrome (amphetamine psychosis) which is virtually indistinguishable from paranoid schizophrenia. Similar administration of amphetamine to selected members of primate social colonies may provide an animal model which can be used to study behavioral aberrations characteristic of psychosis. With this in mind, the following study was conducted. Following a baseline observation period, d-amphetamine (d-Amph), 1.6 mg/kg in time-release form, was administered n.g. every 12 hours for 12 consecutive days to 13 female Stumptail macaques selected from 6 stable, adult social colonies of 4-5 monkeys each. No more than 2 monkeys/group received drug treatment (Tx) during one time interval. Behavioral observation occurred once daily for at least 4 days prior to and for the 12 days during Tx. During this time, "blind" observers quantified and recorded the social and solitary behaviors of all members of each colony for 1 hr. using the focal-sampling technique. In general, d-Amph induced abnormal behavior and altered normal behavioral patterns in all Tx monkeys, however, there was considerable variation in response between animals, some of which could be correlated with social rank. All Tx monkeys developed stereotypy and hypervigilance as abnormal behaviors. The form of stereotypy varied between animals but higher ranking (HR) monkeys displayed more social stereotypy than lower ranking (LR) monkeys. No rank correlation could be detected for hypervigilance. d-Amph-induced changes in normal behavior primarily involved social withdrawal. Most Tx monkeys had decreased social grooming with increased self grooming. Most Tx monkeys became isolated from other monkeys as reflected by increased distancing scores. LR monkeys became isolated earlier in Tx than HR monkeys. HR monkeys had increases in submissive gesture scores during Tx. Several HR females displayed large increases in threats, but rarely followed with attacks. d-Amph-induced excessive scratching in 8 monkeys. Several of the behavioral changes induced in monkeys by d-Amph have been described in humans with amphetamine psychosis including: large individual variation in response, stereotypy, social withdrawal, hypervigilance, and excessive scratching. This study also demonstrates that social status may play a role in some behavioral responses seen with d-Amph. We conclude that chronic d-Amph treatment of selected members of primate social colonies provides a particularly relevant animal model for the study of the psychosociopharmacology of amphetamine and psychosis.

1611 MATERNAL BEHAVIOR AND OFFSPRING AMPHETAMINE RESPONSE. H. Schreiber; Dept. Psychiat., Washington Univ. Sch. Med., St. Louis, MO 63110; R. Bell, J. Palet*, K. Nau*, J. Eatwell*, B. Baker*, Dept. Psychol., Texas Tech Univ., Lubbock, TX 79409.

Recent studies in our laboratory have shown that when rat pups are handled in infancy and returned to a mother-present nest, they show, in adulthood, reduced amphetamine toxicity (Schreiber, et al., Psychopharm. 52, 173, 1977) and reduced stereotypy. Rat pups which are handled and returned to a mother-absent nest show no such diminished response in adulthood, indicating a crucial maternal component. The present study was undertaken to show that certain styles of behavior in rat mothers (elicited by stressing their pups) are sufficient to reduce amphetamine stereotypy--even when the offspring themselves are not directly stressed.

Young, primiparous (PRIMIP) and older, multiparous (MULTIP) mothers were exposed to (a) baskets of actively-signalling cold-stressed donor pups (STRZ), (b) baskets of anesthetized donor pups (ANES), or (c) baskets of ping-pong balls (BSKT) during the first week after parturition while the mothers' own offspring remained undisturbed. Maternal behavior was assessed before and during exposure to the baskets as well as during the week following exposure to the baskets (the second week after parturition). PRIMIP mothers responded to the distress calls of the donor pups by increasing their care-giving behavior. MULTIP mothers responded by decreasing their care-giving behavior. Both PRIMIP and MULTIP responded to ANES donor pups in a fashion intermediate to the STRZ and BSKT conditions, except that mothers exposed to ANES donor pups constructed better rated nests. Following weaning, these mothers' male offspring were subjected to six consecutive daily injections of saline, 2.5 mg/kg or 5.0 mg/kg d-amphetamine 30±5 minutes prior to a two-minute observation in a Y-maze. Following four days of an accelerating drug regimen, subjects were injected with saline. On the next day, subjects were tested in the Y-maze as before, except that all subjects were injected with 5.0 mg/kg d-amphetamine.

Offspring of PRIMIP mothers exposed to STRZ donor pups showed less stereotypy in comparison with the offspring of PRIMIP mothers exposed to ping-pong-ball-filled baskets. Offspring of MULTIP mothers exposed to STRZ donor pups showed more stereotypy in comparison with offspring of MULTIP mothers exposed to baskets. Although offspring of mothers exposed to ANES donor pups showed evidence of greater activity and lower body weight, stereotypy was largely influenced. These results indicate that the rat mother's behavior is sufficient to influence the offspring's later response to amphetamine.

1612 BIPHASIC EFFECT OF ACUTE ETHANOL ON AUDIOGENIC SEIZURES. Robert A. Schreiber, Dept. Biochemistry, UTCHS, Memphis, TN, 38163.

The metabolism of an acute dose of ethanol should lead to a transiently increased amount of ethanol-derived hydrogens in brain NADH, as well as an abundance of acetyl CoA (AcCoA). This should transiently lead to an abundant supply of ATP and should in turn transiently reduce the rate of production of glycolysis-derived and of TCA cycle-derived hydrogens in NADH, and of glycolysis-derived AcCoA. Brain glucose levels would be expected to (and do) transiently rise after acute ethanol, followed by a deep depression in brain glucose hours later, as ethanol is cleared from the body (Arch int Pharmacodyn, 154, 108, 1965). Glycogen levels in brain transiently fall, indicating a greater rate of glycogen to glucose-6-phosphate (G-6-P) than of high-ATP-suppressed glucose to G-6-P.

It has been proposed that decreased total immediately mobilizable energy reserves in brain may underly susceptiblity to audiogenic seizures (SAGS). (Res. Comm. Psychol., Psychiat., Behav., in press; Pharm. Bioch. Behav., 8(5), in press, 1978). Should this model hold, then one would predict an early protection from SAGS by ethanol, followed by a transient heightened SAGS as the ethanol-derived energy in brain (either directly in brain NADH, or indirectly via plasma ketone bodies) was cleared, and glycolytic-based energy reserve levels in the brain remained transiently at a low level prior to recovery.

C57BL/6J mice were subjected to audiogenic priming at 16 days of age (127 ± 2dB for 60 sec.) and tested at 21 days of age. Mice were injected with 1.96 mg/kg ethanol (0.1 ml of 25% per 10 gm mouse) ip; behavioral effects at this dose (staggering, and in some cases, mild sedation) dissipated by 30 min. post-injection.

Mice were tested for SAGS at 30-min or 60-min intervals up to 7 hr. post-injection. Data are shown below: (mice completely protected at 60" and 120" as well)

	control	+30"	+150"	180	210	240	270	300	360	420
N_1	12	4	4	7	7	7	6	6	7	7
$\bar{x}^1$	3.08	0	0	1.00	2.71	2.85	3.50	4.83	2.85	2.57
SEM	0.51	0	0	0.69	0.68	0.80	0.80	0.16	0.80	0.71
t vs C^2		5.73	5.73	2.27	0.39	0.22	0.40	3.08	0.22	0.54

1. Mice were assigned a "seizure severity score" based on the most severe level of seizure attained. Wild run=1, clonic-flexion=2, clonic-extension=3, tonic=4, death=5.
2. Student's t; statistically significant differences ($p<.025$) are underlined.

1613 BEHAVIORAL EVIDENCE FOR ANATOMICAL SPECIFICITY OF ACTION BY CLOZAPINE. Thomas F. Seeger* and Eliot L. Gardner, Depts. of Pharmacology, Psychiatry, and Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461

Biochemical evidence suggests that clozapine has a dopamine (DA) blocking activity specific to the mesolimbic system, while "classical" neuroleptics such as haloperidol have equal potency in both the nigro-striatal and mesolimbic DA systems. However, behavioral evidence for this specificity is lacking, perhaps due to the need for a good behavioral assay for mesolimbic DA function.

We have tested the effect of chronic clozapine or chronic haloperidol treatment on intracranial self-stimulation (ICSS) in rats with electrodes implanted in the A10 cell body area of the ventral tegmentum (origin of the mesolimbic pathway). Following three-week treatment with either 20 mg/kg/day of clozapine, or 1 mg/kg/day of haloperidol, the rats showed an average 35% increase in ICSS rate over pre-drug control levels (N=10 in each group). This increase was long-lasting in both groups, persisting for three weeks before beginning a week-long decline to pre-drug control rates.

In order to compare this apparent induction of supersensitivity in the mesolimbic system with behaviors that have been localized to the nigro-striatal system, we also quantified stereotypic behaviors (chewing, rearing, sniffing, head bobbing, and grooming) after injection of 1 mg/kg of apomorphine. The rats were then given the same chronic clozapine or haloperidol treatment that the ICSS rats received. After drug treatment, all animals showed a significant increase in locomotor activity (a behavior believed to have both striatal and mesolimbic components). However, the haloperidol group showed significant increases in chewing and sniffing (believed to be localized to the striatum), while the clozapine group showed no significant changes in these behaviors (N=6 in each group).

Taken together, we believe that these results show a relative specificity of action of clozapine for behaviors that are mediated by the mesolimbic DA system. In addition, they suggest a possible role for the self-stimulation assay in testing the anti-psychotic potency of atypical neuroleptics such as clozapine.

1614 LONG-TERM EFFECTS OF HALOPERIDOL ADMINISTRATION DURING DEVELOPMENT. Ismail A. Shalaby*, Linda Patia Spear* and John Brick* (SPON: C. VanHartesveldt). Dept. Psychol. SUNY at Binghamton, Binghamton, N.Y. 13901.

Chronic haloperidol treatment during development was found to induce long-term behavioral and psychopharmacological effects. Pregnant Sprague-Dawley rats were injected subcutaneously twice daily with 0.25mg/kg haloperidol or saline, or were noninjected but handled twice a day, from day 1 of gestation until weaning of the offspring at postnatal day 21. The offspring of such treatments were tested on either postnatal days (P) 23-30, 35-42 or 47-54. At least seven animals were tested under each drug condition at each age for each of the treatment conditions (as there were no differences in the response of offspring of saline treated and noninjected control mothers, these two groups were combined into a single control group). Mothers from the experiment were also tested using the same procedures on P23-30 of their offspring.

After termination of a chronic treatment regime of haloperidol to adult rats, animals are typically hyperactive, have an enhanced response to drugs that stimulate the dopamine system (such as apomorphine and amphetamine), and have a decreased response to drugs that block dopamine receptors (such as haloperidol). However, the effects of chronic haloperidol treatment during development did not parallel that of adult chronic treatment, and varied with age at the time of testing. Offspring given haloperidol chronically during development were spontaneously hyperactive in the open field, showed an attenuated response to amphetamine and an accentuated response to haloperidol when tested at the early (P23-30) and late (47-54) testing intervals. Drug treated offspring did not differ from controls on any of these measures at the intermediate (P35-42) testing interval. Thus behavioral and pharmacological effects of chronic haloperidol treatment during development may vary with age at the time of testing. In addition, although both chronic neuroleptic treatment during development and in adulthood may produce behavioral hyperactivity, the later pharmacological responsiveness of such treated animals may vary: adult treated animals show an accentuated response to amphetamine and attenuated response to haloperidol; the opposite is found in developmentally treated animals when tested at early (P23-30) or late (P47-54) testing intervals.

The results of neurochemical studies on the effects of chronic haloperidol treatment during development will be presented. These results may help elucidate the synaptic basis for the paradoxical pharmacological responses observed in this study.

1615 LONG LASTING BEHAVIORAL SEIZURES IN THE YOUNG CHICKEN INDUCED BY PHENCYCLIDINE. Clifford J. Cherry and P. Scott Hunter*. Biology Dept. Texas A & M Univ. College Station, Tx. 77843

The abuse of the hallucinogen, phencyclidine (PCP) on the "street" is increasing at an alarming rate. Unfortunately, the mechanism and site of action of PCP is not clearly known, but the use of PCP is frequently associated with convulsive movements (Johnstone, M. Anesthesia 1959, 31, 433-) and status epilepticus (Kessler, G. F. et al., New Eng. J. Med. 1974, 291, 479-) in humans and seizures in animals (Chen, G. et al., J. Pharmac. Exp. Ther. 1959, 127, 241-) in animals. However, these papers do not give detailed quantitative descriptions of the seizures. In addition, little is known about the effect of PCP on developing organisms.

Male White Leghorn chickens were obtained at on day of age and housed under standard conditions. Seperate groups of chicks were exposed to 10 mg/kg of PCP, intraperitoneally, at 2, 3, 8, 9, 11, and 18 days of age, where the day of injection was choosen randomly. Seperate groups of chicks were exposed to 1, 5, 10, 20, 40, 60, or 80 mg/kg PCP at 2 days of age to determine the lethal dose 50% (LD50) and the effective dose 50% (ED50). The latency to the development and duration of two classes of behavioral seizures were noted: clonic seizures (i.e. the chick would lose posture and the legs and toes would move rapidly in a running motion, with eyes open) and tonic seizure (i.e. the chick would lose posture and the legs and toes would be vigorously extended, with eyes closed and frequently the wings extended up over the back.

The LD50 for PCP is the 2 day old chick is 43.58 mg/kg. The ED50 for seizure development in the 2 day old chick is 7.6 mg/kg. When compared to the 2 day old chick, older chicks tended, on the average, to have more clonic seizures and the average time between clonic seizures and the average length of clonic seizures decreased. In older chicks, the average lenght of tonic seizures tended to increase, while the average time between tonic seizures decreased. When the dose level of PCP was increased to 15 mg/kg in the 2 day old chick, it tended to increase the inter-clonic seizure interval, but during this time a tonic seizure developed which lasted for the entire inter-clonic interval. The higher dose level was also associated with an increase in the average length of clonic seizures and an increase in the average length of tonic seizures, as well as the frequency of tonic seizures.

1616 BEHAVIORAL EFFECTS OF ACUTE AND CHRONIC PHENCYCLIDINE IN THE RAT. R.C. Smith, C.A. Biggs*, D.E. Leelavathi, H.L. Altshuler. Texas Res. Inst. of Mental Sciences, Houston, Texas 77030.

Phencyclidine (PCP) is an anestetic drug with psychotomimetic properties, which has been shown to effect brain dopaminergic, noradrenergic, cholinergic, and serotontic systems. Recent experiments in our laboratory now indicate that pre-treatment with low to moderate doses of naloxone, intensifies some of the behavioral effects of PCP in the rat, and therefore suggests that endorphins and opiate receptors may also be involved in the mechanism of action of PCP. In other experiments rats were chronically administered PCP (10 mg/kg) for 30 days. We found that after 30 days of chronic treatment with PCP, chronic PCP rats exhibited greater behavioral effects of PCP on ataxia, stereotypied sniffing, and rearing, but not on circlinig behavior (during the first 60-90 minutes after i.p. injection of 10 or 15 mg/kg PCP) as compared to control rats treated chronically with saline and then given these acute doses. These results suggest that behavioral supersensitivity may develop to some of the effects of PCP during or after chronic treatment with the drug.

1617 INCREASES IN URINATION AND DEFECATION IN RATS FOLLOWING P-CHLOROAMPHETAMINE. J.M. Stein, K.M. Kantak, C.C. Loullis, M.J. Wayner, R.C. Cook* and J.A. Cudworth*. Regional Primate Research Center, Univ. of Washington, Seattle, WA 98195 and Brain Research Laboratory, Syracuse University, Syracuse, NY 13210.

p-Chloroamphetamine (PCA) produces long term and short term changes in brain amines. The long term effects of PCA include decreases in brain serotonin (5-HT), tryptophan hydroxylase and 5-hydroxyindoleacetic acid concentrations. Short term effects of PCA include increased extraneuronal 5-HT and various effects on central catecholamines. During the initial period, rats injected with PCA display a stereotyped behavioral syndrome which includes hyperactivity, arching of the back, piloerection, reciprocal forepaw treading, and hind limb abduction. It is also during this initial period that large decreases in food and water intakes and body weights have been reported. In a previous study, (Stein, et al., 1978), it was shown that 300 gm rats administered PCA, 5.0 mg/kg, lost up to 10 gm of body weight during the first hr post-injection, and up to 18 gm during the first 3 hr post-injection. Pretreatment with fluoxetine 10.0 mg/kg, a specific 5-HT uptake blocker, did not affect these changes. This weight loss was apparently due to increased urination and/or defecation because: 1) the decreases in weight occurred whether animals were injected during high or low probability eating periods; and 2) the decreases were significantly greater compared to a food and water-deprived control group.

In the present study, the body weight losses, urination and defecation following various doses of PCA were quantified. Rats were adapted to metabolism cages and injected, ip, 1.0 ml/kg of saline containing 0.0, 0.5, 1.0, 2.0, 5.0 or 10.0 mg/kg of PCA. A dose-dependent body weight loss was observed during the 3 hr post-injection period. Weight loss ranged from 4.8 gm in the saline group to 16.3 gm in the 5.0 and 10.0 mg/kg groups. Significant increases in defecation occurred during the 0-1 hr post-injection period in the 2.0, 5.0 and 10.0 mg/kg groups. Significant increases in urination occurred during this same period in the 0.5 - 5.0 mg/kg groups. In the 10.0 mg/kg group, the fur of the rats became saturated with urine, and measurable diuresis was masked. The role of these effects on PCA-induced hypophagia, hypodipsia and subsequent hyperdipsia (Stein, et al., 1978) will be discussed, as will potential central and/or peripheral nervous system involvement in these effects.

1618 THE INTERACTION OF PSYCHOTROPIC DRUGS WITH N,N-DIMETHYLTRYPTAMINE (DMT). David M. Stoff, J. Christian Gillin, Dilip V. Jeste,* Egidio A. Moja* and Richard Jed Wyatt. Lab. of Clinical Psychopharmacology, SMR, IRP, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032.

The hypothesis that schizophrenia results from the endogenous synthesis of methylated hallucinogenic agents was proposed about 25 years ago; among the possible compounds as an abnormally methylated agent N,N-dimethyltryptamine (DMT) has been the most vigorously pursued.

We have already reported dose response disruptive effects of DMT on rat shuttlebox avoidance and suggested that this paradigm may serve as an animal model for the hallucinogenic activity of DMT (Stoff et al., Biological Psychiatry, 1977, 12, 339-346). Here, we present evidence that chronic neuroleptic pretreatment protects against this effect of DMT.

A series of experiments was conducted to study the interaction of acute and chronic pretreatment of various psychotropic drugs with DMT. Fischer 344/mai rats were trained to a high stable conditioned avoidance response (CAR) baseline rate (>80% CARs), pretreated once with neuroleptics: chlorpromazine (1 mg/kg, n=10), haloperidol (.05 mg/kg, n=8), pimozide (.025 mg/kg, n=10), clozapine (2.5 mg/kg, n=9), methiothepin (.0675 mg/kg, n=8); pargyline (MAO inhibitor) (75 mg/kg, n=10); AMPT (inhibitor of CA synthesis) (100 mg/kg, n=10); 1,2,5,6-tetrahydropyridine-3-(N,N-diethylcarboxamide) (THPC) (postulated to occupy the DMT receptor) (20 mg/kg, n=15) or chronically with the same dose daily of chlorpromazine (21 days, n=10), haloperidol (14 days, n=9) or pimozide (14 days, n=10) followed by a challenge dose of DMT 4 mg/kg (n=81).

The following results were obtained: (i) none of the pretreatment schedules, by themselves, influenced the CAR; (ii) DMT caused about a 40% decrease in the CAR rate,; (iii) acutely, none of the drugs influenced DMT disruption; (iv) chronic chlorpromazine, haloperidol and pimozide attenuated DMT disruption with the degree of protection directly related to the length of neuroleptic pretreatment.

The findings that chronic, but not acute, neuroleptic pretreatment is effective in preventing disruptive effects of DMT may be related to the time dependent effects of neuroleptics on dopamine turnover and the therapeutic latency of these agents.

1619 ANTI-CONFLICT PROPERTIES OF THYROTROPIN RELEASING HORMONE (TRH), ALONE OR IN COMBINATION WITH ETHANOL (ETOH) OR CHLORDIAZEPOXIDE (CDZ). R.A. Vogel, B.A. Pappas, J. Wilson*, G.D. Frye, R.A. Mueller and G.R. Breese. Biol. Sci. Res. Ctr., UNC Sch. Med., Chapel Hill, NC 27514.

Anti-conflict activity was measured in water deprived rats using a modification of the procedure of Vogel et al. (Psychopharmacol. 21:1, 1971). Rats deprived of water for 24 hours were allowed 200 unpunished licks in the test apparatus to decrease intersubject variability in the subsequent drug test. After 48 hours of deprivation, the drug-treated rats were allowed to drink for 3 min., but after every 20 licks, licking was punished for 2 secs. by electric shock through the water spout. ETOH (0.5-1.5 g/kg, 10% w/v, ip) increased punished drinking, although not as strongly as CDZ (4-27 mg/kg, ip). Punished drinking was unchanged by 2 g/kg and decreased by 2.5 g/kg ETOH. In surprising contrast to the antagonism of acute depressant actions of ETOH observed after TRH, TRH (20 mg/kg, ip) enhanced the anti-conflict action of ETOH (1 or 2 g/kg). TRH (20 mg/kg) also increased the anti-conflict effect of a marginally effective dose of CDZ (4 mg/kg). TRH alone produced dose related increases in punished responding over a range of doses from 5 to 80 mg/kg (ip). This effect was maximal 15 to 60 min. post injection but could also be observed 2 or 20 hours after TRH administration. Intracisternal injection of TRH (100 µg/rat) also increased punished responding, suggesting that the locus of this action of TRH may be within the CNS. d-Amphetamine (2 mg/kg, ip) antagonized the anti-conflict effect of TRH (40 mg/kg). This observation provides further evidence for the view that TRH does not share a common mechanism of action with d-amphetamine. In summary, the present results indicate that TRH has anti-conflict activity in a paradigm sensitive to the anxiolytics CDZ and ETOH, and can enhance the anti-conflict activity of these agents. Thus, these findings with TRH may be consonant with human subjective reports of "relaxation" following TRH administration (Wilson et al., Archs. Gen. Psychiat. 29:15, 1973). 1620 PENTOBARBITAL-INDUCED CROSS-TOLERANCE TO ETHANOL IS MEDIATED BY LEARNING AND NOT BY DRUG-EXPOSURE PER SE. John R. Wenger*, Pegi M. McEvoy* and Stephen C. Woods* (SPON: R.H. Lovely). Dept. of Psychol., Univ. Washington, Seattle, WA 98195

Cross-tolerance is the phenomenon wherein an organism has a decreased response to a drug as a consequence of having previously been given another drug. Cross-tolerance is a poorly understood phenomenon because the drugs used have often been believed to operate via different mechanisms. A learning interpretation of cross-tolerance can explain the phenomenon by positing compensatory skill learning in the altered physiological/psychological "state" as the common mechanism underlying cross-tolerance. A 3-group design (intoxicated practice vs. drug exposure vs. saline controls) was used to partition pentobarbital-induced cross-tolerance to ethanol into components attributable to learning and to drug exposure per se. Rats were given a 9-day series of i.p. injections using an escalating series of pentobarbital doses (ending with 18 mg/kg) or an equivolemic series of drug vehicle injections. All groups were then tested for tolerance to a 2.8 g/kg test dose of ethanol. The data indicated that all of the cross-tolerance was due to the effects of intoxicated practice (i.e., to learning). There was no support for the concept of drug-exposure-induced cross-tolerance. Moreover, subsequent testing showed that the slope of the ethanol dose-effect curve was less for the intoxicated practice group than for the other two groups (which were identical). This suggests that behavioral practice while pentobarbital-intoxicated causes a change of the receptor population acted upon by the ethanol. This is consistent with the idea that learned cross-tolerance acts via a fundamentally different mechanism than other types of tolerance. (Tolerance was operationally defined by means of the moving-belt task. Gibbins, et al. J. Pharm. Exp. Ther. 159: 236-242.1968)

1621 CAFFEINE-AMPHETAMINE INTERACTION: MULTIPLE CAFFEINE TREATMENTS ATTENUATE SUBSEQUENT AMPHETAMINE-INDUCED ACTIVITY IN RATS. Brent C. White, Karen L. Haswell*, Don Harkins, Jr.*, Cathy D. Kassab*, and Paula M. Crumbie*. Psychobiology Program, Centre College of Kentucky, Danville, KY. 40422.

Similarities and interactions between amphetamine and caffeine were studied through the locomotor activity effects of these drugs in a cross-tolerance design. Five days of twice daily injections of caffeine (30mg/Kg) significantly reduced subsequent amphetamine (1.5mg/Kg) induced activity; whereas, prior amphetamine treatment had no effect on caffeine induced activity.

The role of hepatic enzyme induction was assessed by giving amphetamine and caffeine by subcutaneous and intraperitoneal routes in a 2 x 2 x 2 factorial design (Route of injection x Caffeine x Amphetamine). Regardless of route of injection, caffeine treatment attenuated the activity level during the following 7 days of amphetamine treatment. However, route of injection was an important determinant of amphetamine activity levels across all treatment conditions, with subcutaneous injections producing more activity than intraperitoneal injections.

An additional experiment investigated the effect of prior caffeine treatment on the amphetamine dose/response curve. A general flattening of the dose/response curve would suggest a reduced sensitivity of the caffeine treated rat to amphetamine. A shift of the dose/response curve to the left would indicate an increased sensitivity to amphetamine, and a shift to the right a competitive inhibition. In this experiment, the amphetamine dose/response curve was depressed at each dose by prior caffeine treatment, indicating reduced sensitivity to amphetamine.

This series of studies has implications for several possible neurochemical systems which may account for the caffeine-amphetamine interaction. These include catecholamine metabolism, cyclic nucleotide involvement in neurotransmission, and induction of hepatic microsomal enzymes.

1622 EEG SPECTRAL CHANGES DURING 1-ALPHA-ACETYLMETHADOL (LAAM) SELF-ADMINISTRATION IN DEPENDENT RATS COMPARED TO THOSE DURING MORPHINE AND METHADONE SELF-ADMINISTRATION. Gerald A. Young, George F. Steinfels and Naim Khazan. Dept. of Pharmacol. and Toxicol., Univ. of Maryland Sch. of Pharm., Baltimore, MD 21201.

Five adult female Sprague-Dawley rats were implanted with chronic cortical and temporalis muscle electrodes and i.v. cannulae. Tolerance and physical dependence were induced by automatic hourly i.v. injections of increasing doses of morphine. The rats were then allowed to lever press on a fixed ratio 20 schedule of reinforcement in order to receive LAAM (1,2, or 4 mg/kg) to maintain dependence. Each rat had the opportunity to self-administer each LAAM dose for 6 or 7 successive days. The number of self-injections per 24 hrs were 5.8 ± 0.6, 4.3 ± 0.7 and 2.8 ± 0.5 for the 1,2, and 4 mg/kg doses, respectively. EEG samples of successive REM sleep episodes during the interinjection intervals were subjected to power spectral analyses with a Nicolet MED-80 system. Power spectra derived from REM sleep EEG samples have been shown to be associated with a predominant peak of spectral power in the theta wave range (Young et al, Pharmac. Biochem. Behav. 8: 89, 1978). During LAAM self-administration the first one or two REM sleep episodes occurring in the inter-injection interval were associated with the fastest peak EEG frequency that was observed. There was a general slowing of the predominant EEG frequency during the successive REM sleep episodes, reaching the lowest value in the last one or two episodes. However, a temporary increase in peak EEG frequency during REM sleep episodes was seen towards the middle of the interval. This non-linear trend of shifts in peak EEG frequency with LAAM is in contrast to that previously seen with morphine and methadone self-administration during which a linear slowing of the predominate EEG frequency occurred in successive REM sleep episodes (Young et al, Pharmacologist 19: 140, 1977; Steinfels et al, Fed. Proc. 37: 310, 1978). Each LAAM self-injection reinstated the faster peak EEG frequency. The majority of the lever pressing activity for all three narcotics occurred after the last REM sleep episode. These results suggest that the slowing of the peak EEG frequency may reflect declines in plasma levels of the respective narcotic or changes in the state of the CNS which precede "drug-seeking" behavior. The observed increase in the peak EEG frequency in the middle of the interval during LAAM self-administration may be related to the appearance of its active metabolites. This assumption is currently being investigated. (Supported by NIDA Grant DA 01050).

1623 URINARY MHPG AS A PREDICTOR OF TRICYCLIC-INDUCED MANIA. A.P. Zis,* R.W. Cowdry,* T. Wehr,* and F.K. Goodwin.* (SPON: Robert M. Post). Clinical Psychobiology Branch, NIMH, Bethesda, Maryland 20014 U.S.A.

Recent studies suggest that levels of urinary MHPG may predict the response of unipolar depressed patients to tricyclic antidepressants (TCA's). Specifically, low urinary MHPG is associated with responses to imipramine (IMI) and desmethylimipramine (DMI), which have predominant effects on norepinephrine reuptake; in contrast, high urinary MHPG is associated with response to the more "serotonergic" tricyclic antidepressants, chlorimipramine and amitriptyline.

This study explores the potential usefulness of urinary MHPG in predicting the response of bipolar depressed patients to TCA's. In bipolar patients, the occurence of hypomania or mania provides a particularly unambiguous marker of response. Two issues were addressed: 1) Does urinary MHPG predict the latency of clinical response? and 2) Do low and high MHPG excretors respond differentially to TCA's?

Twenty-three bipolar depressed patients were studied on an affective disorders unit at the National Institute of Mental Health. Twenty-four hour excretion of MHPG was determined while the patients were on placebo medication. Tricyclic response was assessed in a double-blind design.

There was a strongly positive correlation between urinary MHPG and latency of a hypomania or manic response (measured from the time of initiation of TCA treatment) ($r = .87$, $n = 14$, $p < .001$).

Furthermore, patients who developed severe and prolonged episodes of mania in response to IMI ($n = 5$) or AMI ($n = 1$) had low MHPG excretion. In contrast, patients with high MHPG excretion had either no response, a transient, mild hypomania, or an unequivocal therapeutic antidepressant response. Finally, high MHPG patients treated with AMI fared much better than high MHPG patients treated with IMI, a finding consistent with data from unipolar patients.

The theoretical implications of these findings regarding the postulated noradrenergic involvement in the switch process from depression into mania will be discussed.

RECEPTORS

1624 MULTIPLE HIGH-AFFINITY BINDING SITES FOR BUTYROPHENONES IN RAT STRIATUM. Anne C. Andorn* and Michael E. Maguire, Depts. of Psychiatry and Pharmacology, Case Western Reserve University, Cleveland, OH 44106.

^{3}H-Spiroperidol(3H-SP) was used to assay butyrophenone binding sites in crude membrane preparations of rat striatum. The final assay volume of 100 µl contained 3H-SP, test drugs, and approximately 0.15 mg protein in buffer. Bound 3H-SP was isolated by adsorption to glass fiber filters. Specific binding determined as the difference in the amount bound in the absence and presence of 10 µM (+)-butaclamol represented 80% of total binding. (-)-Butaclamol was without effect on 3H-SP binding at 0.1 mM. Specific binding could be competed by physiologically relevant concentrations of putative dopaminergic agonists and antagonists, serotonergic agonists, and α-adrenergic agonists and antagonists. β-Adrenergic agents, γ-aminobutyric acid, and muscarinic agents had no effect on 3H-SP binding at concentrations of 1 nM to 1 mM. Because Scatchard analysis of (+)-butaclamol competition against concentrations of 3H-SP from 0.05 nM to 50 nM was curvilinear, indicating two or more binding sites, and because a multiplicity of agents could compete 3H-SP binding, we attempted to define single binding sites by generating Scatchard plots against representatives of all pharmacologic classes that were effective competitors of 3H-SP binding. A lower affinity site (K_D > 100 nM) was not effectively competed by any of these agents. Dopamine, phentolamine, and serotonin all competed effectively for a single site (K_D = 1.5-2 nM, n = 300-400 fmol/mg) at concentrations above 10 µM. However, even at 3 mM these agents do not compete for the highest affinity 3H-SP binding site. This site is competed by spiroperidol, (+)-butaclamol, and apomorphine at 10 µM ($K_D \sim 0.1$ nM, $n \sim 75$ fmol/mg).

The ability of the above agents to inhibit 3H-SP binding to the intermediate affinity site suggests that this site may behave as a pharmacologic α-receptor, whether or not it is a physiologic dopamine receptor. The inability of dopamine to compete for the very high affinity 3H-SP site suggests that this site is not a pharmacologic dopamine receptor and that actions of butyrophenones may be mediated through a system(s) other than dopaminergic or α-adrenergic.

1625 EFFECT OF ELECTROCONVULSIVE SHOCK TREATMENT ON MONOAMINERGIC RECEPTOR BINDING SITES IN RAT BRAIN. D.A. Bergstrom*, P. Iadarola*, K.J. Kellar. Dept. of Pharmacology, Georgetown University, Schools of Medicine and Dentistry, Washington, D. C. 20007.

Chronic administration of tricyclic antidepressants and monoamine oxidase inhibitors have been shown to decrease the sensitivity of the norepinephrine-stimulated adenylate cyclase in rat brain. In addition, chronic treatment of rats with desipramine for one week or longer decreases the apparent density of β-adrenergic binding sites in rat cerebral cortex without affecting α-adrenergic or serotonergic binding sites.

Sulser and his associates have reported that daily administration of electroconvulsive shock treatment (ECT) to rats for 8 days reduces the responsiveness of the norepinephrine-sensitive cyclic AMP generating system in brain. We have investigated the effect of ECT on rat brain monoaminergic receptor binding sites.

Electroconvulsive shock (150 mA, 200 msec) was administered to rats through saline-moistened corneal electrodes. Control rats were handled in the same manner except no current was passed. Shocks were administered daily for 1, 2, and 7 day durations. All rats experienced tonic forelimb extensions, with some rats experiencing tonic hindlimb extensions. Rats were decapitated 24 hours after their last shock.

The kinetic properties of the β-adrenergic receptor binding sites were measured with (^{3}H)-dihydroalprenolol, the α-adrenergic sites with (^{3}H)-dihydroergocryptine, and the serotonergic sites with (^{3}H)-serotonin. The data were analyzed with Scatchard plots.

We found no difference in the kinetic binding properties of the β-adrenergic, α-adrenergic, or serotonergic binding sites in rat brain cortex after a 1 or 2 day electroconvulsive shock regimen. However, after 7 consecutive days of shock we found a significant decrease, approximately 30%, in the number of cortical β-adrenergic binding sites. There was no apparent change in the affinity of the binding sites for the ligand.

Antidepressant drugs and ECT produce a rapid increase in the availability of norepinephrine to post-synaptic receptors. The present findings with ECT and previous findings with chronic antidepressant drug administration suggest that the delayed onset of these antidepressant treatments may be related to an adaptation of the β-adrenergic receptor binding sites to an increased availability of norepinephrine.

1626 DISPERSAL AND REFORMATION OF ACETYLCHOLINE RECEPTOR CLUSTERS IN CULTURED RAT MYOTUBES. Robert J. Bloch. Dept. of Neurobiology, The Salk Institute, San Diego, CA 92112.

Acetylcholine receptor (AChR) clusters in the plasmolemma of rat myotubes are lost upon treatment of cultures with inhibitors of energy metabolism. This loss was not caused by a variety of other drugs, and was dependent both on inhibitor concentration and time of treatment. It was not due to loss of cells, as cell number and overall AChR titer per culture were only slightly (10-20%) reduced. Furthermore, AChR clusters on identified, living cells were seen to disperse in the absence of any gross morphological changes. Dispersal appeared to be by diffusion of small AChR aggregates away from the cluster. Upon removal of energy poisons, AChR clusters reformed. Reformation proceeded by 1) appearance of small foci of AChR aggregation in a limited region of the sarcolemma; 2) aggregation of AChR in the areas around the foci, to yield clusters or cluster pairs; 3) continued aggregation around cluster pairs to give larger single clusters. Metabolic energy appears to be required to "fix" AChR to the foci and then to surrounding regions; energy metabolism inhibitors weaken this interaction, presumably by blocking ATP biosynthesis.

1627 OPIATE BINDING TO MEMBRANE PREPARATIONS OF NEUROBLASTOMA X GLIOMA HYBRID CELLS NG108-15: EFFECTS OF IONS AND NUCLEOTIDES. A.J. Blume, G. Boone* and D. Lichtshtein* (SPON: J.H. Tarver). Department of Physiological Chemistry and Pharmacology, Roche Institute of Molecular Biology, Nutley, NJ 07110.

The binding of peptide and alkaloid opiate agonists to NG108-15 cell membranes is selectively decreased by mono-valent cations. Dihydromorphine (DHM), leu-Enkephalin (leu-E) and the stable met-enkephalin analogue D-ala^2-Met^5-amide (DAMA) binding under steady-state conditions are reduced about 50% by 135 mM Na^+ and similar inhibition is seen with Li^+, K^+ and choline, but with decreasing affinities respectively. Na^+ also increases the dissociation of leu-E and DAMA from the receptor. In contrast, none of the above cations significantly alters the binding of naloxone or naltrexone, two opiate antagonists. Certain nucleotides will also decrease DHM, leu-E and DAMA binding. The affinity of these nucleotides appears to be increased by Na^+. High nucleotide concentrations completely eliminate specific binding when Na^+ is present. In the presence of Na^+, the relative order of potency is GMP-P(NH)P≥GTP≥GDP≥ITP≥IMP-P(NH)P>>ATP = AMP-P(NH)P>GMP and half-maximal inhibition by GMP-P(NH)P occurs at 5 µM. These same nucleotides have also been found to increase the dissociation of leu-E and DAMA from the receptor. GMP-P(NH)P at 100 µM, with or without Na^+, causes only a 10% and 20% decrease in naloxone and naltrexone steady-state binding respectively. Dissociation of the opiate agonist leu-E is complex, being monophasic and relatively slow in the absence of Na^+ and GMP-P(NH)P; biphasic in the presence of either Na^+ or GMP-P(NH)P, with a portion of the ligand now dissociating rapidly; and finally, monophasic, yet rapid in the presence of both Na^+ and GMP-P(NH)P. The selective effects of Na^+ and nucleotides on opiate agonist binding are not due to the fact that opiate agonists bind to a different opiate receptor than do opiate antagonists. The affinity of DHM, naloxone, naltrexone and morphine as assessed in saturation binding experiments is found to be the same as its affinity determined from the inhibition curves of the binding of any of the other ligands, regardless of whether they are agonists or antagonists or alkaloids or peptides. Opiates, through their plasma membrane receptors, have been shown to inhibit NG108-15 adenylate cyclase. Therefore, nucleotides apparently regulate (within a single cell) receptors which inhibit and receptors which activate (i.e. PGE_1 and adenosine receptors) adenylate cyclase.

1628 NICOTINE CAUSES AN INCREASE IN SENSITIVITY TO MECHANICAL STIMULATION IN A CONTRACTILE PROTOZOAN. Peter A. Boxer* and David C. Wood. Psychobiology Program, Dept. of Psychology, University of Pittsburgh, Pittsburgh, PA 15260.

A suprathreshold mechanical or electrical stimulus triggers an action potential in the ciliated protozoan, Stentor coeruleus, which in turn elicits a contraction of the animal. The animals response to mechanical stimulation is mediated by a receptor potential. Wood (Comp. Biochem. Physiol., 56C, 151, 1977) has shown that the organism's sensitivity to mechanical stimuli can be markedly reduced by addition of 3-60μM d-tubocurarine chloride (d-TC) and several other nicotinic cholinergic antagonists. Since the effect of d-TC is specific to mechanical stimulation d-TC must bind to the site involved in mechanical stimulus transduction. Based on this specificity a [^{14}C]-d-TC binding assay for mechanical stimulus transduction sites has been developed and validated.

To complement the work on cholinergic antagonists we studied the behavioral and biochemical effects of cholinergic agonists. Upon addition of nicotine (0.5 mM) to the medium there is an initial (5-30 min) decrease in the probability of contraction to mechanical stimuli followed in 1-3 hr by a significant increase in response probability. In response to electrical stimulation stentor exposed to nicotine show a similar initial decrease in excitability, but within an hour the response probability returned to pretreatment levels and remained there. Therefore, nicotine's initial inhibitory effect can be attributed to a non-specific debilitation of the contractile response, while the increase in sensitivity is specific to mechanical stimulation.

Nicotine also appears to compete with d-TC at the mechanical transduction site. Incubation in nicotine (0.5 mM) for 1 to 3 hrs. caused a 50% inhibition in the amount of bound [^{14}C]-d-TC, while shorter incubations had little effect. Therefore there is a correlation between the ability of nicotine to inhibit the binding of [^{14}C]·d-TC and its ability to increase the sensitivity of the animal to mechanical stimuli.

Other cholinergic agonists (1.0mM Dimethylphenylpiperazinium (DMPP), 10mM Carbachol (Carb), and 10mM Tetramethylammonium (TMA)) also caused the initial drop in response probability to mechanical and electrical stimulation. Carb and DMPP also produced a small increase in probability of contraction after 1 hr. These drugs produced smaller effects on the binding of [^{14}C]-d-TC than nicotine. The finding that nicotine and other cholinergic agonists affect mechanical stimulus transduction by acting on a curariform binding site implies that this site in stentor has molecular properties somewhat analogous to those found in higher organisms and may serve as a useful, simple model system.

1629 PHARMACOKINETICS OF NEUROLEPTIC DRUGS: IN VITRO INHIBITION OF ^{3}H-SPIROPERIDOL BINDING IN SHEEP CAUDATE BY NEUROLEPTICS AND THEIR METABOLITES. David B. Bylund and Jorge Perez-Cruet*, Dept. of Pharmacology and Missouri Institute of Psychiatry, Sch. Med., University of Missouri, Columbia, MO 65212.

Many of the clinically useful neuroleptic drugs are metabolized to give derivatives which may have clinical efficacy. In order to understand the mechanisms of action of these drugs, it is important not only to have an estimate of the plasma (or even better, CNS) concentrations of the various metabolites, but also an estimate of their potency at the receptor binding sites of various neurotransmitters. Since there is pharmacological evidence to suggest that dopaminergic receptors are involved in the action of neuroleptic drugs, we have evaluated the potency of various metabolites using an in vitro binding assay.

^{3}H-Spiroperidol recently has been shown to label the dopamine receptor binding site in human, rat and calf caudate nucleus. We find that ^{3}H-spiroperidol also appears to label dopamine receptors in the sheep caudate. At 23°, ^{3}H-spiroperidol specific binding to a crude particulate fraction of sheep caudate has an apparent dissociation constant of 0.3 nM and a binding capacity of about 35 pmol/g wet weight tissue. The binding reaches equilibrium in less than 30 min and then remains constant for at least one hour. The rate constant of association is 0.1/nM/min. The concentrations of various compounds which half maximally inhibit specific ^{3}H-spiroperidol binding are given below.

Compound	IC_{50}, nM
Fluphenazine	3
Chlorpromazine	8
Thioridazine	20
7-OH-Chlorpromazine	30
Mesoridazine	30
7-OH-Fluphenazine	60
Fluphenazine Sulfoxide	200
Apomorphine	300
Methoxychlorpromazine	400
Thioridazine-S-Sulfoxide	700
Sulforidazine	3000
Northioridazine	7000
Thioridazine-R-Sulfoxide	8000

All metabolites are less active than the respective parent compounds in this in vitro assay system using dopamine receptors from sheep caudate. Since there is a good correlation between the affinity of neuroleptics for dopamine receptor binding sites and their clinical potency, these results should be helpful in determining the involvement of these metabolites in the actions of neuroleptic drugs.

1630 RATES OF METABOLISM AND SITE OF INSERTION OF A PLASMA MEMBRANE PROTEIN IN RAPIDLY GROWING NEURONS. S.T. Carbonetto* and D.M. Fambrough, (SPON: K.J. Muller). Carnegie Institution of Washington, Baltimore, Md. 21210.

We have previously demonstrated that α-bungarotoxin binds selectively to chick sympathetic neurons, that this binding is saturable (10nM) and is completely blocked by d-tubocurarine (100μM). Chick sympathetic neurons depolarize in response to iontophoretically applied acetylcholine but α-bungarotoxin does not block this response (PNAS 75, 1015, 1978) and therefore may be binding to some membrane protein other than the acetylcholine receptor. The α-bungarotoxin receptor is not extracted from the membrane by 1M NaCl or 1mM EDTA but is readily extracted by non-ionic detergents (Triton X-100, Emulphogene BC720). α-Bungarotoxin-receptor complexes normally dissociate with a half-time of 3.5 hrs at 23° but in solution they can be cross-linked by glutaraldehyde (0.1%) to form complexes that are stable for several days. Both before and after cross-linking, α-bungarotoxin-receptor complexes sediment in sucrose gradients as a single peak with a sedimentation constant of approximately 11S (compared with 10S for skeletal muscle acetylcholine receptors).

Neurons grown in medium containing "heavy" ^{2}H, ^{13}C, ^{15}N-substituted amino acids incorporate these heavy amino acids into α-bungarotoxin receptors during protein synthesis, and the resulting heavy receptors can be separated from light receptors by velocity centrifugation in 25-40% sucrose-deuterium oxide gradients. We have used this technique to study the biosynthesis and degradation of the α-bungarotoxin receptor to obtain information about the kinetics and the localization of membrane synthesis in growing neurons.

The main features of the kinetic data are that new receptor incorporation into the surface begins after a lag of 2 hrs and the half-time for directly labeling the surface population with heavy molecules is about 7 hrs. The degradation rate, obtained by monitoring the decrease in a population of previously synthesized heavy receptors is an exponential decay with a half-time of 10 hrs. The difference in the rate of synthesis and degradation is reflected in a net increase in the number of receptors during the first 3-4 days in culture.

After culturing ganglia whole, rather than as dissociated sympathetic neurons, a "halo" of axons grows from each ganglion that can be simply dissected to yield a preparation of pure axons. Initial experiments to localize receptor incorporation within this preparation indicate that up to 10 times more α-bungarotoxin receptors are incorporated into the ganglion than the axons and that the rate of incorporation of receptors, expressed as per cent of the surface population incorporated per hr, is about the same in both regions. This suggests that receptors are incorporated at several sites in the neuron and not exclusively at the growth cone.

1631 LOCALIZATION OF GAMMA-AMINOBUTYRIC ACID RECEPTORS BY [3H]-MUSCIMOL BINDING: LIGHT AND ELECTRON MICROSCOPE AUTORADIOGRAPHY IN MAMMALIAN CENTRAL NERVOUS TISSUES. Victoria Chan-Palay and Sanford L. Palay. Depts. Neurobiology and Anatomy, Harvard Medical School, Boston, MASS 02115.

Previous reports indicate that muscimol (M) is a potent gamma-aminobutyric acid (GABA) agonist. GABA receptors are visualized by autoradiographic techniques after [3H]-muscimol ([3H]-M) administration into incubated tissue slices, by in vivo injections, and to intraocular transplants in rats. [3H]-M is bound and after fixation subsequent autoradiograhic procedures allow visualization of the [3H]-M binding sites which are equivalent by all three modes of administration. The cerebellar cortex and nuclei, hippocampus, caudate nucleus and cerebralcortex have been studied. Control experiments demonstrate that [3H]-M binding is sensitive to pretreatment with guvacine and -nipecotic acid, two known GABA uptake and transport system inhibitors. Whereas cold M passes the blood brain barrier, [3H]-M does not produce visible autoradiographic label after intravenous administration. Quantitative analyses of [3H]-M autoradiographic label in the cerebellar cortex show highest amounts in the basket area around Purkinje cell somata , primary and secondary dendritic shafts. Intracortical interneurons are also labeled. Electron microscopy reveals label over the axosomatic and axodendritic synaptic membranes at these locations and over axonal membranes in the basket area where few synaptic junctions are found. In the hippocampus highest[3H]-M binding occurs in the area dentata neuropil between granule cells and in the molecular layers of the hippocampus. Cells of varying size between 20 to 40 micronmeters in diameter, non granular in morphology, possibly basket cells are also labeled. It is suggested that [3H]-M demonstrates one of a possible group of GABA receptors.

1632 GLIAL LOCALIZATION OF BENZODIAZEPINE RECEPTORS IN THE MAMMALIAN BRAIN. Raymond S.L. Chang, Vinh T. Tran, Shirley E. Poduslo and Solomon H. Snyder. Dept. Pharmacol., Johns Hopkins Sch. Med., Baltimore, MD 21205.

We have attempted to determine the localization of benzodiazepine receptors (BZR) in the brain by evaluating the influence of specific lesions and by comparing the density in the purified neuronal and glial fractions from rat brain. Lesions destroying most of the neuronal populations of corpus striatum include intrastriatal kainic acid injection, cerebral cortex ablation, hemisection rostral to substantia nigra and nigral injection of 6-hydroxydopamine. None of these lesions reduce BZR binding in the corpus striatum. In the cerebellum, the elimination of almost all the neuronal types except granule cells by intracerebellar kainic acid administration, mutation leading to loss of granule cells (Weaver mice), as well as destruction of climbing fibers with 3-acetylpyridine also fail to reduce BZR binding. The failure of lesions destroying almost all neurons in the striatum and cerebellum to decrease BZR binding suggest that BZR may be associated with glia. Direct assays of ^{3}H-flunitrazepam binding in the purified astrocytic and neuronal fractions show that both fractions display saturable binding with K_D (4 nM) similar to those found in the brain membranes. The number of binding sites is almost twice as great in astrocytic as in neuronal fractions. The drug specificity in the two fractions is similar, with IC_{50}'s of 3, 3, 20 and 1500 nM for clonazepam, flunitrazepam, diazepam and chlordiazepoxide respectively. Oligodendroglia show negligible binding. We also evaluated binding of ^{3}H-flunitrazepam in membranes prepared from C6 glioma (an astrocytoma) culture. The binding is saturable with a maximal number of binding sites of 2 pmole/mg protein, which is comparable to that found in brain membranes and with a K_D of 30 nM, which is about 10 times of that found in the rat brain membranes. The drug specificity of binding sites in the C6 glioma also differs from that of rat brain membranes to a certain extent. The IC_{50}'s of clonazepam, flunitrazepam, diazepam and chlordiazepoxide in these membranes are 5,000, 32, 28 and 22,000 nM respectively.

1633 α-BUNGAROTOXIN BLOCKS NICOTINIC TRANSMISSION IN THE AVIAN CILIARY GANGLION. V.A. Chiappinelli and R.E. Zigmond. Dept. of Pharmacology, Harvard Medical School, Boston, MA 02115

Specific, high affinity binding sites for α-bungarotoxin have recently been found in the avian ciliary ganglion (V. Chiappinelli and E. Giacobini, Neurochem. Res., in press). In order to determine whether α-bungarotoxin has an effect on chemical transmission through the ciliary ganglion, isolated ganglia were exposed to the toxin, and the response of the ganglion neurons to preganglionic stimulation was monitored by recording compound action potentials from their postganglionic nerves.

α-Bungarotoxin (10^{-6}M) completely blocked nicotinic transmission between preganglionic neurons and both the ciliary and choroid neurons of chick and pigeon ciliary ganglia. The time required for complete blockade of chemical transmission was 30-40 min for the ciliary neurons and 60-90 min for the choroid neurons. The blockade was partially reversed by prolonged washing (2-8 h).

Incubation of ganglia with d-tubocurarine (10^{-4}M) prior to the addition of α-bungarotoxin significantly reduced the duration of the washout period necessary to restore transmission. These results suggest that d-tubocurarine and α-bungarotoxin are interacting with the same receptor.

Under similar conditions, α-bungarotoxin did not block nicotinic transmission in the rat superior cervical ganglion, a finding which is in agreement with previously published reports.

The avian ciliary ganglion is the only vertebrate autonomic ganglion in which both α-bungarotoxin binding and α-bungarotoxin blockade of transmission have been shown to occur. The ganglion, therefore, provides a model system for using α-bungarotoxin to study neuronal nicotinic receptors. (Supported by NIH grant NS 12561 and training grant NS 07009).

1634 NUCLEOTIDE EFFECTS ON OPIATE RECEPTOR BINDING. Steven R. Childers and Solomon H. Snyder. Depts. of Pharmacol. and Psychiat., Johns Hopkins Sch. Med., Baltimore, MD 21205.

Guanine nucleotides play an important role in β-adrenergic systems by coupling receptors and adenylate cyclase, and by decreasing affinity of β-adrenergic agonists for receptors to produce desensitization. Blume (Proc. Natl. Acad. Sci., April, 1978) has shown that guanine nucleotides decrease receptor affinity for both opiate agonists and antagonists in brain opiate receptor binding studies. In our laboratory, guanine nucleotides have specific effects on rat brain opiate receptor binding which distinguish between opiate agonists and antagonists depending on the presence of ions in the assay medium.

In the absence of sodium, GTP is potent in decreasing agonist binding and is much less effective in decreasing antagonist binding. At 50 μM concentration, GTP decreases ^{3}H-dihydromorphine binding by 40-50%, ^{3}H-met-enkephalin by 60-70%, but ^{3}H-naloxone binding by only 15-20%. Scatchard analysis of saturation binding data reveals that the principal effect of GTP on ^{3}H-dihydromorphine binding is to reduce the number of high affinity agonist binding sites, while the effect of GTP on ^{3}H-naloxone binding is minimal, with a slight decrease in affinity detected in high-affinity antagonist binding sites. Experiments with different guanine nucleotides showed that GTP, GDP, and GMP-P(NH)P are effective in decreasing agonist binding, but GMP has no effect.

In the presence of sodium, GTP is even more effective in distinguishing opiate agonist and antagonist binding. GTP has no detectable effect on ^{3}H-naloxone binding, but decreases ^{3}H-dihydromorphine binding by 70-80% and ^{3}H-met-enkephalin binding by 90-95%. The order of potency of the various guanine nucleotides parallels that seen in the absence of sodium. These results suggest that guanine nucleotides may play an important physiological role in regulating the actions of opiate agonists. (Supported by USPHS grant MH-18501 and by USPHS postdoctoral grant MH-7329 to SRC).

1635 THE INTEGRATION OF NEURAL AND ANABOLIC STEROID INFLUENCES ON SKELETAL MUSCLE. Harold Chin*, Joseph Tropea*, Joan Warrenski* and Richard R. Almon . Division of Cell and Molecular Biology, SUNY at Buffalo, Buffalo, New York 14260.

Cell populations are presented with a vast array of small molecules that interact with receptor structures and consequently influence the behavior of this tissue. In the case of skeletal muscle, some of the most important influences come from anabolic steroids and surface acting neurotransmitters. In particular, interactions with the acetylcholine receptor population are the determinants of contraction; interactions with the Beta-adrenergic receptor population influence the strength and duration of contraction; and anabolic steroids have a substantial influence on both the character and quantity of protein synthesis in skeletal muscle. The present studies examine the characteristics of the Beta-adrenergic and cholinergic receptor populations in membranes and androgen receptor in cytosol from three unique muscles in the male rat. The first is the predominantly fast fiber, extensor digitorum longus; the second is the predominantly slow fiber, soleus; and the third is the highly androgen sensitive levator ani. The dissociation constant of ^{125}I-alpha burgarotoxin is in the order of $1x10^{-7}$ molar for all three muscles. This is in distinct contrast to the previously reported values with detergent-extracted AcCH receptor (Almon et al., Biochemistry 1974). This result supports our previous observation that the hydrophobic environment of the receptor macromolecule can significantly influence receptor binding affinity. The number of AcCH receptor sites varies amongst the three muscles from $5x10^{-14}$ moles/mg membrane protein to $2x10^{-13}$ moles/mg membrane protein. The Beta adrenergic receptor population was characterized using the ligand ^{125}I-hydroxybenzylpindolol. The dissociation constant of this ligand from the population of characterized Beta-adrenergic sites is $3x10^{-11}$ molar. The number of Beta-adrenergic receptor sites varies amongst the muscles from $1.4x10^{-M}$ moles/mg membrane protein to $5x10^{-14}$ moles/mg membrane protein. The androgen cytosol receptor population was characterized using ^{3}H-dihydrotestosterone. The results clearly demonstrate that muscle cytosol contains a population of androgen receptors which have a binding affinity and specificity comparable to the population previously characterized in prostate cytosol. The dissociation constant for ^{3}H-Dht is in the order of 10^{-9} M. Depending on the conditions, the number of sites varies amongst the three muscles from $7x10^{-15}$ moles/mg cytosol protein to $2x10^{-14}$ moles/mg cytosol protein. In addition, castration has significant and selective effects on the receptor populations in the three muscles. (This work was supported by a grant from the Muscular Dystrophy Association).

1636 BINDING OF OPIATE AGONISTS, ANTAGONISTS AND A PEPTIDE TO C57BL/6J MOUSE BRAIN HOMOGENATES. E.E. Codd and W.L. Byrne, Dept. of Biochem., UTCHS, Memphis, TN 38163.

The "opiate" receptor was first identified using a radiolabeled opiate antagonist ligand (Sci. 179: 1011-1014, 1973). Subsequently, radioreceptor assays for the opiate receptor employed as ligands opiate agonists and antagonists and peptides, with the implied assumption that they all bound to the same receptor. More recently, experiments have begun to discriminate differences between ligands in ligand-receptor interactions. [Eur. J. Pharm. 40: 241-248, 1976; Nat. 267: 495-499, 1977; Eur. J. Pharm. 41: 247-248, 1977]. The present study involves the binding of radiolabeled opiate agonists and antagonists and peptide ligands to opiate receptor(s) from the brains of an inbred strain of mice, C57BL/6J. The binding assay was performed as described previously (Prog. Neuro-Psychopharmac. 1: 259-264, 1977). The tritiated ligands used were: agonists morphine, dihydromorphine; antagonists: naltrexone and naloxone; peptide: D-ala-enkephalin-amide. Saturable binding was defined as the difference between binding in the presence and absence of 10^{-7}M of the unlabeled form of each ligand used. Scatchard plots of saturable binding were linear and indicate fewer sites for dihydromorphine than for any other ligands tested. All other ligands investigated have similar numbers of sites. Since the lower number of sites is obtained for dihydromorphine but not morphine, the difference is not common to agonists as we had previously thought (Neurosci. Abs. vol III, #1447, 1977), but appears to be a property of dihydromorphine itself. However, in a brain slice system, others have reported fewer numbers of sites for morphine than naloxone (PNAS 74: 5764-5766, 1977). Although they did not investigate other agonists or antagonists, they generalize their results with morphine and naloxone to the classes of drugs they represent. Most investigators report ED50's for the displacement of one radiolabeled drug by many other unlabeled drugs. No reports of the independent determination of the number of binding sites for several agonists and antagonists under the same conditions have been found. From the present work it would appear that there are differences in sites labeled even by drugs in the same class.

1637 β-ADRENERGIC RECEPTORS IN THE RAT HIPPOCAMPAL AND DENTATE GYRI. Keith A. Crutcher and James N. Davis. VA Hospital, Duke University Medical Center, Durham, NC 27705.

[^{3}H] Dihydroalprenolol (DHA) binds to β-adrenergic membrane receptors in the rat cerebral cortex. Recent reports that fluorescent analogues of propranolol localize to the stratum pyramidalis of the rat hippocampal gyrus prompted us to study the distribution of [^{3}H] DHA binding in the hippocampal and dentate gyri. Fresh hippocampal formations from decapitated male Sprague-Dawley rats were separated into dentate and hippocampal gyri using the hippocampal fissure as a landmark. The accuracy of this separation was confirmed by histological examination. Some of the hippocampal formations were blocked and frozen on cryostat chucks. Beginning at the alvear surface, 30 μ-thick sections were cut in parallel to the long axis of the hippocampus. Sections from stratum pyramidalis and stratum radiatum were collected using occasional sections for histological examination. Membranes were prepared from these sections and from the separated gyri for binding studies. Nonspecific binding was determined in the presence of 1 μM (±) propranolol. As in whole cerebral cortex, specific binding was 40 to 60% of total binding. [^{3}H] DHA bound to sites on membranes from both dentate and hippocampal gyri with an affinity (K_D) of 9 nM. The density of binding sites was roughly equivalent in both gyri (0.17 pmol/mg in the dentate and 0.19 pmol/mg in the hippocampus) and the ability of catecholamines to compete for [^{3}H] DHA binding was as expected for β-adrenergic receptors. [^{3}H] DHA binding in the strata pyramidalis and radiatum was also similar (28 and 23 fmol/mg respectively at 3 nM [^{3}H] DHA). These data indicate that 1) [^{3}H] DHA binding is roughly homogeneous throughout the hippocampal formation, 2) the distribution of [^{3}H] DHA binding sites does not correlate with the catecholamine innervation of the hippocampal formation, and 3) the distribution of binding sites does not suggest a concentration of β-adrenergic membrane receptors in stratum pyramidalis. (Supported by VA 1680, NIH NS13101, NS06233, AG00029).

1638 ASCORBIC ACID INDUCED DESTRUCTION OF OPIOID STEREOSPECIFIC BINDING SITES IN GUINEA PIG BRAIN HOMOGENATE. Claud E. Dunlap III* and B.M. Cox.* (SFON: D.B. Goldstein).
Addiction Research Foundation, and Department of Pharmacology, Stanford University, Palo Alto, California 94304.

L-ascorbic acid was found to reduce stereospecific binding of ^{3}H-etorphine, ^{3}H-leucine-enkephalin, ^{3}H-naloxone, and ^{3}H-naltrexone to guinea pig brain homogenate. Incubation with 1mM ascorbate destroyed 50% of ^{3}H-etorphine stereospecific binding in 50 min at 22°C, complete destruction occurring within 180 min. Stereospecific binding was not recovered following repeated washing of the ascorbate treated membranes. Dose-response curves in which tritiated ligands were added to homogenates incubated with ascorbate for one hour displayed a dose related inhibition of stereospecific binding by increasing concentrations of ascorbate up to 1mM, above which a decrease in the amount of inhibition produced by ascorbate was observed.

Inhibition of opioid stereospecific binding by ascorbate was observed to be pH dependent, with maximal inhibition occurring between pH 7.4 and 7.8. One millimolar concentrations of ascorbic acid analogs such as dehydroascorbic acid and L-ascorbic acid-2-sulfate did not affect opioid stereospecific binding. D-isoascorbic acid, however, produced dose-response curves similar to those for L-ascorbic acid. Reducing agents, including glutathione, dithiothreitol, and sodium borohydride produced little or no effect on opioid binding at concentrations of 1mM. The mechanism of ascorbate destruction of opioid stereospecific binding capacity is currently under investigation.

1639 A METHOD FOR THE OBSERVATION OF AND RECORDING FROM SINGLE CELLS OF LIVING ORGANS: A REFINEMENT OF TISSUE SECTIONING TECHNIQUES. C. Eyzaguirre, R. Gallego*, Y. Hayashida* and L. Monti-Bloch*.
Dept. Physiol., U. of Utah Coll. Med., Salt Lake City, UT 84132.

Nodose ganglia excised from cats were placed on the removable stage of a Sorvall TC-2 Tissue Sectioner and covered with 4% agar-physiological saline at 38°C. Cat carotid bodies were vascularly isolated, the vessels flushed with physiological saline and then injected with 2% agar-saline. Afterward they were removed and treated like the ganglia. The stage and either preparation were then placed in a refrigerator (about 4°C) until the agar hardened (about 10 mins). The stage and preparation were then positioned in the sectioner and sliced by the vertical strokes of a razor blade mounted on the cutting arm of the instrument. Thus, sections of 25-150 μ were obtained, removed with a thin camel hair brush and placed in a chamber through which physiological saline at 36-37°C was allowed to flow. The chamber consisted of a thin plastic frame whose bottom was a microscope cover glass glued to it. The sections were covered with an EM grid kept in place by a platinum loop, operated by a micromanipulator, exerting pressure on the grid to keep the section flat against the bottom glass. The chamber and preparation were mounted on the stage of an inverted microscope equipped with Nomarski optics. The cells were visualized and impaled with conventional microelectrodes which were slid between the condenser (working distance 6 mm) and the bath. The trajectory of the electrode was seen after closing the condenser diaphragm. Once the cell was impaled and resting potential obtained, the diaphragm was opened for proper Normaski optics and photography. Most cells in the sections survived well. For instance, ganglion cells showed normal resting and action potentials. In addition, neuron visualization and photography (at 640 X) permitted measurements of membrane constants R_m ($\Omega \cdot cm^2$) and C_m ($\mu F/cm^2$) without intracellular staining which has the disadvantage that cells may shrink during histological processing giving spurious values for specific constants. Carotid body (type I) cells could be easily seen and distinguished from other cellular elements in spite of their small size (about 10 μ). For identification of type I cells magnifications of 1600 X were employed, by using oil immersion objectives. The cells had normal resting potentials (20-50 mV) and input resistances (about 40 MΩ). They responded to temperature changes and chemical stimulation in normal fashion. At times, active nerve fibers were impaled although electrodes could not be kept inside these small fibers for long. The glomus cell-nerve ending junctions could be seen and this gives hope of studying these junctions with electrophysiological methods under visual observation. Also, this technique may be useful to others in studying different neurons or other cells. Supported by NIH grants NS 05666 and NS 07938.

1640 ^{3}H-SPIROPERIDOL BINDS TO TWO RECEPTOR SITES IN BOTH RAT FRONTAL CORTEX AND CORPUS STRIATUM. J.Z.FIELDS, N.W.PEDIGO*, T.D.REISINE, AND H.I.YAMAMURA. Dept. of Pharmacology, Univ. of Arizona Health Sciences Center, Tucson, Arizona 85724.

Spiroperidol is both a potent antipsychotic drug and a potent dopamine antagonist. ^{3}H-Spiroperidol (^{3}H-Sp)(NEN, 26.4 Ci/mmol) binds to receptor sites in the frontal cortex (FC) and corpus striatum (CS) of rat brain. In the CS, these ^{3}H-Sp binding sites have been called dopaminergic because pharmacologically active dopamine agonists and antagonists are the most potent inhibitors of ^{3}H-Sp binding. The dissociation constant (K_D) in this area, determined by kinetic experiments using the ratio of the rate constants ($^{K_{-1}}/_{K_{+1}}$) is between 10 and 20 pM. Determination of the K_D by Scatchard analyses yields an apparent K_D (K_D app) of 20 to 40 pM at a tissue receptor concentration ($[R]_t$) of 4 to 8 pM. Since the K_D app increases linearly as a function of the $[R]_t$, extrapolation ofthe K_D app to an infinitely small receptor concentration gives the "true" K_D. In rat striatal tissue the extrapolated "true" K_D is approximately 10 pM, which is in good agreement with the data from our kinetic experiments.

^{3}H-Spiroperidol binding in rat FC is complicated by the existence of two distinct receptor sites. The high-affinity ^{3}H-Sp binding site in the FC has a K_D app similar to the K_D observed in the CS (≈20 pM). However, the density of high affinity sites in the FC (≈2.5 pmol/g tissue) is 16 times less then in the CS (≈40 pmols/g tissue). The high-affinity binding site in FC is revealed only at the lower concentrations of ^{3}H-Sp used in saturation studies (less than 15 pM). Scatchard analyses of ^{3}H-Sp binding at ligand concentrations of 20 pM to 5000 pM indicate a second, low-affinity binding site with a K_D app of approximately 340 pM at an $[R]_t$ of 5 to 9 pM. The density of low-affinity binding sites in the rat FC (≈18 pmoles/g tissue) is approximately 7 times greater than the density of high-affinity sites.

In light of these data, saturation studies were done in rat CS using high concentrations of ^{3}H-Sp (up to 5000 pM). These experiments indicated that a low-affinity binding site is present in CS but at a relatively low density (≈14 pmoles/g tissue). The K_D app for this low-affinity binding site in CS is the same as the low-affinity K_D observed in the FC (approximately 330 pM at an $[R]_t$ ≈3 pM). Thus, ^{3}H-Sp appears to bind to two sites in both rat FC and CS. These binding sites have similar affinities in the two brain areas (20 pM and 340 pM), but the high-affinity site predominates in the CS while the low-affinity site is predominant in the FC. These ^{3}H-Sp binding sites may represent two types of dopamine receptors in rat brain. Alternatively, either of these binding sites may be non-dopaminergic in nature, as recently suggested by Leysen et al. (Nature 272: 163, 1978). Supported by USPHS grant 27257, by the C.C.H.D., by an RSDA(MH-00095) to H.I.Y. & USPHS (MH-05248) to J.F.

1641 A COMPARATIVE STUDY OF THE EFFECTS OF HYPOXIA ON TYROSINE HYDROXYLASE ACTIVITY IN THE CAROTID BODY OF RAT, RABBIT AND CAT. Constancio Gonzalez*, Yan Kwok*, James W. Gibb* and Salvatore J. Fidone. Dept. Physiol. and Dept. Biopharm. Sci., Univ. Utah, Salt Lake City, UT 84108.

The Type I cells of the carotid body are rich in catecholamines, particularly dopamine. However, the possible role of dopamine as neurotransmitter or modulator at the Type I cell synapse is complicated by the apparent finding that exogenous dopamine is excitatory to chemosensory activity in some species (rabbit, dog, and perhaps rat), but inhibitory in others (cat).

The activity of tyrosine hydroxylase (TH) is known to be stimulus-dependent, and a recent study by Hanbauer, Lovenberg and Costa (1977) demonstrated an induction of TH in rat carotid body at 1 and 2 days following exposure of the animals for 1 hr. to 5% O_2 (two 30 min exposures, 20 min apart). In the present study, we repeat the experiments of Hanbauer et al. in the rat, and extend them to include the carotid bodies of rabbit and cat as well.

Carotid bodies were removed from adult cats, New Zealand rabbits and Sprague-Dawley or Lewis rats. The organs were cleaned of surrounding connective tissue and homogenized in Triton X-100 (0.2%). TH activity was assayed according to the method of Nagatsu et al. (1964). The basal levels of TH activity varied widely between the different animal species. Expressed in pmols (hydroxylated tyrosine)/mg carotid body/hr., control TH values were: rat, 5247±461; rabbit, 1291±87; cat, 840±98. When the animals were exposed in a chamber to 5% O_2 for two 30 min periods, 20 min apart, and the enzyme activities assayed 48 hr. later, there was an increase in TH activity of 37% in the rat, 24% in the rabbit, and no change in the cat. In the rat, continuous exposure to 10% O_2 for 3 hr. again resulted in an increase in TH activity of 32% when assayed 48 hr. following the hypoxic episode. However, the enzyme activities were unchanged in rabbit and cat.

The delayed increase in TH activity following hypoxia agrees with the observed induction of TH reported by Hanbauer et al. However, the basal TH level which we find for rat carotid body is more than 100 times larger than the value which they reported. It is difficult to reconcile such a large discrepancy to differences in the assay method (Nagatsu vs. modified Waymire), since the TH levels which we find for rat superior cervical ganglion are similar to theirs, i.e., 6391±188 vs. approximately 4500, respectively. The absense of increased TH activity in cat carotid body following hypoxia is an interesting finding, and may be related to the apparent differences in dopamine action in the cat compared with the rabbit and perhaps rat. 1642 ^{3}H-CLONIDINE AND ^{3}H-WB-4101 BINDING TO TWO α-NORADRENERGIC RECEPTOR POPULATIONS IN PERIPHERAL TISSUES. David A. Greenberg, David C. U'Prichard and Solomon H. Snyder. Dept. Pharmacol., Johns Hopkins Sch. Med., Baltimore, MD 21205.

^{3}H-WB-4101 (25 Ci/mmole) and ^{3}H-clonidine (CLO, 26.7 Ci/mmole) bind to two different postsynaptic α-receptors in CNS (U'Prichard et al., Mol. Pharmacol., 13:454, 1977). These α-receptors may be analogous to α_1- and α_2-receptors respectively (Berthelsen and Pettinger, Life Sci., 21:595, 1977). The WB site is predominant in rat kidney, and exclusive in rat ventricle and vas deferens, where there is little or no CLO binding. WB binding in these tissues represents CNS WB binding. The antagonist ligand ^{3}H-dihydroergokryptine (DHE) binds with high affinity to both WB and CLO sites in CNS (Greenberg and Snyder, Mol. Pharmacol., 14:38, 1978). In rat kidney, heart and vas deferens, the DHE binding site appears identical to the WB binding site. Conversely, in rat salivary gland, there is CLO binding, which resembles CNS CLO binding, but no WB binding. The DHE binding site in rat salivary gland is identical to the CLO binding site. These data suggest that two populations of α-receptors, which have been found in the CNS, also exist throughout the body, and are differentially located in various tissues. (Supported by USPHS grant MH-18501 and by grants from the McKnight and Hartford Foundations).

1643 ISOELECTRIC FOCUSING VARIANTS OF THE NICOTINIC ACETYLCHOLINE RECEPTOR FROM DROSOPHILA MELANOGASTER. Linda M. Hall, Thomas H. Hudson*, Reid W. von Borstel*, Barbara C. Osmond*, and Sydney D. Hoeltzli*. Biology Department 16-711, M.I.T., Cambridge, MA. 02139.

Our laboratory is using genetic approaches to study specific molecular components of the nervous system. We are particularly interested in isolating mutants affecting the acetylcholine receptor because of the key role that this component plays in synaptic function. Previous work from our laboratory (J. Neurochem. 29, 1013, 1977) has shown that the central nervous system of the fruit fly Drosophila melanogaster is a rich source of an α-bungarotoxin binding component which has the properties expected of a nicotinic acetylcholine receptor. In the experiments to be described, we will present the techniques we are using to identify genes involved in the production of acetylcholine receptors in Drosophila. Using heads from adults of the Canton-S wild-type strain as a source of binding component, we have developed a procedure for the solubilization and isoelectric focusing of this component. We show that a complex of this component and ^{125}I-α-bungarotoxin focuses as a single peak with an apparent pI of 6.6. This is substantially more basic than the toxin-receptor complex prepared from purified acetylcholine receptors from Torpedo electroplax since this complex focuses in our system at a pH of 5.2. This isoelectric focusing procedure is being used to screen for Drosophila strains with alterations in their acetylcholine receptors. A strain (designated HR) has been identified in which the isoelectric point is shifted from 6.6 to 6.7. When extracts from the wild-type and HR stocks are mixed, two peaks are clearly distinguishable on the isoelectric focusing gels. Feeding experiments have shown that the HR strain is more resistant to nicotine than is the Canton-S wild-type strain. The alteration in pI and the nicotine-resistance phenotype could both be due to a mutation affecting the acetylcholine receptor. Genetic experiments in progress will allow us to determine if the two alterations are due to a change in the same gene product. These experiments open the way for molecular genetic analysis of the acetylcholine receptor. (Supported by Council for Tobacco Research grant No. 1126 and NSF grant No. BNS 75-22581. LMH is a McKnight Scholar in Neuroscience.)

1644 POSSIBLE EXPLANATION FOR α-TOXIN FAILURE IN BLOCKING CNS ACETYLCHOLINE RECEPTORS INFERRED FROM α-TOXIN BINDING STUDIES.
Michael R. Hanley, Edward L. Bennett, and Ronald J.Lukasiewicz.*
Lab.Chem.Biodynamics, Lawrence Berkeley Lab.,Berkeley,CA 94720 USA

Certain snake venom α-type (post-synaptic) toxins, notably α-bungarotoxin (α-Bgt), fail to block transmission at central nicotinic synapses in spite of their demonstrated potency on neuromuscular junctions. Thus, is the saturable, high-affinity rat brain binding site for radiolabeled α-Bgt related to an authentic nicotinic acetylcholine receptor (nAChR)? To directly address this issue, we have studied the binding of an [^{125}I]-labeled derivative of Dendroaspis viridis long toxin 4.7.3 (Ddt), which exhibits antagonism towards CNS nicotinic synapses, to rat brain and Torpedo californica electric tissue and compared it to that of [^{3}H]- α-Bgt. There are two [^{125}I]-Ddt sites for every [^{3}H]-α-Bgt site in both intact and solubilized rat brain membranes, but the toxin binding is 1-to-1 in intact and solublized Torpedo nAChR-rich vesicles. Unlabeled α-Bgt and Ddt quantitatively displace both the homologous and heterologous radiolabeled toxin in both tissues. Membrane-bound [^{125}I]-Ddt and [^{3}H]/[^{125}I]-α-Bgt sites from rat brain migrate together in a sucrose gradient, co-enrich on solubilization, and have a similar nicotinic pharmacology as judged from cholinergic ligand displacement potencies. Furthermore, differences in the ability of cholinergic agonists to displace [^{125}I]-Ddt and [^{3}H]-α-Bgt emerged when competition effectiveness was tested on nAChR in experimentally-stabilized high- and low-affinity states; arguing against physical overlap of α -Bgt and Ddt sites. These observations indicate: 1) α-Bgt and Ddt bind to the same nAChR in each tissue, 2) Torpedo and rat brain nAChR are significantly different on the basis of their binding sites for closely-related protein toxins, 3) the binding to additional sites in brain must be related to Ddt's physiological blocking-activity in CNS, and 4) while α-Bgt recognizes rat brain nAChR and can apparently prevent all Ddt binding (including presumptive agonist-activation sites), it fails to block agonist triggering of the receptor.

1645 THE HORMONE RECEPTOR/ADENYLATE CYCLASE SYSTEM OF HUMAN ASTROCYTOMA CELLS: DIFFERENTIAL EXPRESSION OF COMPONENTS DURING CELL GROWTH. T.K. Harden, S.J. Foster*, and J.P. Perkins*, Dept. of Pharmacology, Univ. of N.C. Med. Ctr., Chapel Hill, N.C. 27514

Cultured human astrocytoma cells (132 1N1) respond to isoproterenol (ISO) and prostaglandin E_1 (PGE_1), with marked increases in intracellular cAMP levels. The amount of cAMP that accumulates in intact cells in response to maximally effective concentrations of ISO (10 μM) and PGE_1 (10 μM) varies as a function of time after subculture of cells. ISO-stimulated cAMP accumulation increases 3-4 fold during the first 2 days after subculture, then subsequently declines to the initial (6 hr) responsiveness after 8 days of culture. In contrast, PGE_1 responsiveness gradually increases by approximately two-fold over an 8 day culture period. An analysis of the individual components of the hormone receptor/adenylate cyclase system was carried out to determine the mechanism(s) responsible for this differential expression of astrocytoma cell responsiveness to hormones. The changes in intact cell responsiveness were reflected by similar alterations in hormone stimulated adenylate cyclase activity in membrane preparations. ISO-stimulated enzyme activity increased 2-4 fold during the first 48 hr after subculture and decreased during the next 6 days to a level that was 15-25% of the peak activity. PGE_1-stimulated adenylate cyclase activity gradually increased by 1.5-3.0 fold during 8 days of culture. A small increase (1.2-1.5 fold) was observed in basal and NaF stimulated enzyme activity during the first 48 hr after subculture. The role of β-adrenergic receptors in the observed changes in ISO responsiveness was examined using ^{125}I-hydroxybenzylpindolol (^{125}IHYP) as a specific receptor ligand. The affinity (≈0.15 nM) of ^{125}IHYP for β-adrenergic receptors did not change as a function of days in culture. In contrast, the density (moles/mg protein or moles/cell) of receptors increased markedly during the first two days in culture, reaching a level that was 3-5 times greater than the receptor density observed after 6 hr of culture. During the following 6 days β-receptor density decreased, reaching a level that was 20% of the 48 hr receptor density. When cells were plated at high density (> 2×10^5 cells/cm^2), no increase in ISO-responsiveness and β-adrenergic receptor density occurred during the period immediately following subculture. Taken together these results suggest that the individual components of the hormone receptor/adenylate cyclase systems of astrocytoma cells are regulated differentially. The role of cell growth and density in this regulation of the components of the cAMP system are under further investigation. Supported by HL 22490 and GM 25163.

1646 7S NERVE GROWTH FACTOR DOES NOT BIND TO NGF RECEPTORS ON EMBRYONIC CHICK SENSORY NEURONS. RONALD M. HARRIS-WARRICK AND ERIC M. SHOOTER. Department of Neurobiology, School of Medicine, Stanford University, Stanford, California, 94305

When Nerve Growth Factor (NGF) is isolated from mouse submaxillary gland, the active protein, βNGF, is found in a complex with two other proteins, α and γ,with a sedimentation coefficient of 7S. The binding of βNGF and the 7S NGF complex to specific receptors on sensory neurons from 8-day embryonic chick dorsal root ganglia was compared to determine which molecular species of NGF interacts with the cells to elicit neurite outgrowth. When ^{125}I-βNGF is stabilized in the 7S complex by addition of a large excess of α and γ subunits (4×10^{-7}M) and zinc ion (25μM), specific binding of radioactive NGF is completely abolished. There is no binding to either the high affinity receptor, S_I (which mediates neurite outgrowth) or to the lower affinity receptor, S_{II} (with unknown function) over a wide concentration range of ^{125}I-βNGF when it is stabilized as a 7S complex. The kinetics of association of the subunits into the 7S complex were measured using CM52 columns to rapidly separate free ^{125}I-βNGF from that bound in the complex (Bothwell and Shooter, in press). The rate of complex formation is the same as the rate of reduction of binding of radioactive NGF to neuronal receptors under the same conditions. Carboxypeptidase B cleaves the carboxy-terminal arginyl residues from βNGF; the resulting bis-desarg-NGF has been previously shown to be unable to form a 7S complex with α and γ subunits. However, bis-desarg-NGF has normal biological activity and binds specifically to S_I and S_{II}. Mixture of ^{125}I-bis-desarg-NGF with excess α and γ subunits and zinc ion does not inhibit specific binding to either S_I or S_{II}. Incubation of ^{125}I-βNGF with zinc alone, or with α subunit (with or without zinc) does not inhibit binding. Incubation with γ subunit (with or without zinc) selectively inhibits binding of radioactive NGF to S_I, with no effect on binding to S_{II}. The γ subunit, an arginine esteropeptidase, does not degrade βNGF or NGF receptors on sensory neurons. The inhibition of binding to S_I is due to formation of a β-γ or β-γ_2 complex; such complexes have been shown to form under these experimental conditions (Bothwell and Shooter, in press). These results suggest that the biological role of 7S NGF is at a stage prior to interaction with responsive neurons, and that dissociation of the 7S NGF complex is required for the activation of NGF. (Supported by grants from the NIH and NINCDS.)

1647 BIOCHEMICAL AND PHARMACOLOGICAL STUDIES OF PUTATIVE ACETYLCHOLINE RECEPTORS OF INVERTEBRATES. Stephen W. Jones*, Puppala Sudershan* Katumi Sumikawa* and Richard D. O'Brien. Section of Neurobiology and Behavior, Cornell University, Ithaca, NY 14853.

Although some invertebrate tissues have long been known to be sensitive to acetylcholine and other cholinergic drugs, it is not clear whether this is due to nicotinic and/or muscarinic receptors (as in vertebrates) or to novel acetylcholine receptors (AChRs). We report here a more extensive pharmacological comparison of sites in invertebrates that bind cholinergic drugs with the classical vertebrate AChRs.

House fly heads have an α-bungarotoxin (α-BGT) binding site [FEBS Lett. 76:211 (1977)]. It is similar to that of vertebrate brain and autonomic ganglia: α-BGT binds reversibly, with nanomolar affinity and an off time of hours. The potent nicotinic agents decamethonium, hexamethonium, and succinylcholine are rather inactive, and atropine is mildly effective in blocking α-BGT binding, but the pharmacology is otherwise nicotinic.

House fly heads [J. Neurochem. 17: 1287 (1970)] and horseshoe crab axons [J. Neurochem. 29:803 (1977)] contain sites that bind both nicotinic and muscarinic agents. Both sites are present in concentrations greater (per gram tissue) than is the AChR of Torpedo electroplax. The house fly site binds decamethonium, dimethylphenylpiperazinium, benzoquinonium, hexamethonium, methacholine, and dexetimide well (>80% inhibition of 0.1 μM decamethonium binding by 10 μM drug), but also binds the anticholinesterase BW284 and hemicholinium-3. Among other effective agents are the anthelminthic drugs hycanthone (57%), pyrantel (75%), and levamisole (63%), which are thought to act by binding to the AChRs of helminths. The site in horseshoe crab axons also has a "mixed" pharmacology, but it differs in several ways from the house fly site. In particular, it binds both α-BGT and the "specific" muscarinic agent quinuclidinyl benzilate (QNB) with micromolar affinity (compared to nanomolar or better for their classical targets).

The absence of physiological evidence [but see J. Neurobio. 2:247 (1971)] makes it impossible to conclusively identify these sites as AChRs. The location of the horseshoe crab site (in axons) argues against its functioning as an AChR. The similarity of the α-BGT site to that in autonomic ganglia of vertebrates, which is not an AChR, casts suspicion on its physiological role.

1648 ALPHA-ADRENERGIC RECEPTORS IN THE RAT SUPERIOR CERVICAL GANGLION. Marian S. Kafka and Nguyen B. Thoa*. Biological Psychiatry Branch and Laboratory of Clinical Science, NIMH, Bethesda, MD 20014.

A radioactive α-adrenergic antagonist, [^{3}H]dihydroergocryptine (^{3}H-DHE) binds specifically to membranes from Sprague-Dawley rat superior cervical ganglia. The binding is saturable and reversible and the binding sites have a high affinity for ^{3}H-DHE. The binding is stereospecific as l-epinephrine (l-E) and l-norepinephrine (l-NE) inhibit binding more potently than d-norephinephrine. The binding sites are α-adrenergic as the α-adrenergic agonists l-E and l-NE and the α-adrenergic antagonist phentolamine inhibit binding potently, whereas the β-adrenergic agonist l-isoproterenol and the β-adrenergic antagonist dl-propranolol inhibit weakly. Decentralization of the superior cervical ganglia by severing the preganglionic cholinergic nerve supply resulted in a decrease in ^{3}H-DHE binding. The data suggest that there are membrane α-adrenergic receptors in the rat superior cervical ganglion and that some of the receptors are present on pre-ganglionic sympathetic nerve endings where they may participate in the regulation of neurotransmission through the ganglion.

1649 WHITE-NOISE ANALYSIS OF ELECTRORECEPTOR DYNAMICS: A CONCEPTUAL BASIS FOR THE FREQUENCY SELECTIVITY OF THE AFFERENT RESPONSE.

Howard I. Krausz and Terry A. Viancour, UTMB, Galveston, Texas and UCSD, San Diego, California.

The electric fish Eigenmannia produces a continuous, pseudo sinusoidal Electric Organ Discharge (EOD) at frequencies of 250 to 500 per second, depending on the individual. An individual has a 'signature' EOD frequency. The EOD is used for communication, and distortions of the EOD field produced by objects can be detected by the fish. Electroreceptor organs contain modified acousticolateralis receptor cells which respond to local changes in electric field intensity and regulate the spike activity of primary afferent neurons. The afferent discharge is selectively sensitive to the frequency of exogenously applied sinusoidal electric fields -- the maximum frequency sensitivity correlates with an individual's EOD frequency. The afferent discharge occurs in phase with single EOD cycles: some afferents fire a spike for each EOD cycle, others discharge for less than 60% of the EOD cycles. The afferent discharge pattern and its frequency selectivity suggests that the system may act as a linear filter followed by a spike generator with a fixed threshold.
