To test this hypothesis further, we presented white-noise modulated electric fields and averaged the stimulus waveforms that preceded each spike in the primary afferent nerve. If the hypothesis is correct, this trigger correlation or first kernel will be the impulse response of the linear filter that precedes the threshold device. When the noise stimulus was filtered by the measured kernel, a continuous signal resulted that crossed a set threshold at times nearly identical to the actual times of spike discharges. Therefore, we conclude that the first kernel represents the impulse response of the receptive processes prior to spike generation and furthermore, the close resemblence between kernel waveform and EOD waveform suggests that receptors are matched or tuned to the fishes' own EOD waveform, i.e. it is tuned to the entire waveform and not just to the repetition frequency. The frequency tuning of electroreceptors has commonly been measured with sinusoidal inputs at various frequencies, and we now report that such measurements are closely predicted by the Fourier transform of the first kernel.

1650 STATE TRANSITIONS OF A CENTRAL NICOTINIC ACETYLCHOLINE RECEPTOR: INVOLVEMENT OF THIOL GROUPS AND DIVALENT CATION SPECIFICITY. Ronald J. Lukasiewicz*, Hiromi Morimoto* and Edward L. Bennett. Lab. Chem. Biodynamics, Lawrence Berkeley Laboratory, University of California, Berkeley, California 94720.

The ability of cholinergic agonists to displace [^{3}H]α-bungarotoxin (α-Bgt) binding to nicotinic acetylcholine receptors (nAChR) from rat brain when agonist is preincubated with nAChR prior to the addition of toxin (preincubation) is increased relative to the case where toxin and agonist are added to nAChR simultaneously (coincubation). In order to elucidate the molecular mechanisms by which cholinergic agonist induces transformation of nAChR to a high-affinity form toward agonist, the role of receptor thiol groups and some effects of solvent composition in manifestation of this phenomena were examined. Reduction of nAChR thiol groups with dithiothreitol (DTT), followed by alkylation of reduced nAChR sulfhydryls with N-ethylmaleimide (NEM) prevents agonist-induced transformation of nAChR to a high-affinity state; for NEM-treated nAChR, the concentration of acetylcholine (ACh) at which half specific α-Bgt (10 nM) binding is displaced (IC-50) is 30 μM, whether or not nAChR is preincubated with agonist prior to exposure to toxin. This IC-50 value is similar to that for the transient low-affinity form of native nAChR under the coincubation condition. Oxidation of DTT-reduced nAChR thiol groups by treatment with 5,5'-dithiobis-2-nitrobenzoate (DTNB), which presumably promotes formation of nAChR-nAChR disulfide linkages, leaves nAChR in a high-affinity state for both pre- and coincubation; IC-50 is 3 μM for DTNB-treated nAChR, which is identical to that for native nAChR pretreated with ACh. The apparent affinity of ACh for DTT-treated nAChR is markedly altered, IC-50 values being ∿2 mM for coincubation. However, DTT-reduced nAChR is responsive to pretreatment with ACh, as IC-50 values are ∿50 μM for the preincubation case. Furthermore, a low-affinity state of nAChR, with IC-50 of 30 μM, is preserved in Ca^{++}-free medium. These affinity state observations hold for all cholinergic agonists tested, including ACh. In contrast, the IC-50 for d-tubocurarine competition toward 10 nM α-Bgt is identical for NEM- and DTNB-treated or native nAChR, in the presence or absence of Ca^{++}, for either pre- or coincubation paradigms. None of these treatments significantly alter the quantity of α-Bgt sites on nAChR or the affinity of toxin for receptor. These results suggest that the redox state of nAChR thiol groups and/or some primary or secondary effect(s) of Ca^{++} may mediate activation of NAChR and/or receptor desensitization, the presumed physiological correlates of these agonist-specific alterations in receptor state.

Supported in part by the Division of Biomedical and Environmental Research of DOE and by an NINCDS postdoctoral fellowship (RJL).

1651 SEROTONIN RECEPTORS COUPLED TO ADENYLATE CYCLASE IN A NEUROBLASTOMA X BRAIN HYBRID CELL LINE. John MacDermot* and Marshall Nirenberg. Laboratory of Biochemical Genetics, NHLBI, NIH, Bethesda, MD 20014.

Serotonin stimulates adenylate cyclase in neuroblastoma (N18TG2) x fetal Chinese hamster brain hybrid cells (NCB-20). The concentration of serotonin required for half-maximal stimulation (Ka) is 0.5 μM, and an increase of 75-115% in adenylate cyclase activity is produced by a saturating concentration (10 μM) of serotonin. Tryptamine, bufotenine, 5-methoxytryptamine and N,N'-dimethyl-5-methoxytryptamine also stimulate adenylate cyclase (Ka = 0.5-0.7 μM). Hill and Eadie-Scatchard analyses suggest a simple bimolecular interaction between serotonin and its receptor. An increase in adenylate cyclase activity is also produced by D-lysergic acid diethylamide, D-LSD, (Ka = 12 nM) and its analogues metergoline (Ka = 250 nM) and methysergide (Ka = 620 nM). The increase is less than half that produced by serotonin. Serotonin-stimulated adenylate cyclase is inhibited by the antagonists mianserine (Ki= 43 nM) and cyproheptadine (Ki = 95 nM). Similar Ki values are obtained for the inhibition of D-LSD-stimulated adenylate cyclase. Phentolamine and propranolol have little or no effect on the stimulation of adenylate cyclase by serotonin (Ki > 10 μM). However, the dopamine antagonists fluphenazine (Ki = 47 nM) and pimozide (Ki = 250 nM) both inhibit serotonin-stimulated adenylate cyclase. Basal and PGE_1-stimulated adenylate cyclase are partially inhibited by histamine, dopamine, norepinephrine and carbamylcholine; no effect is observed with GABA. Serotonin has little or no effect on adenylate cyclase activity of NG108-15 neuroblastoma x glioma hybrid cells. This confirms the observation that intracellular levels of cAMP are not affected by serotonin (Matsuzawa, H. and Nirenberg, M., in preparation). Serotonin depolarizes NG108-15 cells, but D-LSD neither mimics nor antagonizes this effect (Christian, C. N., et al., in press). Serotonin receptors of NCB-20 hybrid cells also mediate cell depolarization (Higashida, H., unpublished results) and in addition the activation of adenylate cyclase. These results indicate that there are two serotonin receptor functions and that they can be independently inherited in a clonal fashion.

1652 DENDROAXONIC NEUROTRANSMISSION II: EVIDENCE OF NERVE ENDING RECEPTOR SITES FOR DENDRITICALLY RELEASED TRANSMITTER.
P.L. McGeer, E.G. McGeer and V. Innanen*. Kinsmen Lab. Neurol. Sci., Dept. Psych., UBC, Vancouver, B.C. Canada V6T 1W5.

Local injections of kainic acid (KA) into the striatum of rats destroy neurons in the striatum without injuring afferent dopaminergic (DA) nerve endings. Among the neurons destroyed are GABAergic and substance P systems that project to the substantia nigra (SN). Intraventricular injections of 6-OHDA can be used to destroy DA systems selectively. Animals with these lesions were used to study the localization of muscarinic and nicotinic receptors in the striatum and DA receptors in the SN by standard binding assays with ^{3}H-QNB, ^{125}I - α-bungarotoxin (α-Btx) and ^{3}H-spiroperidol: unlabeled excess oxotremorine, D-tubocurarine and dopamine were used in the blanks. Rats were given unilateral injections of KA into the striatum followed one week later in some animals by intraventricular injections of 6-OHDA. Tyrosine hydroxylase (TH), choline acetyltransferase (CAT), glutamic acid decarboxylase (GAD), and protein, as well as QNB and α-Btx binding were measured on the individual striata. Following the lesions, ^{3}H-QNB binding correlated with both residual GAD and CAT activity in the striatum. There was no correlation of QNB binding with TH activity, although this correlated with α-Btx binding. These results suggest that muscarinic receptors in the striatum are on neuronal systems destroyed by KA-injections[1] while nicotinic receptors may exist on dopaminergic nerve endings[2]. Spiroperidol binding in the SN correlated more closely with striatal GAD than with striatal TH. The localization of DA receptors in the SN on afferent nerve endings partly destroyed by striatal injections of KA is in accord with prior reports on DA-sensitive adenylate cyclase in the SN being located on such striatal afferents[3]. Since dopaminergic nerve endings connect with cholinergic dendrites in the striatum, and GABAergic nerve endings connect with dopaminergic dendrites in the SN, these data suggest that dopamine and acetylcholine may be released from dendrites to act on receptors on axonal endings. They support morphological studies (Hattori, McGeer and McGeer, Dendroaxonic Neurotransmission I) indicating that structures suitable for synthesizing, storing and releasing these neurotransmitters are located in dendrites in the striatum and SN

1653 EFFECT OF PHOSPHOLIPASE A_2 ON ACETYLCHOLINE RECEPTOR FUNCTION IN TORPEDO CALIFORNICA MEMBRANES.
Mark G. McNamee* and Terrence Andreasen* (SPON: L. Chalupa). Dept. Biochem. & Biophys., Univ. of California, Davis, CA 95616.

A protein isolated from Naja naja siamensis venom on the basis of its phospholipase A activity inhibits acetylcholine receptor function in postsynaptic membrane vesicles from Torpedo californica. Specifically, the phospholipase A prevents the large increase in sodium efflux that can normally be induced by carbamylcholine, a receptor agonist. The phospholipase A inhibition shows the following properties: 1) it occurs at concentrations 50 times lower than the concentrations required for inhibition by α-neurotoxins; 2) the phospholipase A has no effect on the binding properties of the receptor; 3) the inhibition is abolished by removal of calcium ions; and 4) some phospholipid hydrolysis accompanies inhibition. Introduction of free fatty acids or lysophosphatidylcholine into the membranes also results in inhibition of receptor activation, although much higher concentrations than those generated in situ are required. Lysophosphatidylethanolamine does not inhibit receptor function.

The inhibition by phospholipase A_2 or by fatty acids and lysophosphatidylcholine can be completely reversed by treatment of the membranes with bovine serum albumin. Inhibition and its reversal can be directly correlated with the uptake and removal of fatty acids, using both radioactive and spin-labeled fatty acids.

It is suggested that phospholipase A_2 acts enzymatically to produce fatty acids and some lyso-derivatives that effectively uncouple ligand binding from ion permeability in the receptor containing membrane vesicles.

1654 **CHARACTERIZATION OF STRIATAL ^{3}H-APOMORPHINE AND ^{3}H-SPIROPERIDOL BINDING AND DOPAMINE SENSITIVE ADENYLATE CYCLASE ACTIVITY UTILIZING PROTOBERBERINE ALKALOIDS.**
L.R. Meyerson, B. George*, M. Abel*, H. Phillips*, V.E. Davis and Y.C. Clement-Cormier. VA Hospital, Houston, Texas 77211, Baylor College of Medicine, Houston, Texas 77025 and The University of Texas Medical School at Houston, Houston, Texas 77025.

Tetrahydroprotoberberine alkaloids contain a nitrogen atom in a fixed position (cis;gauche) to the catechol nucleus. These compounds inherently possess two isoquinoline moieties within their molecular geometry. The recent availability of several positional and optical isomers in various states of phenolic methylation and nitrogen quaternarization made it possible to further characterize the geometric, stereospecific and topographic requirements for agonist and antagonist radioligand binding to the dopamine receptor. The optical isomers of 2,3,9,10- and 2,3,10,11-tetrahydroxyberbine (THPB) and selective mono-O-methylated 2,3,10,11-THPBs were tested for their ability to displace 5nM [^{3}H] apomorphine and 0.2nM [^{3}H] spiroperidol and to inhibit adenylate cyclase activity in the presence of 100 μM dopamine. The results of these studies appear in the table below:

COMPOUND	Specific Binding EC_{50} (nM)		DA-Cyclase IC_{50} (nM)
	^{3}H-APO	^{3}H-SPIRO	
(-)-2,3,9,10-THPB	60	500	3000
(+)-2,3,9,10-THPB	500	28000	—
(-)-2,3,10,11-THPB	65	4500	1000
(+)-2,3,10,11-THPB	600	>100000	50000
(±)-10-OMe-THPB	150	4500	59000
(±)-3-OMe-THPB	150	3000	500
(±)-2-OMe-THPB	2000	1200	15000

These data indicate that the S-(-)-isomer of both THPBs was more potent than the R-(+)-isomer in displacing labelled apomorphine and spiroperidol from their respective binding sites. Selective mono-O-methylation altered the potency of these compounds to displace antagonist or agonist labelled recognition sites. It is noteworthy that these compounds were generally as potent inhibitors of dopamine sensitive adenylate cyclase activity as they were antagonists of [^{3}H] spiroperidol binding. However, these same alkaloids were considerably more potent displacing agents of [^{3}H] apomorphine. Results of additional studies employing various quaternary protoberberine and quaternary dehydroprotoberberine salts to further characterize the recognition sites of dopaminergic receptor agonist and antagonist binding will be discussed.

1655 FIBER SIZE CONTENT AND ORIGIN IN THE RAT CAROTID SINUS NERVE.
Jasleen Mishra and Arthur Hess. Dept. Anat., Rutgers Med. Sch., CMDNJ, Piscataway, N.J. 08854.

Before performing experiments involving physiological recording from the carotid sinus nerve of the rat, studies were made of the fiber size distribution and the source of these fibers. Normal nerves were studied, as well as after ganglionectomy (removal of the superior cervical ganglion for 10-12 days), severance of the ninth nerve (for 10-12 days), and section of the sympathetic chain below the superior cervical ganglion (degeneration of preganglionic fibers for 10-18 days). The normal nerve contains about 50-60 myelinated fibers in some rats, up to 150 myelinated fibers in others, probably depending on size and age. The myelinated fibers are scattered throughout the nerve. Most are fairly uniform in diameter and are about 2mμ. The 5-10 larger fibers are about 4-5mμ in diameter and appear more or less segregated in a peripheral area of the nerve. There are about 500-550 non-myelinated fibers. Most of these occur alone in their own Schwann cells and are about 1-1.5mμ in diameter. Smaller non-myelinated fibers (0.3-0.5mμ in diameter) occur in bundles of 3-8 and share a Schwann cell. There are about 20 of these bundles scattered throughout the nerve. It is suggested that the smaller non-myelinated fibers sharing a Schwann cell are sympathetic in origin and are postganglionic fibers arising from cell bodies in the superior cervical ganglion. The larger non-myelinated fibers appearing individually in a Schwann cell are the sensory distal processes of petrosal ganglion cells. Preliminary studies indicate thus far that the bundles of non-myelinated fibers degenerate after ganglionectomy, while the individually ensheathed non-mylinated fibers degenerate after section of the ninth nerve. A combination of operations (ganglionectomy and section of the ninth nerve) results in degeneration of almost all fibers. However, consistently thus far, about 1/3 of the population of myelinated fibers 2mμ in diameter are still present, scattered throughout the nerve and apparently surviving the surgical procedures; the origin of these fibers remains obscure. Section of preganglionic fibers to the superior cervical ganglion results in no degeneration of myelinated or non-myelinated fibers; hence, no preganglionic fibers arising from the spinal cord or fibers having their origin in sympathetic ganglia below the superior cervical ganglion are present in the carotid sinus nerve.

(Supported by NIH RR05576.)

1656 DEVELOPMENTAL STUDIES OF α-BUNGAROTOXIN BINDING SITES IN MAMMALIAN BRAIN. Barbara J. Morley and George Kemp*, Neurosciences Program, University of Alabama in Birmingham, Birmingham, Alabama, 35294.

α-bungarotoxin, (BTX), a specific marker for the nicotinic acetylcholine receptor (nAChR) in skeletal muscle, has been employed to investigate the possibility of these receptors in mammalian brain. Approximately 2-3 pM toxin sites/g wet weight is found in adult brain, with large variation among several brain areas (e.g., Morley et al, Brain Res. 134: 161-166, 1977). Although these binding sites are associated with other cholinergic markers, their function(s) in nervous tissue have not been demonstrated.

Little is known concerning their rate of appearance during development in mammalian brain. One report (Salvaterra & Moore, BBRC 55: 1311-1318, 1973) has suggested that these sites are present in newborns, increases gradually in the cortical/forebrain areas, and reaches adult levels by about 10 days.

We now report a thorough study of BTX binding sites in rat brain during development utilizing a biochemical assay for I^{125} BTX. In addition to large regions (cortex, forebrain, brainstem, cerebellum), selected areas throughout the brain (e.g., olfactory bulbs, inferior colliculus, superior colliculus, raphe, reticular formation) were also investigated from days 1-60 postnatal. In the newborn rat the whole brain levels of BTX binding sites was high (1.5 pM BTX sites/g wt.; .04 pM/mg pro.). The concentration found in cortex and forebrain were similar (approximately 1.2 pM/g wet wt.; 0.36 pM/mg pro.). The concentration in brainstem is very high (1.8 pM/g wt.; .06 pM/mg pro.).

In general the development of BTX sites follows a caudal-rostral pattern and appears to increase gradually during postnatal development in all nuclei. Both rostral and caudal areas contain adult levels of BTX binding by 10 days. Pharmacological studies have not revealed any differences in the inhibition of toxin binding by cholinergic ligands throughout development, suggesting that there is no change in the conformation of receptors postnatally.

Data on the prenatal appearance of BTX binding sites in rat, rhesus monkey, and human will also be presented.

It is hoped that the relationship of toxin binding sites to the development of synapses and other cholinergic markers will shed light on its possible role in the formation and/or maintenance of synapses.

1657 BETA-ADRENERGIC RECEPTOR IN MAMMALIAN CHOROID PLEXUS. James A. Nathanson. Dept. Neurology, Yale Medical School, New Haven, Ct. 06510.

The choroid plexus plays an important role in cerebrospinal fluid (CSF) production but, as yet, control mechanisms for CSF secretion by the choroid are poorly understood. This organ receives adrenergic innervation, and it has been reported that intraventricular cholera toxin, a known activator of adenylate cyclase, increases the rate of CSF production. These facts raise the possibility for an involvement of cyclic AMP in the control of CSF production.

The present study reports the identification of a beta-adrenergic-sensitive adenylate cyclase in broken cell preparations of choroid plexus from several mammalian species. This enzyme is markedly stimulated by low concentrations of isoproterenol (K_a= 2 X 10^{-7}M) and norepinephrine (K_a= 2 X 10^{-5}M) but is only poorly activated by phenylephrine, an alpha-adrenergic agonist. Maximal stimulation by isoproterenol in cat choroid plexus is as much as 800% of basal activity, and the enzyme shows a regional distribution within the choroid. Isoproterenol activation is inhibited by propranolol but not by phentolamine or fluphenazine. This, plus other data, distinguish beta-adrenergic-sensitive adenylate cyclase from dopamine- and histamine-sensitive adenylate cyclases, also present in broken cell preparations of choroid plexus.

Because of the known intimate association of adenylate cyclase with certain hormone receptors, these data support the existence of specific β-adrenergic receptors in mammalian choroid plexus. The cellular localization and possible significance of these receptors in CSF secretion will be discussed.

1658 ACETYLCHOLINE (AcCh) AND LOCAL ANESTHETIC BINDING PROPERTIES OF TORPEDO CAL. NICOTINIC POST-SYNAPTIC MEMBRANES AFTER REMOVAL OF NON-RECEPTOR PEPTIDES. Richard R. Neubig*, Elizabeth K. Krodel*, Jonathan B. Cohen. Dept. Pharmacol., Harvard Med. Sch., Boston, MA 02115.

Comparison of the polypeptide composition of post-synaptic membranes isolated from Torpedo electric tissue with that of the nicotinic cholinergic receptor (AcChR) isolated in detergent solution from that tissue has revealed that the major difference resides in a 43,000 dalton peptide (43K) present in the membranes, but absent in the isolated AcChR (Sobel et al., Eur. J. Biochem. 80:215 (1977)). The 43K protein is distinct from the 40,000 dalton peptide known to contain the site of binding of cholinergic ligands and α-neurotoxin. In order to analyze the possible functional role of the 43K protein in the post-synaptic membrane, we developed a procedure to extract quantitatively the 43K protein and other minor non-receptor peptides while preserving the fundamental structural integrity of the membrane.

Analysis by dodecylsulfate/polyacrylamide gel electrophoresis of the peptide composition of the 43K-depleted membrane established peptide components of 40, 50, and 66,000 daltons, peptides characteristic of isolated AcChR. The 43K-depleted membranes contained 40% of the protein and 80-90% of the initial [^{3}H]-AcCh binding sites. Functional integrity of the 43K depleted membranes was measured by: (1) an analysis of the kinetics of binding of [^{3}H]-AcCh; (2) the effect of local anesthetics on that binding; (3) a determination of the number and affinity of specific binding sites for the local anesthetic [^{14}C]-trimethisoquin. By these three criteria, the ligand binding properties of the 43K depleted membranes were unaltered relative to the control membranes. For example, for both the control and 43K depleted membranes, the kinetics of binding of [^{3}H]-AcCh (35nM) with a suspension 50nM in binding sites was characterized by a biphasic reaction: 45% of the binding occurred with a half time of 45 sec. However, in the presence of 10μM dimethisoquin the AcCh binding attained equilibrium in less than 5 sec. Furthermore, for both 43K depleted and control membranes, the [^{14}C]-trimethisoquin was bound with a dissociation constant K_D=1μM when all AcCh binding sites were occupied by carbamylcholine, and the bound anesthetic was displaced by micromolar concentrations of histrionicotoxin (HTX).

It is concluded that the 43K protein is unrelated to the site of binding of local anesthetics or HTX, which must be associated with one of the remaining peptides. Flux studies will specify whether the cholinergic ionophore remains functional in these membranes.

Supported in part by USPHS grants NS 12408, GM-02220, and by MDAA fellowship to EKK.

1659 CHARACTERIZATION OF THE α-BUNGAROTOXIN BINDING COMPONENT OF GOLDFISH BRAIN. R.E. Oswald*, J.T. Schmidt and J.A. Freeman. Depts. of Biochem. & Anat., Vanderbilt Univ. Med. Sch., Nashville, TN.

Previous work has indicated that the nicotinic cholinergic receptor protein (AChR) might have a role in the maintenance of synaptic connections in the optic tectum (Freeman, Nature, 269, 218 (1977)). Schmidt and Freeman (in preparation) have demonstrated that visual responses in goldfish tectum are abolished by α-Btx. We have undertaken the biochemical characterization of the kinetic and molecular parameters of the goldfish brain nicotinic AChR using ^{125}I-α-Btx. The distribution of receptors was studied using light autoradiography. Equilibrium binding of α-Btx to goldfish brain synaptosomes revealed a single-class of toxin-binding sites with a dissociation constant of 0.92 ± 0.02 nM. Kinetic studies, however, revealed that the binding is more complex. Although a single association rate constant (3.46 ± 0.39 x 10^5 M^{-1} sec^{-1}) is observed, α-Btx exhibits a biphasic dissociation curve. The fast dissociation rate constant (6.6 x 10^{-4} sec^{-1}) is exhibited by approximately 20% of the sites; whereas, 80% of the sites have a slow dissociation rate constant of 4.3 x 10^{-6} sec^{-1}. Dissociation constants calculated from the kinetic constants are 1.9 nM for the low affinity site and 12.5 pM for the high affinity site. The binding of α-Btx exhibits nicotinic pharmacology as evidenced by the following K_I's for cholinergic ligands: d-tubocurarine=10.7 nM, nicotine=36.3 nM; carbamylcholine=1.3 uM; hexamethonium=11.2 uM; and atropine=0.10 mM. The toxin receptor complex is readily solubilized by treatment with 1% Triton X-100. Preparative isoelectric focusing of the toxin-receptor complex yields an isoelectric point of 5.01 ± 0.01. Gel filtration on Sepharose 4B gives a Stokes radius of 88.1 ± 1.2Å and a diffusion constant of 2.4 x 10^{-7} cm^2/sec for the toxin-receptor-detergent complex. Sedimentation velocity experiments in sucrose-H_2O and sucrose-H_2O gradients yield a sedimentation constant of 11.3 S and a partial specific volume of 0.76 cm^3/g. The molecular weight of the toxin-receptor-detergent complex was calculated to be 470,000 daltons, assuming a partial specific volume of 0.735 cm^3/g for the protein portion of the complex, 15% (w/w) or the complex is detergent and 85% is protein. Thus, the molecular weight of the toxin-receptor complex was 400,000 daltons. Using light autoradiography, the optic tectum was observed to contain the greatest concentration of toxin-binding sites. The receptors were distributed in specific lamina with the greatest concentration localized in the layers of optic projection. Thus, the goldfish brain contains an α-Btx binding protein similar in most respects to the nicotinic AChR of electroplax and muscle. A large proportion seems to be in the optic tectum associated with the retinotectal projection.

1660 MECHANICAL PROPERTIES OF THE INTRAFUSAL MUSCLE OF MAMMALIAN MUSCLE SPINDLES. R. E. Poppele, W. R. Kennedy, and D. C. Quick,* Laboratory of Neurophysiology and Department of Neurology, University of Minnesota, Minneapolis, Minnesota 55455

Properties of muscle spindle behavior including sensitivity and adaptation have been assumed to be explainable by the mechanical properties of intrafusal muscle. We have investigated the role of intrafusal muscle in determining the steady-state sensitivity of spindle receptors. Small stretches ($\leq$ 100 μm) were applied to isolated muscle spindles removed from cat tenuissimus muscle for various steady-state lengths of those spindles. The sensitivity of both the primary and secondary endings was greater in stretched spindles than in relaxed ones.

We measured the steady-state strain of intrafusal muscle in sensory and non-sensory regions of the spindles as the incremental length change per unit length induced by the applied stretch. We found that there was a proportional relationship between sensory strain and receptor sensitivity. By comparing intrafusal strain of the sensory and non-sensory areas with and without the spindle capsule, we conclude that the spindle capsule does not contribute to the observed non-linearity. Further measurements of steady-state tension indicated that there is a non-linear stiffness of the striated portions of the intrafusal muscle which can quantitatively account for the increased sensitivity in a stretched spindle. Therefore, we propose that the sensory endings act as proportional strain gauges in transforming steady-state stretches of the sensory endings into receptor potentials. (Supported by NSF grant #76-10791 and USPHS grant NS 109690-04.)

1661 DISSOCIATION BETWEEN THE PRESYNAPTIC DOPAMINE SENSITIVE ADENYLATE CYCLASE AND ^{3}H-SPIPERONE BINDING SITES IN RAT SUBSTANTIA NIGRA. Maryka Quik*, Piers C. Emson*, Eileen Joyce* and Leslie L. Iversen. MRC Neurochemical Pharmacology Unit and Dept. of Experimental Psychol., University of Cambridge, Cambridge, England.

Seven or 14 days after lesions which destroyed various components of the striato-nigral system, ^{3}H-spiperone binding and dopamine (DA)-sensitive adenylate cyclase were measured in rat substantia nigra. Hemisections, which resulted in an approximately 70% decrease in tyrosine hydroxylase (TH), cyclic nucleotide phosphodiesterase (PDE) and glutamate decarboxylase (GAD), led to a 50% decline in ^{3}H-spiperone binding and an almost complete disappearance of DA-sensitive adenylate cyclase. 6-Hydroxydopamine injection into the substantia nigra, which depleted TH in the substantia nigra by 85%, whilst leaving PDE and GAD unaffected, resulted in a 40% decrease in ^{3}H-spiperone binding but no change in DA-sensitive adenylate cyclase. Intrastriatal injections of kainic acid did not alter TH in the substantia nigra, but decreased both GAD (54%) and PDE (68%); ^{3}H-spiperone binding was unaffected by this lesion, while the DA-sensitive adenylate cyclase was greatly reduced (50 to 75%). These results suggest that within the substantia nigra the DA receptor sites defined by using ^{3}H-spiperone are located mainly post-synaptically, while the DA-sensitive adenylate cyclase is bcated pre-synaptically.

1662 PRE- AND POSTSYNAPTIC LOCALIZATION OF NEUROTRANSMITTER RECEPTORS IN THE RAT CORPUS STRIATUM. T.D.Reisine, J.I.Nagy, H.C.Fibiger and H.I.Yamamura. Univ. of Arizona, Col. of Med., Tucson, AZ 85724 and Division of Neurosci., Univ. of Brit. Col., Vancouver B.C. Canada

Presynaptic neurotransmitter receptors have been hypothesized to be localized on dopaminergic (DA) nigral-striatal pathways (NSP). Neurotransmitter receptor binding assays in rats injected with 6-hydroxydopamine (6-OHDA)(into the lateral hypothalamus which destroys the NSP)may help to elucidate the existence of these presynaptic receptors. Dopaminergic (^{3}H-spiroperidol), muscarinic cholinergic (^{3}H-quinuclidinyl benzilate,QNB) and beta-adrenergic (^{3}H-dihydroalprenolol, DHA) receptor binding assays were done on the corpus striatum(CS) and substantia nigra (SN) of 30 day 6-OHDA treated rats. Tyrosine hydroxylase activity and dopamine levels in the CS were dramatically reduced in these animals (>90%). In the CS of these treated rats, we found a significant 20-30% increase in the Bmax of ^{3}H-spiroperidol binding with no alterations in ^{3}H-QNB binding. There was,however, a significant 30% decrease in the Bmax of ^{3}H-DHA binding within the CS of these treated rats. There was also a significant 40% decrease in ^{3}H-spiroperidol binding within the SN of 6-OHDA treated rats. These data indicate, a denervation supersensitivity of postsynaptic DA receptors within the CS, a lack of presynaptic muscarinic cholinergic receptors on the NSP and the possible existence of beta-adrenergic receptors on the NSP. The decrease in ^{3}H-spiroperidol binding within the SN of 6-OHDA treated rats indicates the existence of DA receptors on DA perikarya or dendrites. Supported by USPHS grants and RCDA.

1663 RECEPTORS APOUND VERTEBRAE IN THE CAT NECK. F.J.R. Richmond, D.A. Lakanen and V.C. Abrahams. Department of Physiology, Queen's University, Kingston, Ontario, Canada. K7L 3N6.

A variety of neck reflexes and clinical disorders have been thought to involve "joint" receptors of upper cervical vertebrae, but the morphology and distribution of receptors which might sense vertebral position have not been described. To provide this information, serial sections were made through whole decalcified vertebrae whose muscle and connective tissue attachments were preserved. The muscles, interspinalis,transversospinalis and intertransversarii which have both their origins and insertions on vertebral processes were reconstructed and their receptor contents were mapped. Spindles were particularly numerous in perivertebral muscles, where they commonly occurred in large chain-like complexes of several spindles extending for almost the whole muscle length. In these complexes up to 5 spindles may be seen in juxtaposition at a single level of section. Occasional spindles formed parallel conjunctions or included an extrafusal fibre within their capsules.

Golgi tendon organs were common at musculotendinous junctions, where they were often associated with spindles and/or small pacinform corpuscles. No Ruffini corpuscles were seen but this negative result may relate to the difficulty in distinguishing this receptor in transverse sections. Numerous small nerves coursed within loose connective tissue particularly near blood vessels. However nerves were not observed in highly structured tendon or synovial linings. The obvious receptors of the neck were thus not joint receptors but muscle receptors in perivertebral muscles around vertebral articulations.

1664 BENZODIAZEPINE RECEPTOR BINDING IN 'EMOTIONAL' AND 'NON-EMOTIONAL' RATS: A BIOLOGICAL BASIS FOR ANXIETY?
Harold A. Robertson*, John C. Candy* and Ian L. Martin*
Univ. Lab. of Physiol., Oxford and MRC Unit of Neuropharmacology, Med. Sch., Birmingham, England. (SPON: R.A. Leslie)

The presence of brain-specific benzodiazepine receptors is now established and there is a significant correlation between the affinities of various benzodiazepines for the receptor in rat brain and the anxiolytic efficacy of these benzodiazepines. We have examined benzodiazepine receptor binding in 9 regions of the CNS of 2 inbred strains of rats, the Maudsley Reactive (MR) and Maudsley Non-Reactive (MNR) strains. These strains have been selectively bred for high (MR) and low (MNR) fearfulness and there is much support for the contention that they represent extremes of emotional behaviour. Measurement of specific ^{3}H-diazepam binding (at 2nM ^{3}H-diazepam concentration) revealed a differential regional distribution of binding sites with highest binding in the cortex and lowest in the thoracic spinal cord.

In every brain region examined, the NMR rats showed higher specific benzodiazepine binding than the emotional MR animals although this difference was only statistically significant in the hippocampus, hypothalamus, mid-brain, medulla-pons and thoracic spinal cord. There was no significant difference in benzodiazepine binding between the 2 strains in cortex, entorhinal cortex, striatum or cerebellum. Scatchard analysis of binding activity in hippocampus of the 2 strains indicates that the increased binding seen in the MNR rats is due to an increase in the number of binding sites rather than a change in the affinity of the receptor for the ligand.

There would now appear to be reasonable evidence that the anxiety-lessening effects of the benzodiazepines are due to the interaction of benzodiazepines with the benzodiazepine receptor. Our finding of a difference in benzodiazepine receptor binding between 2 strains of rats representing extremes of emotionality may provide a biological basis for an understanding of emotional behaviour based on alterations in the benzodiazepine receptor and, possibly, in changes in an endogenous ligand for this receptor.

1665 PUTATIVE HEPATIC SODIUM RECEPTORS ACTIVATE NEURONS IN THE VENTRAL BASAL THALAMUS.
Richard C. Rogers*, Donald Novin, and Larry L. Butcher. Brain Research Institute, UCLA, Los Angeles, CA 90024.

Recently there have been several reports concerning the existence and function of hepatic sodium and/or osmoreceptors. Furthermore, it appears that the major afferent nerve carrying such information to the brain is the vagus, since its resection eliminates the physiological and behavioral effects of hepatic osmotic or ionic stimulation.

Although the central pathways carrying this information are presently unknown, Norgren and Leonard (J. comp. Neurol. 166: 17, 1976) hypothesized that taste pathways and visceral afferent pathways share the same anatomical structures, which include the n. tractus solitarius, parabrachial nucleus, and ventral basal thalamus.

Our most recent experiments provide information concerning both the afferent hepatic pathway and the transduction mechanism involved in hepatic-afferent, sodium ion sensitivity.

Both the portal vein and vena cava of rats were cannulated and small volumes, 0.1-0.2 ml, of either water or twice-isomotic NaCl, choline chloride, mannitol, or sucrose was infused simultaneously such that the ionic/osmotic challange was limited to the hepatic circulation. Cells in the anterior ventro-basal complex responded to hepatic infusions of NaCl or choline but not to mannitol or sucrose. Given that the electrogenic Na+-K+ pump is inhibited by both Na+ and choline, this finding lends support to the view that some chemoreceptors may involve the electrogenic cation pump.

Following the electrical recording experiments small amounts of horseradish peroxidase were iontophoresed through the glass recording electrode. With restricted injections of peroxidase (halo diameter < 100 μm) retrogradely labeled neurons appear only in the parabrachial nucleus, a finding that supports the hypothesis of Norgren and Leonard (above ref.). [This research supported by USPHS grants NS 7687 to DN and NS 10928 to LLB]

1666 HIGH AFFINITY DIMETHYLTRYPTAMINE BINDING TO RAT BRAIN MEMBRANES.
Helen Rosengarten* and Arnold J. Friedhoff. Millhauser Labs, Dept. Psychiatry, NYU Medical Center, New York, NY 10016.

Postsynaptic membranes of rat brain were found to bind dimethyltryptamine. Binding of ^{3}H-DMT to a Whittaker membrane preparation was relatively rapid, saturable, reversible, and did not chemically alter the ligand. Scatchard plots revealed both high and low affinity binding sites for DMT. In this report we describe detailed properties of the binding of ^{3}H-DMT to membranes of rat brain.

1667 CHARACTERIZATION OF BRAIN MEMBRANE BINDING SITES FOR [^{125}I]$_2$-α-BUNGAROTOXIN AND [^{3}H]-QUINUCLIDINYL BENZILATE.
Paul M. Salvaterra and Dee Ann Matthews. Div. Neurosci., City of Hope Nat'l. Med. Ctr., Duarte, CA 91010.

As a preliminary step in designing effective experimental protocols for isolation of purified synaptic membranes we have studied the effects of various physical, chemical and enzymatic treatments on the particulate binding sites for [^{125}I]$_2$-α-bungarotoxin (α-BuTX) and [^{3}H]-Quinuclidinyl benzilate (QNB).

Membranes were prepared from rat forebrains by a modification of a combined floatation-sedimentation sucrose density gradient procedure (Jones and Matus, Biochem. Biophys. Acta 356:276, 1974) using a fixed angle rotor. This procedure yields a synaptic plasma membrane enriched fraction as judged by electron microscopy and enzymatic activity (5-7 fold enrichment of Na^+ - K^+ATPase). The specific activity of α-BuTX and QNB binding was enriched 3-4 fold over a total particulate fraction with a 15-25% yield of the binding sites.

Treatment of the membranes with reducing agents such as β-mercaptoethanol and dithiothreitol (DTT) (10^{-2}-10^{-4}M) had little effect on QNB binding. β-mercaptoethanol had only a slight inhibitory effect on α-BuTX binding while DTT treatment showed a dramatic increase in toxin binding possibly due to intermolecular crosslinking of the toxin to membrane proteins. Chelating agents (EDTA and EGTA) show only a slight inhibitory effect on binding at concentrations up to 10^{-2}M. The alkylating agent N-ethylmaleimide shows no effect when used alone but results in a complete loss of binding when used after prior reduction of the membranes with β-mercaptoethanol. Both binding sites are resistant to treatment of the membranes with trypsin, bacterial protease, and DNAse I. Treatment of the membranes with certain phospholipases results in a marked reduction in detectable binding sites. The effects of one phospholipase, β-bungarotoxin were studied in more detail. The decrease in binding due to this protein may not be explained entirely by its enzymatic activity since similar inhibitory effects were seen when the membranes were treated under conditions where it should be enzymatically inactive (ie: no Ca^{+2}, replacement of Ca^{+2} with Sr^{+2}, addition of EGTA to the incubation mixture). Membranes could be prepared at room temperature or 4° with little effect on the binding. Nearly identical results were also obtained when membranes were subjected to several freeze thaw cycles or sheared in a polytron rather than handled with more gentle homogenization techniques. (Supported by NIH 1 RO1 NS13813-01).

1668 THE USE OF FLUOXETINE IN THE BINDING ASSAY FOR SEROTONIN RECEPTORS. Daniel D. Savage*, Alan Frazer* and Joe Mendels* (SPON: B. Weiss). Dept. Pharmacol., Univ. of Penna. and Veterans Administration Hospital, Phila., Pa. 19104.

Because of the possibility of abnormalities in central serotonergic activity in affective disorders, it was of interest to study the effects of antidepressant treatment on 5-hydroxytryptamine (serotonin) receptors using the receptor binding assay developed by Bennett and Snyder, (Mol. Pharm. 12:373, 1976). It was noted that when crude mitochondrial fractions prepared from rat cerebral cortex were incubated for 15 min. at 30° with concentrations of ^{3}H-serotonin (^{3}H-5HT) up to 40nM, saturation of specific binding did not occur. Analysis of these data by the method of Scatchard indicated two populations of binding sites. The apparent binding constant (K_D) and maximum specific binding capacity (V_{max}) of the higher affinity site were 7.0 ± 0.25nM and 178 ± 14fmole/mg protein respectively, (N=4). For the lower affinity site, the K_D was 38 ± 4.2nM and the V_{max} was 453 ± 25fmoles/mg protein, (N=4).

The effect of fluoxetine, a specific serotonin uptake inhibitor, on ^{3}H-5HT binding was examined to investigate whether the lower affinity site was some form of a binding site for serotonin uptake. Fluoxetine in concentrations up to 0.5µM, produced no inhibition of binding of 5nM ^{3}H-5HT. However, when this concentration of fluoxetine was used in studies measuring the binding of ^{3}H-5HT at concentrations up to 40nM, only a single population of binding sites was obtained. The K_D and V_{max} of this binding site were 7.7 ± 0.35nM and 170 ± 8fmole/mg protein, values not significantly different from those of the higher affinity site measured in the absence of fluoxetine. When binding analyses were performed at <1°, only a single population of higher affinity sites were present, whether measured in the absence or presence of fluoxetine.

These data indicate that fluoxetine prevents binding of ^{3}H-5HT to a lower affinity population of binding sites, the characteristics of which are under investigation. The binding sites for ^{3}H-5HT measured in the presence of fluoxetine exhibit the selectivity characteristic of serotonin receptors as evidenced by the order of potency of the following drugs in displacing ^{3}H-5HT: serotonin>d-LSD>5-methoxytryptamine>>tryptamine>methysergide> cyproheptadine>>5-hydroxytryptophan, phentolamine, haloperidol, dopamine, norepinephrine, isoproterenol. (Supported by Research Funds from the Veterans Administration, NIMH Grant MH29094, and USPHSGM 07302).

1669 ELECTROPHYSIOLOGIC EVIDENCE THAT RETINOTECTAL TRANSMISSION IN THE GOLDFISH IS NICOTINIC CHOLINERGIC John T. Schmidt and Robert E. Oswald*, Depts. of Anatomy and Biochemistry, Vanderbilt Univ. School of Medicine, Nashville, TN 37232

Last year's report (Abst.#276) demonstrated three layers of optic input to the goldfish tectum using the anatomical technique of cobalt filling: the superficial gray and white layer (with superficial satellite band), the middle of the central gray layer, and the deep white layer. These correspond to three classes of optic fibers by conduction velocity: two faster ones in the dense superficial band and the slowest in the two sparse deeper bands. Postsynaptic components elicited by optic nerve stimulation were analyzed via the current source density technique: field potentials were recorded at depth intervals of 25µm, averaged on a PDP-12 computer, and their second differences were computed to localize the depths of the sources and sinks of synaptic current. Using this technique, the effects of various nicotinic agents on retinotectal transmission were studied. Alpha-bungarotoxin, when topically applied in Ringers, had no effect even at 10^{-5}M; but when injected into the tectal layers via a micropipette (low pressure, volumetric, with tip size <10µm), it quickly and irreversibly blocked all three components. Control injections of Ringers had very little or no effect on the waveforms or sources and sinks with low pressures (<180mm Hg). Since this system allowed local treatment and did not saturate the tissue, it was used with other nicotinic agents where a return to control was necessary. Acetylcholine (10^{-4}M) greatly diminished the size of all three components of the response. BW284C51 (10^{-4}M), an anticholinesterase, both diminished the size of all three components and prolonged their time course. Curare (10^{-3}M) greatly reduced or abolished the faster two components, but enhanced and greatly prolonged the time course of the slower deeper component. This may reflect either anticholinesterase activity or the elimination of an inhibitory intratectal circuit from the faster optic components. Carbamylcholine (10^{-3}M), an agonist, severly decremented all responses, moreso than acetylcholine but presumably via the same mechanism of receptor desensitization. Atropine (10^{-3}M), a muscarinic antagonist, had no apparent effect at all. The responses are being further tested for sensitivity to other nicotinic agents.

1670 STUDIES OF RECEPTOR BINDING AND CYCLIC AMP SYNTHESIS IN THE BRAINS OF YOUNG AND OLD HUMANS POSTMORTEM. M. J. Schmidt, B. Ghetti, A. Maggi*, and S. J. Enna. Eli Lilly and Company, Indiana Univ. Med. Cntr. and The Univ. of Texas Medical School at Houston.

These experiments were designed to assess the feasibility of using human brain tissue obtained at autopsy for neurochemical studies of drug-receptor interaction. The frontal pole of the cerebral cortex and the lateral pole of the cerebellum were removed from humans of various ages 6-16 hrs after death. Neurohormone-stimulated cAMP accumulation was measured in tissue slices. ^{3}H-Dihydroalprenolol binding, adenylate cyclase assays, and estimates of metabolic intermediates were run on tissue homogenates.

Norepinephrine increased cAMP levels in cortical slices from the brains of neonates 2 day - 2 year of age. Most tissues from older individuals were unresponsive to norepinephrine, histamine or adenosine. cAMP concentrations in the cerebellum were low and no hormone-induced rise in cAMP was detected in any sample at any age.

^{3}H-Dihydroalprenolol bound to membrane fragments from all samples of the cerebral cortex and cerebellum of all samples. There was no difference across age in the affinity constant or number of binding sites in the cerebral cortex, but a significant decline in binding was observed in cerebellar tissue from individuals over 60 yrs. of age. The age-related decline was due to a reduction in the number of binding sites (80 vs. 40 femtomoles/mg prot.) with no change in the affinity constant (1.5 nM vs. 1.4 nM).

Experiments with rats indicated that norepinephrine could stimulate cAMP synthesis as long as 16 hrs after death if the animals were cooled within 1 hr after death. However, elevated body temperatures (36° C) for 3 hrs postmortem, drastically reduced cAMP accumulation. Determination of brain temperature after death revealed that only in the case of the very young would rapid cooling of the brain take place in the clinical setting.

These experiments indicate that ligand binding studies can be conducted on human brain tissue obtained at autopsy. However, components of the cAMP generating system appear to be temperature sensitive postmortem. Studies in progress are examining what defects might account for the malfunction (e.g., adenylate cyclase activity, insufficient ATP concentrations, lowered metabolic conversion of ATP precursors). The data also show an age-related decline in beta adrenergic receptor density in the cerebellum but not cerebral cortex of humans.

1671 DIFFERENCES BETWEEN CURRENT AND VOLTAGE RESPONSES OF TOAD RODS. Julie L. Schnapf* and Robert N. McBurney. LNP, NINCDS, NIH, Bethesda, Md. 20014

Vertebrate photoreceptors respond to light with membrane hyperpolarization. A striking characteristic of these responses is that for bright flashes an initial hyperpolarization decays to a plateau level which is maintained for several seconds. It has been suggested that this transient reflects a transient in the kinetics of the phototransduction process in the outer segment. To test this hypothesis we have compared both outer segment current and intracellular voltage recorded from toad rods (Bufo marinus). A slice of isolated retina was placed in a superfusion chamber. A single rod outer segment was drawn into a glass pipette filled with toad Ringer. The pipette had a resistance of 1-3 MΩ which rose to as much as 10 MΩ with a rod in place. Current was recorded as the voltage output of a virtual-ground current-to-voltage converter connected between the inside of the electrode and the solution bathing the retina. Intracellular voltage changes were measured in an identical preparation except that a single rod was now impaled with a microelectrode (resistance 100-400 MΩ).

Membrane potential responses to bright stimuli in this preparation displayed the initial transient hyperpolarization and plateau phase typical of similar measurements by other investigators. Surprisingly, no such transient was seen in membrane current responses. However, current responses to bright stimuli did have a plateau phase that was maintained for several seconds. We also observed that the peak of the current response saturated at a lower intensity than did peak voltage.

We suggest that the peak component of the voltage response is probably a result not of the kinetics of the transduction process but a second process located proximally to the outer segment. Furthermore, a comparison of the time course of current and voltage responses to dim stimuli indicates that the nonlinear current-voltage characteristics of this second process operates on signals as small as the response to a single photon.

1672 SELECTIVE BLOCKADE OF HYPOTHALAMIC CHOLINERGIC PATHWAYS BY ANTIBODY TO G_{M1} GANGLIOSIDE. Nicole Schupf and Curtis A.Williams Dept.Psychology,Manhattanville Coll.and Div.Nat.Sci.SUNY College at Purchase,N.Y. 10577

Previous investigations of the functional activity of an anti-ganglioside antibody(aGS)have shown EEG abnormalities and inhibition of a passive avoidance task to be induced in rats following intracranial administration of aGS.(Karpiac et al,Science 194:735,1977).Karpiac et al(Neurosci.Abstr.739,1977)demonstrated that this neuroactivity was eliminated by absorption with G_{M1} ganglioside. We have found that focal intrahypothalamic injection of aGS(donated by Dr.M.Rapport)causes depression of drinking in 23-hour water deprived rats, identical to the effect we reported for an anti-rat brain microsomal membrane(aRB)antibody(Williams and Schupf,Science 196:328, 1977). A discriminating assay system, pharmacological induction of food and water intake, demonstrated that the activity of aRB appeared to be selective for inhibitory hypothalamic neurons mediating adrenergic-cholinergic antagonism. This test was employed to determine the functional activity of aGS.

Rats were prepared with cannulae in the perifornical hypothalamus, a region where direct chemical stimulation of sated animals with the alpha-adrenergic agonist norepinephrine(NE)will elicit excessive eating and stimulation with the cholinergic agonist carbamyl choline(CC)will elicit excessive drinking. Treatment with aGS(2ng Ig in 1 ul) 6 hours before drug stimulation depressed drinking in CC-stimulated rats but produced no change in appetitive behavior in either NE-stimulated or saline control rats. The activity of the antibody was eliminated by absorption with G_{M1} ganglioside. These results suggest that the neuroactivity of aGS in this brain region is best defined by blockade of cholinergic neurons. This discrete activity contrasts with that reported for aRB.

While G_{M1} ganglioside is distributed widely on cell membranes in the brain and other tissues, we conclude that it has a close functional relationship either to the ACh receptor itself or to some other gating structure on cholinergic neurones.

1673 PRE-SYNAPTIC DOPAMINE RECEPTORS LABELED BY ^{3}H-APOMORPHINE. P. Seeman and J. Tedesco, Department of Pharmacology, University of Toronto, Toronto, Canada M5S 1A8

Previous work[1] has shown that ^{3}H-apomorphine (at 3 nM) prefers presynaptic dopamine receptors over post-synaptic dopamine receptors in the caudate, since 6-hydroxydopamine lesions of the nigrostriatal fibers caused a 56% fall in the binding of ^{3}H-apomorphine, but a 22% rise in the binding of ^{3}H-haloperidol. Intrastriatal injections of kainic acid, moreover, had no effect on the striatal binding of ^{3}H-apomorphine but did lower the binding of ^{3}H-spiperone, supporting the theory that ^{3}H-apomorphine favours attachment to pre-synaptic dopamine sites, while ^{3}H-spiperone prefers post-synaptic dopamine receptors[2].

To test further the hypothesis that ^{3}H-apomorphine (at 3 nM) prefers pre-synaptic dopamine receptors, we tested a number of dopamine-mimetic compounds for their ability to compete with ^{3}H-apomorphine binding; we then compared these competing concentrations with those which are known to act on peripheral pre-synaptic dopamine receptors[3-5]. The concentrations which 50% inhibited the specific binding of ^{3}H-apomorphine to calf caudate homogenates are shown in the Fig. in correlation to the concentrations which 50% inhibit the cardioacceleration responses[3-5].

The results are thus compatible with the theory that ^{3}H-apomorphine (at 3 nM) may bind to high affinity pre-synaptic sites for dopamine.

1674 IMMUNOCHEMICAL PROPERTIES OF SEROTONIN-BINDING PROTEINS. Jean C. Shih and Helen Young*. School of Pharmacy, University of Southern California, Los Angeles, California 90033.

By affinity column chromatography, two serotonin-binding proteins have been isolated from steer hypothalamus. One of them was eluted from the column by chlorimipramine (SBP-CIP), the other one was eluted by LSD (SBP-LSD). Recently, antibody has been developed against each protein. They are immunochemically identical.

When antiserum-anti-SBP-CIP (or antiserum anti-SBP-LSD) was reacted with rat brain synaptosmal membranes, one immunoprecipitin line was observed and it was immunochemically identical to the purified SBP from steer hypothalamus. Furthermore, both antibodies inhibited specific serotonin-binding to a similar degree.

1675 MUSCARINIC ACETYLCHOLINE RECEPTOR REGULATION IN CULTURES OF EMBRYONIC CHICK BRAIN. Robert G. Siman* and William L. Klein* (SPON: Virginia Carr). Dept. of Biological Sciences, Northwestern Univ., Evanston, Illinois, 60201.

Homogenates of chick embryo cerebral lobes specifically bind 3H-QNB to muscarinic ACh receptors. Pharmacological characteristics of the binding are similar to those reported elsewhere. Aggregate cell cultures of cerebral lobes develop muscarinic ACh receptors as monitored by 3H-QNB binding. Cultures prepared from 8 day old chick embryos and maintained for 7 days have about 100 fmol receptors/mg protein. These cultures can be used to study factors which regulate receptor density.

Muscarinic ACh receptor activation by addition of agonist to culture medium causes a subsequent reduction in muscarinic ACh receptor density. Cells activated for 24 hours with carbachol show a dose-dependent loss of muscarinic ACh receptors which closely resembles the receptor occupancy profile for carbachol. A saturating dose (10^{-4}M carbachol) lowers receptor density by 75%. A half-maximal reduction in receptor density is induced by 10^{-6}M carbachol. The regulation is muscarinic ACh receptor mediated and requires receptor activation and not simple occupancy. Thus 10^{-6}M oxotremorine induces a receptor loss which is blocked by 10^{-8}M atropine. Maximal receptor loss occurs after 9 hours exposure to agonist, while half the effect occurs by 1.5 hours. Receptor density returns to control level 48 hours after agonist withdrawal, indicating that receptor reduction is not due to loss of cholinoceptive cells. Our results suggest that regulation of muscarinic ACh receptors may be a mechanism for CNS synaptic plasticity.

1676 INHIBITORY EFFECTS OF SOME TRICYCLIC ANTIDEPRESSANTS AND IMIDAZOLINE DRUGS ON THE PINEAL α-ADRENERGIC RECEPTOR-MEDIATED STIMULATION OF PHOSPHOLIPID METABOLISM. Thomas L. Smith* and George Hauser, Ralph Lowell Labs., McLean Hospital, Belmont, MA 02178 and Harvard Medical School, Boston, MA 02115.

Norepinephrine (NE) *in vitro* selectively stimulates the incorporation of ^{32}P into phospholipids of the rat pineal gland. The most prominent stimulation occurs in phosphatidylinositol, while modest increases are seen in phosphatidic acid and phosphatidylglycerol. Phosphatidylcholine and phosphatidylethanolamine are not affected. This increased incorporation of ^{32}P by NE has been shown to be blocked by the highly specific α-adrenergic antagonist WB4101, as well as by classical antagonists such as phenoxybenzamine, phentolamine, and dihydroergotamine, whereas sotalol, a β-adrenergic antagonist, has no effect. A variety of α-agonists also enhance ^{32}P labeling of phospholipids producing a labeling pattern similar to that seen with NE. It thus appears that the increased rate of metabolism of certain phospholipids in the rat pineal gland is mediated through activation of α-adrenergic receptors. Pineals incubated with 10 μM NE plus 10 μM cocaine, an inhibitor of presynaptic NE reuptake, exhibit no greater stimulation than with NE alone. Thus, the NE stimulation of phospholipid metabolism in this system is not affected by presynaptic reuptake of NE under the conditions used.

One μM concentrations of the tricyclic antidepressants, amitriptyline, doxepin, imipramine, desipramine, and protriptyline inhibit completely the stimulation of ^{32}P incorporation elicited by 5 μM NE. Amitriptyline (1 μM) displaces the dose response curve for NE to the right, in a parallel manner, indicating a competitive type of inhibition with a K_D for amitriptyline of about 1 μM. Incubations of pineal glands with 1.5 μM tricyclic antidepressants plus 10 μM NE yield a rank order of inhibitory potency tertiary amines > secondary amines, similar to that seen in other α-adrenergic systems. Among the imidazolines, clonidine, oxymetazoline, naphazoline, xylometazoline, and tolazoline antagonized the stimulation caused by 10 μM NE. Clonidine also possesses partial agonist activity. Although many of the tricyclic and imidazoline drugs have strong local anesthetic properties which can affect labeling of membrane phospholipids in a characteristic manner, these effects were not observed at the concentrations tested. Since some of the imidazolines have been reported to act as pineal presynaptic α-agonists, their action inhibiting increased ^{32}P incorporation into phospholipids occurs probably at a postsynaptic α-receptor locus. (Supported by USPHS grant NS06399 from the National Institutes of Health.)

1677 HETEROLYTIC CLEAVAGE OF A CRITICAL DISULFIDE BOND ON THE CHOLINERGIC RECEPTOR. A. Steinacker. Rutgers Med. Sch., Piscataway, NJ 08854.

A modification of the cholinergic receptor has been produced by heterolytic cleavage of a critical disulfide bond on the receptor molecule. Strict reduction of this bond adjacent to the binding site for acetylcholine has been shown to reduce the post synaptic response to acetylcholine and specific alkylating and oxidizing agents have been used as affinity labels for the bond (Karlin, Fed. Proc. 32, 1973). Using sodium bisulfite and the frog neuromuscular junction and hatchetfish Mauthner fiber-giant fiber synapse, I have produced a heterolytic cleavage of a disulfide bond which, unlike the reduction, produces an increased response to acetylcholine. No change in time course or input impedance is produced. The affinity labels used following reducing agents are also active following heterolytic cleavage indicating that the same disulfide bond is involved. The heterolytic cleavage results in the addition of a strongly nucleophilic sulfonate to a site near the cholinergic binding site and increased current flow through subsynaptic ionic channels. This aspect will now be investigated at the single channel level.

There is also a presynaptic effect of this heterolytic cleavage which is manifested as an increase in the frequency of miniature end plate potentials (mepp's) and a decrease in the quantal content. The presynaptic response to modification of this disulfide bond has not been investigated previously sine the reducing agents used decreased the cholinergic response and mepps could not be seen. The most likely hypothesis for the increased frequency (up to 200/sec) and reduced quantal content is action on a presynaptic cholinergic receptor. There is no change in resting potential postsynaptically in either preparation and in the hatchetfish where it is possible to record presynaptically, no change in resting potential is seen. The response is not dependent on external calcium and does not appear to include mitochondrial involvement. The same affinity agents which act on the post synaptic receptor molecule also act presynaptically on the mepp frequency. Both these pre and post synaptic effects can be blocked by prior treatment with physostigmine or acetylcholine. The increased acetylcholine binds to the receptor preventing access to the disulfide bond by the sulfite ion. This data may provide evidence for an activation of a presynaptic cholinergic receptor mediating feedback control of neurotransmitter. (Supported by the General Research Support Grant of Rutgers Medical School.)

1678 VASOACTIVE INTESTINAL POLYPEPTIDE: SPECIFIC BINDING BY RAT BRAIN MEMBRANES. Duncan P. Taylor* and Candace B. Pert. Biological Psychiatry Branch, NIMH, Bethesda, MD 20014.

Immunohistochemical localization of vasoactive intestinal polypeptide (VIP) in central as well as peripheral nerve systems led us to search for specific binding of VIP by brain membranes. High specific activity [^{125}I]VIP was prepared and incubated with once-washed brain membranes in the presence or absence of 10^{-7} M unlabeled VIP. Bound VIP was separated from free by centrifugation of membranes through 10% sucrose. Membranes obtained from cerebral hemispheres, thalamus, and hypothalamus bound VIP specifically. Specific binding of VIP represented 40-50% of total binding. Specific VIP binding was reversible and saturable (B_{max} = 8 fmole/mg tissue). Brain membranes exhibited a high affinity for VIP (K_D = 3 nM) and a Hill plot indicated no cooperativity of binding. Binding was maximal at 37°C and 20 minutes. Millimolar concentrations of calcium, magnesium and manganese cations enhanced binding, while sodium ions decreased binding. Bacitracin and aprotinin preserved binding, presumably by competing with endogenous proteases, while soybean trypsin inhibitor was not effective. Binding of VIP paralleled its immunohistochemical localization, being enriched in cerebral cortex, hippocampus, hypothalmus, striatum and thalamus. Secretin and partial sequences of VIP competed for binding to brain membranes with an order of potency similar to that obtained in binding studies of the VIP receptor found in pancreatic acinar cells (Christophe et al., J. Biol. Chem., 251: 4629, 1976). These characteristics suggest that this binding is associated with a physiologically relevant VIP receptor. (D.P.T. is a NIDA NRSA Fellow.)

1679 PRE-SYNAPTIC DOPAMINE RECEPTOR BINDING: INVOLVEMENT OF THE NITROGEN LONE ELECTRON PAIR. J.L. Tedesco and P. Seeman. Pharmacology Department, University of Toronto, Toronto, Canada.

We have previously reported that ^{3}H-apomorphine receptors in calf striatum crude homogenate (Seeman et al., P.N.A.S. 73, 4354, 1976; Seeman et al., Fed. Proc. 37, 130, 1978) are identical in all respects to high affinity ^{3}H-dopamine receptors. In the current study we have determined that the lone electron pair of the tertiary amine nitrogen of apomorphine is necessary in ligand-receptor binding.

Dopamine itself has an IC_{50} of 2 nM when competing for binding to ^{3}H-apomorphine receptors. Secondary and tertiary amine analogues of dopamine retain high to moderate affinities even when N-propylated. Thus, N,N-dimethyl- ,N,N-diethyl- , N,N-dipropyl-, and N,N-dibutyl-dopamine have IC_{50} values of 10.5, 55, 74 and 625 nM, respectively. The secondary amine analogues N-methyl- , N-ethyl- , and N-propyl-dopamine have IC_{50} values respectively of 2.5, 25 and 215 nM. In contrast the quaternary amine analogue N,N,N-trimethyl-dopamine has a very low affinity (IC_{50} = 1200 nM). This compound lacks a nitrogen lone electron pair. Similarly, while R-(-)-apomorphine and R(-)-N-n-propyl-norapomorphine have high affinities, with respective IC_{50} values of 3.8 and 4 nM, the quaternary amine analogue N-methyl-apomorphine has an IC_{50} value of 710 nM.

We suggest that the position-vector for the amine lone pair is a more critical factor than the actual position of the nitrogen atom in determining potency. All previous studies have stressed the latter. It is however not a trivial problem to separate these two variables. We have tested an apomorphine analogue (Berney et al., Experientia 31, 1327, 1975) which is identical to R-(-)-apomorphine save that the nitrogen is part of a 7-membered ring instead of a six-membered ring. It is inactive in binding at 10,000 nM. However, crystallography indicates that the nitrogen atom and its lone pair have both altered in position. Again, S-(+)-apomorphine has a low affinity, with an IC_{50} of 325 nM for the ^{3}H-apomorphine receptor, but while its amine lone pair is pointing in a direction opposite to that in R-(-)-apomorphine, its nitrogen atom is also about 1.4 Å removed from its position in R-(-)-apomorphine relative to the plane of the catechol ring.

The involvement of the tertiary amine lone pair of opiates in binding to their receptor has been elegantly demonstrated (Belleau et al., J. Med. Chem. 17(8), 907, 1974). A similar demonstration for dopamine analogues would provide a fundamental insight into the nature of the dopamine binding-site. (Supported by the Ontario Mental Health Foundation and MRC of Canada).

1680 PRE- AND POST-SYNAPTIC CATECHOLAMINE RECEPTORS IN CALF CAUDATE. M. Titeler and P. Seeman, Department of Pharmacology, University of Toronto, Toronto, CANADA M5S 1A8.

This study was designed to improve the selective labelling of alpha-adrenoceptors by ^{3}H-dihydroergocryptine (^{3}H-DHEC) in calf caudate homogenates, since it is known that ^{3}H-DHEC can also bind to dopamine receptors[1]. In the presence of 5 nM spiperone, which served to block dopamine receptors, the specific binding of ^{3}H-DHEC was inhibited by 90 nM epinephrine (K_i values), 260 nM (-)-norepinephrine, and 1000 nM dopamine, indicating that ^{3}H-DHEC was selectively binding to brain alpha-adrenoceptors under these conditions. These numbers agree with those for ^{3}H-WB-4101, published by others[2].

An important problem, however, is that these inhibitory concentrations for ^{3}H-DHEC do not match those which inhibit the binding of ^{3}H-clonidine or ^{3}H-noradrenaline. A simple and straightforward resolution of this dilemma would be to propose that ^{3}H-DHEC and ^{3}H-WB-4101 label the post-synaptic alpha-receptors, while ^{3}H-clonidine and ^{3}H-noradrenaline label the pre-synaptic autoreceptors. This suggestion is compatible with the data shown below indicating that the stimulated release of ^{3}H-norepinephrine and the specific binding of ^{3}H-clonidine binding are both inhibited by almost identical concentrations (or K_i values) of the drugs listed.

	EC_{50}% to block overflow[3,4]	^{3}H-Clonidine[2] IC_{50} (25°) Rat Brain	^{3}H-DHEC[1] K_i (25°) Calf Caudate
clonidine	16 nM	10 nM	40 nM
(-)-norepinephrine	30 nM	29 nM	260 nM
phentolamine	50 nM	37 nM	6 nM
phenoxybenzamine	100 nM	102 nM	12 nM

This proposal is analogous to that for dopamine receptors, wherein we suggest that 1-2 nM ^{3}H-neuroleptic labels post-synaptic sites, while 2-4 nM ^{3}H-apomorphine or ^{3}H-dopamine primarily label dopamine autoreceptors (in press).

1681 HISTAMINE H_1 RECEPTOR IDENTIFIED IN MAMMALIAN BRAIN WITH [^{3}H]-MEPYRAMINE. Vinh T. Tran, Raymond S.L. Chang and Solomon H. Snyder. Dept. Pharmacol., Johns Hopkins Sch. Med., Baltimore, MD 21205.

Histamine H_1 receptors have been labeled in mammalian brain with [^{3}H]mepyramine. Binding is saturable, with a dissociation constant of 4 nM and a maximal number of binding sites of 11 pmoles/g tissue. [^{3}H]Mepyramine binds reversibly to the receptor; binding occurs rapidly at 25° C with a $t_{1/2}$ (assoc.) = 2 min, and the bound ligand dissociates from the receptor with a half-life of 2.5 min. [^{3}H]Mepyramine binding is selectively blocked by classical H_1-antagonists with high affinity and stereoselectively, with d-chlorpheniramine being 100 times more potent than its l-isomer, while H_2 antagonists have no effect. The affinities of various H_1 antagonists at the histamine receptor correlate closely with their potencies in reversing histamine stimulated guinea pig ileal contraction. Tricyclic antidepressants block [^{3}H]mepyramine binding potently with K_i values for doxepin, amitriptyline, imipramine and nortriptyline of 0.7 nM, 3 nM, 20 nM and 20 nM respectively. Regional variations of binding do not parallel the distribution of endogenous histamine.

1682 TWO ^{3}H-CLONIDINE α-NORADRENERGIC SITES IN BRAIN WITH DIFFERENTIAL RESPONSE TO 6-HYDROXYDOPAMINE TREATMENT. David C. U'Prichard and Solomon H. Snyder. Dept. Pharmacol., Johns Hopkins Med. Sch., Baltimore, MD 21205.

^{3}H-Clonidine (CLO, 26.7 Ci/mmol) binds to α-noradrenergic receptors in rat and bovine cortex in a pharmacologically similar fashion to that previously reported for low S.A. CLO. Binding is 90-95% specific at low CLO concentrations. Saturation experiments indicate CLO binds to two populations of receptors, with K_D values of 0.4 nM (1-2 pmol/g cortex) and 2-4 nM (8-10 pmol/g cortex). These sites can be analyzed separately. Agonists have higher affinity at the high-affinity CLO site, with K_is of 0.5 and 1.7 nM for epinephrine (EPI) and norepinephrine (NE). α-Methyl-NE is two times less potent than NE at the high-affinity CLO site, but five times more potent than NE at the low-affinity CLO site. The rat CNS regional distributions of high- and low-affinity CLO binding differ. High-affinity CLO distribution is very marked, with highest binding in cortex, followed by anterior thalamus, colliculi and hippocampus, and insignificant binding in striatum, midbrain and cerebellum. Low-affinity CLO distribution is much more widespread, with more than 35% of cortical levels found in all areas. I.c.v. 6-OHDA increases the B_{max} of high-affinity CLO binding by 50-100% in cortex, compared to 50% increases for ^{3}H-EPI and ^{3}H-WB-4101 α-receptor binding. This increase is found in all brain areas except pons, where there is a 50-70% decrease in high-affinity CLO binding. I.c.v. 6-OHDA does not alter the B_{max} of low-affinity CLO binding, but increases CLO affinity two-fold at this site. At a single CLO concentration, a reduction in low-affinity CLO binding is most apparent in striatum, midbrain area ventral to the colliculi, and cerebellum. It is suggested that high-affinity CLO binding is to true neuronal postsynaptic α-receptors, and possibly α-receptors on locus coeruleus NE cell bodies, whereas low-affinity CLO binding is to glial receptors and possibly autoreceptors on NE terminals. (Supported by USPHS grant MH-18501 and by grants from the McKnight and Hartford Foundations.)

1683 REGULATION AND LIGAND SPECIFICITY OF DOPAMINE RECEPTORS. Ted Usdin*, Ian Creese and Solomon H. Snyder. Dept. Pharmacol., Johns Hopkins Sch. Med., Baltimore, MD 21205.

Striatal dopamine (DA) receptors activate an adenylate cyclase and have also been characterized by the binding of various radiolabeled ligands. A potent DA agonist, 2-amino-6, 7-hydroxyl-1,2, 3,4-tetrahydronapthalene (ADTN), has recently become available in a tritiated form (3 Ci/mmol). Rat striatal binding of ^{3}H-ADTN is saturable and occurs rapidly at 37°. Binding is stereospecifically displaced by butaclamol with the (+) enantiomer being 4000 times as potent as the (-) form. Among the agonists the potency order for displacing ^{3}H-ADTN is ADTN (IC_{50} = 13 nM) >apomorphine >dopamine (IC_{50} = 400 nM) >norepinephrine = epinephrine >5HT. Among DA antagonists (+)-butaclamol (IC_{50} = 4 nM) >fluphenazine >chlorpromazine >haloperidol >spiroperidol (IC_{50} = 250 nM) >promazine. The drug specificity of this binding site is similar to that of sites labeled by other DA agonists. The DA antagonist ^{3}H-spiroperidol (^{3}H-SPIRO) also labels sites in rat striatum with a drug specificity similar to that of sites labeled by ^{3}H-haloperidol. Although little cortical binding of ^{3}H-haloperidol is detectable, ^{3}H-SPIRO binding in the cortex is 20% of striatal levels. DA (IC_{50} = 2.2 μM) is 20 times more potent than 5HT in displacing striatal ^{3}H-SPIRO binding, however, 5HT (IC_{50} = 4.4 μM) is 50 fold more potent than DA in displacing cortical ^{3}H-SPIRO binding. That ^{3}H-SPIRO labels 5HT receptors is supported by ^{3}H-SPIRO binding in hippocampus which has a large 5HT but no DA innervation, and the high affinity of SPIRO for 5HT receptors labeled by ^{3}H-LSD (IC_{50} = 30 nM). Kainic acid microinjection into the striatum lesions intrinsic neurons removing almost all DA-sensitive adenylate cyclase activity but only 40% of ^{3}H-antagonist binding. However such lesions remove 70% of ^{3}H-apomorphine (^{3}H-APO) binding suggesting that ^{3}H-agonists may label receptors mediating DA stimulated cAMP production. Supporting this hypothesis guanyl nucleotides, which in other receptor-cyclase systems modulate agonist receptor affinity and cyclase activity, decrease ^{3}H-APO and ^{3}H-ADTN binding (GTP IC_{50} = 10 μM). Adenyl nucleotides are inactive. GTP does not alter absolute binding of ^{3}H-SPIRO. Specific DA receptor binding of ^{3}H-agonists in rat striatum is cation dependent with Mn^{++} active at μM, Ca^{++} and Mg^{++} at mM concentrations while monovalent cations Na^+, K^+ and Li^+ only decrease nonspecific binding at high concentrations. Specific DA receptor binding of ^{3}H-SPIRO does not require added cations, but is increased to the same maximal extent by both mono and divalent cations. These anatomical, pharmacological and biochemical differences between agonist and antagonist binding sites and the DA-sensitive adenylate cyclase indicate the existence of two distinct DA receptors.

1684 REDUCTION IN STEREOSPECIFIC BINDING OF ^{3}H-DIHYDROMORPHINE IN CNS REGIONS OF AGED RATS. Beatriz J. Vasquez, Vina R. Spiehler*, Rita B. Messing, Robert A. Jensen, Joe L. Martinez, Jr., and James L. McGaugh. Department of Psychobiology, School of Biological Sciences, University of California, Irvine, CA 92717, U.S.A.

There is extensive evidence that neuroanatomical and neurochemical changes occur in aged humans and infrahumans. Observed decreases in number of neurons and dendritic spines, which in turn means fewer synapses, suggest that aging may result in a deficit in the number of receptors for various neurotransmitters and neuromodulators. To investigate this we measured opiate receptor-ligand interactions in young and old animals.

The animals used were 10 young (5 month old) and 10 aged (24 month old) F344 female rats. They were killed by decapitation and the CNS dissected into 9 regions. Tissues were homogenized in ten volumes of 0.32M sucrose. Aliquots (0.2 ml) were then diluted in 1.8 ml of 0.05M tris buffer, pH 7.4, to determine stereospecific binding of ^{3}H-dihydromorphine (3 nM). Stereospecific binding was defined as the difference in binding in the presence of dextrorphan minus binding in the presence of levorphanol. Protein content was determined by the Lowry method and the binding reported as fmoles/mg protein. Differences in receptor binding with age are shown in the table.

	fmoles/mg protein	
Region	Young	Old
Cerebral hemispheres	61±2.23	51±3.27*
Hippocampus	19±1.43	15±1.11*
Striatum	58±3.74	45±2.33**
Amygdala	37±4.18	35±3.0
Hypothalamus	30±2.27	30±2.75
Diencephalon	14±1.68	15±2.09
Midbrain	24±2.99	22±2.0
Pons medulla	15±1.40	17±1.50
Spinal cord	7±0.38	7±0.86

* p<.05; ** p<.01, t-test. All values are mean±S.E.M.

These results indicate that there is a significant decrease in opiate receptor binding in cerebral hemispheres, hippocampus, and striatum, all forebrain regions. The decrease in opiate binding may be related to the decline in brain and cognitive functioning observed with age. 1685 DECREASED β-ADRENERGIC RESPONSES IN RAT CEREBRAL CORTEX FOLLOWING CHRONIC ESTROGEN TREATMENT. H. Ryan Wagner*, Keith A. Crutcher and James N. Davis. Duke University Medical Center and Durham VA Hospital, Durham, NC 27705.

Estrogen appears to be capable of binding to and altering the activity of noradrenergic neurons in the central nervous system. Since we previously demonstrated that increases in brain noradrenergic activity may be reflected by decreases (subsensitivity) in postsynaptic β-adrenergic receptor-coupled adenylate cyclase sensitivity, we began to study the effects of chronic estrogen exposure on this system. Six-week old female Sprague-Dawley rats were bilaterally ovariectomized. Following recovery (three weeks) all rats were implanted with a silastic pellet containing ethynylestradiol or nothing. Twelve to fourteen days after receiving the pellet, rats were killed and cerebral cortices from each group were removed and pooled. Approximately 1/2 of the tissue from each group was homogenized, made into membranes, and assayed for its ability to bind the β-adrenergic radioligand, [^{3}H] dihydroalprenolol (DHA). The remaining tissue was sliced (260 μM) and measured for its ability to accumulate cyclic 3', 5'-adenosine monophosphate (cAMP) in response to various concentrations of the β-adrenergic agonist, (-) isoproterenol (ISO). Maximum accumulations of cAMP in the presence of 10 μM ISO were reduced in estrogen-treated rats (31 pmoles/mg protein/12 min, control; 23 pmoles/mg protein/12 min, estrogen). The maximum density of [^{3}H] DHA membrane binding sites was also decreased in ovariectomized females exposed to estradiol (145 fmoles/mg protein, control; 119 fmoles/mg protein, estrogen; $p < .001$) with no change in the affinity of the ligand for the receptor (K_D = 3.7 nM, control; K_D = 3.5 nM, estrogen). Preliminary studies in other brain regions showed [^{3}H] DHA binding capacity was also significantly decreased in the striatum, hypothalamus, and olfactory bulb ($p < 0.05$) but not in the cerebellum, hippocampus, thalamus, midbrain, pons, or medulla. These data indicate 1) that β-adrenergically mediated cAMP responses are reduced by high in vivo estrogen levels, 2) that this subsensitivity is mediated at least in part by a decrease in β-adrenergic membrane receptors, and 3) that receptor changes reflect a decrease in maximum receptor number with no change in the affinity of the remaining receptors for the radioligand. Although these data are consistent with an estrogen-induced increase in noradrenergic neuronal activity, we presently cannot exclude direct effects of estrogen on postsynaptic β-adrenergic receptors or indirect effects on those same receptors resulting from estrogen-induced alterations in a second unspecified variable (e.g., weight loss or decreased body temperature) as alternative explanations. 1686 BINDING OF JUNCTIONAL AND EXTRAJUNCTIONAL ACETYLCHOLINE RECEPTORS BY SERA FROM PATIENTS WITH MYASTHENIA GRAVIS. Crispin B. Weinberg* and Zach W. Hall. Dept. Neurobiol., Harvard Med. Sch., Boston, MA 02115 and Dept. Physiol., Univ. Calif. Sch. Med., San Francisco, CA 94143.

Sera from patients with myasthenia gravis have been reported to bind acetylcholine receptor in crude extracts of denervated rat muscle, but not to bind receptor from normally innervated muscle (Almon and Appel (1975) Biochim. Biophys. Acta 393, 66). We have investigated this difference using highly purified preparations of receptor from denervated and normal rat muscles which were shown by isoelectric focusing to consist largely of extrajunctional and junctional receptors, respectively. Binding was measured by incubation of human sera with a complex of ^{125}I-α-bungarotoxin and receptor, addition of a second antibody to human IgG and determination of precipitated radioactivity. In sera from ten patients, the ratio of the titer against extrajunctional receptor to that for junctional receptor ranged from 1.2 to 2.6. In control experiments antibodies raised in rabbits to purified rat muscle extrajunctional receptor or to receptor from eel electric organ gave equal titers to junctional and extrajunctional receptors. Thus the difference seen with myasthenia gravis sera was not due to the presence of inactive receptor or to an artifact of the binding assay. To compare the determinants present on the two receptor types, myasthenic sera were preincubated with unlabelled receptor prior to incubation with radioactive toxin-receptor complex. These competition experiments demonstrated that the sera contained two types of antibodies: 1) those directed against determinants common to junctional and extrajunctional receptors; and 2) those directed against determinants that are present only on extrajunctional receptors. No evidence for antibodies directed against unique determinants on junctional receptors was found.

1687 STRIATAL INTERDEPENDENCE AND PRE- AND POST-SYNAPTIC DOPAMINE RECEPTORS. P. Weinreich*, T. Lee & P. Seeman (SPON: K. Livingston) Pharmacology Department, University of Toronto, Toronto, Canada.

It has recently been found that 6-hydroxydopamine-induced lesions of the nigro-striatal neurones resulted in a 50% reduction in the number of striatal receptors for ^{3}H-apomorphine, supporting the theory that ^{3}H-apomorphine has a high affinity for pre-synaptic dopamine receptors[1]. To test further this hypothesis, we injected kainic acid into rat striatum and found that ^{3}H-apomorphine binding was unaffected while ^{3}H-spiperone binding decreased by 22% when compared to the contralateral unlesioned side. Since kainic acid destroys neurone cell bodies while sparing the nerve terminals[2,3], these results are compatible with the concept of ^{3}H-apomorphine labeling pre-synaptic receptors, while ^{3}H-spiperone prefers post-synaptic dopamine receptors.

We also found that either a pre- or post-synaptic chemical lesion of the rat striatum (with either 6-hydroxydopamine or kainic acid, respectively) elicited an approximate doubling of the ^{3}H-apomorphine and ^{3}H-spiperone specific binding in the contralateral unlesioned striatum when compared to unlesioned or intrastriatally saline injected animals (Fig.). This indicates that chemically-induced damage of either pre- or post-synaptic neurones in the striatum may cause a non-specific increase in the number of sites for ^{3}H-apomorphine or ^{3}H-spiperone in the contralateral side. These results thus suggest a bilateral communication between the two striata, as postulated by Nieoullon et al.[4].

1688 IMMUNOFLUORESCENCE LOCALIZATION OF ANGIOTENSIN II (AII) AND AII RECEPTORS IN CULTURED RAT BRAIN CELLS. James A. Weyhenmeyer*, Mohan K. Raizada*, Detlev Ganten*†, M. Ian Phillips and Robert E. Fellows. Dept. of Physiology and Biophysics, University of Iowa, Iowa City, IA 52242 and †Dept. of Pharmacology, University of Heidelberg, West Germany.

In our earlier studies, we have found specific high affinity AII receptors in cultured cells from fetal rat brain. Here we report the localization of AII and AII receptors in these cultures by immunofluorescence.

Brain cells from rat fetuses of 20 day gestational age were prepared by trypsinization (Wilson et al.[1972], J. Biol. Chem. 247, 3159). $2.8x10^6$ cells in Dulbecco's modified Eagle's medium (DME) with 10% fetal calf serum were inoculated in Falcon culture dishes containing 11x22 mm coverslips and cultured at 37°C in a humidified CO_2 incubator. On days 3 and 5, the cultures were fed with DME containing 10% horse serum, 40 µg/ml fluorodeoxyuridine and 100 µg/ml uridine. By day 7 the morphological appearance of the brain cells on glass coverslips showed a background monolayer of large flat cells on the top of which were present individual and small clusters of "phase dark" cells. These "phase dark" cells showed numerous processes and resembled neuronal morphology. Four groups of duplicate dishes were tested. Group 1 was incubated with AII for 30 min, washed and fixed to test for receptors. Group 2 was similarly treated but incubated with PBS for 2 hr before fixation to test for nonspecific binding. Groups 3 and 4 were treated in the same way without AII to test for the presence of endogenous AII.

Groups 3 and 4 demonstrated significant intrinsic staining for AII on the cell body. This staining was not evident when the primary antibody was previously absorbed with AII. In group 1, which had been pre-treated with AII and fixed immediately, extensive staining in the processes and cell bodies was observed. Cells in group 2 demonstrated a loss of specific staining in the neural like cell process and perikaryon.

In conclusion, groups 3 and 4 indicated the presence of endogenous AII in fetal rat brain cells. A significant increase in fluorescence in cells from group 1 compared to group 2 indicates the specific AII receptors in these cultures. They are localized in the bodies and processes of the neuronal like cells. (Supported by NSF grant # BNS77-24415 to MIP; NIH grant # 1 RO1 HD11184-01 to REF. JAW is supported by a PMA Foundation Fellowship Award. MIP is recipient of RCDA from NIMH.)

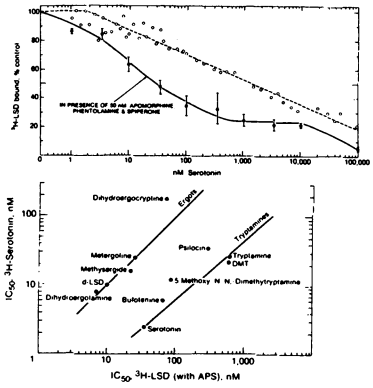
1689 SELECTIVE LABELING OF SEROTONIN RECEPTORS BY ^{3}H-LSD. P.M. Whitaker* and P. Seeman (SPON: P. Brawley). Department of Pharmacology, University of Toronto, Toronto, Canada M5S 1A8.

Since it is known that LSD (d-lysergic acid diethylamide) acts on both catecholamine and indoleamine neurones, we sought conditions wherein ^{3}LSD would selectively label primarily serotonin receptors in vitro.

Using crude homogenate of calf caudate, which contains many types of neuroreceptors, we found that approximately 20% of the total binding of ^{3}H-LSD was inhibited by 50-1000 nM dopamine or apomorphine, 1000-10000 nM noradrenaline, or 10-100 nM phentolamine. These findings indicated that ^{3}H-LSD bound appreciably to alpha-adrenoceptors and dopamine receptors.

We then tested the effect of serotonin in competing against ^{3}H-LSD in the presence of a simultaneous combination of 50 nM apomorphine (to block dopamine autoreceptors), 50 nM phentolamine (to block alpha-adrenoceptors) and 50 nM spiperone (to block post-synaptic dopamine receptors). In the presence of these latter 3 drugs (so-called "APS" system), serotonin inhibited ^{3}H-LSD binding by 50% at about 30 nM; in the absence of these 3 drugs the serotonin IC_{50}% was about 1000 nM, as has usually been found by others (Bennett & Aghajanian, 1974; Lovell & Freedman, 1976; Burt et al., 1976; Bennett & Snyder, 1976; Fillion et al., 1978).

Thus, by blocking dopamine- and adreno-ceptors, the selectivity of ^{3}H-LSD for serotonin receptors was greatly enhanced. We further found that ergots inhibited the binding of ^{3}H-serotonin and of ^{3}H-LSD (APS system) at similar concentrations; tryptamines had a higher affinity for ^{3}H-serotonin than ^{3}H-LSD sites. The results support the concept of two serotonin receptors, one pre- and the other post-synaptic. (Funded by MRC of Canada and the Ontario Mental Health Foundation).



1690 FREQUENCY RESPONSE ANALYSIS OF RECEPTOR POTENTIALS FROM PRIMARY ENDINGS IN ISOLATED MUSCLE SPINDLES OF CAT. R.S. Wilkinson* and C.C. Hunt. Dept. Physiology and Biophysics, Washington Univ. Sch. Med., St. Louis, MO 63110.

Isolated decapsulated spindles were mounted in a chamber containing Locke's solution with one end tied to a force transducer and the other to an electromechanical stretcher. The primary axon was drawn on a recording pipette into oil. After impulse block by tetrodotoxin, tension, displacement and receptor potential were recorded and subsequently analyzed by a computer. The first through fifth harmonics of steady state responses were measured over frequencies, f, from 0.01 to 100 Hz. The gain, A_{RP} and A_T, and phase, ϕ_{RP} and ϕ_T, of the receptor potential and tension (with respect to displacement) of the first harmonic response were used to construct Bode plots. Measurements were performed under linear response conditions, as described below.

For f below approximately 10 Hz, A_T was constant or showed a slight monotonic increase with increasing f, while ϕ_T was 10^o-20^o at 0.01 Hz, decreased slowly with increasing f, and began to lag the applied stretch above approximately 10 Hz. Receptor potential response differed qualitatively from that of tension and was more complex: A_{RP} was an approximate power-law function of f, $A_{RP} \propto f^\gamma$, with $\gamma = 0.3$-0.5, depending on the particular spindle. ϕ_{RP} was 30-45^o at low f, usually rose gradually with f to a peak at approximately 2 Hz, then decreased with increasing f, becoming negative above approximately 15 Hz. Neither ϕ_T nor ϕ_{RP} showed a tendency to approach 0^o as f approached 0.01 Hz, the lowest attainable measurement frequency.

In the range from 1.0 to approximately 10-25 µM peak-to-peak, A_{RP} and ϕ_{RP} did not depend on the amplitude of stretch and harmonic distortion in the response waveforms was negligible. Frequency response measurements were obtained at constant amplitude within this range, determined independently for each spindle. Higher stretch amplitudes were also investigated. A_{RP} decreased with increasing amplitude as a power-law function, independent of frequency. Harmonic distortion increased with amplitude, and was predominantly second harmonic. Neither tension nor receptor potential responses were consistent with simple linear models employing finite combinations of viscoelastic elements.

1691 THE COMPLEX BINDING OF γAMINOBUTYRIC ACID TO A RAT BRAIN SYNAPTIC MEMBRANE PREPARATION. Marvin H. Winkler*, William J. Nicklas* and Soll Berl (Spon: G. Cohen). Dept. Neurology, Mount Sinai School of Med., New York, N.Y. 10029.

The extent to which γ-aminobutyrate is bound to rat brain synaptic membrane preparations was determined over a wide range of free GABA concentrations. The binding curve defined by the data is complex and characterized by no less than four inflection points. The curve is consistent with either the existence of several sets of independent binding sites or with cooperative binding or with a combination of both. The fact that there is more than one set of binding sites is established by exhaustive iodination of separate aliquots of membrane in the presence or absence of an excess of transmitter. The difference between the binding expressed by the two aliquots corresponds to one sixth of the imidazole acetic acid displaceable binding of GABA expressed by the uniodinated membrane at 0.25 uM free GABA. It is concluded, from this result, that one set of sites can be defined as being composed of members having an accessible iodinatable residue whose integrity is essential to the functioning of that site. The difference in binding expressed by the two iodinated aliquots between 0.03 and 0.25 uM free GABA defines a saturable binding curve which fulfills the Scatchard criterion for a set of independent, homogenous sites thus reinforcing the conclusion that more than one set of sites is expressed on the membrane. The experimentally determined curve is further analyzed in terms of a theoretical discussion which assumes that physical occlusion, specific binding and non-specific binding may all contribute to the apparent observed binding. A method for separating physical occlusion from binding and for determining the maximum number of binding sites without the use of competitive binders is described. The use of this analysis in the determination of possible selective inhibition of specific sets of sites by selected agonists or antagonists is discussed. Supported in part by NIH Grant NS 11824 and the Clinical Center for Research in Parkinson's and Allied Diseases, and Grant NS 11631.

1692 EFFECTS OF CHRONIC ALTERATIONS IN RECEPTOR STIMULATION ON β-ADRENERGIC RECEPTORS IN RAT BRAIN. B.B. Wolfe*, D.A. Staunton*, P.M. Groves and P.B. Molinoff. Dept. Pharmacol., Univ. Colo. Med. Ctr., Denver, CO 80262.

Access of norpinephrine to postsynaptic β-adrenergic receptors can be altered by the chronic administration of various pharmacological agents. The effects of such treatments on isoproterenol-stimulated cAMP accumulation and β-adrenergic receptors were measured respectively in slices or membranes prepared from rat cerebral cortex. Chronic administration of (+,-)-propranolol-HCl (10 mg/kg; twice daily) for 9-12 days caused a 30% increase in isoproterenol-stimulated cAMP accumulation. This increase in cAMP accumulation was accompanied by a 33% increase in the density of β-adrenergic receptors as measured by Scatchard analysis of (^{125}I)-iodohydroxybenzylpindolol (IHYP) binding. No change was observed in the affinity of IHYP following propranolol administration suggesting that no residual propranolol remained in the tissue preparation. Chronic administration of desmethylimipramineHCl (10 mg/kg; twice daily) for 7-21 days caused a 35-45% decrease in both isoproterenol-stimulated cAMP accumulation and in the density of β-adrenergic receptors. No changes in the affinities of either agonists or antagonists active at β-adrenergic receptors were observed. The effect of desmethylimipramine was blocked by the simultaneous administration of propranolol. The increases in isoproterenol-stimulated cAMP accumulation and in the density of β-adrenergic receptors caused by propranolol were not affected by the simultaneous administration of desmethylimipramine. Administration of d-amphetamine sulfate (17.2 mg/kg; twice daily) for 8 days resulted in a 30% decrease in isoproterenol-stimulated cAMP accumulation. These studies suggest that manipulations which increase the availability of norepinephrine at β-adrenergic receptors lead to a decrease in the density of receptors with no change in their properties. Conversely, manipulations which decrease the availability of norepinephrine at β-adrenergic receptors cause increases in receptor density. The changes in receptor density appear to be responsible for changes in the ability of catecholamines to stimulate cAMP accumulation.

1693 RECEPTORS FOR NERVE GROWTH FACTOR IN THE NUCLEAR MEMBRANE OF PHEOCHROMOCYTOMA. Bruce A. Yankner* and Eric M. Shooter. Dept. Neurobio., Stanford Univ. Sch. of Med., Stanford, CA 94305.

The binding of β nerve growth factor (βNGF) to nuclei from dorsal root ganglia was observed by Andres, R.Y. et al. (PNAS, USA 74: 2485, 1977). Correlation of this interaction with target tissues for nerve growth factor was well demonstrated. We have studied a continuous line of pheochromocytoma cells (PC12) which responds to βNGF in culture by the outgrowth of neurites. When nuclei were purified from PC12 cells and incubated with ^{125}I-βNGF, specific binding sites were found. Incubation of nuclei in the presence of deoxyribonuclease I resulting in the solubilization of about ninety percent of the nuclear chromatin did not decrease the specific binding. Chromatin was purified from nuclei by the method of Harlow, R. and Wells, J. (Biochem. 14: 2665, 1975) and bound βNGF nonspecifically. The specific binding of βNGF was associated with the nuclear membrane which was purified according to Jackson, R.C. (Biochem. 15: 5641, 1976). Resistance to extraction with Triton X-100 suggests that the nuclear receptor may be localized to the inner nuclear membrane or the pore complex.

The binding of βNGF to purified nuclear membrane is saturable and consistent with two sites; a high affinity site with a K_d in the range of 10^{-11}-10^{-10}M and a lower affinity site with a K_d of 1-3 x 10^{-9}M. The capacity ratio is about 1:13 for the high and low affinity sites, respectively. Neither insulin nor epidermal growth factor could compete for the NGF sites.

When PC12 cells were grown in culture in the presence of 50ng/ml βNGF for 8 days, the receptor capacity of the nuclear membrane increased from about 12,000 sites per cell in confluence to 60,000 sites per cell. Although the DNA content of the nuclear chromatin remained constant, a four to five-fold increase in the protein content of the nuclear membrane was observed.

1694 EFFECTS OF GTP ON BRAIN DOPAMINE RECEPTORS. N.R. Zahniser* and P.B. Molinoff (SPON: M.D. Dibner). Department of Pharmacology, University of Colorado Medical School, Denver, CO 80262.

Guanine nucleotides regulate the hormonal sensitivity of adenylate cyclase in a variety of systems. These nucleotides have also been shown to decrease the affinities of glucagon receptors and β-adrenergic receptors for agonists. The affinities for antagonists were not affected. In the current experiments inhibition of the binding of labelled spiroperidol by agonists was measured in rat brain by a direct in vitro assay in the presence and absence of various purine nucleotides. In striatal membranes GTP (0.3mM) produced a 4-5 fold decrease in the Kd values for dopamine(DA), the DA-receptor agonists epinine and A-6,7-DTN, and the partial agonist apomorphine. Hill coefficients for the agonists showed significant negative cooperativity (0.55 +/- 0.02). These values were shifted slighly closer to unity in the presence of GTP (0.64 +/- 0.03). As shown by Scatchard analysis of binding data, GTP had no sigificant effect on the affinity of spiroperidol for sites on striatal membranes (control: Kd=79+/-6pM; GTP: Kd=85+/-5pM). Similarly, GTP had no effect on the inhibition of spiroperidol binding by the dopamine receptor antagonists (+) and (-)-butaclamol or (α) and (β)-fluphenthixol. Effects identical to those of GTP were found with GMP-PNP, GDP, and ITP while GMP, guanosine, and ATP were ineffective. These observations expand the number of reports of agonist-specific effects of GTP to include another receptor whose effects may be mediated through changes in adenylate cyclase activity. In contrast to the agonist-specific effect of GTP in the striatum, addition of GTP to membranes prepared from frontal cortex had no effect on the inhibition of spiroperidol binding by either DA, DA receptor agonists, or serotonin. These data are consistent with the following conclusions: (1) Spiroperidol binds to DA receptors in the striatum but may be associated with another class of binding sites in the frontal cortex. (2) Agonists for DA receptors can be distinguished from antagonists in the striatum on the basis of the shift in the Kd value in the presence and absence of GTP.

REGENERATION

1695 OLFACTORY NERVE REGENERATION IN THE AXOLOTL FOLLOWING NERVE GROWTH FACTOR (NGF), ANTI-NGF, AND D-AMPHETAMINE TREATMENT. P.M. Adams, M.W. Mellinger, R. J. Perez-Polo and K. Hall*. Depts. of Psychiatry and Behavioral Science, and Pharmacology, Anatomy and Human Biological Chemistry and Genetics, University of Texas Medical Branch, Galveston, Texas 77550.

In previous work we described the extensive central nervous system regenerative capacity of the axolotl (A. mexicanum). We have studied this regeneration following the surgical removal of the anterior two-thirds of the forebrain. The present study examined the effects of treating the axolotl with NGF, an antibody to NGF or d-amphetamine sulfate. The NGF and anti-NGF were administered intracranially immediately after surgery. The d-amphetamine was administered chronically beginning immediately or Day 2 post-operatively and continued until sacrifice at Day 10. Light microscopic examination of the treatment groups indicated an increased fiber density in both the NGF and amphetamine treated animals. There was increased olfactory nerve diameter and better fiber organization in these two groups. High power examination indicated a predominance of fine fibers to heavy fibers for the NGF and amphetamine treated animals. In contrast, in the anti-NGF treated animals regenerating nerves were not as well organized nor was regeneration as extensive as in either controls, or d-amphetamine or NGF treated animals. The extent of regeneration at Day 10 was least in anti-NGF treated animals, and increasingly greater in controls, NGF-treated and d-Amphetamine treated animals respectively. This investigation supported by Grant Nos. DHEW 5501-RR-05427-16GRS and Research Career Development Award 1-K04-NS-00213.

1696 CELL-TO-CELL SPECIFICITY OF REGENERATED GIANT AXONS IN EARTHWORMS. Stewart C. Birse* and George D. Bittner
Dept. of Zoology, University of Texas, Austin, Texas 78712

Previous experiments in our laboratory have shown that severed giant axons in the earthworm ventral nerve cord (VNC) regenerate with a high degree of cell-to-cell specificity within 2-4 weeks (Birse and Bittner; Brain Res. 113:575, 1976). This regeneration is accomplished by outgrowing axonal processes which may originate in one or both halves of the giant axon and functionally connect it with its severed counterpart. Similarly, VNC's with 1 or 3 ablated segmental ganglia regenerate within 1 to 8 months by the same mechanism with a lesser degree of success and possibly less cell-to-cell specificity (Birse and Bittner; Fed. Proc. 36:554, 1977). It was necessary, then, to determine 1) from which severed axonal stump outgrowing processes arise, 2) if outgrowing processes connect only to their severed counterparts, and 3) whether those processes morphologically fuse with their severed counterparts or form electrotonic synapses. To accomplish this goal, animals suffering either simple VNC transections or ganglion ablations were injected with 0.5M $CoCl_2$, developed with ammonium sulfide, embedded in paraffin, sectioned at 10 microns, and the cobalt stain enhanced with the Timm's procedure. Preliminary results indicate that the cobalt stain does not proceed through the lesion site suggesting that morphological fusion of the outgrowing processes and the severed giant axon may not occur. (Supported by NIH grant NS-14412 and an RCDA to G.D.B.)

1697 RETENTION OF SPECIFICITY FOR APPROPRIATE SYNAPTIC SITES BY REGENERATING FROG OPTIC AXONS. Ronald C. Bohn* and Dennis J. Stelzner. Dept. Anat., Upstate Medical Center, Syracuse, NY 13210

Most studies of regeneration in the visual system have shown that regenerating optic axons retain remarkable specificity in reinnervating normal visual targets. However, certain investigations have demonstrated that by ablation of normal visual targets (tectum) the regenerating optic axons will form connections in anomalous regions. Optic axons in neonate hamsters will even form connections in the medial geniculate body following destruction of superior colliculus and section of the brachium to inferior colliculus (Kalil and Schneider, 1975). The question remains whether regenerating optic axons form anomalous connections because they are forced to do so by removal of their normal targets or because regenerating axons are attracted to denervated sites made available by the ablations. Our experiments were designed to test whether or not regenerating optic axons will reinnervate inappropriate denervated regions in close proximity to visual projection areas without damaging the normal visual targets.

The right optic nerve was crushed in 12 adult Rana pipiens which also received a left hemisection through the isthmal region at the same time. The latter lesion cuts axons which make synaptic contact in regions of thalamus which lie adjacent to contralateral optic nerve terminal sites. After survival periods ranging from 1 week to 6 months, the right eye of each frog was injected with 4 µl of ^{3}H-proline (10 µCi/µl) and brains were prepared for autoradiography. Spread of label from normal optic tract terminal zones into adjacent regions denervated by the isthmal lesion would imply that regenerating optic axons establish connections with inappropriate targets even though the normal optic nerve projections remain intact.

Examination of the distribution of label within contralateral thalamic visual targets at all survival periods indicated that the regenerating optic nerve did not expand its projection to occupy sites vacated by the isthmal lesion. Distribution of silver grains within contralateral visual targets was similar to grain distribution in animals receiving only right nerve crush. These results are most easily interpreted to imply that adult regenerating optic axons retain their specificity for thalamic visual targets and will not form contacts in adjacent denervated thalamic regions. A second possibility is that fibers cut by the isthmal lesion regenerate and return to fill their normal sites in thalamus. To exclude this possibility, regenerating optic axons are being studied in 6 frogs where regeneration of ascending projections to thalamus was prevented by teflon block at the isthmal lesions. (Supported by NIH Grant NS14096)

1698 THE EFFECT OF REPEATED NERVE INJURY ON THE RETINAL GANGLION CELL AND AXONAL REGENERATIVE RESPONSE IN THE OPTIC NERVE OF THE NEWT (Triturus viridescens). T. O. Brock, III and J. E. Turner. Dept. of Anat., Bowman Gray Sch. of Med. of Wake Forest Univ., Winston-Salem, NC 27103.

In the transected newt optic nerve, pioneer regenerating axons enter the distally denervated stump 4-6 days post lesion, before the glial scar is maximally developed (Turner and Singer, J. Exp. Zool. 190: 25, '74). A series of experiments was designed to delay the entrance of these axons into the distal stump to ascertain whether a fully developed glial scar would hinder regeneration (Brock, Anat. Rec. 190: 349, '78). The results from repeated nerve lesion experiments indicated that a well developed glial scar did not offer a hindrance to regenerating fibers, in fact a second lesion appeared to enhance axon outgrowth. In a second series of experiments the lesion sequence was reversed. An initial optic nerve crush was made on all animals at a point midway between the eyeball and the optic foramen and animals were divided into various groups. Two groups were further treated in a manner to test the effect of delayed entrance of axons into the distal stump. In these groups, nerves were transected at midpoint between the initial crush and the eyeball 4 and 11 days post initial lesion and the animals were sacrificed 7 and 11 days respectively, after transection. Control groups were sacrificed 7, 11, and 22 days post initial crush. Comparisons of numbers of axons per nerve cross section and axon densities by EM morphometric analysis indicate that a fully developed glial scar did not hinder axon outgrowth into and within the distal stump. As in the previous studies the second lesion appeared to enhance axonal outgrowth. Examinations of the retinal ganglion cell layer of animals treated to delay axon outgrowth demonstrate prominent nucleoli and chromatin changes in 40-50% of these neurons by day 11.

1699 THE EPENDYMAL CELLS OF THE SPINAL CORD IN RAT AND STINGRAY Richard E. Coggeshall and Robert B. Leonard, Depts. of Anatomy and of Physiology and Biophysics, and The Marine Biomedical Institute, University of Texas Medical Branch, Galveston, Texas 77550.

In most areas of the vertebrate nervous system, there is a proliferation of neurons very early in development, followed by a precisely programmed cell death. After this, it is generally felt that the number of neurons in any particular part of the nervous system is constant. In recent years, however, this opinion has been modified because it has been shown that a population of small neurons in the forebrain keep proliferating into adult life. Nevertheless, it is still felt that most neuronal populations in vertebrate brain and spinal cord have a constant number of elements throughout the life of the animal. Recently, however, it has been shown that the Atlantic Stingray, Dasyatis sabina, does not have a stable population of neurons in various well defined neuronal groups in the spinal cord in that the number of dorsal root axons and ganglion cells as well as ventral root axons and motor cells increase steadily as the animal ages. This presumably implies that new neurons are added to an already functioning adult nervous system and the fact that these animals retain the capacity to make new neurons in adulthood may well be related to the ability of these animals to regenerate parts of the nervous system.

In an attempt to determine the mechanism underlying the proliferation of spinal neuronal elements in the stingray, the ependymal cells of the spinal cord were examined. The ependymal cells of the stingray can be divided into 2 populations, first a typical columnar cell that forms the bulk of the ependymal lining and second a cell type that is relatively round and has a distinctive nuclear pattern, a basal location, and moderately large numbers of lysosome-like bodies. Synapses end upon these cells, which probably implies that they are small neurons.

The ependymal cells of the stingray were compared with those of the rat, which is stated to be an animal that does not increase the number of spinal neuronal populations as it ages. As expected, there were few, if any, second ependymal cell types as described above. It was of interest, however, that there did seem to be synapses on the typical ependymal cells in this animal. Synapses have previously been described on tanycytes of the 3rd ventricle in mammals, but they are not described, to our knowledge, in the spinal cord. The relation of these findings in stingray and rat to the question of proliferation or non-proliferation of adult neuronal populations will be discussed. Supported by grants NS 07377, NS 11255, NS 10161, The Muscular Dystrophy Society of America, and NIH Fellowship NS 05434.

1700 A QUANTITATIVE ULTRASTRUCTURAL STUDY OF AXOTOMIZED FELINE BETZ CELLS. M.P. Dentinger and K.D. Barron. Department of Neurology, Albany VA Hospital and Albany Medical College, Albany, NY 12208.

Adult cats underwent unilateral left lateral funiculotomy at the second cervical (C2) level. Observations were made on animals surviving 1 to 153 days with several survival times being paired. One hundred and twenty large pyramidal neurons (Betz cells) from pericruciate cortex were analyzed using quantitative stereologic methods. The morphometric observations on organelle composition were evaluated by analysis of variance statistics. Chromatolytic changes appeared exclusively in Betz cells of the cortex contralateral to the spinal cord lesion. Estimation of Betz cell population at the light microscopic level indicated approximately a 50% reduction in the right pericruciate cortex at a later survival time (153 days). Analysis of the neuronal organelle composition showed a decrease in the percent of cytoplasm occupied by mitochondria at survival times of 5 and 10 days. At all survival times, including the time of maximum chromatolysis 10 days postoperatively, reactive neurons showed no depletion of rough endoplasmic reticulum, Golgi apparatus, nor lysosomes. Analysis of somatic bouton coverage showed no definite displacement or stripping of boutons at any survival time. An increased percentage of somatic surface covered by boutons was found for large neurons in the right cortex at later survival times (49 and 153 days). Thus, in normal Betz cells the percent coverage of the somal surface by axosomatic boutons is 22.2% and at 49 days after funiculotomy axotomized Betz cells have a percent bouton coverage of 30.2%. (Supported by VA Medical Research Service and NINCDS Research Grant 08735.)

1701 SELECTIVE RE-INNERVATION OF SLOW MUSCLE FIBERS OF THE FROG. Alejandro Elizalde and Enrique Stefani. Department of Physiology and Biophysics, Centro de Inv. del IPN. Apto. Postal 14-740, México 14, D. F.

Following denervation by crushing the sciatic nerve, fast motor axons regenerate faster than slow motor axons and re-innervate non selectively twitch and slow muscle fibers. Slow axons reach the muscle later and re-innervate selectively slow muscle fibers (Schmidt & Stefani, 1976). The initial non-selective re-innervation of slow muscle fibers could be explained by the fact that fast motor axons reach the muscle earlier than slow motor axons. To test this hypothesis experiments were performed to determine the selectivity of re-innervation by crushing the nerve just before its entrance into the muscle. By reducing the regenerating distance one may expect that slow and fast motor axons will reach the muscle almost simultaneously. Muscle fibers of the piriformis muscle were impalled with two intracellular microelectrodes and were characterized as twitch or slow fibres according to the electrical properties. The piriformis nerve was crushed 1-3 mm from its entry into the muscle. Re-innervation was studied by stimulating the sciatic nerve in two different points. The conduction velocity of an individual nerve fiber was calculated from the difference in latency of the synaptic potential and the interelectrode stimulating distance. Fast and slow axons were distinguished according to conduction velocity and threshold. Functional re-innervation started 9 days after the operation. From the beginning, slow and twitch muscle fibers were selectively re-innervated. 25 slow fibers studied 9-40 days after the operation were re-innervated by slow axons (cond. vel. <5 m/sec, threshold 2-4 V). In the same muscles 53 twitch fibers were re-innervated by fast axons (cond. vel 8-25 m/sec, threshold 0.3-0.8 V). These results indicate that re-innervation is selective for fiber type and that regenerating axons can recognize the corresponding muscle fibers.

1702 SELECTIVITY IN THE LOSS OF SYNAPTIC INPUT TO FROG SPINAL MOTONEURONS FOLLOWING VENTRAL ROOT SECTION. Paul B. Farel. Dept. Physiol., Sch. Med., Univ. N. Car., Chapel Hill, NC 27514

A variety of electrophysiological studies have shown that frog spinal motoneurons receive spatially segregated synaptic input from two sources: (1) fibers descending in the lateral columns (LC) synapse upon soma and proximal dendrites; (2) dorsal root (DR) fibers synapse upon more distal dendritic regions. These results are consistent with the finding that in normal motoneurons the time to peak of the monosynaptic DR-EPSP is approximately 1-2 msec longer than the time to peak of the monosynaptic LC-EPSP. The present investigation indicates that after section of their axons motoneurons undergo a selective desynapsis such that the electrotonic distance from the soma of the DR inputs is now shorter than that of LC inputs.

Slow waves can be recorded from ventral roots of the isolated frog spinal cord which reflect the time course of the monosynaptic EPSPs elicited by activation of different synaptic inputs. Normally, the mean time to peak of the LC-elicited slow wave recorded from ventral root 9 is 2.77±.34 msec ($\bar{X}$±SE) and 3.92±.34 msec to DR stimulation. Following ventral root section 21-42 days previously, these values are now 7.41±.68 msec for LC stimulation and 4.19±.3 msec time to peak for the slow wave reflecting the monosynaptic DR-EPSP.

Intracellular recordings revealed that, after correction for distortion by extracellular field potentials, the time to peak of the monosynaptic LC-EPSP was twice that of the monosynaptic DR-EPSP by 30 days postaxotomy. These changes were progressive in the period following axotomy and were associated with an increase in firing threshold to both synaptic activation and to injected current.

To the extent electrotonic distance as measured by time to peak can be equated with physical distance, axotomy can be seen to disrupt selectively those synaptic inputs from descending fibers while sparing those from primary afferent fibers. These results cannot be attributed to a general somatic to dendritic gradient of desynapsis. Such a gradient would be expected to produce DR- and LC-EPSPs of similar risetimes. An anatomical correlate of these results may be seen in the work of Sumner (1976) who found axotomized rat hypoglossal motoneurons lost boutons only of certain morphological types. Whether similar anatomical distinctions can be made between terminals derived from LC and DR fibers remains to be determined.

Supported by NSF grant BNS 76-24528 and NINDS grant NS 11132.

1703 LECTIN BINDING IN THE REGENERATING GOLDFISH VISUAL SYSTEM. E.L. Feldman*, A.M. Heacock and B.W. Agranoff. Neuroscience Laboratory, University of Michigan, Ann Arbor, MI 48109.

Recent reports from this laboratory have described an in vitro approach to the study of optic nerve regeneration in the goldfish. Explant culture of the adult goldfish retina results in vigorous neuritic outgrowth, provided that the optic nerve has been crushed in vivo a week prior to explantation. Histological studies have shown that these neurites derive from retinal ganglion cells and, therefore, may be considered regenerating optic nerve fibers. Since glycoproteins and glycolipids have been postulated to play a role in cellular recognition and in retinotectal specificity, it was of interest to investigate the nature of the cell surface carbohydrates of the retinal explant neurites. By means of fluorescence microscopy, we studied the binding to neurites of lectins, plant proteins which recognize specific sugars or sugar linkages. Of the fluorescent lectins applied to the retinal cultures thus far, two have been found to bind to the neurites--ricin and wheat germ agglutinin. The binding of ricin, a lectin specific for terminal galactose residues, was inhibited by pre-incubating the lectin with 50 mM lactose. Wheat germ agglutinin shows an affinity for the linkage (N-acetyl-β-(1,4)-D-glucosamine)$_2$. Its binding to neurites is blocked by 20 mM N,N',N"-triacetylchitotriose. Two other lectins, from Ulex europeus (fucose) and from Dolichos biflorus (N-acetyl-α-D-galactosamine), do not appear to bind to the retinal neurites.

We have also examined lectin binding to the goldfish optic tectum. Frozen sections were taken with a cryostat through the tectum of goldfish whose optic nerve had been crushed 14 d previously. The sections were dried and either used directly or fixed by a variety of methods. Lectin binding specificity for the tectum was the same as that found for the retinal neurites. The characteristics of ricin and wheat germ agglutinin binding depend upon the method of fixation.

These studies offer a combined approach toward characterization of cell surface carbohydrates of the regenerating goldfish visual system. The tectal sections are useful in that, in addition to the optic nerve, membranes of adjacent cell types can be examined. In contrast, the retinal explant preparation permits analysis of the carbohydrate nature of optic nerve membranes in the absence of adjacent structures.

1704 HISTOLOGICAL EVIDENCE FOR AXONAL REGENERATION IN BRAINS OF ADULT RATS. Anne P. Foerster. Dept. of Physiology, Univ. of Toronto, Toronto, Ontario, Canada, M5S 1A8.

Precisely placed brain lesions were made with a cutting device consisting of a 90μ diameter cross-wire, 1-2 mm long, supported between two long parallel 90μ wires which extended 1/2-1 mm beyond the horizontal cutting wire. The device was lowered through the brain (adult male rats, 350-600g) by a micromanipulator, and the two protruding vertical wires cemented to the upper skull. The device was left in situ until after the brain was fixed; it was then removed from the ventral surface, leaving two vertical "marker" channels between which the cutting wire had passed through the brain tissue. Survival times ranged from about one minute to many months. Brains were block silver stained (Ranson), and horizontal sections usually counterstained with Luxol Fast Blue and Nuclear Fast Rubin. Because of their predominantly parallel-fibred alignment, the horizontal parasaggittal tracts of midbrain-hypothalamus-subthalamus were studied in detail.

In brains fixed immediately after insertion of the device, masses of severed axons were clearly defined along the borders of the incision; a few intact fibres in the path of the device deviated for variable distances (never exceeding 200μ) around the holes left by the support wires. By 3-6 days, there was degeneration and a loss of fibres on both sides of the lesion, and terminal enlargements were found on many of those remaining, some of which appeared to have turned along the line of the lesion and even to have passed around the vertical holes, where axon numbers were now increased. By 18 days terminal enlargements were scarce, and a massive bundling of axons was visible, parallel and close to the lesion, on one or both sides; in addition, and related to this, there was a striking increase in the number of axons coursing around one or other of the holes. These surrounding axons turned obliquely to assume the normal orientation and position of the particular lesioned tract within 500μ or less of the cut. These appearances were not observed after implantation of two perpendicular wires minus a cutting cross-wire. When a tract lesioned 18 or more days earlier failed to have detoured in this characteristic manner, measurements indicate that the cut had extended more than about 200μ outside its borders.

The results seem most readily explained by regeneration of the cut axons around the lesion (only in 15% of sections did a few axons appear to have crossed the cut). The eventual restoration of normal appearances of lesioned tracts at distances of about 500μ from the cut emphasizes the usefulness of unambiguous markers of the boundaries of the original lesion.

1705 EFFECTS OF NERVE GROWTH FACTOR, ANTIBODIES TO NERVE GROWTH FACTOR AND D-AMPHETAMINE ON FOREBRAIN REGENERATION IN THE AXOLOTL. Kimberley Hall*, Perrie M. Adams, Melvyn W. Mellinger and J. Regino Perez-Polo. Depts. Human Biological Chemistry and Genetics, Psychiatry and Behavioral Sciences, Pharmacology and Anatomy, Univ. Texas Med. Br., Galveston, TX 77550.

The axolotl (Ambystoma mexicanum) is a neotenic amphibian with an extensive regenerative capability within the central nervous system. In control animals, bilateral removal of the anterior 2/3 of the forebrain results in a sequence of morphological events which involves the forward growth of the regenerating forebrain and inversion of the lateral walls to complete ventricle closure, followed by the functional reinnervation of the caudal forebrain stump along the midline by the olfactory nerve, with hemisphere regeneration complete by six weeks postsurgery.

A single intracranial injection of 15,000 biological units of Nerve Growth Factor (NGF) at the time of forebrain removal resulted in an increased cellular density within the anterior cavity of the brain and olfactory nerve reinnervation of the forebrain stump by day ten, a time course significantly earlier than that seen in controls. The olfactory nerves also showed a greater cellular density with NGF treatment as determined by light microscopic analysis, and hemisphere lengths were significantly longer by day ten than controls, with anterior closure of the ventricles. Animals kept in daily changes of 2500 cc dechlorinated water with .5 mg d-amphetamine from time of surgery until sacrifice showed earlier contact of the olfactory nerve with the regenerating forebrain, earlier closure of the lateral ventricles, and an increase in cellular density and organization of nerve fibers in the olfactory nerve. Treatment with antibodies to NGF at the time of surgery resulted by day ten in a distinct cellular disorganization within the olfactory nerves, with no reinnervation of the caudal forebrain stump and a marked eversion of the lateral walls of the hemispheres showing no signs of ventricle closure. Supported by PHS grant NS14034, RCDA to J.R.P. K04 NS 00213, DHEW 5502-RR-05427-16GRS.

1706 FURTHER STUDIES ON THE BIOCHEMICAL CONSEQUENCES OF OPTIC NERVE CRUSH IN THE GOLDFISH. A.M. Heacock, H.R. Burrell* and B.W. Agranoff. Neuroscience Laboratory, University of Michigan, Ann Arbor, MI 48109.

This laboratory has been engaged in studies of the biochemical correlates of optic nerve regeneration in the goldfish. We have previously shown, by means of a double-label in vitro incubation of control and post-crush retinas, that tubulin labeling is selectively augmented within 5 d after optic nerve crush and remains elevated for several weeks. Colchicine binding studies indicate that the retinal tubulin content does not show a comparable increase, suggesting that the altered labeling pattern represented increased tubulin turnover, or that there was increased transport of newly synthesized tubulin out of the retina.

Axonally transported protein was examined following intraocular injection of ^{3}H-proline into control fish or into fish whose optic nerve had been crushed 14 d previously. Contralateral tecta were removed at various times, from 8 h to 30 d following isotope injection, homogenized and separated into soluble and membrane-bound fractions by high speed centrifugation. One and two dimensional acrylamide gel electrophoresis patterns were examined by fluorography and by scintillation counting.

At each time point examined, the amount of radioactivity transported by the regenerating nerve was increased 6-8 fold over controls. Comparisons of the labeling patterns revealed changes during regeneration in several transported proteins. Prominent among these was tubulin, which as expected was confined to the slow phase of axonal transport. Thirty days following injection of precursor, tubulin comprised 19% of the labeled soluble protein in contralateral tecta from control fish, whereas, in the post-crush fish, 36% of the labeled soluble protein comigrated with tubulin.

Recent studies (Burrell et al, in preparation) have demonstrated that tubulin mRNA is increased in the post-crush retina. This finding suggests that the observed alterations in tubulin labeling in the regenerating goldfish visual system are regulated in the ganglion cell nucleus.

1707 A COMPARATIVE STUDY OF CNS NEURON REGENERATIVE ABILITIES. Claire E. Hulsebosch* and George D. Bittner (SPON: Robert G. Grossman). Dept. of Zoology, University of Texas at Austin, Austin, Texas 78712.

One way to interpret current data on nerve cell body regeneration in central nervous systems (CNS) of metazoans is to hypothesize that the ability of a species to regenerate nerve cells correlates with the ability of that species to add CNS neurons during ontogeny. As a corollary to this "neuronal addition" hypothesis, those species in which the CNS nerve cell numbers are constant or decreasing in number during ontogeny would be expected to lack the ability to regenerate ablated nerve cells. To test this corollary, several species in the phylum Annelida were examined for the ability to regenerate ablated CNS nerve cells.

Ganglion, quarter ganglion and single cell ablations were performed in several species of leeches (Hirudo medicinalis, Haemopis grande and Macrobdella sp.), a class of annelids in which the CNS nerve cell numbers are constant within a species. In agreement with the neuronal addition hypothesis, no nerve cell body regeneration occurred in the species of leeches examined.

To test this corollary further, a second species in which we found the CNS nerve cell numbers to be constant, Clymenella torquata, was examined for CNS nerve cell regenerative ability. In this species, regeneration of nerve cell bodies does occur in response to CNS ablations. Consequently, in this case, the ability to regenerate entire CNS neurons would not have been predicted by the neuronal addition hypothesis since this species has a constant number of CNS nerve cells.

However, in agreement with the neuronal addition hypothesis, other species which do add CNS neurons during ontogeny may demonstrate CNS nerve cell regeneration.

1708 FURTHER EVIDENCE THAT 4S RNA IS AXONALLY TRANSPORTED IN REGENERATING OPTIC NERVES OF GOLDFISH. Nicholas Ingoglia. Dept. of Physiol. and Neurosci., N.J. Med. School, Newark, N.J. 07103

Following the injection of ^{3}H-uridine into the eye of goldfish, ^{3}H-RNA is found within regenerating optic axons in the optic tectum (Gambetti, et al., 1978, Brain Res., in press). It is likely that this RNA was synthesized in retinal ganglion cell bodies in the eye, and then transported axonally into regenerating optic axons. Indirect evidence indicates that only 4S RNA may be intra-axonal (Ingoglia & Tuliszewski, 1976 Brain Res. 112: 371-381). The present experiments offer two additional lines of evidence that 4S RNA is the predominant, if not the only RNA species transported in this system.

Both optic nerves of goldfish were crushed and 18 ds. later 10.0 ug of cordycepin, an inhibitor of RNA synthesis, was injected into the right eye. ^{3}H-uridine was injected into the same eye 3 hrs. later and trichloroacetic acid soluble and insoluble radioactivity was analyzed from both tecta after 6 ds. The amount of precursor arriving in the tectum was decreased by approx. 60% of control, while the amount of ^{3}H-RNA was decreased by 88%. If 4S RNA is the only RNA species axonally transported, we would predict that the 88% decrease in transported RNA would represent a greater loss in 4S than ribosomal RNAs. Polyacrylamide gel electrophoresis (PAGE) of tectal RNA following the procedures outlined above, showed that ribosomal ^{3}H-RNA was decreased by $\sim$ 70%, whereas ^{3}H 4S RNA was decreased by >90%. These results are interpreted as evidence that the decrease in tectal ribosomal ^{3}H-RNA is due to a decrease in the availability of ^{3}H nucleotides for tectal RNA synthesis, and that the decrease in ^{3}H 4S RNA is due to the same process plus a loss of axonally transported ^{3}H 4S RNA. In the second experiment both optic nerves were crushed in 36 fish and 18 ds. later ^{3}H-uridine was injected into both eyes of all of the fish. One group of 12 fish was killed 6 ds. later and tectal ^{3}H-RNA was characterized by PAGE. The second group of 12 fish had both optic nerves cut 6 ds. after injection and were killed 7 ds. later, allowing for optic nerves in the tectum to degenerate and thus leaving an optic tectum with degenerated optic axons. Group III was killed along with Group II and tectal ^{3}H-RNA was analyzed by PAGE. If 4S RNA is intra-axonal we would predict relatively less ^{3}H 4S than ribosomal RNA in Group II compared to Groups I and III. In Groups I and III approx. 70% of tectal ^{3}H-RNA was 4S, whereas in Group II (tecta in which optic nerves had degenerated) 4S RNA was approx. 25% of total RNA. It is likely that the loss of ^{3}H 4S RNA, in tecta with degenerated optic axons, is due to the loss of axonally transported intra-axonal 4S RNA. Supported by NIH Grant NS 11259.

1709 UTILIZATION OF EMBRYONIC HIPPOCAMPAL IMPLANTS TO PROMOTE REGENERATION OF THE CHOLINERGIC INPUT TO THE HIPPOCAMPUS IN THE ADULT RAT. Lawrence F. Kromer, Anders Björklund* and Ulf Stenevi*. Dept. of Histology, Univ. of Lund, Lund, Sweden.

Embryonic hippocampal (HPC) tissue (taken from 20-30 mm embryos) was transplanted into a cavity produced by transecting the fornix-fimbria at the septal end of the HPC in adult rats. After 6-15 weeks survival in situ, both the implant and host HCP were analyzed for the presence of acetylcholine esterase-positive (AChE) fibers. Only those specimens which possessed a complete transection of the fornix-fimbria were used in the present experiments. Animals with fornix-fimbria transections but no implants served as controls.

At 6 weeks survival, the HPC implant is in contact with the septum-fimbria rostrally and the host HPC caudally. Regenerating AChE fibers enter the implant only at regions where it has fused with the host fornix-fimbria, septum, the contralateral HPC formation, or the anteriodorsal thalamus. An AChE terminal plexus extends throughout the implanted tissue. This plexus is sparse at the early survival time, but by 3 months it has developed a density similar to that observed in the normal adult HPC. AChE fibers are also observed to grow into the adjacent regions of the host HPC. At 6 weeks, cholinergic fibers are present only in the most rostral regions of the host HPC which are immediately adjacent to the HPC implant. However, there is a progressive invasion of the host HPC by these regenerating fibers so that by 3 months, a moderately dense plexus of AChE fibers has formed within the dorsal HPC. This plexus is densest in the hilar region of the dentate gyrus and among the subicular neurons. Cholinergic axons are also present in regions of the dentate molecular layer nearest the implant, in strata oriens and radiatum of regio inferior and the area of regio superior which is adjacent to the subiculum. More caudally, the AChE fibers gradually disappear with no fibers being present in the most caudal regions of the dorsal HPC or within the dorsal fornix, fimbria, or cingulate bundle. AChE fibers are absent from the entire dorsal HPC of control animals.

The results suggest that intracerebrally matured HPC implants are capable of stimulating the lesioned cholinergic neurons of the adult host brain to regenerate a new terminal system within the implant. The HPC implants also provide a tissue bridge and favorable environment whereby regenerating axons can reach their appropriate postsynaptic target neurons within the adult CNS. In addition, our experiments demonstrate that lesioned adult neurons can regenerate new axons that are capable of growing for considerable distances to reach their normal target neurons provided there is a favorable environment for their regeneration.

1710 ELECTRON MICROSCOPIC COMPARISON OF THE MECHANISM OF AXONAL ELONGATION IN TRANSECTED SPINAL CORDS AND SCIATIC NERVES. R. Liu* D. Rigamonti, J. Wrathall* and C.C. Kao* (SPON: B. Hamilton). Department of Anatomy, Georgetown Univ. Schools of Medicine and Dentistry, Washington, D.C. 20007.

In studying central nervous systems (CNS) regeneration, much can be gained by comparing events in the CNS to those during regeneration of the peripheral nervous system (PNS). In the CNS, despite a sharp and bloodless spinal cord transection, outgrowth of the transected axons from the cut ends of the spinal cord rarely occurs. In the PNS, in contrast, the transected axons emerge, as a rule, from the proximal cut end of the nerve. The reason for this difference between the CNS and PNS is not well understood.

Recent electron microscopic studies of tissue sections obtained at the cut ends of both the spinal cord and the sciatic nerve within minutes to hours after transection have provided some explanations for this difference. In both CNS and PNS, passive leakage of axoplasm from cut ends of fibers occurred almost immediately after transection, thereby shortening the axon. Consequent to the escape of axoplasm, the fiber near the cut end was devoid of axoplasm. The actual end of the axon was set back 1 to 2mm, or sometimes further, from the cut end of the fiber with an axoplasm-free sheath tube extending to the point of transection. Thus, the first requirement necessary for the proximal axon to emerge from the proximal end of the fiber was its advancement within the 1 to 2mm empty sheath tube, which included at least 1 or 2 nodes of Ranvier, to reach the cut end.

In the PNS, the axon advanced wihin its own sheath tube and successfully reached the proximal cut end and then emerged from the cut end of the nerve. The sheath tube in the PNS, consisting of myelin sheaths, Schwann cell cytoplasm and a basement membrane, provided a durable structure for the passage of the axon that was uninterrupted as the nodes of Ranvier were also ensheathed by the continuous neurilemma basement membrane.

The CNS myelin sheaths were without an outer basement membrane. Furthermore, the nodes of Ranvier were normally bare. Loss of axoplasm at the node was seen to cause actual disconnection of the internodal myelin sheaths. Thus, the spinal cord axons were not only unable to advance within the internodal myelin sheaths due to many mechanisms reported previously (J.Neuropath. Exp. Neurol. 36: 140, 1977) but also were unable to cross the nodal space to enter the next paranodal myelin sheath due to the actual discontinuity at the node. Axonal elongation in the CNS after transection was only seen in the form of naked axons advancing within the interstitial space, towards the cut end of the spinal cord.

1711 *PROTEIN SYNTHESIS AND FAST AXONAL TRANSPORT IN REGENERATING* GOLDFISH RETINAL GANGLION CELLS: EFFECT OF A CONDITIONING LESION. Irvine G. McQuarrie and Bernice Grafstein. Dept. Physiol., Cornell University Medical College, New York, NY 10021.

Axonal outgrowth following a lesion of the goldfish optic axons (testing lesion) was enhanced if a similar lesion (conditioning lesion) had been made 14 days earlier. With the testing lesion alone, the delay preceding axonal outgrowth was 4.3 days and the elongation rate was 0.34 mm/day; the regenerating axons began to arrive at the contralateral optic tectum 13-17 days after the testing lesion. When the testing lesion had been preceded by a conditioning lesion, the delay decreased to 2.5 days and the elongation rate increased to 0.74 mm/day; axons arrived at the tectum by 7-11 days.

Protein synthesis and fast axonal transport were also altered as a result of a conditioning lesion. With a testing lesion alone, the incorporation of tritiated proline into the ganglion cells and the amount of newly-synthesized labeled proteins entering the optic axons increased together to reach a peak of 5 times normal at 15 days postoperative. When a conditioning lesion had preceded the testing lesion, incorporation at 1 day following the testing lesion remained at the high level that it had reached at the time the testing lesion was made, whereas the amount of fast-transported protein showed a 70% increase. By 8 days after the testing lesion, incorporation had increased a further 60% but the amount of fast-transported protein had declined nearly to the level that would have been seen in the absence of a conditioning lesion. Thus, the improvement in axonal outgrowth resulting from a conditioning lesion is associated with a transient early increase in the amount of newly-synthesized protein entering the optic axons, occurring prior to any increase in protein synthesis.

A sham conditioning lesion (i.e., a lesion of the contralateral axons) preceding the testing lesion had an effect in increasing protein synthesis, but there was little or no effect on fast axonal transport; axonal outgrowth was slower than in the conditioning lesion group.

1712 *THE REGENERATING SUPRAESOPHAGEAL GANGLION AND ITS CONTROL OF* WITHDRAWAL RESPONSES IN EARTHWORMS. Thea Mendelson* (Spon: B. M. Twarog. Psych. Dept., SUNY Stony Brook, Stony Brook, NY 11790.

The influence of the supraesophageal ganglion on the withdrawal responses of earthworms (L. terrestris) was investigated using morphological and behavioral techniques. The withdrawal response was elicited by applying a bright light spot to the anterior 10-15 segments of the animal. Normal animals responded primarily by withdrawing from the light, either by contracting the anterior part of the body, or by moving the entire body backward with a series of alternating tail extensions and body contractions. Extirpation of the supraesophageal ganglion resulted in photic responses that were often anterior extensions followed by forward locomotion. Animals tested during the course of ganglion regeneration exhibited a gradually increasing tendency toward withdrawal responses until the normal level was reached again at 28 to 35 days post-op.

At this time, although the ganglion was structurally discrete entity, it was strikingly different from the original. The normal ganglion contains obvious neurosecretory granules within unipolar neurons and abutting the capillary network in the area between the cortex and neuropil. In the 35-day regenerate the absence of neurosecretory products in both neurons and storage area suggested that neurosecretion was not a factor in the control of withdrawal responses. This was confirmed in animals whose supraesophageal ganglia were surgically separated from the rest of the CNS but left in situ. They responded as though the ganglion had been removed entirely.

The normal ganglion has a broad dorsal cortex containing many distinct cell types: large pale-staining unipolar neurons medium sized granule-filled neurosecretory cells, very small cells with little cytoplasm, and dopamine and serotonin-containing cells located in specific areas within the cortex. The ganglion of the 35-day regenerate contained only small, non-fluorescing neuron somata similar to the small cells in the original ganglion. This difference in cell population was reflected in the 65% reduction in size of the regenerated ganglion. Furthermore, the neuropil was disproportionately decreased in comparison to the cortex. It was not clear whether a decrease in the size or number of neurons, a decrease in arborization of the neuron processes, or a combination of both produced the decreased size. However, the necessary circuitry to control the withdrawal reflex is contained within this minimally regenerated ganglion.

1713 MATURATION OF REGENERATED SPINAL CORD SEGMENTS IN XENOPUS TADPOLES. M. E. Michel* and P. J. Reier. Dept. Anatomy, Sch. Med. Univ. MD., Baltimore, MD. 21201.

During spinal cord regeneration in Xenopus laevis tadpoles, continuity between the rostral and caudal cord stumps is re-established within 10 days following transection. This process consists of ependymal and neuroblast outgrowth from the rostral and caudal cut ends. In the present investigation, the spinal cords of Stage 54 tadpoles were transected within the lumbar region. The morphology of the regenerated cord segment was studied with the light and electron microscope at post-operative intervals between 2 to 6 weeks. Extensive maturation of the reconstituted cord had ocurred by the fourth week; thereafter, only subtle differences in fiber and cell number were observed. Ependymoglia in this region either surrounded a central canal or aggregated into cellular clusters at the blind ends of central canal diverticula. The organization of gray matter in this segment did not conform with the appearance of the mantle layer at more rostral and caudal levels. The parenchyma of the regenerated cord primarily consisted of unmyelinated axons, ependymoglial processes and oligodendrocytes. The population of myelinated axons progressively increased during the period studied but remained substantially less than that seen at levels within 400 μm of the lesion site. Specifically, large caliber, descending axons within the rostral ventrolateral funiculus were less frequent near the lesion site; even fewer of these axons were observed within the regenerated segment. The animals from which cord specimens were obtained had advanced to later prematamorphic and early postmetamorphic stages of development by the time they were sacrificed. As seen in a companion study of normal spinal cord maturation and within more rostral segments of the operated cords, a considerable increase in fiber number and further cellular maturation were seen during the larval periods represented in this investigation. These observations indicate that reconstitution of a cord segment in this system is occurring during relatively dynamic maturational periods. Such further normal development of the spinal cord, however, does not appear to be reflected by corresponding changes in the axonal and cellular content of the restored segment. (Supported by NIH Grant NS-13836 and the Paralyzed Veterans of America).

1714 "HYBRID" SYNAPSES PRODUCED BETWEEN SOMATIC AXON TERMINALS AND AUTONOMIC NEURONS. W. R. Proctor, S. Frenk* and S. Roper. Depts. Anat. and Physiol., Univ. Colo. Med. Cntr., Denver, CO 80262.

To study the factors which govern how regenerating nerve terminals recognize and re-establish synapses with target cells, we have attempted to reinnervate parasympathetic ganglion cells in the frog heart with a somatic motor nerve. Our aim was to determine the influence postsynaptic targets have on the anatomy, physiology, and pharmacology of nerve endings, and vice versa.

Vagal preganglionic axons terminate in boutons on the cell bodies of cardiac ganglion cells. These synapses are cholinergic and are fairly resistant to α-bungarotoxin (α-BuTX). In contrast, motor nerves in the frog form long branch-like endings without marked varicosities. Furthermore, neuromuscular transmission is highly sensitive to α-BuTX. We here report the properties of functional connections which have been formed by cross-innervating denervated autonomic neurons with the hypoglossal nerve.

These results were obtained as follows: the left hypoglossal nerve (1st spinal motor nerve) was cut and its proximal end sutured to the distal end of the sectioned left vagus nerve. The proximal ends of both vagus nerves were tied into the skin to prevent reinnervation. As a further precaution against spurious vagal reinnervation, in some animals the remaining central stump of the left vagus nerve was resected 7-14 days before analysis.

Ten to 18 weeks after the original operation, somatic innervation to the heart was first tested by stimulating the left hypoglossal nerve at its exit from the spinal cord. Successful cross-innervation was shown by a rapid and complete block of the heart beat caused by repetitive stimulation of the hypoglossal nerve. Next, the heart and the entire length of the cross-innervating hypoglossal nerve (which could easily be traced into the heart) was removed and placed in a chamber for intracellular recording. Stimulating the hypoglossal nerve evoked excitatory postsynaptic responses in 86% of the ganglion cells (23% of these received suprathreshold responses). The conduction velocity of axons reinnervating the ganglion from the hypoglossal was about 0.5 M/sec. Light microscopic (zinc-iodide staining) and electron microscopic evidence showed that the hybrid synapses looked more like vagal boutons and unlike motor end-plates. In addition, α-BuTX studies showed that transmission at these hybrid synapses resembled that in autonomic ganglia; they were resistant to concentrations of α-BuTX which completely abolished neuromuscular transmission in the frog (10^{-8}M).

Our studies suggest that in the frog cardiac ganglion, the target tissue has a pronounced influence on some features of reinnervating pre-terminal endings and furthermore, that the postsynaptic cells retain their transmitter receptor characteristics.

1715 PROPERTIES OF INDIVIDUAL SENSORY AND MOTOR NEURONS ISOLATED FROM THE LEECH CNS AND MAINTAINED IN CELL CULTURE. Donald Ready and John Nicholls. Dept. Neurobiology, Stanford Univ. Med. School, Stanford, CA 94035.

Sensory cells, motor neurons and interneurons in the CNS of the leech show remarkable powers of regeneration. Both in the animal and in organ culture axons grow across the site of a lesion to reform synaptic connections with a high degree of precision. As a next step in approaching the mechanisms that cause neurons to sprout and to send their axons towards appropriate targets, we have devised a technique for isolating single cells, and keeping them alive for prolonged periods.

The connective tissue capsule surrounding a ganglion is cut, exposing the neuronal cell bodies and washing away glial cytoplasm. An individual neuron can be readily identified by its shape, size, position and electrical properties. A noose of fine nylon monofilament is slipped over the neuron and pulled, tying off the cell body. The neuron is then removed by gently pulling the nylon thread away from the ganglion. Individual sensory cells responding to touch, pressure or nociceptive stimuli, Retzius cells, motor neurons and interneurons isolated in this way survive for periods of three weeks or more in medium consisting of Leibovitz 15 with 2% fetal calf serum. Such cells continue to give characteristic action potentials, to produce afterpotentials following trains of impulses and to respond to transmitters applied to the soma.

When single neurons or groups of cells are applied to cover slips coated with polylysine they adhere to the surface and send out sprouts. After about four days a profuse arborization develops and in certain instances adjacent cells become coupled by low resistance, nonrectifying electrical junctions.

Such preparations promise to be valuable for studying the ability of identified neurons to form synapses in vitro and the chemosensitivity of invertebrate neurons and their processes.

1716 PENETRATION OF IMPLANTED ASTROCYTIC SCARS BY REGENERATING AMPHIBIAN OPTIC NERVE FIBERS. Paul J. Reier, Department of Anatomy, University of Maryland School of Medicine, Baltimore, MD. 21201

Previous studies of optic nerve regeneration following surgical transection in amphibian and teleost species suggest that glial scars formed by reactive astrocytes do not impede axonal outgrowth. In Xenopus tadpoles, such scars consist of a loose matrix of astrocytic processes at the time when the first outgrowing neurites enter the degenerating, distal nerve stump. The present investigation was undertaken to determine whether regenerating axonal sprouts in this system are capable of penetrating a dense glial scar. Glial scars were produced in the optic nerves of post-metamorphic, juvenile Xenopus by unilateral enucleations. By 30-40 days the degenerated optic nerve consisted almost entirely of perikarya and densely-packed processes of hypertrophic astrocytes. These degenerated nerves were removed and cut into 0.5-1.5 mm segments. The optic nerves of Stages 54-56 tadpoles were then transected with the entire distal nerve stump being removed. One or more segments of the prepared glial scar was immediately implanted at the cut end of the proximal nerve stump. The tadpoles were sacrificed 2-14 days later, and the astrocyte allograft was examined with the electron microscope; no rejection of the implant occurred within this two week period. The astrocytes within the graft remained hypertrophic; their processes were highly-compacted. By 7-10 days, numerous, unmyelinated axons were present within the implant and appeared to extend the full length of the implanted scar. Growth cones were observed both deep within the implant and at its surface. These observations demonstrate that under the conditions of this experiment, an extremely dense glial scar formed by mature, hypertrophic astrocytes, does not constitute a barrier to axonal outgrowth. In mammals scars formed by reactive astrocytes are believed to inhibit axonal outgrowth. Whether neuroglial scarring in this system is comparable to that occurring in mammals remains to be determined; nevertheless, these results emphasize the need for re-evaluating the significance of astrocytic scarring in the failure of mammalian CNS regeneration. (Supported by NIH Grant NS-13836 and the Paralyzed Veterans of America).

1717 AN INVESTIGATION OF SELECTIVE REINNERVATION OF RAT SKELETAL MUSCLES. Dan A. Riley. Dept. Anat., Sch. Med., UCSF, San Francisco, Calif. 94143.

Most workers examining reinnervation of mammalian skeletal muscles conclude that the process is non-selective. However, Hoh (J. Physiol. 251, 1975) reported that in the rat the soleus nerve cross-reinnervated, at best, 50% of the fast EDL muscle whereas self-reinnervation of the slow soleus muscle was nearly 100%. In contrast, the nerve of a fast muscle was able to reinnervate fully both fast and slow muscles. The apparent inability of the soleus nerve to innervate the EDL muscle was investigated further in the present study. Although EDL muscles are composed primarily of fast fibers, there is a small population of slow fibers. The possibility exists that soleus nerve fibers preferentially reinnervate slow fibers leaving fast fibers denervated. This was checked in 16 rats in which the soleus nerve was directed to reinnervate the EDL muscle under optimal conditions, i.e., no competition from the EDL nerve and the soleus muscles were removed completely to prevent self-reinnervation. Three to 8 wks following surgery, the degree of innervation was assessed by comparing the tension generated by soleus nerve stimulation with that obtained by massive direct stimulation of the whole muscle. Functional innervation of individual EDL fibers was affirmed by the glycogen-depletion technique of Kugelberg and Edström (J. Neurol. Neurosurg. Psychiat. 31, 1968). Serial cryostat sections were stained histochemically with the PAS reaction for glycogen and for myosin ATPase and NADH dehydrogenase activities to identify fiber types and assess the functional state of their innervation. At 3 wks only EDL muscles contracted in response to soleus nerve stimulation. However, 5-8 wks after surgery in over half of the cases neighboring denervated muscles, such as the TA and PL, were innervated by the soleus nerve. In other instances, nerve fibers grew back over the surface of non-denervated muscles without synapsing. Thus, these results indicate that the incomplete reinnervation of the EDL in part accounted for by the failure of soleus nerve fibers to reach the EDL. Even so, tension measurements indicated that on the average 83% of the EDL muscle fibers were cross-reinnervated. Those nerve fibers reaching the EDL functionally innervated both fast and slow fibers. The total number of innervated fibers exceeded the normal number of slow fibers. Therefore, it is unlikely that incomplete reinnervation was due to a failure of soleus nerve fibers to innervate fast fibers. The present results reveal that incomplete cross-reinnervation of the EDL by the soleus nerve is a problem of nerve fiber ingrowth rather than selectivity in forming connections. Supported by a grant from the Musc. Dyst. Assoc. of Amer., Inc.

1718 NEONATAL 6-HYDROXYDOPAMINE-INDUCED NORADRENERGIC SPROUTING IN THE RAT CEREBELLUM: INTRACISTERNAL DOSE-RESPONSE STUDIES. Richard H. Schmidt* and Ranbir K. Bhatnagar. Dept. Pharmacology, University of Iowa, Iowa City, IA 52242.

Treatment of neonatal rats with 100 mg/kg 6OHDA by the subcutaneous route is known to result in derangement of the development of the noradrenergic locus coeruleus system. This is characterized by extensive, permanent loss of norepinephrine (NE) from telencephalic structures and spinal cord, but a marked increase in NE content in the brain stem and cerebellum. As part of a more extensive study of the reasons for this developmental response to 6OHDA, a dose-response relationship for this effect was determined using intracisternal 6OHDA application in order to obviate any influence of the blood brain barrier.

On the day of birth Sprague-Dawley rat pups were distributed 10 per litter and injected intracisternally with 10, 20, 40 or 80 µg 6OHDA or 4 µl vehicle while cold-anesthetized. At 32-35 days of age various brain regions were dissected for NE assay by a radioisotopic method. The cerebellum was cut in a cryostat in .5 mm thick saggital sections from which 7 discrete regions were sampled by micropunching.

At all doses NE content of the cervical and upper thoracic spinal cord was reduced by more than 95%. In several cortical regions NE depletion was 50-75% after 10 µg, and greater than 90% at the 3 higher doses. In the cerebellum 10 µg of 6OHDA resulted in NE levels ranging from 140-190% of control; after 20 µg the range was 190-225%; after 40 µg the range was 120-225%; and after 80 µg the range was 10-20%. At doses of 6OHDA between 10-40 µg, NE content, both absolute and as percent of control, was highest in vermian lobules I-III and IV-VIa and lowest in lobules VIb-VIII and IX-X. There was no tendency for a gradient of NE following proximity to the locus coeruleus.

Intracisternal 6OHDA treatment of 20-40 µg thus duplicates the salient features of 100 mg/kg 6OHDA s.c. At 80 µg NE terminal growth is prevented throughout the brain, but at lower doses occurs to a considerable extent in the cerebellum but not cerebral cortex or spinal cord. The high resistance of the neonatal cerebellar noradrenergic innervation does not appear to be due to a resistance to the degenerative effects of 6OHDA, first because of the lack of a simple dose-response relationship between 10-80 µg, and secondly because 12-48 hours following injection, initial drug-induced depletion of NE exceeds 95%. Regenerative growth and collateral sprouting thus probably account for the recovery and hypertrophy of NE levels in the cerebellum. The neonatal cerebellum may possess some unique attribute which promotes reinnervation from axotomized locus coeruleus neurons, and this attribute is not present in either the cerebral cortex or spinal cord.
(Supported by USPHS grant NS-12121.)

1719 PRELIMINARY STUDIES OF PROTEIN SYNTHESIS IN THE FROG RETINA 1-6 DAYS AFTER SECTION OF THE OPTIC NERVE. Thomas M. Scott and Alen J. Mathewson. Faculty of Medicine, Memorial University of Nfld., St. John's, Newfoundland, Canada A1B 3V6.

While regeneration in the CNS of mammals is limited, reformation of original connections occurs readily in lower animals. Many factors have been cited as contributing to the lack of CNS regeneration in mammals. One of these factors is the ability of the axotomised neuron to synthesise protein necessary for regrowth. These preliminary investigations form part of a larger comparative study of factors involved in CNS regeneration.

The left or right optic nerves were cut, close to the chiasma in 25 rana pipiens. At daily intervals from 1-6 days, each animal was injected I.V. with 30μCi ^{3}H-leucine. Three hours later the animals were decapitated and the retinae removed into 3ml of 0.9% saline. The retinae were homogenised in a glass homogeniser and 50μl were removed for estimation of protein content. 3ml of 10% TCA was then added to the homogenate. 20 minutes later the homogenate was filtered through a millipore filter, rinsed twice with 2ml 5% TCA and once with 3ml 95% ethanol. After drying, the discs were placed in scintillation vials to which 1ml Protosol was added. The vials were then left for 12 hours before adding 10ml Liquifluor and counting in a Beckman LS 9000 scintillation counter. The 50μl of homogenate removed before TCA precipitation were used for protein estimation using the Bio-Rad protein assay.

In this way readings were obtained for cpm/mg protein. This figure was compared for the operated and control retinae and expressed as a ratio. The ratio of operated to control was compared at one to six days. No significant difference was found, in incorporation rate into the TCA precipitable fraction between regenerating and control eyes from one to six days after section of the optic nerve.

While no similar studies have been reported in frogs, Grafstein and Murray (Exp. Neurol. 25, 494-508, 1969) have reported an increase in transport, perhaps reflecting an increase in synthesis, occurring between 6 and 8 days after section of the optic nerve in the goldfish. It is intended to extend these studies to cover longer periods.

1720 BIOCHEMICAL EFFECTS OF NERVE GROWTH FACTOR ON NORMAL AND AXOTOMIZED SUPERIOR CERVICAL GANGLIA FROM ADULT RATS MAINTAINED IN VITRO. D.V. Sinicropi* and F.C. Kauffman. Dept. Pharmacology & Exp. Ther., School of Medicine, Univ. Maryland, Baltimore, MD. 21201.

Conditions were established for the culture of adult superior cervical ganglia to determine if biochemical alterations initiated by axotomy in situ are maintained in vitro. Whole desheathed ganglia from 150-175 g rats (7-8 weeks of age) were placed on stainless-steel grids just below the atmosphere-media interface and cultured in 200 μl of Eagle's minimum essential medium supplemented with 10% (v/v) fetal calf serum. Incorporation of leucine-H^{3} into acid precipitable material of cultured ganglia was linear for at least 48 hours. In contrast, concentrations of ATP and phosphocreatine in the tissue were reduced more than 5-fold after 21 hours in vitro. NAD:NADH ratios, calculated from measured levels of pyruvate and lactate, decreased to approximately 20% of control (not cultured) values within 6 hours and subsequently remained constant for at least 21 hours. Despite this rapid decline in energy status of the cultured tissue biochemical changes elicited by axotomy are maintained.

Enhanced activity of 6-phosphogluconate dehydrogenase (6PGDH) and elevated protein content that occur after axotomy of the ganglion in situ (Harkonen and Kauffman, Brain Res. 65: 141-157, 1974) are maintained in culture as indicated in the table below.

hours culture		6PGDH activity $\mu mol \cdot min^{-1} \cdot g\ protein^{-1}$	protein content $\mu g \cdot ganglion^{-1}$
		NORMAL GANGLIA	
0		7.17 ± 0.15	62.5 ± 2.0
48	-NGF	8.81 ± 0.26	85.7 ± 2.0
	+NGF	10.68 ± 0.53	71.8 ± 3.0
		2-DAY AXOTOMIZED GANGLIA	
0		8.77 ± 0.20	92.9 ± 4.2
48	-NGF	12.62 ± 0.52	117 ± 6.0
	+ NGF	11.35 ± 0.60	105 ± 6.9

The increase in 6PGDH activity that occurs in normal ganglia placed in culture is enhanced by nerve growth factor (NGF). NGF did not enhance the activity of axotomized ganglia maintained in vitro. These results support the hypothesis that selective increases in metabolism via the pentose pathway occur in nerve cell bodies subsequent to axonal injury, and suggest that similar biochemical alterations are elicited in normal ganglia maintained in vitro.

1721 RETINAL GANGLION CELL RESPONSE TO AXOTOMY AND NERVE GROWTH FACTOR IN THE REGENERATING VISUAL SYSTEM OF THE NEWT: AN ULTRASTRUCTURAL MORPHOMETRIC ANALYSIS. James E. Turner and Rebecca K. Delaney*. Dept. Anat., Bowman Gray Sch. Med., Wake Forest Univ., Winston-Salem, NC 27103.

Nerve growth factor (NGF) treatment, given as a single 200 BU intraocular injection at the time of optic nerve transection, was found to significantly alter the retinal ganglion cell response to axotomy in the newt (Triturus viridescens). In the control series the percent of neurons in the retinal ganglion layer demonstrating nuclear reactivity (i.e., chromatin changes) reaches a peak by 14 days post axotomy (14 DPA), plateaus through 21 DPA and falls thereafter returning to control levels by 90 DPA. NGF treatment is shown to significantly accelerate the entrance of responding retinal ganglion cells into the reactive nuclear phase between 1-7 DPA and by 7 DPA nuclear reactivity has reached a peak, in contrast to 14 DPA for control values. Consequently, NGF treatment causes retinal ganglion cells to remain in the nuclear reactive state a week longer than controls but reactivity diminishes after 21 DPA like control values. Electron microscopic morphometric analysis further substantiates these observations by demonstrating that NGF treatment can elicit certain cellular organelle changes a week earlier (i.e., at 7 DPA) than they would normally occur (i.e., at 14 DPA). In addition to eliciting cellular hypertrophy at 7 DPA, NGF treatment significantly increases mitochondrial and Golgi field densities in the neuronal perikaryal cytoplasm as well as a doubling of the number of nucleoli per nucleus and stimulates a significant increase in nucleolar cross sectional areas. A dose response relationship exists between the percent of retinal ganglion cells demonstrating nuclear reactivity at 7 DPA and various NGF concentrations which compares favorably with the dose response study involving the number of regenerating axons per nerve cross section at 14 DPA. Studies to determine if the NGF mediated responses were a specific effect elicited by this protein molecule or whether they are also produced by other peptides which share some properties in common with NGF demonstrate that only NGF is capable of eliciting these responses.

Supported by a Basil O'Connor Starter Research Grant from the National Foundation March of Dimes; a grant from the National Society for the Prevention of Blindness made possible through the Adler Foundation and an NIH grant NS 12070 awarded to Dr. Turner. Dr. Turner is also the recipient of an NIH Research Career Development Award NS 00338.

1722 REINNERVATION OF RAT EXTENSOR DIGITORUM LONGUS MUSCLES AFTER AUTOGENOUS FREE GRAFTING. Kenneth R. Wagner, Bruce M. Carlson*, and Stephen R. Max. Depts. Neurol. & Peds., Univ. Md., Sch. Med., Baltimore, MD 21201 and Dept. Anat., Univ. Mich., Sch. Med., Ann Arbor, MI 48104.

Morphological and biochemical studies were undertaken to determine the time-course and extent of reinnervation of freely-grafted muscles. Extensor digitorum muscles were removed from rats and injected with a solution of 0.75% Marcaine. After incubation in Marcaine solution for 10 min., the muscles were grafted into their original beds (Carlson, Exp. Neurol., 52:421, 1976). Grafts and contralateral control muscles were removed at 4, 7, 11, 15, 19, 25, 31 and 90 days postoperatively. One series of muscles was examined histologically. A parallel series was assayed for the activity of choline acetyltransferase (CAT), a marker for formation of cholinergic synapses. CAT was 2% control by day 4 and 6% by day 7. Between days 7 and 11 there was a 4-fold increase in activity, to 27% control. After this time, CAT rose continuously to 60% control by day 90, an overall increase of 30-fold. Morphological data to be presented indicate that early changes in CAT are closely correlated with the pattern and time-course of reinnervation of the grafts. These results indicate incomplete innervation of grafted muscles which may be one factor accounting for the incomplete recovery of fresh weight (< 50%) and a number of enzyme activities observed previously (Wagner et al., J. Neurol. Sci., 34:373, 1977). For maximal functional development of transplanted muscles, efforts should be directed to facilitation of reinnervation. (Supported by grants from the Muscular Dystrophy Assn., Inc., NIH - NS 13116 and the National Amyotrophic Lateral Sclerosis (ALS) Foundation).

1723 POLYACRYLAMIDE GEL SEPARATION OF AMINO ACID LABELLED PROTEIN FROM BRAIN AND SPINAL CORD AFTER SPINAL CORD HEMISECTION IN THE RAT. M. R. Wells, Dept. of Neurosci., Univ. of Fla., Gainesville, Fla.,

Following spinal cord hemisection in the rat, general increases in amino acid incorporation into protein occur in brain and spinal cord which appear to be associated with operative stress (Wells and Bernstein, Exp. Neurol. 57: 900-912, 1978). Local increases in protein incorporation also occur in the spinal cord at the site of lesion between one and three days postoperative. Proteins mediating these changes have been studied in the present experiments. Male, Long-Evans Hooded rats were given a laminectomy and dura cut (sham) at spinal segment T2, a left spinal cord hemisection, or no operative procedures. One hour prior to utilization at 1, 3, and 14 days postoperative, animals were injected subcutaneously with 200μCi of [^{3}H]-L-lysine and 200μCi of [^{3}H]-L-amino acid mixture. Samples were taken from somatomotor cortex and left side of spinal cord extending 2mm rostral and caudal to the lesion. Samples were prepared for electrophoresis and protein separated on 3.0mm, gradient (7.5-18.75% acrylamide), SDS polyacrylamide slab gels. Gels were fixed in trichloroacetic acid, stained with Coomassie Blue, photographed, cut into slices, and processed for scintillation counting.

In somatomotor cortex there was evidence for a general stimulation of amino acid incorporation at one day postoperative in sham and spinal hemisected animals. At three days proteins in the regions of 70-80,000 molecular weight (MW) and 50-65,000 MW showed transient increases in radioactivity compared to normal, while protein in the region of 35-50,000 MW decreased in both sham and hemisected groups. At 14 days only an increase in radioactivity of heavy molecular weight proteins (>125,000) was present in both operated groups. In spinal cord at one day postoperative, significant increases ($p<0.05$) occurred in the radioactivity of proteins of 10-20,000 MW, 45-55,000 MW, and 70-80,000 MW in both sham and hemisected animals. At three days postoperative, spinal hemisected animals exhibited significant increases in the radioactivity of proteins in the regions 40-55,000 MW. By 14 days postoperative patterns of radioactivity had returned to normal except for an increase in the region of 10-35,000 MW for sham and hemisected animals. The above data indicate that increases in amino acid incorporation into brain and spinal cord of laminectomized and spinal hemisected animals have specific and nonspecific components. (Supported by a grant from NINCDS [NS-06164] and the Paralyzed Veterans of America).

1724 SYNAPTIC REGENERATION IN THE LAMPREY SPINAL CORD. Malcolm R. Wood* and Melvin J. Cohen. Dept. of Biol., Yale Univ., New Haven CT 06520

Spinal cord regeneration in the larvae of lamprey has been previously reported based on the return of swimming and the tracing of axons with light microscopy following spinal transection. Our aim in this study was to determine, ultrastructurally, whether identified regenerated spinal neurons establish synaptic contact distal to the lesion. We find clear ultrastructural evidence that severed spinal axons grow across the lesion and establish synaptic connections.

Larvae of the sea lamprey Petromyzon marinus were anaesthetized and the spinal cord was transected. There is no swimming for several days following spinal transection. By 4-5 weeks coordinated swimming has returned in 90% of the survivors. In the functionally recovered animals, 4% horseradish peroxidase (HRP) was intracellularly injected by iontophoresis into the cell bodies of identified giant reticulo-spinal neurons (Mauthner and MUller cells) at postoperative intervals from 30 to 200 days.

In cleared whole mounts of the brain and spinal cord, axons of the injected neurons often branch and run parallel to each other as they approach the lesion. Some of the regenerating neurites cross the lesion and proceed up to 4mm into the distal region of the cord. Other branches of the same neuron may make a sharp "U" bend at the lesion and return toward the brain, while still other neurites terminate at the lesion. After crossing the lesion, the regenerating axons may also branch several times. Some of these neurites may then turn and grow rostrally to re-cross the lesion and end in the proximal part of the cord. Thick (5μm) serial sections show that branching may start 1-2mm proximal to the lesion. The growing fibers on each side of the cord diverge laterally from their normal mid-ventral location and grow toward the periphery of the cord. After crossing the lesion, they grow distally in the periphery of the cord and show little affinity for the mid-ventral area where the distal axonal stumps of these neurons have degenerated.

Electron microscopic examination of regenerating axons filled with HRP show an overall darkening of the filled processes. Regenerating axons distal to the lesion bear numerous club-shaped spines (up to 1.7mμ in length) that are frequently filled with spherical lucent vesicles. Spines containing these vesicles form typical synaptic junctions consisting of para-membranous densities and a uniform membrane separation characteristic of a synaptic cleft. The regenerated spines are always presynaptic and the postsynaptic element is invariably a small process. Synapses are also found on the regenerating neurite in regions devoid of spines, and here also the marked process is invariably presynaptic.

Our observations provide direct ultrastructural evidence that regenerating spinal axons can form new synaptic junctions distal to a lesion. This preparation provides a model system with identified elements for investigating some of the factors controlling synaptic regeneration in the vertebrate central nervous system. (Supported by NIH grant 5RO1 NS 08996).

1725 FUNCTIONAL REPAIR OF INJURED PERIPHERAL NERVE TISSUE WITH NERVE ALLOGRAFTS BEARING ONLY MINOR TRANSPLANTATION ANTIGENS. Andrew A. Zalewski and Willys K. Silvers*. LNC, NINCDS, NIH, Bethesda, Md. 20014 and Dept. of Human Genetics, Univ. of Pa. Sch. Med., Philadelphia, Pa. 19174.

We previously reported that neurilemmal (Schwann) cells survived longer in allografts which contained minor rather than both major and minor transplantation antigens. Since the neurilemmal cells of a nerve aid nerve fiber regeneration we investigated whether host motor nerve fibers would regenerate through a nerve allograft and reinnervate denervated muscles. Inbred Fischer and Lewis rats which differ only in minor antigens were used. Injury to nerve tissue which resulted in the denervation of the extensor digitorum longus (EDL) and tibialis anterior (TA) muscles was produced by removing a 1.4 cm segment of the host peroneal nerve and replacing it with a 1.8 cm peroneal nerve allograft. After 110 days myelin could be seen grossly throughout the length of nerve allografts and staining of these tissues showed the presence of nerve fibers, myelin and occasional foci of lymphocytes. Stimulation of the peroneal but not the tibial nerve of allografted animals caused a contraction of the EDL and TA muscles which now weighed 70-85% of normal. Sections of muscles revealed the presence of nerve fibers, neuromuscular junctions, and large-diameter muscle fibers which were localized into larger type-groups than normal.

In other studies rats, which had nerve allografts in residence for 110 days, were grafted intramuscularly with a skin or ganglion allograft that bore the same minor antigens as the nerve allograft. As expected these skin and ganglion allografts were rejected, but their rejection was not accompanied by any cellular infiltration of the nerve allograft or by any deterioration of muscle innervation. What apparently had happened was that allogenic cells in the nerve graft survived long enough to permit host nerve fiber regeneration and then they were rejected and replaced by host cells, some of which myelinated the nerve fibers. This seems to be the case since acute myelin degeneration and lymphocytic infiltrations were observed in long-term nerve allografts when previously established tolerance to alloantigens of the nerve donor was broken. It is of interest that allografts cultured overnight at 4° C later permitted host nerve fiber regeneration through them while still maintaining their antigenicity. Our results demonstrate that it is possible to rapidly and functionally repair a large injury to peripheral nerve tissue with a nerve allograft bearing minor antigens in nonimmunosuppressed rats and we suggest such allografts be used in man.

SLEEP

1726 THE EVOKED POTENTIAL SOMNOGRAM - HUMAN AND ANIMAL STUDIES. R.G. Bickford, R. Hajdukovic*, K. Hanson*, Y. Kammer*, C.B. McCutchen, and J. Franke*. Department of Neurosciences, EEG Laboratory, University of California, San Diego, La Jolla, CA and the Veterans Administration Hospital, La Jolla, CA 92093.

The somnogram (K. Hanson, et al., Proc. San Diego Biomed. Sympos., 13:545-548, 1974) is a computer generated (PDP/12 and PDP/1140) data display employed in sleep and coma studies. It allows the sequential relations of EEG, EOG, EMG, respiration to be viewed over periods up to 48 hours in a highly compressed format (3-6 pages). We have recently introduced evoked potential data into this format so that average evoked responses to click, flash or shock are recorded alongside spectral changes of the spontaneous EEG. This display provides increased information in the following areas: Human. 1) Onset of sleep in the human (see figure below) with the remarkable enhancement of the auditory evoked response (AER). This appears to be a sensitive index of sleep onset. 2) In narcolepsy, there are abnormalities of both frequency spectrum and evoked response. 3) In coma, patients may show a) absence of AER, b) monotonic unchanging AER, c) modulation of the AER as seen in normal sleep. Animal. Clearly depicted sequential changes in the rat AER provide a useful index for staging and for sleep and coma studies in this animal.

1727 CIRCADIAN RHYTHMS OF SLEEP, ACTIVITY, AND TEMPERATURE IN THE RAT UNDER ENTRAINED AND FREE-RUNNING CONDITIONS. Charmane Eastman. Sleep Lab., Univ. of Chicago, Chicago, IL 60637.

Long-term recordings of circadian rhythms of three different variables in the rat were made under various lighting conditions to gather normative data and reveal properties of the underlying oscillator(s). Sleep and waking were scored in 30 sec epochs by the computer system of Bergmann et al. (Sleep Res. 6: 206, 1977). Temperature was recorded from thermistors implanted in the intraperitoneal cavity, on the surface of the brain, or cemented to the skull under the temporalis muscle. Tilt-cage activity was registered by a microswitch. All three variables were recorded simultaneously 24 hrs a day and were stored every 30 sec by a PDP-11 computer. Periodograms measured the degree of entrainment to the light-dark (LD) cycles and the period length in free-running conditions. Acrophases, determined by the maximum of the best-fitting cosine wave to the average curves, were used to measure the external phase relationships to the Zeitgeber (LD cycle) and the internal phase relationships between the three rhythms. Data were displayed graphically by computer.

So far, six rats have been run on a 24 hr day (L,D;12,12). After entrainment was established, the rats were assigned to a variety of lighting schedules including DD (dim), LL, increasingly longer days e.g., 26 hrs (L,D;13,13) and 28 hrs (L,D;14,14) and shorter days e.g., 22 hrs (L,D;11,11). Temperature, activity, and waking followed a parallel course, peaking near the middle of dark in the 24 hr day. As predicted by oscillator theory, the phase of all three rhythms advanced relative to the Zeitgeber as the period of the Zeitgeber increased. In constant conditions, the circadian component was gradually diminished as ultradian rhythms in the range of 3 to 6 hrs became more prominent. The period lengths in LL (25.6 hrs) were longer than in DD (24.6 and 24.8 hrs), as predicted by Aschoff's rule.

Some rats in the 22 and 28 hr days showed two frequencies in the rhythm of each variable, one corresponding to the imposed LD cycle and one in the circadian range with period lengths of, for example, 24.8 or 25.4 hrs. The simultaneous presence of two frequencies will give rise to "beats," a waxing and waning in the amplitude of the rhythms. The observed beat frequency matched the predicted beat frequency calculated from the two periods seen in the periodograms. These results suggest that these rhythms are controlled by two oscillators, one of which remains entrained by the LD cycle, and one which breaks away and free-runs through the LD cycle.

1728 EFFECT OF β-(NAPHTHYL-1)-ALANINE, A TRYPTOPHAN ANALOG, ON MONOAMINES IN SPECIFIC BRAIN STRUCTURES AND SLEEP IN RATS. Casimir Fornal*, Walter J. Wojcik, Miodrag Radulovacki, and Hans G. Schlossberger* (SPON: H. K. Proudfit). Dept. of Pharmacol., Univ. Ill. Med. Ctr., Chicago, IL. 60680 and Max-Planck Inst., Martinsried, West Germany.

We showed (Wojcik et al., this meeting) that the administration of L-tryptophan (30 mg/kg, i.p.) to rats affected brain monoamines and sleep. We were interested to see whether DL-β-(naphthyl-1)-alanine hydrochloride (β-NA), a tryptophan analog, had similar effects. In one group of adult rats we analyzed 5-hydroxytryptamine (5-HT), 5-hydroxyindoleacetic acid (5-HIAA), dopamine (DA) and norepinephrine (NE) in the cortex (CX), hippocampus (HIPP), pons-medulla (PM) and striatum-thalamus (ST) fifteen and forty-five minutes after a single injection of β-NA (30 mg/kg, i.p.). The animals were sacrificed by decapitation and the monoamines and 5-HIAA were determined by spectrophotofluorometric methods. Fifteen minutes after injection, there was a reduction of DA in the CX by 40% and NE in the HIPP by 16%. In addition, 5-HT levels in the CX were reduced by 10%. 5-HIAA concentration did not change. There was no change in 5-HT, 5-HIAA, DA and NE in all studied structures forty-five minutes after administering the agent.

In another group of adult rats, cortical and neck muscle electrodes were implanted for EEG and EMG recording. One week after surgery the animals were injected with either saline or β-NA (30 mg/kg, i.p.) and polygraphically recorded for six hours. On the following day the same protocol was repeated with the same group of animals but with reverse administration of the agents. Records were analyzed for the amount of time spent in wakefulness (W), slow-wave sleep (SWS), and paradoxical sleep (PS). Furthermore, latencies to first SWS and first PS episodes were determined. Paired t analysis performed at half-hour intervals showed that β-NA increased SWS by 11% and decreased W by 11% during the first half-hour period. We also found that β-NA reduced SWS latency by 50%. There was no change in PS or PS latency. Our data show that SWS latency coincides with the reduction of DA, NE, and 5-HT. Since increased 5-HT turnover has been found to correlate with SWS (Buckingham and Radulovacki, 1975; Kovacevic and Radulovacki, 1976), obtained decrease in 5-HT and no change in 5-HIAA could not account for decreased SWS latency. Therefore, we suggest that the decrease in SWS latency may be due to the reduction of catecholamines in the CX and HIPP.

1729 METHOD FOR INTRACELLULAR RECORDING OF LUMBOSACRAL MOTONEURONS DURING NATURAL SLEEP IN CATS. Loyd L. Glenn, Arthur Poutz and William C. Dement. Stanford University School of Medicine, Stanford, CA 94305.

In order to analyze the changes in motor control during sleep and wakefulness, a method has been developed which enables the intracellular recording of spinal motoneurons in unanesthetized and unparalyzed cats. Cats were chronically implanted for sleep recordings and stimulation of the tibial nerve. The lamina and pedicles of vertebrae L4-L6 were exposed and stainless steel screws inserted into the body of each vertebra. A 1.5 mm opening was drilled 1.8 mm from midline in L5 and the exposed dura mater excised. After a cylinder was placed around the microelectrode opening and knurled nuts placed on each of the adjacent vertebrae, the entire assembly was fused together with acrylic cement. Agar and a cylinder cap temporarily sealed the microelectrode opening. After recovery from surgery, the cats were periodically habituated to simultaneous cranial and lumbral restraint prior to any microelectrode descents. Although it was possible to impale antidromically invaded cells, another identification criterion was used to increase the chances of recording from motoneurons. After either spontaneous discharges or after spikes elicited by short intracellular current pulses, a long and scallop-shaped after-hyperpolarization can be used, according to current knowledge, as a strong indication that the recorded cell is a motoneuron. Ten lumbosacral motoneurons identified by these methods were held 4-15 min covering at least one transition between two different states per cell (wakefulness, NREM, and REM sleep). Three of these cells were recorded continuously through all three states. The main barrier to longer recordings were cord movements during spontaneous postural readjustments by the cat.

Preliminary results indicate little or no change in membrane potential during the transitions from wake to NREM, contrasting with an abrupt hyperpolarization at the onset of REM sleep muscular atonia. This hyperpolarization usually followed a more gradual one just preceding the onset of REM sleep. Although the length of time that individual neurons can be studied is low by comparison to acute studies, this preparation is useful in studies on motor and postural control during sleep and wakefulness.

1730 EFFECTS OF DIAZEPAM ON SLEEP, TEMPERATURE, 5-HYDROXYINDOLEACETIC AND HOMOVANILLIC ACIDS IN CISTERNAL CSF OF CATS. Mindaugas L. Griauzde*, Edward H. Chen* and Miodrag Radulovacki (SPON: L. Isaac). Dept. Pharmacol. Biomed. Prog., Univ. of Illinois, Chicago, IL. 60612.

Administration of benzodiazepines produces a decrease in brain dopamine (DA) metabolism while data on brain 5-hydroxytryptamine (5-HT) metabolism are inconclusive. We have examined the effects of various doses of diazepam (DZ) on sleep, cerebrospinal fluid (CSF) concentrations of 5-hydroxyindoleacetic acid (5-HIAA), a 5-HT metabolite, and homovanillic acid (HVA), a DA metabolite, and rectal temperatures of cats. CSF was obtained from a cannula in the cisterna magna (Radulovacki, 1974). 5-HIAA and HVA were determined by the method of Korf and Valkenburgh-Sikkema (1969). Five days after implantation the animals underwent continuous EEG, EMG and EOG recordings from 9:00 AM until 2:30 PM each day for four days with CSF samples taken at two-hour intervals starting at 10:30 AM and ending at 2:30 PM. Doses of DZ (0.3 mg/kg - 1.5 mg/kg) were administered i.p. at 9:00 AM on experimental days and polygraphic recordings, along with CSF samples and rectal temperature measurements, were taken in the same manner as controls.

Our results show that administration of DZ produced a significant increase ($p < 0.02$) in slow-wave sleep (SWS) with a peak occurring at a dose of 0.9 mg/kg. Further increase in doses of DZ decreased SWS. DZ administration produced no change in REM sleep, rectal temperature, and CSF 5-HIAA and HVA levels. Since no correlation between various doses of DZ and CSF concentrations of 5-HIAA and HVA was found in the presence of an increased percentage of SWS, this suggests a possible mode of action by DZ mediated through pathways other than those associated with normal sleep mechanisms.

1731 THE EFFECT OF SLEEP UPON THE TRANSMISSION OF AFFERENT ACTIVITY IN THE SOMATIC AFFERENT SYSTEM. Gündüz Gücer. Dept. Neurosurgery, Sch. Med., Johns Hopkins Hospital, Baltimore, MD 21205.

Macaque monkeys were trained to fall asleep while sitting in a primate chair with head restrained. A gentle vibratory stimulus was delivered to the glabrous skin of the hand; it did not provoke awakening or change the sleep cycle of the macaque. Postcentral neuronal response to the amplitude of a sine-wave mechanical stimulus and neuronal spontaneous activity were observed repetitively during all the phases of normal night sleep cycles. 106 neurons which could be entrained by a cutaneous mechanical stimulus were studied during both waking and sleep. At threshold, cyclic entrainment of the discharges of postcentral neurons decreased to 81 ± .25% during light sleep (S_1+S_2), to 64 ± .26% during deep sleep (S_3+S_4), and to 9 ± .98% during desynchronized sleep with rapid eye movements (REMs).

The responsiveness of neurons of the primary sensory cortex (Brodmann area 1,2,3) appears to be a balance of the specific thalamocortical input versus the generalized thalamocortical input. During slow wave sleep a progressive increase in the influence of the generalized thalamocortical system is felt to lead to a decrease in postcentral neural entrainment. Superimposed on this decreased entrainment is a further loss of entrainment during REM's of desynchronized sleep which is felt to be secondary to post and presynaptic inhibition at the dorsal column nuclei, in the brain stem.

1732 EFFECT OF HEROIN WITHDRAWAL UPON RAPID EYE MOVEMENT (REM) SLEEP IN HUMANS. Richard C. Howe, Frederick W. Hegge*+ and Jerry L. Phillips*. Dept. of Physiology and Bioengineering, Eastern Virginia Medical School, Norfolk, VA 23501 and +Dept. Experimental Psychophysiology, Walter Reed Army Institute of Research, Washington, D.C. 20012.

The objective of this study was to examine the effect of withdrawal from pure heroin upon various sleep parameters. The data was obtained from young military personnel who were addicted to pure heroin, used no other drugs concurrently, utilized the nasopulmonary route of administration and had short heroin use histories. This setting thus provided a good model to evaluate heroin withdrawal without the many complications associated with statewide drug users.

Electroencephalogram (EEG), electrooculogram (EOG) and other physiological parameters were recorded on a 24-hour per day basis for 5-7 days. Twenty heroin dependent patients and five drug-free controls were studied. Control subjects were non-addicts undergoing the exact same experimental procedures as the addicts. EEG records were manually scored into the standard awake and sleep states. All scored EEG data were transferred to a computer for subsequent analyses.

Preliminary results for REM sleep have been summarized below (see table). Day 1 was not included in the final means because the addicts did not begin withdrawal until midway through Day 1, after they had "nodded out" and/or slept through the first part of Day 1. By contrast, the controls did not sleep well on Day 1 showing the typical "first night" effect. On Day 1, both the controls and heroin addicts averaged approximately the same amount of REM sleep (53-54 minutes). On days 2-5, REM sleep increased for the controls to a mean value of 95 minutes. The addicts during withdrawal (Days 2-5) showed a marked decline in REM sleep to approximately 29 minutes. Also, the heroin addicts during the "nodding out" phase on Day 1 showed less REM sleep (54 minutes) than the control values on Days 2-5 (mean 95 minutes). These results indicate that REM sleep time is significantly decreased during heroin withdrawal. Further analyses of interstate intervals, duration and frequency of REM periods is necessary in order to examine the biological periodicity of this state during heroin withdrawal.

1733 L-TRYPTOPHAN AND METHYSERGIDE EFFECTS ON SLEEP IN CATS. Herbert L. Jackman and Miodrag Radulovacki. Dept. Pharmacol., Univ. Ill. Med. Ctr., Chicago, IL 60612.

5-Hydroxytryptamine (5HT) has been implicated in the mediation of sleeping behavior (Jouvet, 1969). The exact role of 5HT in sleep mediation probably involves an increased turnover of the amine at critical CNS sites. The administration of L-tryptophan (L-TRYP) is the most appropriate method of increasing 5HT's concentration (Wurtman and Fernstrom, 1975) and turnover (Radulovacki, 1974) in the CNS. It may then be possible to manipulate sleeping behavior by the administration of L-TRYP. Methysergide (ME) is a 5HT receptor blocker and should antagonize the effects of 5HT action.

Two groups of cats were surgically prepared with EEG, EMG, and EOG leads to evaluate sleep states during a 6-hour experimental sleep period. EEG records were evaluated to determine latency to first slow-wave sleep (SWS) and first paradoxical sleep (PS) episode and the percent time spent in either wakefulness (W), SWS or PS was also determined.

The first group of cats was treated with 30 mg/kg L-TRYP, but showed no significant changes in sleep pattern. The second group of cats was treated with 0.5 mg/kg ME and showed large changes in sleep patterns. This group of cats was then pretreated with 30 mg/kg L-TRYP and significant reversals toward normal sleep patterns were seen (Table).

	Placebo + ME	L-TRYP + ME
First SWS Episode (Latency in min.)	160.4 ± 6.5	116.8 ± 6.4*
First PS Episode (Latency in min.)	324.5 ± 16.8	254.1 ± 9.1*
Total % W	67.8 ± 6.8	52.3 ± 3.4*
Total % SWS	30.7 ± 6.3	45.0 ± 3.2*
Total % PS	1.5 ± 0.6	2.7 ± 0.4 ns

The results seen with L-TRYP pretreatment in ME treated cats point to separate and independent mechanisms for SWS and PS. This experiment also shows that sleep patterns disrupted by ME can be partially reversed by L-TRYP pretreatment. This response could be predicted if L-TRYP enhances those parts of the sleep mechanism mediated by 5HT and whose receptors are sensitive to competitive blockade by ME. We conclude that 5HT plays a role in the separate and independent mechanisms of SWS and PS and that 5HT plays a more important role in the initiation of PS than in its maintenance.

1734 LESIONS OF NON-MONOAMINE NEURONS OF THE PONTINE TEGMENTUM ELIMINATE PARADOXICAL SLEEP IN THE CAT. Barbara E. Jones. Depts. Neurol., Neurosurg. and Psychol., McGill Univ., Montreal Neurological Institute, Mtl., P.Q., Canada H3A 2B4.

Previous theories regarding the neural control of the sleep cycle assigned a major role to the monoamine neurons of the brain stem tegmentum (see Jouvet Ergebnisse Physiol. 64: 166-307, 1972). However recent studies by the present author (BR 124: 473-496, 1977) indicated that in the case of paradoxical sleep (PS), major destruction of the noradrenaline locus coeruleus neurons did not eliminate this state. In the present experiments it was found that lesions of the pontine tegmentum which damaged neither the noradrenaline locus coeruleus neurons nor the serotonin raphe neurons greatly disrupted the sleep cycle and eliminated all signs of PS.

These lesions concerned the pontine gigantocellular tegmental field (FTG) and portions of the lateral tegmental field (as defined by Berman). The lesions were successfully performed by a Kopf Radio Frequency Lesion Generator in five adult cats which were chronically implanted for EEG recording and were continuously recorded (24 hours around the clock) one week before and three weeks after the lesion. At the end of the experiment, the animals were sacrificed for histological verification of the lesion and biochemical assay of serotonin and noradrenaline.

The state of paradoxical sleep was totally eliminated following pontine FTG lesions. Muscle atonia, normally typical of this state, was absent for the duration of the survival period. PS phasic activity (REM and PGO spikes) was not observed in association with a desynchronized EEG typical of this state. In fact PGO spikes were virtually absent from the record in the first week and only returned as isolated events in association with a synchronized EEG the second week after the lesion. At this time (16th day post-lesion) the total number of PGO spikes per day was only 15% of the control count. In addition to the elimination of PS, Stage II slow wave sleep was also disrupted (40% of normal amount) after the lesion. Endogenous levels of noradrenaline and serotonin were normal in cortical and spinal cord regions corroborating the histological evidence that neither the locus coeruleus nor raphe neurons were damaged by the lesions.

These results suggest that neurons of the pontine FTG, and not monoamine neurons, are crucial for the initiation and maintenance of both phasic and tonic components of PS and also for the normal functioning of the sleep cycle.

1735 PONTO-GENICULO-OCCIPITAL SPIKES IN RATS: A COMPONENT OF THE ALERTING RESPONSE. Laura S. Kaufman* and Adrian R. Morrison, Dept. Psychobiol., Oberlin Coll., Oberlin, OH 44074 and Labs. Anat., Sch. of Vet. Med., Univ. of Penna., Phila., PA 19104.

Although ponto-geniculo-occipital (PGO) spikes are a prominant feature of paradoxical sleep in the cat, their presence in albino rats has only recently been confirmed (Farber et al., Sleep Res. 5/21, 1976). Our studies of this phenomenon in rats reveal an additional finding which lends support to the recent theory of Bowker and Morrison (Brain Res., 102/185-190, 1976), stating that PGO spikes are an indicator of alerting, and that they can occur during wakefulness and slow wave sleep (SWS), as well as paradoxical sleep (PS).

Five albino rats were chronically implanted for sleep recording, with bipolar electrodes placed stereotaxically in the dorsolateral pontine tegmentum. Sharp spikes (80-100uv) were recorded from 3 of the pontine placements. These electrode tips were histologically determined to be located in the area of the locus coeruleus. 85% of all spikes occurred during PS, 4% occurred during SWS in the 1 min. preceeding PS onset, and 6% in the 1 min. preceeding spontaneous arousals from SWS. The mean frequency of spiking during PS was 15-20 per min. Bursts of spikes averaging 5 spikes per burst and lasting 2-3 seconds were only recorded during PS. During the transition from SWS to PS, no more than 2-4 singularly occurring spikes were observed, and occasionally the rats would pass into PS without exhibiting any PGO spikes during the transition. The above confirms Farber et al.

It was also found that spikes identical in amplitude, shape and duration to those occurring spontaneously during PS could be produced with startling auditory stimulation (1500 and 2500 hz pure tone bursts of 18 msec duration) during wakefulness and SWS. As previous studies have demonstrated in the cat, stimulation at less than 5 sec. intervals resulted initially in activation of the EEG, gross body twitches or orienting movements, and PGO spikes. With continued presentation of the stimulus, EEG signs of alerting gradually disappeared followed by habituation of alerting behaviors and PGO spikes. PGO spiking could not be evoked in the 2 animals which did not exhibit spontaneous PGO spikes during PS.

These data indicate that certain structures which are spontaneously active during PS can also be activated by environmental stimuli in wakefulness and SWS. When analyzed in this context, PGO spikes can no longer be considered as spontaneous phenomena which are limited in their occurrence to paradoxical sleep.

1736 SLEEP PATTERNS IN QUADRIPLEGIC PATIENTS Lawrence W. Kneisley MD. From the Research and Spinal Cord Injury Services, West Roxbury Veterans Administration Hospital, Boston, Mass., Department of Neurology, Peter Bent Brigham Hospital, Harvard Medical School and the Department of Neuroscience, Childrens Hospital Medical Center, Boston, Mass.

To determine the effect of cervical spinal cord transection on human sleep, all-night EEG-EOG sleep recordings were measured in 9 quadriplegic subjects aged 19 to 34. The subjects, who had clinical evidence of recent or longstanding spinal transection above the C-8 level, and were taking no sedatives or alcohol at the time of the recordings, were studied for two consecutive nights. Serum samples were collected for endocrine studies from some by an indwelling intravenous catheter. The second night sleep-EEG tracings, scored by the methods of Williams et al (1), were evaluated for this report.

The mean amounts of sleep stages zero (wake), and 1, expressed as percentages of sleep period time (SPT) were significantly greater than those of normal controls ($p<.05$), while, conversely, mean percentages of stages REM (Rapid Eye Movement), 4, and 3 & 4 combined were significantly less than those of normal control subjects ($p<.05$). The sleep efficiency index (SEI), calculated by dividing total time actually spent sleeping (TST) by time spent in bed attempting to sleep (TIB), was .84± .07, which was significantly less than that of normal subjects from this and other laboratories (.95± .04, $p<.01$). One explanation for the increased amounts of waking (stage zero) and light sleep (stage 1), the diminished REM, and the low sleep efficiency may be the periodic body repositioning required by some of these individuals. However, those subjects not requiring these repositionings demonstrated the same abnormalities. Relative inactivity and immobility due to motor paralysis may be an important factor in reducing the "deeper" phases of sleep (stages 3 & 4), since exercise may increase the amount of these stages in the sleep of normals. These studies indicate that the sleep patterns of individuals with cervical spinal cord trauma are dramatically and persistently altered.

1737 MULTIPLE SLEEP LATENCY TEST IN NORMAL AND NARCOLEPTIC DOGS E.A. Lucas, A.S. Foutz, M.M. Mitler*, D. Brown*, W.C. Dement Univ. of Arkansas for Medical Sciences and Stanford University

The purpose of this study was to evaluate the effectiveness of multiple, serial sleep latency trials to differentiate between normal and narcoleptic dogs on the basis of their sleepiness. Six dogs, (4 miniature poodles and 2 beagles) were prepared surgically for chronic sleep recordings. Following a 2-week recovery period, one affected and one normal dog were placed in separate recording chambers with food and water ad libitum. A 48-hr period of adaptation was followed by an 84-hr observation which included a 48-hr baseline period and a 24-hr test period, during which the animals were removed from the chamber and kept alert for the first 30 minutes of each hour, and allowed to sleep ad libitum in the chamber during the second half hour. Polygraphic recordings included tracings from eye, sensorimotor and visual cortex, neck muscle and lateral geniculate leads at a paper speed of 10 mm/sec on Grass 78 recorders. The data were scored in 30 sec. epochs into six categories: alert, drowsy, light slow wave sleep, deep slow wave sleep, REM sleep and cataplexy. These data were entered into the computer and analyzed for each of the tests. The sleep latency scores were measured as the time in minutes from the closing of the chamber door until the first 30 seconds of sleep states. In comparison to control data, latencies to sleep tended to be shorter in affected dogs, particularly during the first 12 hours of the test. It became progressively more difficult to keep all affected dogs awake preceding each trial. The test clearly differentiated between the affected narcoleptic dogs and the normal dogs. The beagle appeared to be less affected than the poodles. This study needs to be extended to include more animals and the test applied to human narcoleptics and normals.

Mean (N=24 trials) sleep latencies (in min.) following 30 min. wakefulness

	12 h	24 h
Poodle Narc.	1.1 ± 1.1	.81 ± .83
Control	24.6 ± 10.1	19.1 ± 12.4
Poodle Narc.	1.7 ± 2.6	1.1 ± 1.9
Control	28.5 ± 5.3	21.5 ± 12.4
Beagle Narc.	3.3 ± 2.4	3.8 ± 3.6*

1738 PATTERN ANALYSIS OF NEURONAL SPIKE TRAINS DURING SLEEP AND WAKEFULNESS IN THE CAT. Thaddeus J.Marczynski and Leslie L.Burns*.

Action potentials from single neurons in the dorsal hippocampus and nonspecific thalamic nuclei were recorded chronically in freely moving cats, using "floating" microelectrodes.The long trains of up to 60,000 spike intervals were then subjected to analysis of temporal patterns. The technique was based on inequality testing of intervals in consecutive pairs ; if the second interval in a pair was longer or shorter than the first interval, a (+) or a (-) sign was recorded respectively in sequential bins of computer memory. Subsequently, the trains of signs were analyzed for presence of specific patterns (Marczynski and Sherry, Brain Res.,35:533,1971; Sherry and Marczynski,Intern. J.Neurosci. 3:259,1972). In this manner, the sign permutations composed of 3 through 6 signs were studied. Using chi squared statistics, the empirical distribution of sign patterns was then compared with the theoretical distribution based on the assumption that spike intervals are independently arranged (cf. Brudno and Marczynski, Brain Res.,125:65,1977).

During slow wave sleep (SWS), five neurons in the dorsal hippocampus showed distribution of intervals consistent with the theoretical model. Four of these neurons during REM sleep, and three of them during quiet wakefulness (QW) showed significant deviation from the theroetical model. Similarly, during SWS, five neurons in the region of the nuc. reticularis thalami and two neurons in the pulvinar showed pattern distribution consistent with the theoretical model, and a significant departure from it during QW. However, of six neurons in the centro-median-parafascicular complex (CM-PF), only one fired during SWS in a manner consistent with theoretical distribution of patterns and increased deviation from this model during QW. One neuron showed no changes in patterns, and four neurons showed greatest departure from the theoretical model during SWS, and a tendency toward theoretical distribution of patterns during QW.

The results indicate that 11 of 12 neurons in the dorsal hippocampus, pulvinar and the vicinity of the nuc. reticularis thalami fire in a manner consistent with the hypothesis that SWS is characterized by a relaxation of constraints in neuronal connectivity resulting in an independent distribution of spike intervals. Significant departures from the theoretical model during REM sleep and QW may be associated with integrative processes and information transmission. The results also suggest that neurons in the CM-PF may behave differently.

1739 EFFECT OF NEONATAL ADMINISTRATION OF MSG ON SLEEP IN THE MOUSE, John Metz, William J. Pizzi, June E. Barnhart* and James R. Unnerstall*. Neuropsychology Lab., Northeastern Illinois University.

When monosodium glutamate (MSG) is administered to neonatal mice, it produces permanent CNS damage along with somatic and behavioral dysfunctions. Previous studies have shown a lowered metabolic rate and obesity. Metabolic rate and body size have been related to various aspects of sleep across mammalian species (Zepelin & Rechtschaffen, Brain Behav. Evol., 10: 425, 1974). Of primary interest to this study is the finding that species with higher metabolic rates also have longer daily sleep times. The MSG pretreatment utilized in this study provides an adult animal whose metabolism and body size have been chronically altered, without confounds from short-term drug, environmental, or stress factors. It thus allows an assessment of the relationship between metabolism and sleep within a species.

Six male neonatal mice were given subcutaneous doses of MSG from days 2-11 after birth, according to a dose schedule which started at 2.2 mg/g b.w. and increased to 4.4 mg/g b.w. by the last day of injection. The six control mice received equal volumes of bacteriostatic saline. When the mice reached adulthood they were implanted with skull screws and wires in the neck muscles for chronic recording of the EEG and EMG. Recordings were taken for 20 hrs/day for two days (8 hrs light, 12 hrs dark). The polygraph records were scored by an experimenter who was blind to the treatment condition.

Table 1 summarizes the percentage of time spent in each of the sleep stages during both the light and dark periods. The MSG-treated mice showed significantly more sleep and less waking during the dark period than did control mice (two-tailed t-test, $p < 0.05$). The control animals displayed a marked light-dark difference in W and SWS but the MSG animals did not. In light of the gross physiological abnormalities seen in MSG mice it is striking that sleep is so little affected.

Table 1: Sleep stage percentages for control & MSG mice.

	Control		MSG	
	Light	Dark	Light	Dark
Waking	29.7 ± 8.0	45.3 ± 10.7	33.2 ± 9.1	33.9 ± 6.4
SWS	61.0 ± 6.1	47.1 ± 7.8	60.0 ± 9.0	57.6 ± 7.7
PS	9.2 ± 3.7	7.5 ± 3.6	7.6 ± 2.7	8.4 ± 2.9

These results fail to extend within a species the finding of a direct correlation between metabolic rate and total sleep time. This could mean that the relationship between sleep and metabolic rate across species is regulated genetically and is not subject to postnatal manipulation.

All of the additional sleep in the MSG animals occurred during the dark period, suggesting a specific deficit in the ability to regulate the light-dark distribution of sleep.

1740 STATE DEPENDENT EFFECTS OF PNEUMOTAXIC CENTER LESIONS AND VAGOTOMIES ON BREATHING IN THE CAT. A. Netick*, T. L. Baker*, A. S. Foutz, and W. C. Dement. Psych. Dept., Calif. State Univ., Hayward, CA 94542 and Sleep Res. Cent., Stanford Univ. Sch. Med., Stanford, CA 94305.

Lesions of the pneumotaxic center are best known to produce apneuses (prolongations of inspiration) especially during anesthesia in vagotomized animals. We have examined the effects of these lesions, later combined with vagotomies, on breathing in unanesthetized cats as a function of natural sleep. The purpose was to determine whether sleep produces the same effect as anesthesia on these preparations as well as to determine whether the effect of sleep upon breathing in the intact preparation (slowing during non-rapid eye movement sleep, NREM, and speeding and irregularity during REM) is modified by destruction of rostral pontine structures.

Ten cats were prepared for measuring sleep states; an endotracheal tube inserted into a chronic fistula in the trachea served to measure respiration. Following adaptation to atraumatic restraint, control baseline recordings were followed by bilateral lesioning of the pneumotaxic center under ether anesthesia. Recordings were made during the procedure and at intervals for at least two weeks. Cats were then vagotomized under ether and recorded for two succeeding days.

Apneusis was a frequent but not invariable concomitant of the pneumotaxic lesioning procedure. More commonly observed were prolonged expiratory pauses, or apneas. When apneusis occurred, the breathing pattern usually became apneic upon recovery from anesthesia. In subsequent recordings, the apneic pattern intensified during NREM; apneas sometimes lasted over a minute. During REM, the pattern invariably improved; the post-lesion pattern during REM was similar to the pre-lesion REM pattern.

During the vagotomy, breathing became apneustic. Withdrawal of anesthesia was followed by recovery from apneusis. Two patterns of breathing during sleep were observed. One pattern was similar to that of the nonvagotomized, lesioned cat (apneas primarily during NREM); the second pattern was a reappearance of apneusis during REM but not during NREM nor wakefulness.

The results demonstrate an interactive effect of sleep and pneumotaxic center lesions. REM sleep, like anesthesia, can produce apneusis in the vagotomized, lesioned cat. The effect of state upon breathing observed in the intact cat survives extensive destruction of rostral pontine structures eliminating them as generators of these effects.

1741 STREPTOMYCIN: ELECTROGRAPHIC AND BEHAVIORAL EFFECTS IN THE CAT. R.Pivik, J. Metz* and A. Rechtschaffen*. Dept. of Psychiatry, University of Ottawa Faculty of Medicine, Ottawa, Ont. Canada, and Dept. of Psychiatry, University of Chicago, Chicago, IL 60637.

Electrolytic lesioning of the medial and descending vestibular nuclei has been reported to eliminate bursts of phasic activity (PGO spikes and associated autonomic and spinal reflex modulations) during paradoxical sleep (PS) in the cat. Apart from the difficulty in creating complete, replicable lesions of the vestibular nuclei, this method of lesioning usually destroys a great deal of non-vestibular tissue. The present study sought to create vestibular lesions using an antibiotic -- streptomycin, which is reported to have toxic effects on the vestibular system via the inhibition of the intracellular production of nucleic acids.

Four adult cats chronically implanted for recording EEG, EMG, EOG and LGN activity were administered streptomycin subcutaneously over periods of time ranging from 14 - 25 days. The total amounts administered were 21.5 cc, 27.4 cc, 28 cc and 29.4 cc. Polygraphic sleep recordings were taken prior to and periodically during and after drug administration. The animals were subsequently sacrificed, perfused, and their brains prepared for histological processing (histological results will not be presented since processing is incomplete at this time).

Subsequent to drug administration all animals exhibited vomiting, ataxia, loss of righting reflexes, circling behavior and an absence of response to loud auditory stimuli. The cats experienced a 13% to 16% loss of body weight during the drug administration period. Streptomycin administration was associated with an increase in slower EEG frequencies as demonstrated in increased amounts of drowsiness and slow wave sleep. There was no effect on PS.

In the present study, then, streptomycin effected distinct alterations in behavior and electrographic activity. The behavioral signs indicate malfunctioning of auditory and vestibular mechanisms. Electrographically, increased amounts of slow activity are present in the EEG during sleep, but the effect on PS is negligible. Phasic activity recorded at the level of the LGN is enhanced during slow wave and paradoxical sleep, and bursts of such activity persist.

1742 ACTION OF BROMOCRIPTINE AND α-FLUPENTHIXOL ON SLEEP IN RATS DEPRIVED OF PARADOXICAL SLEEP. Miodrag Radulovacki, Walter J. Wojcik and Casimir Fornal*. Dept. of Pharmacol., Univ. of Il. Med. Ctr., Chicago, IL. 60612

Previous work in this laboratory with L-DOPA and d-amphetamine (Radulovacki et al., FASEB, 1978) has shown that these two agents increase wakefulness (W) and can partially substitute for paradoxical sleep (PS) rebound in PS-deprived (PSD) cats. We have shown in rats a correlation between decreased PS and an increase in brain dopamine (DA) following the administration of a DA β-hydroxylase inhibitor, diethyl dithiocarbamate (Kovacevic-Ristanovic et al., FASEB, 1978). To further delineate the role of DA in the mechanism of PS we utilized the DA receptor agonist, bromocriptine mesylate (CB) and antagonist, α-flupenthixol (FL) in PSD rats. Four groups of adult rats were implanted with cortical and dorsal neck muscle electrodes for polygraphic recordings. One week after surgery, the rats were selectively deprived of PS for twenty-four hours by the "flower pot" technique. To standardize the degree of PS deprivation, all rats were placed on platforms whose surface area corresponded to their body weight. At the twenty-third hour of PSD, animals were pretreated with either vehicle (C) or FL (0.2 mg/kg, i.p.) and placed back on PSD for the remaining hour. All rats, 2 1/2 hours after pretreatment, were injected with either C or CB (5 mg/kg, i.p.).

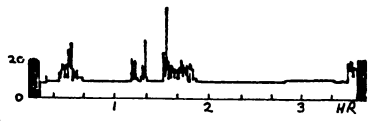
Groups one and two, pretreated with C, received C and CB, respectively. Groups three and four, pretreated with FL, received C and CB, respectively. After all drug combinations were administered, EEG and EMG were continuously monitored for thirty hours. All records were analyzed for W, slow-wave sleep (SWS) and PS. Statistics were performed at five-hour intervals. All observed changes occurred during the first five hours of polygraphic recording.

We found that CB increased W by 65% and reduced PS by 73% in spite of a strong PS pressure caused by PSD. CB administration had no effect on SWS. These results are similar to those that we obtained previously with DDC which significantly increased brain DA while PS was decreased, W increased and SWS remained within control values. It is of interest that the effects of CB were completely blocked by the FL pretreatment. The only effect of administration of FL alone was an elevation of SWS by 28%. From our results we conclude that DA is involved in the mechanisms of both W and PS.

1743 CHANGES IN RESPONSIVENESS OF THE JAW OPENING REFLEX ELICITED BY TOOTH PULP STIMULATION IN THE CAT DURING SLEEP AND BARBITURATE ANESTHESIA. Kenneth H. Reid, George C. Stege III* and S. Wilson. Dept. of Physiology and Biophysics, Univ. of Louisville Health Sciences Center, Louisville, Kentucky 40232.

In REM sleep, muscle tone is lost and the jaw-opening reflex (JOR) is suppressed (Chase & McGinty, Exptl. Neurol. 19: 127, 1970). The suppression is not absolute; a JOR can be obtained during REM sleep if a sufficient stimulus is given to the pulp of the ipsilateral upper canine tooth in the cat. Changes in JOR responsiveness were followed for periods of 4 to 20 hours in 4 cats chronically implanted with bipolar amalgam stimulating electrodes in the upper canine teeth and wire recording electrodes in each digastric muscle. JOR thresholds were evaluated at 30 sec intervals by a computer-driven stimulator doing a binary search in a closed-loop mode, using the peak-peak EMG as the response index. Each cat was also followed through induction and recovery from a surgical level of anesthesia (sodium pentobarbital 35 mg/kg). Representative results are shown below:

Normal sleep:



Anesthesia:

35 mg/kg IP inj at dot

Under barbiturate anesthesia, the JOR threshold rises slowly for 15-30 minutes after IP injection. It then rises, often in abrupt steps, to 3-10 x the initial level, where it stays for 30-120 minutes. Recovery occurs in from 1 to 4 abrupt step changes. During normal sleep the threshold remains near that seen in the waking state except during episodes of REM sleep where it is abruptly elevated to 2-10 x waking level. Stability of the elevated threshold varies greatly from cat to cat during both REM sleep and anesthesia. It is concluded that barbiturate anesthesia and REM sleep may suppress motor responses to noxious stimuli through a common mechanism.

1744 SLEEP AND WAKING ACTIVITY OF NUCLEUS RETICULARIS PONTIS ORALIS-CAUDALIS, AND MEDULLARY GIGANTOCELLULAR NUCLEUS CELLS IN UNRESTRAINED CATS. J. M. Siegel, D. J. McGinty and S. M. Breedlove*, Sepulveda V. A. Hospital, Sepulveda, CA 91343.

The nucleus reticularis pontis oralis-caudalis (RPO-RPC) and medullary nucleus gigantocellularis (MNGC) occupy the medial reticular formation areas anterior and posterior to the pontine nucleus gigantocellularis (PNGC). Carli and Zanchetti[1] identified the RPO-RPC region as the area whose destruction eliminated REM sleep. Netick, Orem and Dement[2], recording in restrained cats, recently described 6 cells in the medullary gigantocellular region which discharged selectively in REM sleep. They speculated that these cells might have a role in REM sleep generation. Therefore, it is of interest to determine the sleep-waking discharge correlates of these cell groups in unrestrained cats.

A total of 60 cells were studied. We found that both of these areas contain the same 3 cell types seen in the PNGC area[3]. Type one cells had no spontaneous activity during quiet waking and sleep, discharging only during movements. Type 2 cells had high rates of tonic activity (>4 spikes/sec) during both quiet waking and sleep states with increased discharge during waking movements and REM sleep. Type 3 cells had low spontaneous activity rates (≤4 spikes/sec) during quiet waking and slow wave sleep, but discharged at high rates during both waking movements and REM sleep. Waking discharge related to specific head, neck, back, forepaw, and facial movements. In the MNGC we saw several cells that fired at high rates only during specific waking postures and in REM sleep. These cells might appear to discharge selectively in REM sleep if critical postures were prevented by restraint. This finding may account for previous reports of REM selective cells in this area. It is also conceivable that medullary REM sleep selective cells are rare and were not encountered in our explorations.

In summary, RPO, RPC and MNGC cells, like PNGC cells, exhibit augmented discharge during both waking movements and REM sleep. We have not observed any cells in these areas which discharged selectively in REM sleep. Our results are consistent with an hypothesis of medial reticular formation involvement in the motor activation common to both active waking and REM sleep, but are not consistent with an executive role for these neurons in the triggering of the REM sleep state.

1745 VISUAL PATHWAYS MEDIATING THE EFFECTS OF LIGHT ON PARADOXICAL SLEEP IN RATS. C. L. Sisk and F. K. Stephan. Dept. Psychol., Florida State University, Tallahassee, FL 32306.

In rats, approximately 70% of the daily slow wave sleep (SWS) and rapid eye movement sleep (REM) occur in the light phase of a 12 hr light-12 hr dark cycle (LD 12:12). However, when maintained on very short LD cycles (e.g., LD 0.5:0.5), most REM episodes occur in the dark periods, whereas the distribution of SWS remains relatively unaffected (Borbely, Huston, and Waser, 1975; Brain Res. 95, 89). This investigation was an attempt to determine which component of the visual system mediates the shift of REM sleep into short dark periods. Cortical EEG, neck muscle activity and brain temperature were recorded from rats with bilateral lesions in the primary optic tract, leaving only retinohypothalamic fibers (RHT) and the inferior fasciculus of the accessory optic tract (IAOT) intact. During 48 hrs on a LD 0.5:0.5 cycle, an average of 62% of REM sleep occurred in the dark periods in rats with lesions, compared to an average of 88% for intact rats, with no overlap between the two groups. The functional integrity of the IAOT was assessed by observing a pronounced reduction in water intake in constant light and the entrainment of drinking rhythms to a LD cycle indicated that the RHT was also functional (c.f. Stephan and Zucker, 1972; Physiol. Beh. 8, 315-320).

These results suggest that neither the RHT nor the IAOT is capable of shifting REM sleep into short dark periods to the extent observed in intact rats. Further experiments are in progress to assess the role of the lateral geniculate nucleus, optic tectum and the superior accessory optic tract in the effects of short dark periods on REM sleep.

1746 INDUCTION OF REM SLEEP IN RATS BY PERIPHERAL WARMING. R. S. Szymusiak*, Timothy Schallert*, Evelyn Satinoff, and Ian Q. Whishaw*. Department of Psychology, University of Illinois at Urbana-Champaign, Champaign, IL 61820 and Department of Psychology, University of Lethbridge, Lethbridge, Alberta, Canada T1K 3M4.

Peripheral warming produces a decrease in tonic postural support followed by REM sleep in infant rats (Schallert, Whishaw, and Teitelbaum, 1977). In the present study, we demonstrate that during slow-wave sleep, peripheral warming decreases muscle tone and induces REM sleep in adult rats as well. Rats were implanted with neck EMG and cortical EEG electrodes. Hypothalamic (T_{hy}) and subcutaneous (T_{sc}) temperatures were continuously recorded. A redbulb infrared heat lamp (total power dissipation 182 W) was placed 35 cm above the animals. Following a one minute period of continuous cortical synchronization, the heat lamp was turned on, and the animals were warmed until they either woke up or entered REM sleep (30 sec-2.5 min). An increase in T_{sc} of 1-3°C, accompanied by only a slight change in T_{hy} (less than 0.3°C), resulted in REM bouts in 78% of the experimental trials, compared to 21% of the control trials when the animals were not warmed. Warming decreased tonic EMG activity while the cortex remained synchronized. Then, as cortical desynchronization occurred, EMG activity completely disappeared. The REM bouts outlasted the warming stimulus, having a duration similar to control (non-warming) bouts (about 80 sec). The relationship between temperature-induced changes in tonic postural support and REM sleep is discussed.

1747 EFFECT OF PUSH-PULL TOPIC PERFUSION OF CARBACHOL ON THE MULTIPLE UNIT ACTIVITY OF THE GIGANTOCELLULAR TEGMENTAL FIELD. Marcos Velasco, Francisco Velasco, Carlos Cepeda* and Ranulfo Romo*. Sci. Res. Dept., Natl. Med. Ctr. IMSS. México, D. F.

The effect of chemical stimulation of the pontine reticular formation with various cholinergic compounds on the wakefulness-sleep states of cats has been previously studied with contradictory results (Hernández-Peón et al 1963, Mitler and Dement 1964, Amatruda et at 1975). These apparent controversial results may be partially explained by a lack of control of certain methodological factors as the precise site and extent of perfusion and the type and doses of the injected compounds.

In this work performed on cats with implanted electrodes and cannula guides and immobilized by means of a head holder device, we studied the effect of push-pull topic perfusion of Carbachol (5 ug/50 ul/min) of the gigantocellular tegmental (FTG) field on the local multiple unit activity and the wakefulness-sleep state of animals.

We found a linear relationship between the doses of Carbachol injected and the number of FTG active units within a range between 7 and 30 ug. The effect started and finished immediately after the Carbachol push-pull injection. Doses larger than 30 ug produced an immediate blockage of the active units (saturation doses). During Carbachol injection, animals remained with their eyes open and with a variable degree of EEG synchronization but with a constant and progressive muscular hypotonia. No other motor or vegetative signs were present and the number of ocular movements, the EKG and respiration frequencies and rectal temperature were unchanged.

1748 THE EFFECT OF L-TRYPTOPHAN ON MONOAMINES IN SPECIFIC BRAIN STRUCTURES AND SLEEP IN RATS. Walter J. Wojcik, Casimir Fornal*, and Miodrag Radulovacki, Dept. of Pharmacol., Univ. of Ill. Med. Ctr., Chicago, IL 60612.

The administration of L-tryptophan (L-TRY) reduces sleep latency and waking time in humans (Hartmann, 1977). Similar results in reduction in sleep latency have also been observed in rats (Hartmann, 1972). According to the monoamine sleep theory, this hypnotic effect of L-TRY was attributed to the increased 5-hydroxytryptamine (5HT) turnover in the brain. While there is abundant evidence for the effects of L-TRY on 5HT metabolism in the brain, there is little information on L-TRY effects on brain catecholamines. We decided to analyze dopamine (DA) and norepinephrine (NE), as well as 5HT and 5-hydroxyindoleacetic acid (5HIAA) in the cortex (CX), hippocampus (HIPP), striatum-thalamus (ST) and pons-medulla (PM) of adult rats fifteen and forty-five minutes after L-TRY (30 mg/kg, i.p.) administration. The animals were sacrificed by decapitation and the monoamines and 5HIAA were determined by spectrophotofluorometric methods. Fifteen minutes after the injection, DA levels in the CX and the HIPP were reduced by 27% and 18%, respectively. At the same time, 5HIAA levels were elevated by 38% in the PM, while 5HT and NE concentrations did not change in any of the mentioned structures. Forty-five minutes after administering L-TRY, 5HT levels were elevated by 18% and 5HIAA concentrations showed an increase, although not statistically significant, in the PM. In all studied structures, NE and DA remained unchanged. In another experiment, adult rats were implanted with cortical and neck muscle electrodes for EEG and EMG recordings. One week after surgery, the animals were injected with either saline or L-TRY (30 mg/kg, i.p.) and polygraphically recorded for six hours. On the following day the same protocol was repeated with the same group of animals but with reversed administration of agents. All recordings were analyzed for wakefulness (W), slow-wave sleep (SWS) and paradoxical sleep (PS). Paired t analyses performed at half-hour intervals showed that the administration of L-TRY increased SWS by 11% and PS by 7%, while W was reduced by 19% during the second half-hour period. However, these effects occurred without changing either SWS or PS latencies. Since the increase in SWS and PS (see also Jackman and Radulovacki, this meeting), occurring in the second half-hour period, coincides with the forty-five minute increase in 5HT and 5HIAA in PM, we suggest that this effect of L-TRY on sleep is mainly due to the increased 5HT turnover.

SOMATOSENSORY SYSTEMS

1749 DEVELOPMENT OF SEGMENTED CORTICOTHALAMIC PROJECTIONS TO THE VENTROBASAL COMPLEX OF THE RAT. R. M. Akers and H. P. Killackey. Dept. Psychobiology, Univ. of Calif., Irvine, CA 92717.

Studies based on succinic dehydrogenase histochemistry have demonstrated that trigeminal projections to the ventrobasal complex of the rat are organized in discrete, segmented clusters which can be related to individual peripheral receptors. This pattern of segmentation is well developed in the seven day old rat but is much less discrete in adults (Killackey and Belford, Anat. Rec., 1976). An autoradiographic analysis of cortico-thalamic projections in neonatal rats suggests that trigeminal and cortical afferents to the ventrobasal complex are organized in a complementary fashion in young animals. Following cortical injections of ^{3}H-leucine or proline, bundles of labeled axons can be seen in the ventrobasal complex as early as the first post-natal day (birth=P0). During the next three days of development, the grain density over the nucleus increases, and a highly organized pattern of corticothalamic projections emerges. By the second postnatal day, contrasting zones of high and low grain density are visible. The low density areas are organized in wide, curving bands which are oriented along the ventrolateral-to-dorsomedial axis of the nucleus. Narrow strips of much higher grain density are intercalated between adjacent low density bands. These strips of higher grain density undoubtedly represent collections of corticothalamic axons, which invade the adjacent bands of lower grain density on the third postnatal day. The growth of corticothalamic axons into the low density bands is discontinuous and further subdivides each band into a curvilinear row of lightly labeled patches separated by narrow zones of high grain density. This pattern is not fully developed until the fourth postnatal day and is most distinct in animals younger than ten days of age. In the adult, patches of lower grain density can be distinguished within the ventrobasal complex following cortical injections of tritiated amino acids, but the contrast between these patches and adjacent strips of high grain density is much lower than in the neonate.

When the pattern of labeling following cortical injections is compared with material stained for succinic dehydrogenase activity, it appears that the corticothalamic axons are preferentially localized in portions of the ventrobasal complex which do not receive dense trigeminal projections. Further, the development of segmentation in these two afferent systems follows a similar time course, beginning on the second postnatal day and being virtually complete by postnatal day four. Finally, it is of interest that developmental processes after the perinatal period obscure the discreteness of segmented organization in both cortical and trigeminal afferents to the thalamus. Supported by NSF grant #GB41294 and NIMH grant #MH14599-02.

1750 NORMAL AND ABNORMAL SEGMENTATION IN THE TRIGEMINAL COMPLEX OF THE YOUNG RAT. G.R.Belford* and H.P.Killackey (SPON: E. Davis). Dept. of Psychobiology, Univ. of Calif., Irvine 92717.

In the young rat anatomical correlates of the facial vibrissae are seen in the trigeminal complex of the brainstem, the ventrobasal complex of the thalamus, and layer IV of somatosensory cortex. Rows of dense clusters of succinic dehydrogenase (SDH) activity within the neuropil of each structure mimic the pattern of vibrissae on the face. Further, neonatal damage to a row of vibrissae follicles results in an aberrant organization within these structures. We have previously reported on the time course of development of the normal and abnormal organization in the ventrobasal complex (Belford, Anat. Rec., '78) and somatosensory cortex (Killackey and Belford, Neurosci. Abst., '76). In the present experiments we extend our study of the development of vibrissae representations to those in the trigeminal complex.

In the first part of the present study, littermate rats with no vibrissae manipulations were sacrificed on postnatal Days 0 through 5. In the second part, littermate rats had a row or rows of vibrissae damaged at birth. These rats were also sacrified on Days 0 through 5. Finally, in the third part, littermates had a row or rows of vibrissae damaged at Days 0 through 5. These rats were sacrificed on Day 7. The brains of all animals were processed with SDH histochemistry.

The trigeminal complex contains three separate representations of the vibrissae, one each in the subnucleus caudalis and subnucleus interpolaris of the spinal trigeminal and the third in the principal trigeminal nucleus. These representations are present on the day of birth. Removal of vibrissae at birth results in abnormalities that are apparent by Day 2 in all three representations. The portion of each representation that is related to the damaged vibrissae shows a density of SDH activity much lower than normal. Further, the row of clusters normally seen in this area is sometimes replaced by a band of activity, but more often the area is amorphic. Finally, removal of vibrissae at different postnatal ages results in variations in the pattern as seen at Day 7. The density of SDH activity progressively increases from a low level with damage on Day 0 to one of almost normal density with damage at Day 5. Removal on Days 0 through 2 leads to the pattern described above for removal at Day 0, with an increased tendency towards bands at the later ages. Day 3 removal results in either a band or clusters. For Days 4 and 5, clusters of below normal density are seen.

These results indicate that the vibrissae representations in the trigeminal complex are plastic for the first few days of postnatal life. (Supported by NIMH MN 14599-02 and NSF GB 41294.)

1751 PSYCHOPHYSICAL COMPARISONS OF ANOMALOUS AND NON-ANOMALOUS REPORTS TO CUTANEOUS COOLING STIMULI. Sherry L. Berg* (SPON: J. E. Aschenbrenner). Depart. Psychology, Florida State University, Tallahassee, Florida 32306.

The results from five male subjects were compared with one anomalously reporting male subject using the psychophysical methods of magnitude estimation and fractionation. Contact thermal stimuli were presented to the right dorsal forearm after the site had been preadapted to 32.6°C. Rates of temperature change varying from 0.1° to 2°C/sec were administered for a 3 sec duration producing stimulus intensities that ranged from 0.3° to 6°C. Five stimulating surfaces (1,2,4,7.5 and 18cm^{2}) were introduced for both magnitude estimates and fractionation measures.

In addition, bilateral, warm-cool and forearm-forehead comparisons along with the neurological pinprick test and subjectively different verbal reports all argue for a unique anomalous effect and sufficient reason for exclusion of this subject from the combined magnitude estimation and fractionation analyses. Furthermore, closer examination of the anomalous and nonanomalous data demonstrates the discreteness of the effect as opposed to one which might have ranged along a continuum. (Supported by USPHS Grant NB-02992 and Training Grant MH 11218)

1752 UNIT RESPONSES FROM THE ISOLATED RAT CORNEA. R.W. Beuerman and D.L. Tanelian, Stanford University Medical Center, Stanford, CA 94305.

Anatomical studies have shown that all axons entering the cornea terminate in the epithelium as so called free nerve endings. The purpose of the present experiments has been to determine whether or not these receptors are similar physiologically by examining their response characteristics. In this preparation the eye is quickly removed from a deeply anesthetized rat (280-300 g) and mounted in a lucite chamber by compressing the bulbar conjunctiva between a stainless steel ring and a plastic disc. This holds the globe in a manner similar to the intact state and assures that the tissue of interest is not stressed mechanically. After incising the sclera around the optic nerve, the ciliary nerves are obtained intraocularly. As many as five nerve bundles (100-150 μm) spaced around the cornea can be dissected in one preparation. The iris is removed with fine tweezers. These bundles are further dissected to obtain identifiable unit activity with a suction electrode. The posterior surface of the cornea and nerves are perfused by a bicarbonate-buffered ringer at 35°C, while the cornea is perfused by a HEPES ringer at 35°C. All units are tested for their receptive fields with a calibrated hair and are tested with the following: an ascending NaCl series, pressure and thermal stimuli delivered by a saline jet (200 μm) dia.) Conduction velocity has not been measured. All units found have been rapidly adapting; receptive fields have varied from spot size to more than a quarter of the corneal surface. Two general types of units have been found: those responding to mechanical stimuli and those excited by temperature changes. Many of the mechanically sensitive units have receptive fields located at the periphery of the cornea, and they respond to a brief punctate mechanical stimulus with a stereotyped burst of action potentials. Most of these fibers show no response to NaCl even at 0.5 M, or to moderate temperature change (±5°C). The receptive fields of the temperature units are generally small (1-3 mm dia.) and located more toward the center of the cornea; they have little or no responsiveness to the calibrated hair but do respond to concentration changes. It is concluded that there is functional evidence for more than one unit type in the rat cornea.

1753 ACTIVITY FROM NERVES INNERVATING THE PERIPHERAL VASCULATURE IN SQUIRREL MONKEY. Bruce E. Bradley. Dept. of Oral Biol., School of Dentistry, Univ. of Michigan, Ann Arbor, MI. 48109.

Several functions of the innervation of the peripheral vasculature have been suggested by a number of indirect experimental observations, but these functions have seldom been substantiated by detailed electrophysiological studies. Peripheral vascular afferent nerves thus provide an interesting substrate for experiments in sensory neurophysiology which might potentially contribute to a broader understanding of the reflex control of the cardiovascular system.

To identify peripheral nerves innervating blood vessels and to begin to investigate their functions, neuronal activity was recorded in six squirrel monkeys anesthetized with ketamine and pentobarbital.

In one example, whole intact nerve activity was inhibited within 2-3 sec following intra-arterial (IA) injection of 10 µg of phenyl diguanide (PDG). Activity returned gradually and was again abolished by proximal section of the nerve trunk. Subsequent IA injection of PDG elicited neuronal activity. The inhibition of presumed sympathetic activity corresponded closely to a transient depressor response. This observation would tend to substantiate the reflex nature of responses to IA injection of veratrum alkaloids proposed by Krayer and Acheson (Physiol. Rev. 26:383,1946). The location of the nerve corresponded to the distribution of the nerves to the superficial femoral artery described by Potts in human material (Anat. Anz. 47:138,1914).

Thirteen seconds after occlusion of the femoral vein, several units were identified which fired slowly and adapted prior to release of the occlusion. The nerve trunk had been divided centrally prior to venous obstruction and thus the neuronal response might correspond to afferent reflex activity suggested by Haddy and Gilbert (Circ. Res. 4:25,1956).

One single unit was activated by punctate stimulation of an apparently rapidly adapting mechanoreceptor located on the saphenous artery 1.2 cm from the origin of the vessel. The unit appeared to have a single receptive field and was excited neither by occlusion of the saphenous artery several cm distal to the receptive field nor by IA injection of 100µg PDG.

It is tentatively concluded that the nerve fibers innervating the peripheral vasculature have been identified and can be isolated to yield electrical recordings of their neuronal activity.

1754 DISTRIBUTION OF MECHANORECEPTORS IN SQUIRREL PAWS. G.L. Brenowitz* (SPON: E.F. Domino). Neurosci. Prog. and Dept. Zool., Mich. State Univ., East Lansing, Mi. 48824.

The morphology and distribution of sensory endings in the glabrous paw skin of Fox squirrels (Sciurus niger) and Thirteen-lined ground squirrels (Spermophilus tridecemlineatus) were examined in material prepared with Sevier and Munger's (J. Neuropathol. exp. Neurol. 24:130) silver staining method. Techniques were developed to estimate receptor density, examine dispersion patterns and determine the degree to which different receptors are segregated from each other.

Fox squirrels use their forepaws in skilled climbing and tactile exploratory behaviors and ground squirrels use theirs in excavating extensive burrow systems. Also, I recently showed that Fox squirrels depend upon tactile input from the forepaw more than do ground squirrels in food handling tests. Therefore it was predicted that the density of receptors in the Fox squirrel's forepaw would be relatively greater (forepaw density/ hindpaw density ratio would be greater) than in the ground squirrel's.

Fox squirrels have intraepidermal fibers, dermal free endings and simple and Pacinian corpuscles. Ground squirrels have intraepidermal fibers, dermal free endings and simple and Meissner's corpuscles. As predicted, the forepaw density/ hindpaw density ratio is significantly greater in Fox squirrels (3.3 ± 0.5) than in ground squirrels (1.3 ± 0.3). Unexpectedly, the density of receptors in the palmar region is significantly higher than in the digits for Fox ($95/mm^2$ vs. $16/mm^2$) and ground squirrels ($48/mm^2$ vs. $26/mm^2$). The proportions of different receptor types (corpuscular vs. non-corpuscular) do not differ between species. Receptors were randomly dispersed (Coef. of Dispersion = 1) and different types of receptors were intermingled (Index of Segregation = 0.3) in the skin of both species. These results indicate that the relative densities of receptors may vary with the particular use of the forepaw in different species, but that the basic pattern of the receptor array remains similar.

1755 A SINGLE UNIT STUDY OF CORTICAL AREAS ADJACENT TO THE SECOND SOMATIC SENSORY CORTEX IN THE CYNOMOLOGOUS MONKEY. H. Burton and C.J. Robinson. Depts. of Anat. & Neurobiol., and Elec. Engr., Wash. Univ., St. Louis, MO 63110

The boundaries of the second somatic sensory cortex (SII) in primates are difficult to define physiologically because cutaneous stimulation activates several regions around SII that do not receive projections from the ventroposterior nucleus of the thalamus. In this study, the locations of somatically activated neurons within the lateral sulcus were correlated with retrograde labeling of the thalamic nuclei projecting to these regions and/or with cortical cytoarchitecture in the vicinity of the electrode tracts.

The granular insular cortex (Ig), which receives projections from the supragenicular region of the thalamus, contains neurons that primarily respond to stimulation of hairs over large (>100 cm^2), generally bilateral receptive fields. These borders were often not well defined.

Neurons within the retroinsular cortex (Ri), which receives projections from the posterior nucleus (PO), primarily respond to light tactile stimulation of rapidly adapting skin receptors. Less than 10% responded to moderate or high threshold cutaneous stimulation. Receptive fields were of moderate size (<100 cm^2), with fairly precise borders, and were generally on the contralateral side of the body. The response properties of Ri neurons closely resemble those of SII (Robinson and Burton, this vol.). The transition between SII and Ri was often marked by sudden changes in the location of receptive fields and not in response properties.

The part of area 7 bordering SII and Ri in the lateral sulcus receives a projection from ventral portions of the anterior pulvinar. Cutaneous stimulation reliably activated over half of the neurons isolated in this region. Large, often bilateral receptive fields, with imprecise borders, frequently involved the whole body. Although rapidly adapting inputs predominated, a greater number of neurons than in SII showed slowly adapting discharges to light touch. This part of area 7 was also the region within the depths of the lateral sulcus containing the largest number of neurons with noxious drive characteristics.

Frequently, our designation of cortical areas could only be made after correlating the recording sites with connectional analyses in the same animal because of the great similarity in the somatic response properties especially in the awake and unparalyzed animal. Consequently, previous physiological studies may have designated some of the somatic areas seen here as SII proper. (Supported by PHS NS-09809 and GM-01827)

1756 ORIGIN OF PROPRIOCEPTIVE FIBERS INNERVATING THE TEMPOROMANDIBULAR JOINT CAPSULE. Norman F. Capra*, John H. Romfh* and Glenn B. Gatipon. Depts. Anat. and Pharm., Univ. MS Med. Center, Jackson, MS 39216.

That the mesencephalic nucleus of the trigeminal nerve (MNV) mediates proprioceptive impulses for the head region is generally accepted. In cats, we are unable by electrophysiological methods to identify MNV neurons that respond to passive movements of the temporomandibular joint.

Unilateral injections of the retrograde axonal transport marker horseradish peroxidase (HRP), were made in the joint capsule of 8 animals to identify the location of the first order neurons which innervate the temporomandibular joint. Four of the eight animals also received unilateral injections of HRP in the contralateral masseter and temporalis muscles. Following 48-72 hours of survival the animals were killed and selected tissues processed according to Mesulam (J. Histochem. - Cytochem. 24:1218, 1976).

Careful examination of serial transverse frozen sections throughout the rostrocaudal extent of MNV revealed no labelled neurons in animals receiving unilateral injections of HRP in the temporomandibular joint. Labelled neurons were found only in the MNV of animals receiving muscle injections. In 6 of 8 cats, the trigeminal ganglion ipsilateral to the HRP injected joint capsule contained a substantial number of labelled neurons ranging 35-60 micrometers in diameter. These cells were located in the most caudal part of the mandibular division of the ganglion.

The somatotopic localization was striking when compared with the distribution of labelled cells in the contralateral trigeminal ganglia of the animals receiving muscle injections. In the latter, labelled cells were distributed in more rostral portions of the mandibular division.

Preliminary microelectrode studies of the trigeminal ganglion have allowed identification of neurons with specific response patterns to jaw opening, jaw closing and intermediate angular excursions.

1757 DEVELOPMENT OF SOMATIC SENSORY FUNCTION IN NORMAL AND BRAIN LESIONED INFANT RHESUS MONKEYS. Mary Carlson. Dept. Psychiatry, Harvard Medical School, Boston, MA 02115.

In previous studies of adult rhesus monkeys, surgical lesions of the hand area of primary somatic sensory cortex (SI) produced severe and permanent deficits in the acquisition of manual tactile discriminations. Partial lesions of single hand representations in cytoarchitectural subdivisions of SI produced selective discrimination deficits and recovery of function was not found despite some redundancy of physiological input to remaining subdivisions.

As infant animals are generally believed to have a greater capacity than adults for functional recovery following cortical damage, studies of the correspondence between physiological input to SI and tactile discrimination capacity of normal and lesioned infant monkeys were designed. The results of both electrophysiological and behavioral studies in the normal infant monkey suggest that SI is functionally mature as early as 2-10 weeks of age. Single cortical cells in the hand and arm area of SI responded to either joint or cutaneous stimulation in recording studies of awake infants as young as 2 weeks of age. Furthermore, infants as young as 10 weeks of age (when first developing the motor control necessary for performing the task) were able to master tactile discriminations at a level similar to the adult.

The consequences of SI lesions in infants differed from those found in adult monkeys. Infants receiving partial lesions (Brodmann's area 3, or areas 1 and 2) at 3 weeks of age, made more errors and learned more slowly than normal infants, but performed at normal levels within 14 weeks of training. Animals with a total SI hand area lesion (areas 3, 1, and 2) had a normal discrimination capacity as well, but learned at the same rate and with comparable numbers of errors as normal infants. This difference in the time course of recovery for the two infant groups suggests that the remaining SI cortex in the partial lesioned animals disrupts rather than facilitates the recovery process. Juvenile monkeys receiving either partial or total lesions at 18-24 months of age show a significant impairment in discrimination performance comparable to the adults in previous studies.

These studies are the first to demonstrate recovery of normal function following lesions of sensory cortex in infant primates. Although SI is functionally mature in the first weeks of life, it has a capacity for compensation of tactile discrimination function lacking in the adult and juvenile cortex.

1758 SPINAL PROJECTIONS FROM THE MIDBRAIN OF RAT. A. J. Castiglioni, S. P. Wise, E. A. Murray and J. D. Coulter, Marine Biomedical Institute, and Depts. of Physiology and Biophysics and Psychiatry and Behavioral Sciences, University of Texas Medical Branch, Galveston, Texas 77550.

Horseradish peroxidase was injected into the spinal cords of rats into either the lumbar enlargement, thoracic cord, cervical enlargement, upper cervical cord, (C2-C4) or spinal trigeminal complex. The brains were cut at 50μm and reacted either with diaminobenzidine, o-dianisidine or tetramethylbenzidine to visualize retrogradely labelled neurons. Caudally in the midbrain, beginning at the level of the trochlear nucleus and extending rostrally to levels of the medial geniculate body, large numbers of cells in the medial reticular formation were labeled. These cells were found mainly ipsilateral to injections at all levels of the cord. Scattered cells throughout the central gray were also labeled and were most numerous laterally in that part adjacent to the medial reticular formation which contained labeled cells. The central grey also contained labeled cells in similar locations following injection of the spinal trigeminal nuclear complex. Rostrally many labeled cells were found in the region of the nucleus of Darkschewitsch, the nucleus of Edinger-Wesphal and the interstitial nucleus of Cajal, mainly ipsilateral to injections at all spinal levels. The red nucleus contralateral to injections contained labeled cells with a somatotopic distribution. Those projecting to the cervical cord were located dorsomedially while those projecting to the lumbar cord were found ventrally. HRP labeled cells were also found in the deep layers of the superior colliculus after cervical injections contralaterally. Ipsilateral to injections of the upper cervical cord many labeled neurons were found in the zona incerta. Cervical spinal injections also resulted in labeled cells scattered in the ventral midbrain tegmentum surrounding the decussation of the brachium conjunctivum

Rapid Golgi studies of the medial portion of the rat midbrain reticular formation, in those regions which send axons to the spinal cord, reveal both rounded and elongated neurons with cell diameters of 10-25μm. Most have 3 to 4 primary dendrites which branch to various degrees. Dendrites of nearly all neurons possess varicosities of 2μm x 5μm along the length of the dendrites. Dendrites extending as far as 300μm from the soma have been seen in transverse sections, but do not extend far from the soma in the rostrocaudal direction. Cells in the medial reticular formation can be seen to send their dendrites across the border of the central gray, and far into the central gray substance itself.

1759 TOPOGRAPHIC ORGANIZATION OF THE LATERAL CERVICAL NUCLEUS IN CAT. A.D. Craig, Jr., and H. Burton, Dept. Anat. & Neurobiol., Wash. Univ. Sch. Med., St. Louis, MO 63110

The topographic organization of cells in the lateral cervical nucleus (LCN) with ipsilateral somatic receptive fields (RFs) was examined with extracellular unitary recordings. Closely-spaced (100 μm grid) microelectrode penetrations were made, angled along the transverse axis of orientation of the LCN (dorsolateral to ventromedial) in the dorsolateral funiculus (DLF). RF location, stimulus sub-modality, antidromic latency (from the thalamus), and unit position were recorded for 371 LCN neurons in six recording loci in four cats. LCN neurons with hindlimb (H) RFs were located dorsolaterally (superficially), those with forelimb (F) RFs were located more ventromedially, and those with facial RFs were most medial within the LCN. Most units with thoracic RFs were located between H and F units. Some interspersion of H and F units was observed; it was thus not possible to distinguish whether the underlying organization is "segmentotopic" or "somatotopic". A special subpopulation of units (17%), i.e. those which had widefield RFs, and/or had deep, visceral, or noxious input, and/or did not project to thalamus, was histologically verified to lie in the most ventromedial LCN. This group may contain interneuronal elements.

A corresponding topography has been observed in the contralateral projection of LCN neurons to ventrobasal thalamus with the horseradish peroxidase (HRP) technique. Cells in the lateral LCN (hindlimb area) were labeled after HRP injections in VPL, pars lateralis; medially-located (forelimb area) LCN cells were labeled from VPL, pars medialis. Some of the most medially-located cells could be labeled from all parts of VPL, and from VPM: this result is consistent with the physiological identification of a special subpopulation of neurons in the LCN.

These results together indicate a consistent pattern in the organization of the spinocervicothalamic pathway, analogous to that of the dorsal column system, albeit with less discriminable precision in its topography. The analogous organization is further underscored by the identification of a special subpopulation of LCN neurons, which is separable from the main population of projecting neurons and which probably contains interneurons.

1760 LOCALIZATION BY THE HORSERADISH PEROXIDASE TECHNIQUE OF MEDULLARY NEURONS PROJECTING EFFERENT FIBERS TO THE CAROTID SINUS NERVE OF THE CAT. William C. de Groat, Charles Morgan, Irving Nadelhaft, Thomas Schauble*. Dept. Pharmacol., Univ. of Pittsburgh, School of Medicine and Veterans Administration Hospital, Pittsburgh, PA 15261

The carotid sinus nerve (CSN) of the cat contains efferent axons which are thought to provide an inhibitory input to the carotid body. In the present investigation the technique of retrograde axonal transport of horseradish peroxidase (HRP) has been used to identify the location within the central nervous system of the cell bodies of this efferent pathway. In anesthetized cats the CSN was sectioned near the carotid sinus and the central end of the nerve was exposed to 25% solution of HRP for 6-12 hours. In two experiments the central end of the sectioned glossopharyngeal nerve was also exposed to HRP. After an additional 12-40 hours transport time the animals were sacrificed and perfused with fixative. Frozen sections (42 μ) of the medulla, caudal pons and petrosal ganglion were processed in benzidine and examined with darkfield illumination. Neurons containing HRP reaction product were detected in 5 of 10 preparations following application of HRP to the CSN. The cells were round or spindle shaped, 10-20 μ in diameter and located in the region of the ipsilateral nucleus ambiguus and the adjacent reticular formation (nucleus parvocellularis). A few cells were also observed in a more dorsal position in the reticular formation. Usually only one or two cells were detected in a section. The maximum number of cells identified in single preparation was 58. These occurred over a rostro-caudal length of 1.4 mm. In different animals cells were detected from AP coordinates -8 to -10. The number of labelled afferent neurons identified in petrosal ganglion varied in different preparations from 175 to 613 (average 367). Afferent axons in the medulla were also labelled with HRP. These were evident as lines of fine granules within the central projections of the CSN nerve. These HRP labelled axons could be traced to the nucleus tractus solitarius. Afferent labelling and larger numbers of labelled cell bodies were observed after application of HRP to the glossopharyngeal nerve. Labelled cells were distributed in the nucleus ambiguus and more widely in the reticular formation.

It is concluded that efferent fibers in the carotid sinus nerve are derived from small neurons in the medullary reticular formation adjacent to the nucleus ambiguus.

1761 EFFECTS OF L-DOPA ON DORSAL HORN UNIT RESPONSES TO MECHANICAL STIMULI. Jonathan Delatizky, Charles J. Hodge and Charles I. Woods*. Dept. of Neurosurgery, Upstate Medical Center, Syracuse, NY 13210.

Studies of the effects of L-Dopa on sensory transmission have suggested an inhibitory role for norepinephrine (NA) in the spinal cord. (Anden et al, Acta Physiol. Scand. 67:373, 1966)

In contrast, studies of morphine and stimulus produced analgesia show an elevation in nociceptive thresholds following depletion of NA and a decrease in analgesia with increased NA. (eg Akil & Liebeskind, Brain Research 94:279, 1975). Thus there is evidence that NA has both inhibitory and facilitatory roles. NA endings in spinal cord all originate supraspinally, and can release transmitter after intravenous L-Dopa (Anden et al, op. cit.). We have investigated the effects of L-Dopa on transmission of innocuous mechanical stimuli to lumbar dorsal horn units in acute spinal cats.

Cells were characterized using extracellular single unit recordings on the basis of response to innocuous stimuli only (group I) or to innocuous as well as noxious stimuli (group II). A repeated identical deflection of skin or hair was presented at 5 second intervals and the responses were recorded for 5-15 minutes before and at least 60 minutes after intravenous L-Dopa (10-25 mg/kg). Average spikes per stimulus and average spontaneous activity were determined for each 5 minute block. Cell locations were marked by dye ejection after recording.

Results were 1) Most group I cells were facilitated. 2) Most group II cells were inhibited, sometimes with late facilitation. 3) Most facilitated cells were in lamina IV, while most that were inhibited were in laminae I and V-VI. 4) No change in receptive field size or response type occurred. Since L-Dopa can cause serotonin release, experiments were repeated in cats pretreated with p-clorophenylalanine (PCPA) to deplete 5-HT. In these animals most cells were facilitated without regard to group or laminar location. About one third had an increase in receptive field size. Responses of group II cells in PCPA treated animals were significantly different from those of the untreated cats. In chronic spinal cats all but one of nine cells showed no changes from control following L-DOPA, confirming the supraspinal origin of the effects.

The results suggest 1) Metabolites of L-Dopa (presumably NA) facilitate transmission of innocuous stimuli at the spinal cord level. 2) L-Dopa causes overflow of 5-HT in a descending pathway selective for cells with nociceptive inputs. Attempts to confirm NA as responsible for the changes, as well as extension to noxious stimuli, are in progress. (supported by PHS grant NS 12761-01)

1762 CODING OF STIMULUS LOCATION AND INTENSITY IN SOMESTHESIS: A NEURONAL POPULATION RESPONSE MODEL. G.S. Doetsch and R.P. Erickson. Depts. Surg. (Neurosurg.) & Physiol.,Med. Coll. Ga., Augusta, Ga. 30901 & Dept. Psych., Duke Univ., Durham, NC 27706.

The broad sensitivity of individual neurons to several stimulus parameters (e.g. location, intensity, quality) presents difficulties for any model of sensory coding which considers single neurons to serve specific, unitary functions. The large receptive fields (RFs) of somatosensory neurons alone are problematic in explaining the precision of tactile localization and discrimination. This was evident to Adrian (1931) who showed that individual somatosensory RFs on the frog's skin range from 4-100 mm^2 and to Tower (1940) who observed that RFs on the cornea and sclera of the cat range from 50-200mm^2. Many investigators, using suprathreshold stimulation, have confirmed the existence of RFs that are large relative to tactile discriminability. Adrian hypothesized that stimulus location is signaled by the "particular combination of fibres in action, together with the relative intensity of the discharge in each;" a similar coding mechanism was suggested by Tower. Their similar theoretical positions have gone largely unnoticed in those modern theories of coding which suggest that the identity and location of a stimulus are signaled by individual neurons specifically labeled in their meaning to the organism.

The problems raised by the large RFs and multiple sensitivities of somatosensory neurons are analogous to the problems posed in other sensory systems with broadly-tuned neurons. However, a neuronal population response model, consistent with the ideas of Adrian and Tower, provides a solution. Application of the model shows that precise information about taste quality, limb position, sound localization, temperature, color, etc. can be signaled by the profile of impulse frequencies in a responding population of neurons (an "across-fiber pattern," AFP) rather than the discharge of individual neurons per se. Intensity can be signaled by the total discharge frequency in the responding neuronal population. For example, it is shown that taste stimuli which are similar in quality produce similar AFPs.

Preliminary studies on the somatosensory system of the rat (Cassel, Anz; unpublished data) indicate that the AFP model is applicable to the problem of tactile localization. Analysis in terms of AFPs suggests that localization on the rhinarium exceeds that on the forepaw, which in turn exceeds that on the hindpaw--in this analysis, innervation density (neurons/cm^2) is more relevant that RF size. The breadth and complexities of the RFs, which may be troublesome for labeled-line coding, are advantageous in the AFP model. More detailed applications of the model to somesthesis are given by Ray and Doetsch (these proceedings). (Supported by grants from U.S. Army, NSF, and NIH)

1763 NON-SPECIFIC THALAMIC PROJECTIONS TO SENSORY-MOTOR CORTEX. John P. Donoghue and Ford F. Ebner. Neurosciences Section, Brown University, Providence, RI 02912.

The central intralaminar nucleus (CIN) of the opossum (D. virginiana) thalamus is located dorsal and medial to the ventrobasal complex. CIN receives inputs from at least spinal cord, cerebellum, and dorsal column nuclei (Walsh and Ebner, '73). Lesions of CIN result in a widespread projection from this nucleus to layer I of somatic sensory-motor (SSM) cortex (Killackey and Ebner, '72; '73). The present results demonstrate several additional features of these non-specific thalamocortical projections. Following injection of horseradish peroxidase (HRP) into physiologically defined zones of SSM cortex, retrogradely labelled neurons are present in CIN as well as in the ventral nucleus (VB & VL.) Injections of HRP into hand area leads to labelling in more lateral parts of CIN, while injections in the face area label more medial parts. This topography is crude compared to that seen in VB. Electrophysiological criteria can be used for placement of injections or lesions in CIN. CIN neurons respond at a long (20-50 msec) and variable latency after electrical stimulation of the contralateral body surface. They fail to respond consistently at repetition rates above 1 per 2 sec. Subsequent to localization of CIN and injections of H^3 leucine and proline, silver grains are concentrated in the outer 1/3 of layer I, over a wide area of SSM cortex. In cases with no spread of label from the injection into VB, there is no concentration of silver grains in any other cortical layer. These injections confirm the HRP topography. EM autoradiography and degeneration procedures reveal CIN terminals in the same subdivision of layer I, with only rare terminal degeneration in other layers. CIN terminals contain round synaptic vesicles and are associated with an asymmetrical membrane differentiation. Approximately 80% of these synapses contact dendritic spines. These studies demonstrate the properties of one type of non-specific thalamocortical projection that are clearly different from the "specific" VB projection. Based on connectional information, CIN appears comparable to some part of the posterior complex in other mammals. (Supported by USPHS grant NS-13031).

1764 VELOCITY DEPENDENCE OF A DIMENSION OF CUTANEOUS SENSIBILITY. D. Dreyer, M. Hollins, B. Whitsel and M. Young. Dent. Res. Ctr. & Depts. of Physiol & Psychol, U.of N.C., Chapel Hill, NC 27514.

Three different psychophysical experiments were performed in order to assess the effects of stimulus velocity on perception of the distance traversed by a moving tactile stimulus in normal human subjects. In all experiments, constant velocity stimuli were applied to the dorsal surface of the left forearm; 10 different velocities between 1 and 250 cm/sec were employed. All stimuli moved from distal to proximal and the length of skin contacted by the brush was fixed by a plate having a 4 X 0.5 cm aperture. The 16 subjects were naive as to the design of the experiments. Subjects were required to compare the distance traversed by a test stimulus delivered 2 sec after a standard stimulus. In Exp. 1, the velocity of the standard stimulus was 15 cm/sec. In that experiment, each subject was instructed to assign to his sensations of the distance moved by the standard stimulus a value of 50, and to rate his estimate of the distance moved by the test stimulus accordingly. In Exp. II, subjects were asked to use a drawing of the stimulated region of the arm as the basis for their reports of stimulus distance. The drawing illustrated the region on the arm as a linear array of 9 segments that were numbered sequentially. The most distal segment was assigned the number "0" and the most proximal "8". Subjects were required to identify the segments traversed by the test stimulus delivered 2 sec after the standard (15 cm/sec) which they were told moved continuously from segment "2" through segment "6". Exp. III utilized the same design as II except that sessions were run using standard velocities of 2.5, 15, 75 and 150 cm/sec. The data from this experiment indicate that the velocity dependence of estimated stimulus distance (ESD) is not influenced by the velocity of the standard stimulus. Several observations are common to the data from all three experiments. First, although the actual length of skin contacted by the brush was 4 cm for all stimuli, the ESD is a decreasing function of stimulus velocity. Second, the function relating ESD to velocity is relatively flat in the range of 10-30 cm/sec (ESD is independent of velocity over this range) but possesses an appreciable negative slope at both lower and higher velocities. It is of some interest that the flat portion of the function (where ESD remains constant in the face of changes of velocity) occurs over a range of velocities that is identical to the range of velocities required for optimal performance in a direction discrimination task. The present study has identified dimension of cutaneous sensibility that exhibits a pronounced dependence on stimulus velocity and provides the basis for subsequent investigations of the underlying central neural events.

1765 THE SEGREGATION OF SUBMODALITIES IN PRIMARY SOMATOSENSORY CORTEX OF THE CAT. R. W. Dykes, D. D. Rasmusson*, P. B. Hoeltzell*, Department of Physiology & Biophysics, Dalhousie University, Halifax, Nova Scotia.

In 15 adult mongrel cats the primary somatosensory cortex was studied with glass-coated tungsten microelectrodes which effectively recorded from single neurons and small clusters of units in most layers of cortex. Special attention was given to (1) the details of somatotopy and (2) the nature of the stimulus adequate for eliciting a response. In two animals numerous vertical penetrations throughout SI allowed reconstruction of a precise somatotopic map. In 13 of the cats, electrodes were introduced into the forelimb region of SI in long slanting penetrations which crossed several cytoarchitectonic boundaries. This allowed detailed analysis of both the sequence of adequate stimulus submodalities and the sequence of body parts without the errors of electrode placement which accompany repeated vertical penetrations.

Electrolytic lesions placed at points of interest allowed reconstruction of the path taken by the electrode and permitted function to be related to cytoarchitecture.

Our results suggest that somatosensory submodalities are localized in narrow bands of cortex that stretch along the mediolateral extent of SI. These functional bands are more distinct in some animals than in others, but in all cases it was possible to identify bands of deep and cutaneous modalities. In most cases the cutaneous band could be further divided into regions with either rapidly adapting or slowly adapting characteristics.

This functional segregation within SI cortex may reflect the terminal stage of a sensory system containing separate but paralled relay paths for different receptor classes or it may arise as the result of different kinds of processing mechanisms within the cortex, operating on the same afferent information in completely different ways.

1766 DEGENERATIVE CHANGES IN DENDRITES OF INTERNEURONS IN LAYERS II AND III OF THE DORSAL HORN OF THE MEDULLA IN DEVELOPMENTAL STUDIES IN NEWBORN KITTENS AND FOLLOWING PULPOTOMIES IN ADULT CATS. William Falls and Stephen Gobel. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD. 20014

Most of the small caliber primary trigeminal axons entering the substantia gelatinosa of Rolando in the caudal medulla synapse in layers II and III on dendrites of two major kinds of interneurons, stalked cells and islet cells. At birth, numerous dendrites radiate in all directions from the cell bodies of the most immature forms of both of these cells. During maturation, a few of these dendrites continue to elongate while many others bead up and disintegrate. Within the beads, small vesicles collect in aggregates and begin fusing with each other to form small cavities. These cavities continue to enlarge and hollow out the beads. Their membranes fuse with the plasma membranes of the beads and the cavities ultimately open to the intercellular space. Finally, the beads fragment and disintegrate. Disintegration of beaded dendrites takes place despite synaptic input from non-primary axons. However, beaded dendrites have never been observed in synaptic contact with a primary axon.

In adult cats, the tooth pulps, which contain the distal ends of large numbers of primary (Aδ and C) trigeminal neurons, were removed from all mandibular teeth on one side and prevented from regenerating. This procedure results in degeneration of axonal endings of affected primary neurons in layers I, II and III (Gobel and Binck, Brain Res. 132(1977)347-354) and transsynaptic degenerative changes in stalked cell and islet cell dendrites 30 and 60 days after surgery. The process of dendritic degeneration proceeds through the same sequence in this experimental situation as in the normal developmental situation with numerous cavities developing in layer II and III dendrites. These cavities hollow out the dendrites, open to the intercellular space and lead to fragmentation of the dendrites. Cavitation of dendrites occurs following a partial loss of primary input despite appreciable synaptic input from non-primary axons.

These studies show that the presence of synapses from non-primary axons on stalked cell and islet cell dendrites is not sufficient to assure their continued elongation during development nor are they sufficient to assure their survival in the adult should even part of their primary afferent input be lost. These studies suggest that the establishment of synaptic connections between primary trigeminal axonal endings and stalked cell and islet cell dendrites is essential for these dendrites in terms of their progressive elongation during postnatal development as well as for their survival in adulthood.

1767 COLLATERAL AFFERENTS TO THE INFERIOR OLIVE AND SUPERIOR COLLICULUS ORIGINATING IN THE SPINAL TRIGEMINAL NUCLEUS. Anthony Frankfurter, John Persing, and Oswald Steward.Depts. of Neurosurgery and Physiology,Univ.of Virginia School of Medicine,Charlottesville,VA

Horseradish peroxidase in conjunction with poly-l-ornithine was used as an anterograde and retrograde tracer to identify the connections of the superior colliculus with midbrain, brainstem, cerebellar, and spinal cord cell groups in the rat. For comparison, the superior colliculus in each of a control series of rats was injected with tritiated proline, and the brains of these animals were processed for autoradiography. The anterograde labeling of fibers and their terminations with HRP is comparable to that seen in the controls. The most significant findings of this study are the extremely large number of labeled neurons in the contralateral interpolar division of the spinal trigeminal nucleus, a lesser number of labeled cells in the contralateral cuneate nucleus, the axon collaterals associated with these cell groups, and the presence of terminal fields in the inferior olive not demonstrable in the tissue which was processed for autoradiography.The labeled cells in the interpolar division of the spinal trigeminal complex are predominantly of the large multipolar type. Two fiber bundles can be identified originating from these neurons. One bundle can be traced exiting from the ventral aspect of the cell group and coursing dorsomedially across the midline and rostrally. The other bundle can be traced exiting from the medial aspect of the cell group and coursing ventromedially through medial levels of the ipsilateral inferior olive, and terminating within the contralateral principal and dorsal accessory nuclei. A smaller contingent of trigemino-olivary fibers can be traced to caudal levels of the inferior olive, where they appear to terminate within a medial segment of the medial accessory nucleus which is coextensive with neurons which receive direct afferents from the superior colliculus. Fibers could also be identified exiting from the rostral portion of the cuneate nucleus and joining the trigeminoolivary bundle. Although these fibers could not be traced in their entirety, terminal label and axon fragments are present in laterally located cells in caudal portions of the contralateral medial accessory nucleus. This segment of the inferior olive is known to receive dorsal column afferents. In summary, this preliminary evidence suggests that the same neurons which provide the cerebellum, via the inferior olive, with cutaneous input from the face and neck also contribute to the somatosensory map contained within the deep layers of the superior colliculus.

1768 BODY SOMATOTOPY IN THE SECOND SOMATIC SENSORY CORTEX OF THE MONKEY. D.P. Friedman* (SPON: E.G. Jones). Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

The topography of the connections between the first (SI) and second (SII) somatic sensory areas was examined in cynomolgus and rhesus monkeys in an attempt to define the body representation in SII. Anterograde labelling patterns were studied in SII following injections of tritiated amino acids into parts of the representation in SI. It was assumed that an injection in SI would label a corresponding part of the representation in SII.

Groups of small injections into different parts of the SI representation in each case labelled obliquely oriented bands within SII. In the case of the forelimb area the label ran from posterolateral to anteromedial across an extensive region of the frontoparietal operculum. The evidence indicates that the face is represented anterolateral and the hindlimb posteromedial in relation to the forelimb representation outlined in this way. Portions of the lower trunk and leg representation were traced onto the upper part of the insula. Injections of horseradish peroxidase into SI which retrogradely labelled cells in SII tended to confirm this pattern for the reciprocal projection from SII to SI.

The larger bands of label seen in the autoradiographic experiments were composed of smaller columns approximately 0.25 to 0.5 mm wide. Each of these anterogradely labelled columns in SII involved layers I through IV with the densest label concentrated in layer IV.

Injections in SI with an effective width of about 0.5 mm labelled columns in SII also about 0.5 mm wide. The fact that SI is larger than SII and that its constituent fields (areas 3b, 1 & 2) were each shown to project onto SII indicates that SI projections converge onto specific areas of SII.

Contrary to previous reports, no projection could be traced from the motor cortex to SII, though a projection was confirmed passing from SII to the motor cortex.

1769 EXCITATORY AND INHIBITORY INTERACTION OF MULTIPLE POINT STIMULI IN THE SOMATOSENSORY CORTEX OF ALERT MONKEYS. Esther P. Gardner and Richard M. Costanzo. Dept. of Physiology, NYU School of Medicine, New York, N.Y. 10016.

To determine principles of sensory coding of spatial information on the skin, we examined how single neurons in primary somatosensory cortex (SI) of alert monkeys integrate information from multiple points on the skin. Brief (10 ms) airpuffs were presented both individually, and simultaneously at 3 points 15 mm apart on forearm hairy skin along the longitudinal axis of cortical receptive fields, and the number of spikes produced at each position were measured. Each pattern was tested with a resolution up to 2.5 mm on the skin in order to reconstruct the spatial distribution of activity in SI. Cortical response profiles of the number of spikes per stimulus as a function of field position evoked by simultaneous stimulation of 3 closely spaced points were unimodal: peak activity occurred when the middle airpuff was directed close to the center of the receptive field and the lateral airpuffs straddled the field center. The response profile gently curved across the span of the airpuffs and was much broader than the profile produced by only one airpuff of the same intensity. Most cortical neurons in alert monkeys showed no increase in the overall amplitude of the three probe response profile compared to the single probe profile, but instead displayed a broadening and spreading out of its peak. Responses to 2 of the 3 airpuffs straddling the field center were bigger than responses to separate presentation of any of them, but the lateral airpuff representations were suppressed and smaller than the response to single airpuffs on the field center. Summation of excitation from multiple stimulus sites is non-linear, suggesting occlusion of the three inputs.

To test the role of in-field inhibition on non-linear summation of excitation from multiple stimulus points within cortical receptive fields, strong test airpuffs were delivered near the field center 30-40 ms after conditioning single and 3 point stimuli at various positions within the field. Test response suppression paralleled excitation; in-field inhibition was maximum at points producing the most excitation. Three point stimuli elicited slightly more inhibition than single point stimuli, suggesting occlusion in the inhibitory as well as excitatory pathways.

1770 INTERACTION OF ORTHO- AND ANTIDROMIC ACTIVITY IN HAIR FOLLICLE AFFERENT UNITS. M.D. Goldfinger and V.E. Amassian. Dept. of Physiology, SUNY, Downstate Medical Center, Brooklyn, N.Y. 11203.

Activity of a single primary afferent axon is recorded with a glass-insulated tungsten microelectrode in the cuneate fasciculus of Nembutal anesthetized, Flaxedil immobilized cats during mechanical stimulation of one or more guard hairs of the axonal receptive field. During continuous airjet stimulation, the evoked spike train is largely random (ref.1) with a mean frequency which is non-linearly proportional to the number of driven innervated receptive field hairs (ref.2).

The primary afferent axonal branches are myelinated distally until near the receptor. To assess the effect of antidromic propagation, the parent axon was stimulated electrically some 5 mm central to the edge of the receptive field with one or a train of 0.1 msec suprathreshold shocks. Antidromic stimulation at 10/sec during continuous airjet stimulation of the entire receptive field at either strong or weak intensities revealed in the Post Stimulus Histogram a brief (2-3 msec) silent period subsequent to the antidromic spike. Following this silent period, a steady-state level was reached either rapidly (~1 msec) or slowly (~5msec or more), depending upon whether the unit fired at a high (> 60/sec) or low (< 60/sec) rate, respectively, during airjet stimulation alone of the whole field at maximal intensity. Significantly, for each unit, such pattern of recovery and steady-state level during mixed anti-dromic electrical plus orthodromic airjet stimulation closely resembled that observed in the Expectation Density function of the spike train evoked by an airjet alone at the same intensity. Thus, excitability appeared to recover rapidly when tested with an airjet stimulus.

By contrast, the threshold amplitude of a fast (~2 mm/msec) triangular displacement of a single innervated hair was increased for longer periods (eg. 8 to 25 msec) following one or a train of electrically evoked antidromic spikes (cf analogous changes in velocity threshold following an antidromic spike:ref.3). No sign of such long recovery was observed during airjet alone or airjet plus antidromic electrical stimulation.

Evidently, even weak airjet stimulation soon overcomes the excitability changes caused by electrically evoked activity, and any excitability changes that might be caused by mechanically evoked activity in the branched complex of the parent axon.

1771 VIBROTACTILE SPATIAL RESOLUTION OF THE QUICKLY ADAPTING FIBER POPULATION. A.W. Goodwin*, M.E. Pierce* and B.D. Youl* (SPON: I. Darian-Smith). Dept. Physiol., Univ. of Melbourne, Parkville, Victoria 3052, Australia.

Psychophysical studies have indicated that vibrotactile resolution is better at 250 hz than it is at 40 hz. It has been suggested that this information is conveyed by the Pacinian corpuscles as they are more sensitive at 250 hz than the Meissner endings which serve the Quickly Adapting fibers (QA's). However Pacinians seem ill suited to convey spatial information because of their large receptive fields whereas the QA's, with their more confined receptive fields, are more likely candidates for this task. We have studied the ability of the QA population in the glabrous skin of the monkey to represent a simple spatial pattern consisting of two probes vibrating in phase. The features of this representation were compared at stimulating frequencies of 40 hz and 200 hz.

The stimulus consisted of two 1 mm diameter lucite probes, separated by 2 mm or 3 mm between centers, vibrating in phase. Single QA's were isolated and their response measured as a function of vibratory amplitude, frequency and position of the probes in the receptive field. Response and stimulus amplitude were related by a piecewise linear function of ramps and plateaux, as for single vibrating probes. Individual fibers differed only in their sensitivities which defined the corners of the function. The effect of position in the receptive field was quantified at both frequencies, independently of fiber sensitivity. Thus for our stimulus a QA's response was determined by a fiber-independent field factor plus the sensitivities of the particular fiber.

From this general description the response of any QA at any position with respect to the probes could be calculated for any stimulus amplitude at either frequency. This allowed us to reconstruct the response of the whole QA population to two vibrating probes and examine the effect of various parameters. The spatial configuration of the stimulus was represented in the QA population even at 200 hz. Moreover, at an amplitude of 100 microns, this representation was more precise at 200 hz than at 40 hz. The reconstruction allows ready visualization of the effect of different QA innervation densities and the effect of variation of sensitivity within the QA population. Population responses were compared for vibrating stimuli and vibrating stimuli scanned across the skin such as occur with the Optacon.[1] The results show that the QA population is capable of transmitting spatial information used by blind people reading with the Optacon.

1772 RESPONSES OF JOINT AFFERENT NEURONS TO CONTROLLED AXIAL LOADINGS OF POSTERIOR JOINT CAPSULE.
Peter Grigg Dept. Physiol., Univ. Massachusetts Medical School, Worcester, Mass. 01605.

Recordings were made from joint afferent neurons innervating sections of posterior joint capsule from the cat knee. The joint capsule section and its innervation, the posterior articular nerve (PAN) were excised from the knee and studied in vitro using an apparatus which produced controlled loadings in 2 axes of the section. Displacements were produced in the femur-to-tibia axis and in the medial-to-lateral axis. Capsullar afferents were activated in response to loadings in both axes. Thresholds for activation were very low, and the frequency of response of afferents was roughly linearly related to the applied stress in either axis. Only slowly adapting discharge was observed. These results are in sharp contrast to the results of similar experiments done on knee joint medial capsule, where the majority of afferents are sensitive to compressive rather than axial loadings.

1773 A NORMAL AND ALTERED CORTICAL COLUMN: A QUANTITATIVE AND QUALITATIVE (^{14}C)-2 DEOXYGLUCOSE (2DG) MAPPING STUDY. Peter J. Hand, Joel H. Greenberg, Richard R. Miselis, W. Lee Weller, and Martin Reivich. Depts. Animal Biology and Neurol., Sch. Vet. Med. and Med. and Inst. Neurol. Sci., U. of Pa., Phila., PA 19104.

A previous qualitative 2DG metabolic mapping study of rat vibrissal - cortical barrel system (Neurosci. Abst., 3, 1977) confirmed the topographical organization of the SI barrel field and demonstrated the one-to-one vibrissal-barrel relationship. The laminar distribution of 2DG labeling in cortical barrel column #3, row C was also determined. This investigation examined, quantitatively and qualitatively (Sokoloff et al., J. Neurochem. 28, 1977), the laminar distribution of 2DG labeling in normal and developmentally altered cortical column #3, row C in 8 unanesthetized, restrained adult rats. All vibrissae, excepting #3, row C, were clipped acutely. Vibrissa #3 was stroked 2-3x/second for 35-50 minutes, using a hand-held brush, to increase activity and uptake of 2DG in neurons of cortical barrel column #3, row C. The single column extended from Lamina I(deep) through VI, with densest labeling occurring in layer IV (laminae were determined in counterstained serial sections). The column, not of uniform diameter, was candle-pin shaped. Lamina IV was its widest portion. As the column extended through the remaining superficial and deep cortical layers, a narrowing of its diameter occurred. The laminar analyses of the mean values of the local cerebral metabolic rates for glucose (LCMRG) confirmed the qualitative findings of 2DG labeling density in the individual laminae. Within cortical column #3, row C, the LCMRG (μ mol/100g/min) were determined for each of the cortical laminae: I-83.8; II-III-98.3; IV-143.8; V-107.2; upper VI-93.8; and lower VI-73.3. The LCMRG for laminae of the barrel field, which surround column #3, row C were as follows: I-76.1; II-III-72.7; IV-77.2; V-77.2; upper VI-67.2, and lower VI-58.3. The normal laminar distribution of 2DG labeling in column #3, row C of the adult rat was significantly altered by vibrissal follicle removal (sparing #3, row C) one day postnatally. At 90 days post-follicle removal, labeling in layer IV remained focal, but was of reduced density and size. The oval, focal pattern of labeling (tangential sections) was not discernable in laminae I-III or V-VI. Their labeling appeared diffuse; extending over a wide area of the surrounding barrel field. Thus the metabolic (functional) alterations in lamina IV, the major recipient layer of thalamocortical projections, are minimal, but become accentuated in the remaining cortical laminae presumably via changes (unknown) in local corticocortical connectivity resulting in an "hour-glass"-shaped cortical column. (Supported by Grants NS-06716 and NS-10939).

1774 PRE-INTRALAMINAR NUCLEI IN THE OPOSSUM BRAINSTEM. James C. Hazlett, Dept. of Anatomy, Loyola University, Stritch School of Medicine, Maywood, IL 60153

Brainstem nuclei whose efferents ascend to or through the thalamic intralaminar area have been identified using the retrograde transport of horseradish peroxidase. Unilateral hydraulic injections of 0.02 μl-0.2 μl (25%-50%) of HRP were centered in the thalamic intralaminar nuclei (parafascicular complex and paracentral nucleus) as delineated by Oswaldo-Cruz and Rocha - Miranda '68. While brain slices were exposed to one of several substrates, we found that o-dianisidine yielded exceptional results in our material. Retrograde neuronal labelling subsequent to small intralaminar placements (.02μl - .05μl of HRP) was observed in the following locations: ipsilaterally in the superior colliculus and areae cuneiformis; contralaterally in the interstitial tegmentum, caudal portion of the nucleus pontis caudalis, nucleus gigantocellularis and deep cerebellar nuclei and bilaterally in the nucleus pontis oralis and nucleus locus coeruleus. A few labelled cells were also present in the nucleus raphe magnus. The larger intralaminar placements (0.1 or 1-0.2μl of HRP) resulted in retrograde labelling in the above mentioned areas but additionally included reactive neurons in the pars reticulata of the ipsilateral substantia nigra and in the contralateral spinal trigeminal complex (oralis and interpolaris), dorsal column nuclei, paratrigeminal nucleus and a portion of the lateral reticular nucleus. Retrograde neuronal labelling in these latter nuclei also is present following HRP injections centered in the VB and VL complexes. Interestingly, several of the larger intralaminar injections have resulted in retrograde labelling of neurons adjacent to the abducens nucleus, in the nucleus prepositus hypoglossi and Roller's nucleus. This work supported by NIH Grant number 05384-16.

1775 STUDIES ON THE TONIC EXCITABILITY OF SINGLE C-FIBERS' CENTRAL TERMINALS. Ian D. Hentall and Howard L. Fields. Depts. of Neuro. and Physiol., UCSF, San Francisco, CA 94143

Single C-afferents, recorded with NaCl-filled micropipettes in L6 or L7 dorsal root ganglia of cats, were stimulated through intraspinal microelectrodes in the region of their terminals. With each stimulus, pulse width was adjusted in the direction of the preceding threshold by a single uniform step. The computer program performing this threshold-tracking procedure was set to deliver test pulses with a 2 s. period, initial width of 200-300 μs., and width adjustment of ±7.5 μs. Antidromic thresholds, minimized by placement of the stimulating electrodes, were 4-270 μA (median 66 μA) at 300 μs. The 78 units studied were either classified as high threshold mechanoreceptors (10%), polymodal (15%), or C-mechanoreceptors (28%), or else they possessed no identifiable receptive field (32%).

All units had increased thresholds after being orthodromically active. The time course of this effect (4 min. to recover after orthodromic electrical stimulation of 30 Hz for 10 s.) resembled that of the hyperpolarization due to sodium pumping seen in peripheral nerve (Rang and Ritchie, J. Physiol. [1968], 193, 183). Various natural cutaneous stimuli were applied for 10-20 s. in the vicinity of a receptive field without causing the unit to fire. Significant increases (I) or reductions (R) of threshold occurred as follows: Noxious mechanical stimuli, I-41% and R-3%; innocuous mechanical stimuli (brushing), I-3% and R-32%; noxious heat, I-35% and R-18%. No qualitative effect of the class unit, of the exact site of the conditioning stimulus, or of the 3 kinds of preparation (low spinal/decerebrate, decerebrate, and anesthetized with chloralose-urethane) was discerned. It seems therefore that more than one class of primary afferent can affect the excitability of C-fibers' terminals.

Morphine (2 mg/kg) or naloxone (0.1 mg/kg) did not change thresholds in 10 units. However, this does not preclude opiates having some presynaptic action, not affecting excitability, which influences post-synaptic responses.

Trains of electrical pulses (20-50 Hz, 50-100 μA) in nucleus raphe magnus or adjacent reticular formation in 25 units gave I-56%, in both chloralose-urethane and decerebrate cats. Temporary cold block of the thoracic spinal cord produced R-2, I-2, and 8 without effect. Thus descending influences are either tonically active and of opposite effect from different brainstem regions, or not tonically active and mainly causing decreased excitability.

We conclude that terminals of C-fibers are modifiable by both segmental and descending influences.

1776 THE INTRACORTICAL AND INTERHEMISPHERIC CIRCUITRY OF THE FUNCTIONAL SUBDIVISIONS OF THE SI CORTICAL REGION IN THE RACCOON. Paul Herron*(Spon: J.L. Zacks). Dept. of Psychology, Michigan State Univ., E. Lansing, Mich. 48824

The intracortical and interhemispheric connections of functional subdivisions of SI was investigated. Behavioral data have shown that the SI and SII cortical regions are critical for the interhemispheric transfer of tactile habits. Anatomical data have shown that certain areas in both SI and SII are devoid of or receive relatively sparse projections from the contralateral SI and SII cortical areas. Those areas devoid of interhemispheric projections correspond to those areas that receive electrophysiological projections from the densely innervated regions on the animal's body surface such as the forepaw in the raccoon. The purpose of this study was to determine and compare the topography of intracortical and interhemispheric afferents and efferents of the functional subdivisions of SI which receive interhemispheric projections with those functional subdivisions of SI which are devoid of interhemispheric projections.

Injections of horseradish peroxidase and tritiated adenosine restricted to a particular functional subdivision of SI such as the forepaw were used in this study.

The results show that:

1. The forepaw area of SI is reciprocally connected with the ipsilateral forepaw area of SII. The terminals from SI as well as the cell bodies in SII which send efferents to SI are located primarily in layers three and five of the forepaw area in SII. The forepaw area in SI did send efferents nor did it receive afferents from the contralateral SI and SII.
2. The hindpaw area of SI is reciprocally connected with the ipsilateral hindpaw area of SII. The origin and termination of these reciprocal connections within the hindpaw area of SII is very similar to that decribed for the forepaw above.
3. The hindpaw area of SI is reciprocally connected with the contralateral hindpaw area in SI. The cell bodies in the hindpaw area which sends efferents to the contralateral SI area are located primarily in layers three and five. The terminals are located in all layers but primarily in layers three through five.

The present results indicate that the intracortical and interhemispheric projections of SI subdivisions are to homofunctional areas within SI and SII.

1777 RECORDINGS FROM CAT SPINAL CORD NEURONES WITH THALAMIC CONNECTIONS. James A. Holloway, Richard E. Fox*, Ainsley Iggo* and Sukhbir S. Mokha*. Department of Veterinary Physiology, University of Edinburgh, Summerhall, Edinburgh EH9 1QH. U.K.

Adult cats were anaesthetized with α-chloralose,subsequently paralyzed with gallamine triethiodide, and artificially ventilated. Following a lumbar laminectomy, glass micropipettes containing 3M KCL and pontamine sky blue dye were utilized for recording and marking single unit electrical activity from the spinal cord dorsal and ventral horns. An array of 8 concentric bipolar stainless steel electrodes, for antidromic electrical stimulation (150μa, 0.3 msec duration) of spinal cord cells, was stereotaxically placed in the following contralateral thalamic nuclei : ventralis lateralis, ventralis postero-medialis, and centrum medianum. These nuclei are thought to receive spinothalamic tract axon terminals. Quantitative mechanical and thermal stimuli were applied to the skin of the hind limb contralateral to the site of thalamic stimulation. Receptive fields of neurones responding to thalamic stimulation varied considerably in size from an area of a few mm^2 to the entire limb surface. Proximal fields tended to be larger than distal fields. Units were observed in the dorsal horn in laminae I-IV that responded to : a) low threshold mechanoreceptive afferents, b) low threshold mechanoreceptive afferents and nociceptive afferents, or c) nociceptive afferents exclusively. Some units were activated antidromically by thalamic stimulation, and may be described as spinothalamic tract neurones; other units excited post-synaptically from the thalamus were in spinal cord laminae VI and VII. Post-synaptically activated responses were by far the most frequently recorded in response to thalamic stimulation. It is likely that at least part of this post-synaptic information is relayed via excitatory thalamo-reticulospinal neurones[1]. The results emphasize the diversity of response properties in some spinal cord neurones.

1778 DEVELOPMENTAL CHANGES IN THE DISTRIBUTION OF THE THALAMOCORTICAL RELAY CELLS OF THE VENTROBASAL COMPLEX OF THE RAT. G.O.Ivy* and H.P.Killackey. (SPON: M. Snyder). Dept. of Psychobiology, Univ. of Calif., Irvine, CA, 92717.

During the first few days of life, the pattern of the trigeminothalamic afferents to the rat ventrobasal complex undergoes a marked transformation. At the time of birth these fibers are distributed in a uniform fashion, but by the fourth postnatal day they are discretely organized into rows of clusters which replicate the topographical organization of the mystacial vibrissae on the snout of the rat (Belford, Anat. Rec., '78). Further, the corticothalamic afferents to the ventrobasal complex show a similar discrete organization, which develops along a similar time course (Akers and Killackey, this volume). The purpose of the present investigation was to determine if the thalamocortical relay cells of the ventrobasal complex were themselves organized in a discrete fashion, and if a developmental time course comparable to that of the afferents could be observed.

In the present experiment, one "early" group of rats received parietal cortex injections of horseradish peroxidase on Day 0 (day of birth), and at postnatal Day 1, before the development of the discrete afferent segmentation. A second, "late", group received similar injections on postnatal Days 5 and 7, after the development of afferent segmentation. After a survival of 4 to 24 hours, the animals were perfused and the brains processed according to the technique of Mesulam (J. Hist. Cyt., '76).

These experiments reveal that the distribution of labeled neurons in the ventrobasal complex differs markedly between the early and late groups. In the early group of animals, labeled neurons do not appear to be segregated into clusters, and the visible dendrites of labeled neurons can be seen radiating from the cells in all directions. However, although the neurons appear to be uniformly distributed throughout the extent of the ventrobasal complex at Day 0, there is some tendency for these neurons to form rows by Day 1. This corresponds well to the observed trigeminothalamic pattern at this age. In the older group of animals, the distribution of labeled neurons is even more clearly related to the distribution of trigeminothalamic afferents. Neurons are segregated into rows with distinct row boundaries and the dendrites of labeled neurons are oriented inward, toward the center of a row, thus respecting the row boundaries. Further, there is a noticeable tendency toward clustering of neurons within a row, although within-row boundaries are not as clear as those between rows. Thus a developmental sequence can be detected in the thalamocortical relay neurons of the ventrobasal complex, and this sequence parallels that of the afferents to the nucleus. (Supported by NIMH MH 14599-02 and NSF GB 41294.)

1779 FUNCTIONAL ORGANIZATION OF NEURONS IN AREA 2 OF MONKEY SOMATOSENSORY CORTEX(SI). Yoshiaki Iwamura, Michio Tanaka* & Okihide Hikosaka* Dept. Physiol., Toho Univ. Sch. Med., Otaku, Tokyo Japan.

The receptive field(RF) properties of the neurons in the first somatosensory cortex(SI) were studied in alert monkeys. Monkeys were surgically prepared for chronic single unit recording from the region of SI representing the hand and fingers, and were trained to permit hand manipulation during experiments. The cortical unit recording was done with glass-coated platinum-iridium micro-electrodes. Well isolated initially-negative units were recorded. All electrode tracks were identified histologically and the cytoarchitectural area of each recording site was determined. Units were classified into several categories according to their RF characteristics: 1) simple skin units, 2) complicated skin units, 3) units responding specifically to joint manipulation, 4) units responding to both skin stimulation and joint manipulation, 5) units undrivable by ordinary skin stimulation or joint manipulation. In area 3, the majority of units were of simple skin type with small RFs. In contrast, in area 2 the RFs of skin units tend to be larger, and the number of simple skin units decreased. The category of complicated skin units included those responding preferentially to the moving probe over the skin, or those for which narrowness of the stimulated area was most important: they were activated most remarkably when certain elongated shapes of objects were passively contacted on the monkey's hand. Many units with definit skin RFs also responded to joint manipulation. The most adequate stimuli for this type and some other non-skin units were often the complex patterns of stimuli produced by certain natural movements of monkey's hand such as scratching the table surface with fingers or grasping of objects of certain shapes. When the RFs and other properties of sequentially recorded units were compared with each other, it was found that a set of neurons with similar skin RFs were arranged vertically and that the largest RFs included other smaller ones in the vicinity. In addition, within the same vertical organization non-skin units as well as skin and deep units were intermingled. It is suggested that the hand and finger region of area 2 of the monkey SI is organized not in simple somatotopy but in terms of multiple clusterings of neurons each with particular RF characteristics and functional role such as processing complex sensory information concerning special features of tactile objects, or hand and finger movements.

1780 SOMATOSENSORY REPRESENTATION IN THE ANTERIOR WULST OF THE OWL (Speotyto cunicularia). H. J. Karten, M. Konishi and J. Pettigrew, Dept. Psychiatry, S.U.N.Y., Stony Brook, NY 11794 and Cal. Inst. Tech., Div. Bio., Pasadena, CA 91110.

The posterior (visual) wulst of the owl is both anatomically and physiologically similar to the striate cortex of mammals (Karten, et al., 1973; Pettigrew and Konishi, 1976). In contrast, the smaller quadrilaminate anterior wulst (Wa) was noted to be distinct by Karten (1971), projecting to thalamus, red nucleus, medial reticular formation, medial pons, cuneatus-gracilis and contralateral dorsal funiculus. Burrowing owls were anesthetized, the anterior wulst exposed and tungsen electrodes inserted stereotaxically into Wa. Brisk unit responses were elicted only to extremely localized stimulation of the toes of the contralateral hindlimb. No responses were observed to stimulation of the legs immediately proximal to the toes, ipsilateral foot, wings, trunk, head including beak, cornea, visual stimuli, auditory stimuli or tilting of the head. A series of units lying in contiguity along a single penetration often responded to contiguous points on the ventral aspect of a single toe. Receptive fields were often 0.5 mm or less in diameter and responded to extremely light pressure of von Frey hairs. Occasional units responded to brushing movements over 1-3 mm, with evidence of preferred direction of movement. Due to obliquity of the electrode tract relative to the pial surface we could not construct an absolute map of the topography of projections of the individual toes upon the Wa. Each of the four toes was represented, with responses to the ventral surface, single hair-like modified feather cartridges on the dorsum of the toes and the base of each talon. Injection of HRP into the Wa labeled cells in only a single dorsal thalamic cell group, the nucleus dorsalis intermedius ventralis anterior (DIVA) caudomedial to the visual OPT complex. In pigeons, DIVA receives input from the contralateral nuclei cuneatus-gracilis via the medial lemniscus, suggesting that the Wa receives somatosensory input via the medial lemniscal system. Study of efferent projections of Wa with tritiated amino acids confirmed the earlier report of Karten (1971) though indicated a heavier projection to the cuneatus-gracilis than previously appreciated. Spinal cord projections could be followed only to rostral cervical levels. No evidence of projections to lumbosacral levels was observed.

The similarities to the somatosensory system of mammals are evident. The refined use of the lower extremity by owls to strike and manipulate prey is well known and may involve the Wa.

1781 RECEPTIVE FIELD PROPERTIES OF PRIMARY AFFERENTS IN THE ATLANTIC STINGRAY, DASYATIS SABINA. R.B. Leonard, D.R. Kenshalo, Jr. and W.D. Willis. Marine Biomedical Institute and Depts. of Physiology & Biophysics and Anatomy, U. of Texas Med. Br., Galveston, TX 77550

Previous work has shown that the peripheral somatic nervous system in the stingray is composed of two groups of myelinated fibers with a virtual absence of unmyelinated fibers. On the basis of their conduction velocities and fiber diameters, these two groups correspond to Aαβ and Aδ fibers of other vertebrates. As this distribution stands in marked contrast to other vertebrate groups, it is of interest to determine the types of receptive fields in this animal and to correlate these with the fiber diameter distribution.

The discharges of single primary afferent fibers were recorded from the dorsal roots of decerebrate, curarized and artificially ventilated stingrays using 4M NaCl glass electrodes with resistances of 25-40 MΩ. Electrical stimulation of exposed peripheral nerves was the search stimulus, and the spike latencies were used to determine the conduction velocities.

Among the fastest conducting fibers in our preliminary survey are many which respond to proprioceptive stimuli. These units are characterized by a very regular discharge pattern that is modified by elevation or depression of the pectoral fin or a portion of it. The patterns are very similar to those of muscle stretch receptors recorded in isolated preparations. These fibers are not activated by cutaneous stimuli which do not move the fin. In contrast, other fibers have small cutaneous receptive fields, several mm in diameter, overlying 1-3 cartilaginous rays. These fibers have von Frey threshold ranging from 4.5 mg to 2 g, the majority being less than 1 g. The response is graded with stimulus intensity and is rapidly adapting. Large movements of the fin are relatively ineffective in activating these fibers.

Our preliminary survey includes several fibers with slow conduction velocities that appear to have low von Frey thresholds and small receptive fields. This group also includes fibers with higher von Frey thresholds which appear to be activated by stimulation of larger areas.

We conclude that the peripheral receptor population in the elasmobranch includes cutaneous mechanoreceptors and perhaps nociceptors as well as proprioceptors. It is possible that some of the proprioceptors correspond to the Poloumordwinoff ending reported by others.

1782 THALAMIC PROJECTIONS TO S-II CORTEX OF RHESUS MONKEY. P. R. Loe, B. L. Whitsel, D. A. Dreyer, E. A. Cooper, and C. B. Metz. Dept. Physiol., Sch. Med., U. of N. Carolina, Chapel Hill, N. C. 27514.

Most of the neurons in the rostral part of the second somatosensory cortical area (S-II/r) possess bilaterally symmetrical cutaneous receptive fields. We were interested in determining whether or not this property is accounted for by the convergent projection to S-II/r of inputs from the somatosensory thalamus of both sides, and in describing the distribution of the thalamic neuron populations projecting to S-II/r. Horseradish peroxidase (HRP, 0.2 to 0.6 ul of a 30% solution) was injected into regions of S-II/r whose neurons had been characterized according to modality and receptive field location by means of single unit microelectrode recording in the absence of general anesthesia. HRP was visualized, after a 48 hr survival period, by the use of the Hanker-Yates reagent mixture.

Injections of HRP into S-II/r resulted in the labelling of thalamic neurons only ipsilateral to the injection site. Labelled neurons were concentrated in the medial and oral pulvinar (according to the nomenclature of Olszewski, 1952), as well as in the ventral posterior inferior (VPI) nucleus. A few labelled neurons were observed in the ventral posterior lateral (VPL), ventral posterior medial (VPM), and medial dorsal (MD) nuclei. The data suggest that, to a large extent, the thalamic input to S-II/r derives from neurons other than those within the ventrobasal complex that project to S-I. It appears that neurons in the pulvinar and VPI, some of which are known to have bilateral receptive fields, constitute the major source of thalamic input to S-II/r. By the use of a double labelling technique (Hayes and Rustioni, 1978), we are attempting to elucidate further whether S-I and S-II/r receive their thalamic input from wholly distinct neuronal populations or also receive input from thalamic neurons that send collateral branches to both S-I and S-II/r.

1783 MULTIPLE UNIT ANALYSIS OF CUTANEOUS RECEPTORS USING PHASED BINARY CORRELATION. F.J. LOOFT and M.S. FULLER* Bioelectrical Sciences Laboratory, University of Michigan, Ann Arbor, MI 48109

Binary, phased correlation (Heetderks W. and Williams W., Science 188:373,1975) was used to separate single units from population responses in peripheral cutaneous nerves.

Adult cats, anesthetized with sodium pentobarbital, were used for preliminary experiments. The saphenous nerve was exposed from the knee joint dorsally for approximately 8 cm. Proximal and distal sections of the nerve were separated from surrounding tissue and elevated on silver hook electrodes in a mineral oil pool. Electrode separation was between 4 and 6 cm.

A punctate stimulator was drawn across the skin at a constant velocity in a raster scan covering 1 to 4 square cm. Stimulus force was 1 gm.

Recorded data were analyzed by a combination of hardware binary correlation and computer software. Topographic plots of single unit responses were reconstructed from the phased latency histograms(fig.1). Up to six active units have been separated using this technique.

Reconstructed single unit responses were compared to receptive field maps generated from single unit recordings (Looft F. and Williams W. IEEE Bio-Med. Engin.,to be published). Field, type I, and type II receptors produced similar topographic maps using single or multiple unit analysis (fig.2).

Binary correlation appears to be applicable to the analysis of complex spatial-temporal stimuli coding in peripheral cutaneous nerves. (supported by USPHS grant NS 08470)

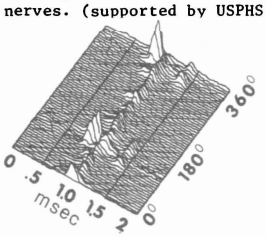

FIG.1 Phased latency histogram. The X direction represents conduction latency, Y the phase or position of the stimulator, and Z the number of action potentials.

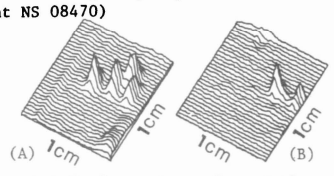

FIG.2 Comparison of a single unit (a) and reconstructed (b) topographic plot of type I mechanoreceptors. The reconstructed map is made by processing data from 32 phased latency histograms all produced from a single raster scan. This particular unit had a conduction latency of .875 msec. Electrode separation was 5 cm.

1784 AFFERENT PROJECTION TO THE NUCLEUS CENTRALIS LATERALIS IN THE CAT AS DEMONSTRATED BY RETROGRADE TRANSPORT OF HORSERADISH PEROXIDASE. Charlotte M. McGuinness* and George M. Krauthamer (Spon: S. Rosner). Dept. of Anatomy, CMDNJ-Rutgers Medical School, Piscataway, New Jersey 08854.

As part of a series of experiments to define the anatomical connections of the intralaminar thalamus of the cat, horseradish peroxidase (HRP) was injected into the nucleus Centralis Lateralis (CL) and the brain examined for retrogradely labeled neurons. Electrophoretic injections through glass micropipette electrodes were used to ensure a small, dense, well localized deposit of HRP. Tissue from the brain and spinal cord was processed by a method utilizing Tetra Methylbenzidine after thirty-six to seventy-two hour survival times.

HRP labeled neurons were found in the ipsilateral superior colliculus in both the stratum griseum intermedium and the stratum griseum profundum; in the dorsal median nucleus of the raphe; and bilaterally in the cuneform nucleus, and pontine tegmental fields. HRP labeled neurons were also located in the cerebellum, in the dentate nucleus, and in the cervical spinal cord, bilaterally in lamina 5.

These results, considered in conjunction with previous studies in the intralaminar thalamus, indicate notibly different systems of afferent projections, and therefore of functions for these nuclei. Further studies on both the anatomy and, importantly, physiology are clearly indicated.

(Supported by NIH grant NS10922)

1785 EFFECTS OF GENERAL ANESTHETICS ON THE BODY REPRESENTATION IN S-I. T. McKenna*, B. Whitsel, D. Dreyer and C. Wong* Dept. of Physiol. & Dent. Res. Ctr., U. of N.C., Chapel Hill, NC 27514

It is known that the dynamic properties of somatosensory cerebral cortical neurons are altered by the administration of central depressants, but these agents are generally considered to exert only minor influences on the static properties of the neurons of the S-I cortex. Consequently, the results obtained from analysis of the topographic organization of S-I performed in the presence of general anesthetics are routinely regarded as providing a relatively undistorted view of the cortical representation of spatial information in the conscious animal. The purpose of this study was to examine the actions of several commonly employed general anesthetics on the static properties of S-I neurons. Neurons in S-I of Macaque monkeys and cats were initially studied in the absence of general anesthesia. Receptive field (RF) dimensions, submodality, and the threshold stimulus at various positions within the RF (using calibrated von Frey hairs) were determined. In addition, measures (PST histograms) of the response evoked by moving tactile stimuli were obtained. Measures were repeated during and after recovery from i.v. injection of the general anesthetics. For neurons in cytoarchitectural areas 1 and 3, general anesthetics led to; (i) progressive reduction in the size of RFs on proximal body parts with progressive increments in anesthetic dose; in addition, there was a general tendency for the most proximal portions of these RFs to be differentially susceptible to depression by anesthetic; (ii) reduction to a small focus limited to one digital surface of RFs that formerly included both the dorsal and ventral surfaces of one or more individual digits; (iii) conversion to a discrete field on one or several digits of RFs that formerly included large portions of a distal limb; (iv) elevation of von Frey thresholds at all locations within a RF, with the thresholds obtained for loci in the periphery of the RF being most susceptible to the effects of the anesthetics. For both cutaneous and deep neurons located in cytoarchitectural areas 3a and 2 the administration of general anesthetic in doses at or below those required for induction of anesthesia reduced stimulus-evoked activity to the point that it became difficult to determine RF and submodality properties. The results suggest that general anesthetics introduce a major bias into any study of somatosensory neuron populations, and recommend cautious use of data obtained under this condition for the reconstruction of the cortical representation of somatosensory stimulus events. Supported by NS10865, DE2668, RR05333 and DE00011.

1786 MULTIPLE REPRESENTATIONS OF THE BODY SURFACE IN POSTCENTRAL PARIETAL CORTEX ("SI") OF THE SQUIRREL MONKEY. R. J. Nelson, M. Sur* and J. H. Kaas. Depts. of Anat., Elec. Eng., and Psych., Vanderbilt University, Nashville, TN 37232.

Four separate architectonic zones have traditionally been included in the "Primary Somatosensory" cortex or "SI" of primates, i.e., Areas 3a, 3b, 1 and 2. In microelectrode mapping experiments in 10 squirrel monkeys (Saimiri), we have extensively explored two of these fields, Areas 3b and 1, and have found each to contain a complete and separate map of the body surface. These studies allow the following major conclusions. (1) In each area, the tail and genitalia are represented most medially, followed laterally in order by the posterior leg, foot, anterior leg, trunk, occiput, ear and shoulder, arm and forearm, hand, and face. Major body parts are represented in parallel in the two representations. (2) The representations of similar body regions in the two areas share a common border and are oriented in mirror-image fashion with respect to each other. (3) The two representations differ in many details. For example, the dorsum of the foot is split in Area 3b with the medial dorsal foot represented laterally and the lateral dorsal foot represented medially, whereas in Area 1, the entire dorsal foot is represented lateral to the digits. (4) Within each field, some adjacent body regions are represented in a non-adjacent manner on the cortical surface. The representations of the posterior and anterior leg are separated, in both areas, by the representation of the foot. The occiput, ear and shoulder representation is separated from that of the remainder of the face by the representation of the hand in each area respectively. Thus, each representation is best described as a composite of somatotopic regions rather than as a continuous map of the contralateral body surface (homunculus). (5) Major differences exist in the organization of the two representations in different New World Monkeys. In the owl monkey (Merzenich et al., J. Comp. Neurol., '78), the trunk is represented in Area 3b with the ventrum caudal and the dorsum rostral; the opposite i. true for Area 1. In squirrel monkeys, the ventrum of the trunk is rostral in Area 3b and caudal in Area 1 with the dorsum of the trunk at the 3b-1 border. These two species also differ in the representation of the face. In owl monkeys, the upper lip forms the common border of the two representations, while the common border is formed by the lower lip in squirrel monkeys. (6) Some features of organization remain constant across simian species. In no simian that we have studied have the tips of the digits of either upper or lower extremities been oriented in a manner other than rostrally in Area 3b and caudally in Area 1.

These studies indicate that "SI" in primates requires redefinition.

1787 HRP MAPPING OF THE TRIGEMINAL GANGLION IN EMBRYONIC AND HATCHLING CHICKS. Drew M. Noden* (SPON: S. A. George) Dept. Zool., Univ. Massachusetts, Amherst, MA. 01003

Sensory nerve fibers emerging from the avian trigeminal ganglion (TG) project peripherally to facial, oral and jaw regions. There are 2 neural cell types in the embryonic TG: small, densely-packed immature cells of neural crest origin found in the medio-dorsal core, and larger, more mature neurons which are mostly of placodal origin and are located peripherally and in the ventrolateral TG. The experiments reported here examine the following: 1) is there a spatial organization of sensory neurons such that all cells projecting to each specific peripheral locus are localized in a particular region of the TG, 2) is the dual embryonic origin of the TG correlated with the different cytological characteristics, locations or functions of TG neurons in either the embryo or the hatchling? To answer these questions horseradish peroxidase (HRP) was injected subcutaneously in 7-day embryos (stages 30-32) or 3-5 day chicks and subsequently visualized in 8 um paraffin sections of the TG.

In the embryo most injected HRP is later localized in the large TG cells. The distribution of labeled cells in the maxillo-mandibular but not the ophthalmic lobe varies depending upon the site of injection, although there are often many labeled cells scattered throughout the TG. In some cases neurons in the trigeminal motor nucleus are also labeled, indicating extensive diffusion of the injected HRP. Application of HRP to areas of maxillary nerve innervation results in labeling of a few core cells.

In the hatchling, injections in regions innervated by branches of mandibular or infra-orbital nerves results in labeling of sensory neurons located exclusively in specific parts of the TG. The location of these cells corresponds to the region of the TG from which nerves to the injection site emerge, and is similar to that seen in the embryo. Labeled cells are always interspersed with unlabeled neurons. Injection of supra-orbital regions results in the labeling of twice as many neurons but these are more scattered. HRP is not preferentially localized in cells of any size class or cytological type, nor are any parts of the TG devoid of neurons with cutaneous projections.

These data prove that there is a patterned arrangement of TG exteroceptive neurons which is correlated with the pattern of peripheral fiber distribution but not with embryonic origin or neuronal cytology.

1788 THE PROJECTION OF CERVICAL AND TRIGEMINAL AFFERENTS TO THE DORSOLATERAL SPINAL CORD - MEDULLARY TRANSITION ZONE. Samuel G. Nord, Charles J. Hodge, David E. Rolince* and Charles I. Woods*. Depts. of Neurosurgery and Neurology, Upstate Medical Center, Syracuse, NY 13210.

Clinical evidence reveals that there is a functional overlap between the trigeminal and upper cervical sensory systems. Although both trigeminal and segmental projections to the CNS have been studied extensively, the location of neurons capable of mediating such an overlap has not been established. The area most likely involved is the spinal cord-medullary transition zone where the trigeminal nucleus caudalis is continuous with the morphologically homologous cervical dorsal horn. The present study explored this zone. Unit activity, evoked by graded mechanical stimulation, was recorded from rostral spinal cord and caudal medullary sites in anesthetized, paralyzed cats. Dye, deposited iontophorectically through recording microelectrodes, identified the locations of responsive neurons. Each of the units studied had an ipsilateral mechanoreceptive field. The numbers of cells which had trigeminal, segmental or combined trigeminal-segmental fields were similar. The trigeminal fields consisted of circumscribed portions of single divisions. Areas of the posterior, or peripheral, face were commonly represented while regions of the anterior, or central face (including oral structures) were encountered infrequently. Segmental fields, in most cases, received input from the C_2 or the C_3 dermatome. The fields were moderate in size and, frequently, were limited to well defined anatomic areas such as the pinna or the posterior neck, or to a part of such an area. Units with exclusively trigeminal, with exclusively segmental and with mixed fields were interspersed at all depths of the dorsolateral gray matter and at every rostro-caudal level of the lower medullary-upper cervical zone studied. All but a few of the fields with both trigeminal and segmental representation were continuous. In these, the ophthalmic trigeminal division usually was associated with the C_2 distribution and the mandibular division with various C_3 areas. Our results demonstrate that facial and segmental afferents project to cells in the transition zone between the nucleus caudalis and the dorsal horn, indicating that this zone is not exclusively a bulbar or a spinal cord entity. The profusion of interrelated upper cervical and posterior (peripheral) trigeminal inputs to the region supports the view that its component neurons are involved in the functional overlap of trigeminal and upper cervical sensibility.

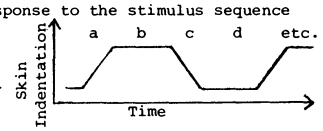
1789 ON VS. OFF RESPONSES OF RACCOON GLABROUS SKIN RAPIDLY ADAPTING CUTANEOUS MECHANORECEPTORS. Benjamin H. Pubols Jr. Dept. of Anatomy, College of Medicine, Pennsylvania State University, Hershey, PA.

The mammalian rapidly adapting (RA) cutaneous mechanoreceptor is defined by its pattern of response to the stimulus sequence depicted in the figure at right. When ramp-and-hold stimuli are applied to the receptive field of an RA unit, the response consists of a discharge during a (the on-response), silence during b, and usually a discharge during c (the off-response). During d, the unit is silent.



a. on-ramp
b. static indentation
c. off-ramp
d. interstimulus interval

A frequent finding in previous studies has been that the response during a has been more vigorous than that during c. However, where specified, d > b, and results may thus be due to the fact that pre-ramp time has been less preceding off-ramps than on-ramps, allowing less time for recovery from fatigue in the former case.

In the present study, the responses of raccoon median nerve RA mechanoreceptive afferent fibers were studied. For any given experimental condition, a = c, and b = d (see figure).

Principal findings were as follows:

1. At stimulus levels well above indentation and velocity thresholds for on-responses, ≈ 85% of units yield a more vigorous on-response than off-response (as measured by the total number of ramp impulses); in ≈ 5%, the reverse is true, while in the remaining ≈ 15%, the off-discharge is absent.
2. On and off indentation thresholds are approximately equal (on median ≈ 45μ; off median ≈ 40μ).
3. On velocity thresholds are significantly lower than off velocity thresholds (on median ≈ 1 μ/msec; off median ≈ 4.5 μ/msec).
4. Exponents of power functions relating discharge rate to ramp velocity are consistently greater for on than for off responses (b = d > 10 sec).
5. On discharge rate remains constant as preramp time (b, d) decreases from 10 sec to zero; off discharge rate also remains constant down to a critical pre-ramp time (100 msec - 6 sec, depending on the unit), but then drops precipitously.

The present results generally confirm previous findings that RA units possess a "linear directionality" favoring on-responses, and suggest that, even though RA units do not discharge during static indentation, such indentation may nevertheless suppress the subsequent off-response.

1790 SCALING OF VELOCITY AND DEPTH OF SKIN INDENTATION BY HUMAN SUBJECTS. Lillian M. Pubols and Benjamin H. Pubols, Depts. Anat., The Med. Coll. of Pa., Pa. 19129 and The M. S. Hershey Med. Ctr., Hershey, Pa., 17033.

Studies of radpily and slowly adapting first-order afferent fibers innervating squirrel monkey and raccoon glabrous forepaw skin (B. H. Pubols and L. M. Pubols, J. Neurophysiol., 39: 773, 1976) revealed that response rate in these fibers is a power function of mechanical stimulus velocity during constant velocity skin indentation. In slowly adapting fibers response rate during static indentation of the skin is a linear, log, or power function of indentation amplitude, but correlation coefficients are usually less than those seen for the power function relating response rate to velocity. The present study was performed to determine whether this ability of first-order fibers to code stimulus velocity and amplitude is reflected in the capability of human observers to make magnitude estimations of these parameters, and, given the higher correlation coefficients for velocity coding, and the larger number of fibers participating in it, whether scaling of velocity is more reliable than scaling of amplitude.

Ramp-and-hold mechanical stimuli were applied to the ventral skin of distal digit 3 of the right hand in 5 adult subjects. Each day's session consisted of 70 trials at a given constant onset velocity (1μ or 100μ/msec) or constant final amplitude (200μ or 800μ), within which amplitude or velocity were varied in 7 steps, evenly spaced on a logarithmic scale (200μ to 800μ, or 1μ to 100μ/msec, respectively). The subject's task was to match the seven stimulus intensities, presented in random order, with a magnitude estimation of 1 to 7. Responses occurred before the offset of the stimulus. Two sessions under each velocity or amplitude condition were presented to each subject in counterbalanced order.

Under all conditions subjects made magnitude estimations that were monotonically related to stimulus intensity. Linear regression analysis yielded highly significant ($p<.01$) correlation coefficients (0.571 to 0.908). For all but one subject, amplitude discrimination was better at 100μ/msec than at 1μ/msec. For all subjects, velocity discrimination was better at 800μ than at 200μ. For three of the five subjects, the best performance was velocity scaling at 800μ, and the worst, amplitude scaling at 1μ/msec. Thus, both velocity and amplitude can be scaled reliably by human observers. For the stimulus values used in this study there is better scaling of velocity than of amplitude by the majority of subjects.

1791 CODING OF STIMULUS LOCATION AND INTENSITY IN POPULATIONS OF PRIMARY MECHANOSENSITIVE NERVE FIBERS OF THE RACCOON. R.H. Ray and G.S. Doetsch. Dept. Physiol. & Depts. Surg. (Neurosurg.) & Physiol.,Med. Coll. Ga., Augusta, Ga. 30901.

The broad sensitivity of individual somatosensory neurons to several stimulus parameters poses a problem for the differentiation of stimulus location, intensity, and quality. However, a neuronal population response model can be used to show how these various stimulus parameters may be differentially encoded (see Doetsch and Erickson, these proceedings). The aim of this study was to describe the coding of stimulus location and intensity on the skin in terms of this model. Recordings were made from single primary mechanosensitive nerve fibers innervating the glabrous skin of the forepaw and hindpaw of the raccoon. The discharges of individual fibers were recorded in response to stimulation of six standard test sites on digit #1 and the contiguous foot pad of each paw. Tactile stimuli of varying intensities were delivered to each test site with calibrated nylon filaments. The receptive field (RF) of each fiber responding to at least one test site was mapped at a standard series of stimulus intensities; discharge characteristics at different stimulus sites and intensities were examined.

The size and functional organization of individual RFs varied dramatically as a function of stimulus intensity--from punctate fields at threshold intensities, to relatively large fields with complex characteristics (including on, off, on-off subdivisions) at higher intensities. Thus an individual neuron cannot unequivocally discriminate between changes in stimulus location, intensity, and other stimulus parameters. However, the various stimulus parameters can be distinguished by differences in the impulse frequency patterns across populations of nerve fibers. This is demonstrated by reconstructing the across-fiber pattern (AFP) produced by stimuli of each intensity at each test site. A specific stimulus location is thus disclosed by an AFP which is unique for that test site; intensity is signaled by the total amount of activity in the responding fiber population. According to this model, discrimination is a direct function of the total difference in impulse frequency produced by any two stimuli across all responsive fibers. The major factor which influences the total difference in AFPs is innervation density (neurons/cm^2) rather than RF size. In this study, differences in innervation density were estimated by comparing the integrated voltages of the compound action potentials recorded from the median and tibial nerves in response to mechanical stimulation. Such estimates gave the expected differences in point localization on distal versus proximal skin regions of any one paw and on corresponding regions of different paws. 1792 A SINGLE UNIT STUDY OF THE SECOND SOMATIC SENSORY CORTEX IN THE CYNOMOLOGOUS MONKEY. C.J. Robinson and H. Burton, Depts. of Elec. Engr., and of Anat. & Neurobiol., Wash. Univ., St. Louis, MO 63110

Recordings were obtained from over 1100 neurons located within the lateral sulcus of awake, unparalyzed or lightly tranquilized monkeys. With the aid of cortical cytoarchitecture and with analyses of connections to this region of cortex (Jones and Burton, '76, JCN 168) from the ventroposterior nucleus of the thalamus or from SI, we assigned 660 neurons to SII by correlating electrode tract locations with the anatomy.

Our findings indicate an anteroposterior organization of the body within SII as suggested by Burton and Jones, '76 (JCN, 168). Units with trigeminal receptive fields are found most rostrally, occupying the deepest parts of the parietal operculum bordering on the granular insular (Ig) cortex and Prokoniocortex (Pk). Immediately caudal, the hand representation is interposed between the SI and SII face representations. Further caudally, a large hand and arm representation occupies most of the parietal operculum extending from Ig to the overlying SI and area 7. A smaller foot representation lies buried in the depths of the lateral sulcus caudal to Ig and is bordered by the retroinsular (Ri) cortex in the fundus, by an overlying SII hand representation in its anterior extent, and by area 7 in its posterior extent.

Of the 501 neurons reliably responding to somatic stimulation, a majority were activated from the skin with a rapidly adapting discharge; approximately 25% were activated by low and/or high velocity hair movement; the major portion of the remaining neurons responded to stimulation of subcutaneous tissue. Over 50% had only contralateral input (c/1); ≈13% had predominantly c/1 fields; ≈33% had symmetrical bilateral fields and, 3% had predominantly ipsilateral input. Neurons with similar laterality properties clustered together, suggesting a possible columnar organization. Receptive field boundaries could be precisely delimited in ≈45% of the cases (with 26% < 10 cm^2), moderately in ≈31%, and poorly in the remainder. In the hand representation, the predominant response appears to be activated by transient mechanical stimulation of the type that would occur during active contact with textured surfaces. 1793 MODULATION OF SOMATOSENSORY CORTICAL NEURONS BY CHANGES IN BEHAVIORAL AROUSAL AND ATTENTION IN THE RHESUS MONKEY. J.R.Roppolo and J.G.Collins. Dept.of Pharmacology,Sch.of Med. U.of Pittsburgh Pittsburgh, PA 15261

Previous studies from our laboratory (Fed.Proc.26:411,1977) have shown that drugs (alcohol and pentobarbital) which induce changes in arousal and attention can profoundly alter spontaneous activity (spon.act.) and stimulus representation in the primary somatosensory cortex (S-I). The purpose of the present study was to examine the effects of "natural" changes in arousal and attention on these neurons. To this end extracellular recordings were made from single neurons in S-I of awake, non-paralyzed rhesus monkeys. Peripheral receptive fields, located on the glabrous skin of the hand, were stimulated by a fine brush moved back and forth across the cutaneous surface. The experimental animals were placed in three behavioral states: (1) awake state-in which the monkey simply sat quietly in a sound attenuating recording chamber with the door open; (2) slow-wave sleep (SWS)-here the door was closed and the animal allowed to fall asleep. (cortical EEG was recorded); (3) attentive state (ATT)-in which the monkey performed a previously trained behavioral task. The behavioral paradigm consisted of pressing a bar(using the hand not stimulated by the brush) for a fruit juice reward with a fixed ratio of 10. A 30 sec. red light on period indicated reward available followed by a 30 sec. green light on period indicating no reward available. The brushing stimulus was presented every 5 sec., but provided no behavioral cue, nor did it disrupt the SWS. Twenty-five stimuli in each direction were averaged. The most dramatic effects were seen with SWS on both driven and spon. act. The spon. act. was more easily influenced by SWS with 52% of the neurons increasing their firing rate while only 28% of the driven units increased their rate. Decreases were seen in 25% of the spontaneous and 28% of the driven. The variability of the firing frequency measured by the coefficient of variation (C.V.) was also increased during SWS; 84% of the neurons studied showed an increase in C.V., while 12% showed a decrease. SWS also increased the number of units which showed directional selectivity (i.e. neurons which respond preferentially to one direction of brush movement). The effects of the behavioral task were more subtle with most units showing little or no change. The driven activity however did increase in 15% of the units in both the red and green light period. No effect was seen on directional selective units in the ATT. These results indicate that changes in arousal and attention may have important influences on the ability of S-I neurons to transmit and process tactile information. (Supported in part by Psychobiology Training Grant MH11114 and Research Grant MH11682).

1794 PATTERN OF AFFERENT SUPPLY TO CANINE SPINAL TRIGEMINAL NUCLEUS. R.J. Schneider & A.L. Itani*. Division of Neurosurgery, Dept. of Surgery, University of MD. Hospital, Baltimore, Maryland 21201.

Electrical activity was recorded from the branches of the trigeminal ganglion in dogs. Wire electrodes were insulated in silastic and secured to the branches exposed in the middle cranial fossa for acute recording or left in place during recovery and used for chronic recording. A conventional electrophysiological system was used to amplify and display the signals. The object of these experiments was to define the boundaries of the opthalmic, maxillary and mandibular receptive fields in dogs.

Previous studies had suggested the spinal trigeminal tract could not be differentiated by the level at which certain cranial skin regions terminated. This contradicted results which reported a more caudal spinal termination for opthalmic fibers with maxillary and mandubular fibers ending progressively less caudad, respectively. An opposing notion, of the terminations being "Zwiebelschalenförmig," onionskin-like, had developed from observations of patients with sensory losses due to syringomyelia. In humans, these onionskin layers are centered around the nose tip to lip region and form concentric lamellae progressing caudad. To determine if the former hypothesis was supported, we had to define the respective receptive fields of each division of the trigeminal ganglion. Thus, the object of this study was to seek evidence for either divisional or onionskin-like segregation within the canine spinal trigeminal nucleus.

The maxillary division of the dog's trigeminal ganglion represented a greater body surface proportion among the branches than was the case for its human equivalent. The behavioral importance of this area in exploration and manipulation of extrapersonal space would seem to account for this. The fields of the other branches were distributed, however, as anticipated.

Conduction velocities indicated that the fibers projecting to the spinal trigeminal tract and nucleus were not the fastest in the sensory groups, averaging 41.5m/sec, i.e., toward the lower range of A-beta & gamma fibers. This was supported by the slowness of the response to receptive field hypoxia in decreasing activity in the spinal trigeminal. However, local anaesthetics applied to receptive fields also had minimal effect.

We conclude that the afferent population which terminates in the spinal trigeminal nucleus cannot be segragated into trigeminal ganglion divisions differing in locus of termination on electrophysiological grounds. However, because we did not sample pain and temperature afferents exclusively, the possibility remains that they can be so segregated. Alternatively, we cannot exclude the possibility of an onionskin arrangement for pain and temperature afferents, but the total population of spinal trigeminal afferents in dogs is not so arranged. (Funded by a Bressler Grant)

1795 SENSORY UNITS WITH AFFERENT C-FIBERS INNERVATING THE SKIN OF THE RABBIT EAR. Virginia Shea* (SPON: E.R. Perl). Neurobiology Program, University of North Carolina, Chapel Hill, N.C. 27514

Recordings were made from fine filaments dissected from the great auricular nerve. When an isolated action potential conducting at C velocity was evoked by electrical stimulation of the nerve, a systematic effort was made to characterize its sensory properties. Of the 114 single C-fibers isolated, 19 could not be activated by mechanical or thermal stimuli. Insufficient data for characterization were obtained for 6 units.

The majority of sensory units (57/89) had the characteristics of polymodal nociceptors (PMN), typically having small, punctate receptive fields (RF), and elevated thresholds to mechanical stimuli. Heating the RF's of these units elicited responses at elevated thermode temperatures (41°-56°); sensitization (increased on-going activity and/or decreased thermal threshold) appeared in repeated sequences of heating in 55 PMN's. Cooling RF's after sensitization often decreased on-going activity. In general, irritant chemicals (acetic acid and/or xylene) effectively activated PMN's.

Two groups of high-threshold receptors differed from PMN's. Four units with punctate RF's and mechanical thresholds similar to those of PMN's, displayed no response nor increased on-going activity to repeated noxious heating (61°), but responded to intense cold. These units are termed "cold-mechanonociceptors". Seven units with punctate or multiple spot-like RF's had mechanical thresholds somewhat higher than those of PMN's and little or no responses initially to noxious heating (61°), but developed ongoing activity and responses to heat when retested (resembling Aδ high-threshold mechanoreceptors of cat and primate).

Fourteen units had larger RF's generally located along the edge of the ear and responded maximally to very gentle, slowly-moving, mechanical stimuli in a fashion typical of C mechanoreceptors. Rapid innocous temperature changes, particularly cooling, also elicited weak transient responses from these elements.

Three units were sensitive to innocuous cooling. Four units responded to innocuous warming and could have been warming thermoreceptors or possibly sensitized PMN's.

It is concluded that the unmyelinated afferent units innervating the skin of the rabbit ear largely can be grouped into categories similar to those established for the cat and primate. The present sample differs in reporting a group that responds only to intense cold and strong mechanical stimuli. Moreover, units similar to Aδ high-threshold mechanoreceptors of the cat and primate may, in part, have C-fibers in the rabbit. 1796 INFLUENCE OF PUDENDAL NERVE STIMULATION ON NEURONS IN PERICRUCIATE CEREBRAL CORTEX OF ADULT MALE CATS. J. C. Slimp and A. L. Towe. Dept. Physiol. & Biophysics, Univ. Wash. Sch. Med., Seattle, 98195.

Neurons in pericruciate cortex (field 4γ) may be classified on the basis of their responsiveness to various inputs. Some neurons respond to somatic input from limited regions of the body surface, either contralateral or bilateral, whereas others respond to input from anywhere on the body surface, and even from visual, auditory, vestibular and splanchnic input. The present study examined the influence of pudendal nerve stimulation on pericruciate neurons. The pudendal nerve — a somatic nerve — has two branches, one of which innervates the penis and the other the rectum. The pudendal nerve was exposed dorsally, placed on hook electrodes, and covered with mineral oil. Bipolar needle electrodes were placed in each paw, the contralateral forepaw input serving as hunting stimulus. Extracellular recordings were made of neurons in the contralateral forepaw region of pericruciate cortex in chloralose-anesthetized male cats. Neurons were classed as *sa* if they responded only to one contralateral paw, as *sb* if they responded to both forepaws or both hindpaws, and as *m* if they responded to all four paws. Most *m* neurons (85%) were excited and the remainder were facilitated by pudendal nerve stimulation, whereas few *sb* (18%) or *sa* (3%) neurons were either excited or facilitated by this input. All *sa* and *sb* neurons influenced by pudendal nerve stimulation were facilitated by stimulation of the nonexcitatory paws — suggesting that they share some characteristics in common with *m* neurons. When tested, both contralateral and ipsilateral pudendal nerves were found to be effective. So also were both branches of the contralateral nerve, although the branch innervating the rectum appeared less effective. The average latency to pudendal nerve stimulation was similar to that for contralateral hindpaw stimulation, and the mean number of spikes/response was similar to that for the paws. The coadunate behavior observed previously among the *m* neurons (Towe, Tyner & Nyquist, *Exp. Neurol.*, 1976, *50*:734-756), and found to extend to the responses to splanchnic nerve stimulation (Tyner, in press), was also observed in the responses of the *m* neurons to pudendal nerve stimulation. That is, the position of any *m* neuron with respect to its fellows in the responding population remains about the same for all inputs that do not activate local *s* neurons. For example, an *m* neuron that responds one standard deviation earlier than the mean latency for the responding population after ipsilateral forepaw stimulation also responds about one standard deviation earlier than the mean to each hindpaw input, to each splanchnic nerve input and to each pudendal nerve input. Except for the effect of local *s* neurons, *m* neurons appear to behave similarly to a wide variety of inputs. (Supported by NS00396 and NS05136 from NINCDS.)

1797 POSTCENTRAL SOMATOSENSORY CORTEX IN MACAQUE MONKEYS: MULTIPLE BODY REPRESENTATIONS AND NEURON PROPERTIES. M. Sur*, R. J. Nelson, and J. H. Kaas. Depts. of Elect. Engrg., Anat., and Psych., Vanderbilt Univ., Nashville, TN 37240

Previous microelectrode mapping studies of postcentral parietal cortex in the owl monkey, a New World monkey, revealed that "SI" is not a single representation of the body but includes at least three separate maps of the body corresponding to architectonic Areas 3b, 1, and 2, respectively (Merzenich et al., J. Comp. Neurol., '78). Similar studies of 10 Old World monkeys, Macaca fascicularis, also indicate that each of Areas 3b, 1 and 2 contains a separate representation of the body. All three representations are organized in parallel with the feet and tail medially and the face laterally in the architectonic strips. Common body surfaces are represented at the boundaries between areas, while progressions of recording sites away from a border yield receptive fields that are approximately mirror-images of each other. Thus, the hand representations in Areas 3b and 1 are adjoined along the interdigital pad representations, while the digit tips face rostrally and caudally in the two areas respectively. The hand representation in Area 2 faces rostrally and adjoins that in Area 1 along the digit tips. The dorsal midline of the occiput and trunk is represented along the rostral border of Area 3b and caudal border of Area 1, while the ventral midline is represented close to the 3b-1 border in each area. In the face region, the medial chin and lower lip are represented rostrally in Area 3b and caudally in Area 1; the upper lip and face are represented near the 3b-1 border. Discontinuities occur within the representation, and the detailed organization of the representation in each architectonic area differs significantly and consistently from the others. For example, the dorsum of the hand digits is represented laterally (digit 1) and medially (digits 2-5) to the glabrous hand representation in Area 3b, but in Area 1 it occupies a strip of cortex between the representations of the glabrous digit tips and middle phalanges.

Single unit studies of adaptation properties of neurons in Areas 3b and 1 indicate that both fields receive input from slowly and rapidly adapting receptors. In addition, inhibitory influences markedly affect the response properties of the cortical neurons. Most neurons have a phasic "on" discharge to steady skin indentation, a 50-150 msec. period of almost complete suppression of activity, followed by recovery to the rapidly or slowly adapting "envelope" rate of discharge. The inhibition is sometimes cyclical and many neurons exhibit "off" discharges. Area 2 receives significant input from cutaneous as well as deep body receptors. Pacinian receptor input appears to be confined to Area 1. Supported by NSF Grant BNS-81824.

1798 STRUCTURAL AND FUNCTIONAL POPULATION PARAMETERS DETERMINING INPUT-OUTPUT RELATIONS AT THE CUNEATE. J. P. Walsh and D. Whitehorn. Dept. of Physiol. and Biophys., Univ of Vermont, Burlington, Vt. 05401

The evoked total impulse activity (TOTACT) within a neural population is the product of the number of active cells (NACT) and the number of impulses per active cell (NIPACT). Prior input-output (IO) studies using evoked potentials to measure output provide only the IO relation between TOTACT and input. We have additionally acquired the IO relations for NACT and NIPACT by recording from individual, identified cuneothalamic (CUTH) projection neurons in chloralose anesthetized cats. Electrical stimuli, graded from sub-to supramaximum intensities, were applied to the ipsilateral superficial radial nerve (SRN) at 1 Hz. Input was quantified by digital integration of the compound action potential recorded from a second site on the nerve. The IO relation for TOTACT accumulated over a sample of 63 CUTH cells was identical to that obtained using evoked potentials from the medial lemniscus under the same conditions. The IO relation for NACT closely paralleled that for TOTACT, both rising steeply and displaying saturation. NIPACT increased only slightly with increasing input.

We conclude that the IO relation for TOTACT is primarily determined by the recruitement of CUTH cells into activity (NACT) with changes in the number of impulses per active cell (NIPACT) having a minor role.

The IO relations for TOTACT and NACT are well described by equation 1:

(1) $y=1-\exp(-kx)$ where y=fraction of output cells active and x=fraction of input cells active. The equation is consistent with a population model with more afferents than required for complete activation of the output population. The constant k is the product of the activation ratio (AR: number of output cells activated per active afferent) and the population innervation ratio (PIR: number of afferents/number of efferents). k values of 4.9 result from the IO measurements made here. A value of 2.5 is obtained when correction is made for noncontributing fibers in the nerve or when stimulation is applied to the dorsal columns or within the nuclei.

1799 ORGANIZATION OF THE IPSILATERAL AND CONTRALATERAL INPUT TO THE NEURONS OF S-II/r IN UNANESTHETIZED MONKEYS. Whitsel, B., Dreyer, D. and Loe, P., Dept. of Physiol. and Dent. Res. Ctr., U. of N.C., Chapel Hill, NC 27514.

Responses of single neurons and neuron clusters were studied in the course of microelectrode penetrations of the anterior portion of the second somatosensory receiving area (S-II/r). The effectiveness of hand-held tactile stimuli applied separately and simultaneously to bilaterally symmetrical cutaneous body regions was determined for a large population of S-II/r neurons. With the exception of a small population of neurons that could be activated only by unilateral stimulation, most S-II/r neurons could be classified as follows: (i) dominated by contralateral input; (ii) dominated by ipsilateral input; (iii) activated equally from both sides of the body. It was found that neurons located in close proximity to one another usually belonged to the same dominance class. Moreover, tangential penetrations across S-II/r frequently encountered sequences of neurons that exhibited the same dominance properties. Simultaneous bilateral stimulation of symmetrical cutaneous body regions either evoked a response (i) greater (summation) or (ii) equal or lesser (occlusion) than that evoked by the most effective unilateral stimulus. It is anticipated that further aspects of the functional organization of bilateral input to area S-II/r will be revealed by plotting the distribution of each neuron class.

To date, a limited sample of S-II/r neurons has been studied quantitatively using dual servo-controlled mechanical stimulators, each of which moves a fine brush at constant velocity over the skin. In addition to confirming the observations obtained using hand-held stimuli, these studies have revealed that the static and dynamic properties of the responses evoked from a single S-II/r neuron by separate stimulation of the ipsilateral and contralateral components of its receptive field (RF) are "matched" (i.e., exhibit the same directional preference, RF organization, and velocity dependence). The use of controlled stimulation has permitted quantification of the effects of simultaneous bilateral stimulation of the ipsilateral and contralateral receptive field components.

1800 POSITION AND MOTION SENSE UNDER WHITE NOISE STIMULATION W. J. Williams and R. W. Bossemeyer, Jr.* Bioelectrical Sciences Laboratory, Univ. of Michigan, Ann Arbor, MI 48109

Position and motion sense have been considered to be separate sensory entities since the time of Goldscheider. Under normal conditions of joint movement and positioning the two types of sensation are entwined and difficult to separate experimentally. Preliminary experiments using very low frequency sinusoidal joint motion showed that sensation of motion was lost below 0.01 Hz. Position sense remained, but was discontinuous and new positions were suddenly perceived in a succession of rachet-like jumps as the joint continued to move. Since it is difficult to apply a succession of very low frequency sinusoidal stimuli and obtain reliable results, we have devised a method of evaluation of position and motion sense using band limited (0-0.1Hz) white noise.

The general protocol was similar to that previously reported (Kokmen, et al, Ann. of Neurol., 2: 279, 1977). The MCP joint of the index finger was articulated and the subject pressed buttons that indicated whether the finger was up or down and whether the finger was moving up or down. A binary position signal (up, down) and a binary motion signal (moving up, moving down) were derived from the results. Theorems of communication theory were used to determine the transfer functions between white noise input and position and motion sensation. Reaction time effects were minimal due to the low frequencies involved.

The results are shown in Fig. 1. This represents the average of three subjects responding for a total of 120 minutes. These results indicate that position sensation is nearly constant with frequency up to about 0.03 Hz and declines for higher frequencies. Motion sensation increases with frequency. Motion sensation declines precipitously for very low frequencies below about 0.01 Hz. Supported by U.S.P.H.S. Grant NS 08470.

Under White Noise Stimulation

1801 SOMATOTOPIC ORGANIZATION OF THE RAT CORTICOSPINAL AND CORTICOTRIGEMINAL SYSTEM. Steven P. Wise and Elisabeth A. Murray. Marine Biomedical Institute, Galveston, Texas 77550.

The projection from the rat sensory-motor cortex to various levels of the spinal cord and to the spinal trigeminal complex (SpV) was examined with the horseradish peroxidase (HRP) method. In different animals, injections of HRP involving two to four segments of the lumbar or cervical enlargements or the rostral cervical segments of the spinal cord (0.3-1.0µl; 50% HRP) or SpV (0.5µl) were made through glass micropipettes. Care was taken to avoid damage to the corticospinal fibers which are situated in the dorsal column in rats. Thus, fibers of passage to more caudal levels of the spinal cord were not involved in the injection. Retrogradely transported HRP was demonstrated by the dianisidine and diaminobenzidine techniques.

In both the first somatic sensory area (SI) and the motor area (MI), as well as in two additional sensory-motor areas, the corticospinal and corticotrigeminal neurons are grouped in a clear somatotopic pattern. The somatotopy in SI can be determined by comparison of the location of retrogradely labeled cells in layer V with the overlying dense, granule cell aggregates in layer IV, since Welker (J. Comp. Neurol., 166 (1976) 173) has shown that these granule cell aggregates receive peripheral mechanoreceptive input from specific regions of the contralateral body surface in a somatotopically organized manner. The somatotopic organization of corticofugal cells in the sensory-motor areas adjacent to SI can be determined, although with less precision, by examining the patterns of retrograde labeling in these areas in relation to established maps showing the spatial relationship of MI and the second somatic sensory area (SII) with SI.

The somatotopic pattern is clearest for SI and MI. Corticospinal fibers which extend to lumbar levels of the spinal cord originate mainly from neuronal somata located in the hindlimb representation of the SI-MI cortex. Those neurons projecting to the cervical enlargement have somata mainly in the rostrally and laterally situated forelimb representation of SI and MI. Cortical projections to the rostral cervical spinal segments appear to originate from the posterior head and neck representations of SI and MI. Neurons exclusively within the head, muzzle, and vibrissal representation of SI project to SpV.

Neurons in cortex near the frontal pole and in SII also project to the spinal cord. The corticospinal and corticotrigeminal projections of these areas also appear to be organized in a somatotopic manner. (Supported by Grants NS 12481 and 05736).

1802 VELOCITY DEPENDENCE OF SOMATOSENSORY NEURON RESPONSE TO MOVING TACTILE STIMULI. M. Young, R. Schreiner, B. Whitsel, and D. Dreyer. Physiol. Dept., UNC, Chapel Hill, NC 27514.

Peak mean firing rate evoked by a moving tactile stimulus has been measured as a function of stimulus velocity for single somatosensory neurons with receptive fields on the hairy skin of Macaque monkeys. Discharge activity was evoked by moving a soft brush across the neuron's receptive field at velocities between 0.7 cm/sec and 250 cm/sec by a servomotor. Each neuron was tested with at least 8 different velocities within this range, presented in random order. A minimum of 10 replications of each velocity was delivered. For first-order afferents the relationship between peak response and velocity over the velocity range of 0.7-75 cm/sec could be fit by power functions with exponents less than one (average R^2=.89). At higher velocities the plots tended to saturate and, for a few units, to decline. On the basis of these data it is suggested that individual fast conducting first-order mechanoreceptive fibers from hairy skin are not capable of reliably transmitting information about stimulus velocity (using a peak mean firing rate code) at velocities much above 75 cm/sec. Some first-order neurons were incapable of signaling changes in stimulus velocity above 20 cm/sec. Surprisingly, there were no consistent differences in the velocity response relationships obtained for the different classes of first-order afferents. Two distinct populations of S-I neurons were observed in unanesthetized Macaques. The first exhibited peak mean rate vs. velocity plots whose shapes resembled very closely those seen for first-order neurons, whereas for the second, the plots increase in an approximately linear fashion (average R^2=.84) across the entire range of stimulus velocities used. These data are interpreted to suggest that the latter type of S-I neurons is capable of signaling changes in stimulus velocity over a much wider range of velocities than was observed for first-order afferents. These neurons continued to reliably reflect changes in stimulus velocity at locations along the velocity continuum where the response of the first-order afferent fibers in our sample was saturated. Both classes of S-I neurons show a greater degree of variability in response between individual stimulus sweeps delivered at the same velocity than do the first-order neurons. Velocity transinformation calculations using the stimulus-response matrix method are being utilized to specify more precisely the capacity of both first-order and cortical somatosensory neurons to signal information about stimulus velocity. The laminar distribution of the two populations of cortical neurons is being determined by reconstruction of the electrode tracts.

SPINAL CORD

1803 PERIPHERAL INPUTS TO LONG DESCENDING PROPRIOSPINAL NEURONS IN CAT. Robert J. Adams, Robert D. Skinner, and Ronald S. Remmel. Depts. Anatomy and Physiology-Biophysics, Univ. Arkansas for Medical Sciences, Little Rock, AR 72201.

Long descending propriospinal neurons located in the cervical cord project to the lumbar cord (Skinner et al., Neurosci. Abs. 3: 508, 1977). Cats anesthetized with ketamine were spinalized at C1, anemically decerebrated, and the anesthetic discontinued. The cord at L1 was stimulated to antidromically excite cervical neurons, which were recorded from extracellularly with micropipettes. Criteria for antidromicity: predominantly negative spikes with sharp threshold, the ability to follow four shocks at above 300 Hz. Collision with orthodromically-excited spikes was verified. In half of the experiments the intact peripheral nerves (the suprascapular, deep radial, superficial radial, ulnar, medial and musculocutaneous) were stimulated with cuff electrodes.

In segments C6-T1, 236 long descending propriospinal neurons were recorded, with conduction velocities ranging from 12-110 m/sec (63 ± 39 m/sec, av. and std. dev.). Of these, 100 (42%) could be activated by natural stimulation of the forelimbs. The receptive fields ranged from rather small (one digit) to very large (a whole forelimb and part of the other). Of the neurons with peripheral fields, 38% responded to deep pressure, primarily to muscles in the elbow region; 35% to cutaneous touch, heat and noxious pinch; 23% to joint movement, usually from the metacarpophalangeal or interphalangeal joints; and 4% to hair movement. Of these, 9% received multimodal input.

Peripheral fields included the paw (57%), the forearm (43%) and the arm (46%), with 59% of the neurons receiving input from more than one of these regions. Fields restricted to one region were 18% to the paw, 5% to the forearm and 18% to the arm. Inhibition of spontaneous or evoked activity was observed from the ipsilateral limb in 10 cells and from the contralateral limb in 5 cells.

Of 102 cells tested with electrical stimulation to peripheral nerves, 68 were excited by at least one nerve and 43 were excited from three or more nerves. Minimum latencies of the spike as measured from the arrival of the afferent volley at the cord dorsum were 6.6 ± 3.8 msec (mean and std. dev), which indicates a multisynaptic path. Only a few latencies were short enough to suggest a monosynaptic connection.

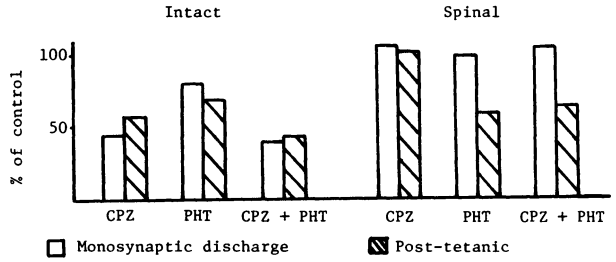
1804 INTERACTION OF PHENYTOIN AND CHLORPROMAZINE ON CAT SPINAL CORD ACTIVITY. R.J. Anderson and J.S. Carp*, Dept. of Pharmacol. Geo. Washington Univ., Washington, D.C., 20037.

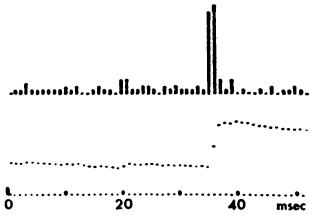
The effects of phenytoin (PHT) and chlorpromazine (CPZ) on spinal cord monosynaptic discharges and post-tetanic potentiation (PTP) were compared in two groups of α-chloralose anesthetized cats: (1) cats with high spinal section and (2) intact cats. PHT produced no significant change in the monosynaptic discharge of either the intact or spinal cats. On the other hand, CPZ produced a dose-related decrease (0.0156-0.125 mg/kg) in the monosynaptic potential in intact cats, a decrease which plateaued at 60%. In spinal cats CPZ produced no change in the monosynaptic discharge. PHT selectively depressed PTP in both intact and spinal animals in a dose-related fashion (5-20 mg/kg). CPZ, on the other hand, had no effect on PTP in spinal animals but significantly decreased PTP in intact cats.

In spinal cats the effects of PHT + CPZ on monosynaptic discharges and PTP was the same as the additive effects of each drug alone. However, PHT + CPZ in intact cats did not produce an additive depression but rather produced a moderate depression of both the monosynaptic discharge and PTP and restored the PTP ratio to the control level. These effects are summarized below for doses of 0.5 mg/kg CPZ and 20 mg/kg PHT.

These results demonstrate: (1) PHT selectively depresses recruitment of subliminal fringe neurons in the spinal cord, (2) CPZ depresses descending excitatory influences on the spinal cord without interfering with recruitment, (3) the effects of CPZ + PHT in the spinal cord are simply additive, and (4) the effect of CPZ + PHT in the intact cat act only to depress slightly spinal cord activity but more importantly to maintain the balance between low and high frequency neuronal traffic through the segmental reflex pathways. This latter effect may be of significance in normalizing spinal cord imbalances due to abnormal descending neuronal activity. (Supported by PMA Foundation).



1805 THE 1A EPSP IN MAN. Peter Ashby, Duane Zilm*, Richard E. Poppele, University of Toronto and Addiction Research Foundation, Toronto, Canada, and Dept. of Physiol., University of Minnesota. Minneapolis 55455, U.S.A.



The spike train produced by a rhythmically discharging human motoneuron was extracted by inserting a needle electrode into a contracting muscle and identifying each occurence of a given motor unit action potential. Alterations in the probability of firing (as a result of afferent volleys) were used to deduce the underlying post-synaptic potentials produced in that neuron.

Homonymous group 1 volleys produced an early peak of increased impulse density in the post-stimulus time histogram (PSTH) of rhythmically firing human tibialis motoneurons which was of appropriate latency to represent the 1a EPSP. We derived the characteristics of this EPSP in 4 stages:

1. The rise time of the 1a EPSP was determined from the width of the early peak in the PSTH (fig.1) as the profile of the PSTH represents the first derivative of the contour of the post-synaptic potential (provided that the combined slope of the membrane potential and the post-synaptic potential remains positive).

2. The amplitude of the 1a EPSP was determined by injecting a group 1 volley at increasing intervals after a spontaneous discharge to find the position (as a percentage of the mean interspike interval) at which the EPSP caused the membrane potential to reach threshold. If the interspike membrane potential trajectory can be considered to be a nearly linear rate of rise from the afterhyperpolarization to a threshold potential about 10 mv less, the amplitude of the EPSP can be obtained by simple geometry.

3. The duration of the falling phase of the 1a EPSP was determined by delivering double group 1 volleys in such a way that the second would fail to bring the membrane potential to threshold without temporal summation from the first.

4. The validity of these methods was tested by inserting the derived EPSP into a computer simulation of a rhythmically discharging neuron in an attempt to reproduce the original PSTH.

We conclude that the method may be used to derive the characteristics of post-synaptic potentials in man. As spike trains can be recorded from CNS neurons in man, the method is not restricted to the study of spinal motoneurons.

We thank the Connaught Foundation. Computer facilities were made available by the USAF; AFOSR 75-2804.

1806 THE EFFECT OF ACUTE EXPERIMENTAL SPINAL CORD TRAUMA ON MONOAMINE OXIDASE ACTIVITY. Neal J. Bannon, Norman Allen and Ronald Yates*, Dept. Physiol. Chem. and Div. Neurol., OSU Coll. Med., Columbus, OH. 43210.

Monoamine oxidase (MAO) activity was measured in microdissected samples of central grey matter (GM) and surrounding white matter (WM) from canine spinal cord at various intervals following 400 gm-cm trauma. Both [^{14}C]-serotonin (5HT) and [^{14}C]-tryptamine (TRY) were utilized as substrates. Non-dissected whole cord sections were also assayed utilizing TRY. In the latter case, no significant differences from control were found within one hour of trauma.

Activities obtained, in terms of nmoles deaminated product formed/min/mg. dry wt., for non-traumatized controls were:

substrate	whole cord	GM	WM
5HT	----------	0.3312±0.022(11)	0.1440±0.010(7)
TRY	0.1341±0.018(4)	0.1810±0.008(12)	0.1395±0.004(8)

mean ± SEM (n)

MAO in traumatized GM dropped significantly (50%) from control levels, with 5HT as substrate, as early as 15-minutes post-trauma and remained so through one hour post-trauma. TRY deaminating activity in GM was not significantly decreased until 30-min. post-trauma (17%) and showed a continued decline (nearly 50% of control) at one hour post-trauma.

MAO activity in WM of traumatized tissue was stable for at least one hour when assayed utilizing TRY. 5HT deaminating activity, however, began to show a significant decrease (33%) at one hour in WM.

Since MAO in the CNS is almost exclusively an outer membrane mitochondrial enzyme, these results suggest a possible GM mitochondrial lesion as an early occurrence in acute experimental spinal injury. These data are consistent with the previous work of Ito et.al.(J.Neurosurg:48,434,1978) in which the inner membrane cytochrome oxidase complex exhibited an early decrease in activity following spinal injury. These data also suggest a heterogenous response by MAO to spinal injury. This may reflect differences in localization of specific isozymes of MAO in the canine spinal cord as well as differences in susceptibility of various cell types to traumatic injury.

1807 LARGE PRIMARY AFFERENTS IN THE SUBSTANTIA GELATINOSA OF THE ADULT MONKEY: A GOLGI STUDY. John A. Beal, Dept. Anat., Sch. Med. in Shreveport, LSU, Shreveport, LA 71130.

It is apparent from recent physiological and certain anatomical studies that the main primary afferent input to the substantia gelatinosa (SG) consists of unmyelinated fibers with additional fine myelinated fibers to the superficial region of the SG. Input from large caliber primary afferents, on the other hand, is "limited and of only a modulatory nature" (Kumazawa and Perl, J. Comp. Neur. 177: 417, 1978). However, Ramón y Cajal (1909) and subsequent authors using the Golgi technique have demonstrated large caliber afferents which enter the dorsal horn from the ventral aspect forming an arbor of considerable complexity within the SG. This apparent contradiction between anatomical and physiological observations prompted the present study. Here Golgi impregnated axonal arrays were serially reconstructed in horizontal sections through the dorsal horn. Confined ansiform axonal complexes, previously described in the monkey (Beal and Fox, J. Comp. Neur. 168: 113, 1976), are shown to be derived from large caliber fibers which enter the SG from its ventral aspect. These axonal arrays are extremely complex entanglements and certainly leave the observer with the impression that they represent a powerful input to the SG. Considering their complexity, however, close inspection reveals that these arrays give rise to surprisingly few boutons. In addition, the boutons on these arrays are generally smaller in the more superficial sections (lamina II) than in the deeper portions of the dorsal horn. Fine caliber afferents to the SG, on the other hand, have relatively simple arbors but are nonetheless predictably more significant physiologically than the large afferents since they are more abundant and give rise to larger boutons.

1808 SYNAPTIC ORGANIZATION OF PRIMARY AFFERENT TERMINATIONS IN THE DORSAL HORN OF THE CAT SPINAL CORD DEMONSTRATED BY ANTEROGRADE INJURY-FILLING OF DORSAL ROOTS WITH HORSERADISH PEROXIDASE. Michael S. Beattie, Jacqueline C. Bresnahan, Deborah L. Lewis and James S. King, Department of Anatomy and Division of Neurosurgery, The Ohio State University, College of Medicine, Columbus, Ohio, 43210.

In order to study the synaptic organization of dorsal root primary afferents to the spinal cord, we have employed a modification of the technique described by Proshansky (Neurosci. Lett., 5: 130, 1977) for the anterograde injury-filling of these axons and their terminals with horseradish peroxidase (HRP). Our procedures have been described elsewhere (Beattie et al., Brain Res., in press). Adult cats were anesthetized and one or more dorsal rootlets from the lumbar spinal cord were exposed to a 40% solution of HRP for 12-18 hrs. Tissue was processed according to established histochemical procedures for the visualization of HRP reaction product.

Filled axons and terminals were readily distinguishable with both the light and electron microscope. Large diameter axons of the dorsal columns were labeled, as were their collaterals, which could be followed to their terminations in the dorsal and ventral horns. The small diameter axons of Lissauer's tract and their ramifications into the dorsal horn were also labeled, and it appeared that at least a sample of the full fiber diameter spectrum of dorsal root axons contained label.

Electron microscopic observations of synaptic terminations in the marginal layer (ML) and substantia gelatinosa (SG) revealed a large number of labeled synaptic profiles. Most terminals contained round, clear synaptic vesicles, while the remainder contained round, clear vesicles as well as large dense-cored vesicles. Terminals with dense-cored vesicles were confined to the ML and outer portion of the SG. The majority of terminations formed the central elements of complex, multi-synaptic arrays (glomeruli) and made synaptic contact with dendritic spines and with small vesicle containing profiles reminiscent of the type 2 spines described by Gobel (J.C.N., 167: 165, 1976) in the SG of the spinal trigeminal nucleus. Some terminals made synaptic contact with larger dendritic profiles located outside of glomeruli, although such observations were more common in regions deep to the SG neuropil. Labeled profiles within the SG tended to be larger and to exhibit more synaptic contacts than those in the ML. (Supported by N.I.H. Grant NS-10165 and Postdoctoral Fellowship NS-05394.)

1809 CROSS CORRELATION ANALYSIS OF CONNECTIVITIES AMONG CELL PAIRS 0.25-2 SEGMENTS APART IN CAT LUMBOSACRAL DORSAL HORN. Paul B. Brown, Robert P. Yezierski, and H. Richard Koerber. Department of Physiology and Biophysics, West Virginia University Medical Center, Morgantown, WV 26506.

Adult cats were anesthetized with urethane (1.1 gm/kg), paralyzed with Flaxedil, and artificially respired. The spinal cord was transected between T_{10} and T_{12}. Pairs of cells were recorded simultaneously from independently manipulated stainless steel microelectrodes. Recording sites were verified to be located in laminae I-VI of L_4-S_1 segments. Of 83 cell pairs, 65 (78%) had flat cross-correlograms, indicating no causal relation in their discharges. Of these, 44 cell pairs were found in which both cells had cutaneous input: 36 (82%) had flat cross-correlograms.

Most cell pairs with non-flat cross-correlograms were indicative of net excitatory causal relations in discharge: that is, their cross-correlograms deviated from baseline only in the positive direction. These deviations were 15-100 msec. wide, and extended into both positive and negative delays. We interpret these as indicating shared input. No signs of monosynaptic excitatory connections (brief positive deviations at monosynaptic delays) were seen.

Inhibitory interactions, indicated by negative deviations from baseline, were rare. Those which were observed were all too broad to suggest a direct inhibitory connection from one cell to the other. All except one were purely inhibitory, the one exception being biphasic.

All cutaneous cell pairs with non-flat histograms had cutaneous receptive fields which overlapped, as would be expected if the implied common input is cutaneous.

1810 AUTORADIOGRAPHIC MEASUREMENT OF CAT SPINAL CORD BLOOD FLOW AFTER MODERATE AND SEVERE IMPACT INJURY. David F. Cawthon*, Franklin C. Wagner, and William B. Stewart. Depts. Neurosurg., Physiol.; Yale Univ. Sch. Med., New Haven, Ct. 06510

Both hyperemia and ischemia have been reported following moderate and severe injuries to the spinal cord. These results have come from several laboratories, using several different injury models and different techniques to measure spinal cord blood flow (SCBF). We sought to test the hypothesis that hyperemia is more common after moderate than severe trauma. For this purpose, we used the ^{14}C-antipyrine autoradiographic method to measure SCBF at 1,4, and 8 hours after moderate (260 g-cm) or severe (500 g-cm) impact injury to the cat spinal cord at T6. We measured SCBF in 2 cats at each interval, for each trauma dose. Control mean SCBF for cord 3 cm or more from the center of trauma in the 260 g-cm group was 11.6 g blood/min/100 g tissue for white and 46.0 for gray. These flows agreed with those obtained by Landau et al. in awake intact cats (63 ml/min/100 g for gray and 14 for white), also using quantitative autoradiography (Trans. Am. Neurol. Assoc. 80: 125, 1955). This report will discuss only white matter SCBF.

At the center of moderate trauma, mean SCBF expressed as percent of control values was 120% at 1 hour and was reduced to 75% at both 4 and 8 hours. Similar values at each time were obtained 2 mm from the center of trauma. At the center of severe trauma, mean SCBF was 83% at 1 hour, 37% at 4 hours, and returned to 71% at 8 hours. In this group, the flows at 2 mm away were similar to flows at the trauma center at 1 and 8 hours, but at 4 hours were significantly greater (62% of uninjured). Longitudinal spread of ischemia and hemorrhagic necrosis were greater for severe than for moderate injury. Also, at 1 and 8 hrs, relative hyperemia was more commonly seen after moderate trauma. Above we report mean white matter SCBF, but this obscures differences between flows within a cord segment. For example, at 1 hour after 500 g-cm trauma, one cat showed hyperemia (18.2 to 23.2) in ventral white and normal flows (12 to 14) in lateral and dorsal white within 2 mm rostral and caudal to the trauma center. At 1 and 4 hours after both severe and moderate trauma, the ventral white matter had higher flows than dorsal or lateral white, regardless of absolute flows. We also noted that mean SCBF was most variable at 8 hours: i.e., in some animals SCBF returned to near control values while in others it did not. We conclude that long tract deficits observed following severe injury (500 g-cm) may be due in part to the greater white matter ischemia near the site of severe trauma compared to moderate (260 g-cm) trauma. The return of function following moderate injury may also be a reflection of greater areas of white matter sustaining normal or relatively hyperemic SCBF.

Supported by USPHS Grants NS10174 and NS05429.

1811 AN ELECTRON MICROSCOPIC STUDY OF THE TRACT OF LISSAUER. Kyung Soon Chung, Arnold E. Applebaum, and Richard E. Coggeshall, Depts. of Anatomy and of Physiology and Biophysics, The University of Texas Medical Branch, Galveston, Texas 77550.

In 1885, Lissauer described a tract of finely myelinated fibers that was located over the dorsal horn of the spinal cord. Lissauer felt that the majority of fibers in this tract were primary afferents. In later years, however, this view has been superceded and it is now felt that the fibers in the tract of Lissauer are predominately propriospinal in nature. The primary evidence for this conclusion is that few fibers in the tract of Lissauer appeared to be affected when the dorsal root was cut. There are 2 difficulties with this data however. First it is often impossible to tell whether or not one is examining a normal myelinated fiber in the light microscope because a myelin figure can often be mistaken for a normal fiber, and second the light microscope does not provide the resolution needed to study the unmyelinated fibers. Accordingly the tract of Lissauer was reexamined, both in the normal rat and after dorsal root section at the T_8 and L_6 levels. Our first results are as follows:

Segment T_8

	Normal Side	Operated Side (dorsal rhizotomy)
Myel. Fibers	2715	575
Unmyel. Fibers	6850	800

These figures suggest that 85% of the axons in the tract of Lissauer are primary afferents. Similar findings have been obtained from an L_6 segment, but the count is not yet complete. If further counts confirm these preliminary observations then the obvious conclusion is that the great majority of axons in the tract of Lissauer are primary afferents.

In addition synaptic terminals were found in the tract of Lissauer. At present we are characterizing the synaptic types. We are also examining the tract of Lissauer after dorsal rhizotomy to determine if the synapses are connections between dorsal root afferents. If so they may provide a morphologic basis for primary afferent interactions which have recently been reported.

Supported by Grants NS 10161, 11255 and Fellowship NS 05430 from the NIH.

1812 PERSISTENCE OF HABITUATION EFFECTS ON FLEXOR WITHDRAWAL RESPONSES AND SYMPATHETIC ACTIVITY MEDIATED BY THE FUNCTIONALLY TRANSECTED HUMAN SPINAL CORD. Marcus J. Fuhrer. Depts. of Rehab. and Psychiat., Baylor Coll. Med., Houston, Tx. 77030.

The study was one of a series concerned with the stimulus parameters that influence the persistence of habituation effects mediated by the chronically transected human spinal cord. The specific goal was to establish whether spontaneous recovery is retarded and retention of habituation facilitated by continuing to apply the habituating stimulus at widely spaced intervals following habituation training. Nine persons with relatively long-standing (16-49 months) transection of the cervical spinal cord participated in two daily sessions. Each individual had been examined neurologically by two examiners, and in no case was voluntary motor functioning or sensation detected below the lesion. The stimulus consisted of a 40-msec pulse train applied unilaterally to the plantar surface. Lower extremity withdrawal activity was assessed in terms of the integrated EMG activity of the tibialis anterior muscle. Phasic sympathetic activity evoked by the stimulus was recorded in terms of skin conductance responses from the volar surfaces. The essential procedure was to: 1) establish baseline responsiveness to test presentations of the stimulus applied at 10-sec intervals, 2) apply habituating stimulation at the rate of 1/sec until EMG responsiveness was extinguished, 3) readminister test presentations of the stimulus at 10-sec intervals, 4) continue to apply a single presentation of the stimulus at 30-sec intervals for a 3-min period, 5) assess the degree of spontaneous recovery and retention of habituation by repeating steps 1-3. The comparison condition was conducted in the same manner except that the stimulus was withheld during the 3-min period following habituation training.

Applying the habituating stimulus infrequently following habituation training resulted in significantly less spontaneous recovery of both withdrawal activity and electrodermal responsiveness. No effect was demonstrable, however, on the retention of habituated withdrawal activity in terms of either the number of stimulus repetitions to extinction or effects on the amplitude of responses. This outcome is consistent with other evidence suggesting that the spontaneous recovery and retention of habituation are distinctive processes that share some but not all of the same determinants. Supplemental analyses revealed a substantial degree of coupling between withdrawal responses and evoked electrodermal activity.

Supported in part by NINCDS Grant NS 07755-09 and by the Rehabilitation Research and Training Center No. 4 (Rehabilitation Services Administration Grant 16-P-56813-6/14).

1813 PROFILE OF MYELINATED AXONS IN THE LUMBAR VENTRAL ROOTLETS OF THE CAT. P.L. GILDENBERG, K. G. CHATMAJIAN* and K. S. K. MURTHY. Department of Surgery (Neurosurgery) and Department of Neurobiology & Anatomy, University of Texas Medical School, Houston, Texas 77030.

Adult cats were anesthetised with sodium pentobarbital and a lumbar laminectomy (L_3-S_1) was carried out. After perfusion of the animal with 12% formalin, the spinal cord was dissected to remove the segments L_4 through L_7 along with the respective dorsal and ventral roots. The ventral quadrants with the respective ventral roots were then carefully removed and mounted on a cardboard with the roots stretched perpendicular to the axis of the cord. Such a preparation permitted the identification of the orientation (in a rostral-caudal direction) of the component rootlets in any ventral root. After fixation for 24 hours in 12% formalin, these roots were impregnated with a buffered solution of osmium tetroxide (Palade, 1952) for 30-48 hours. After dehydration, the roots were embedded in paraffin wax. Serial sections at 5μ thickness were cut transverse to the rootlets and mounted on slides. The rootlets were photographed on 35 mm film (magnification 400) which was then projected on a screen for the measurement of fibre diameters.

The histograms of fibre diameters indicate that within each ventral root, the smaller alpha and the gamma axons are found more frequently in the caudal rootlets (which also join the cord more medially). As one compares the organization of the roots L_4 to L_7 in a caudad direction, the ratio of larger alpha axons increases with respect to the smaller alpha and gamma axons. While the occurrence of gamma axons is of the order of 30-40% in L_5, L_6 and L_7 ventral roots, they outnumber the alpha axons in L_4. It was also observed that near the point of exit from the cord, the gamma axons often are present in small clusters. The significance of this feature is not at present clear.

1814 GLUCOCORTICOID EFFECTS ON SPINAL CORD REPETITIVE MONOSYNAPTIC TRANSMISSION AND APPARENT TRANSMITTER TURNOVER. EDWARD D. HALL & THOMAS BAKER. Dept. Pharmacol., Cornell University Medical College, New York, N. Y. 10021

In recent studies, an intensive short term glucocorticoid pretreatment regimen (triamcinolone diacetate 8 mg/kg i.m. daily/7 days) was found to facilitate excitatory spinal reflex function in acute spinal (C-1) cats (Hall et al., Neurosci. Abst. 3:502 and J. Pharmacol. Exp. Ther., in press). The principal findings were an enhanced monosynaptic (2N) post-tetanic potentiation, an increased rate of 2N synaptic recovery after single impulse transmission and an increased polysynaptic discharge.

In the present work, the effects of the intensive triamcinolone regimen were examined on the 2N input-output characteristics and the ability of the primary afferent (Ia) terminals to maintain repetitive transmission at moderate frequencies. Experiments were performed on the first post-treatment day. Stimulation was applied to the triceps surae nerves of one leg. All sensory action potentials and reflex responses were recorded at the L7 dorsal and ventral roots, respectively. First of all, in the treated cats, there was a shift in the 2N input-output relationship such that less primary afferent activation was required to initiate a liminal 2N discharge: 15.7% of maximum Ia activation in the treated vs 27.4% in the untreated ($p<0.05$). The slopes of the input-output curves were identical, however. Secondly, the treated animals exhibited significantly less rundown in 2N response amplitude during trains of ten stimuli at 5 or 10Hz. The response plateau in the treated after rundown was 13.9% ($p<0.01$) higher at 5Hz and 17.0% ($p<0.001$) higher at 10Hz than in the untreated. Comparative analysis of the extent of decline in terms of apparent transmitter release parameters (Capek and Esplin, J. Neurophysiol. 40:95, 1977) revealed no significant effects on the apparent fractional release of transmitter (p) by the Ia terminals, but the rate of replenishment of the available transmitter store (r) was more than doubled in the treated preparations.

The decrease in the Ia afferent activation necessary to just evoke a 2N response, without an increase in apparent transmitter release, suggests that the safety factor for terminal impulse invasion is improved. Furthermore, the enhanced maintenance of repetitive transmission at moderate frequencies reflects an increased rate of transmitter mobilization. These direct facilitatory effects on central monosynaptic function may partly explain the benefits of glucocorticoids in acute spinal cord trauma and certain other central neurologic disorders.

1815 CONVERGENCE OF CUTANEOUS, MUSCULAR, AND ARTICULAR INFORMATION ONTO SPINAL NEURONS IN THE CAT.
Christopher N. Honda*, Hiroshi Ryu*, and Irving H. Wagman (SPON: E. Sassenrath). Department of Animal Physiology, University of California, Davis CA 95616.

The degree of convergence between the sural nerve (SN), the nerve to the medial head of the gastrocnemius m. (MGN), and the posterior articular nerve (PAN) onto single neurons was studied. Extracellular unitary responses were elicited in the lumbosacral spinal cord of the unanesthetized, spinalized, and anemically decerebrate cat in response to electrical stimulation of peripheral nerves. After dissection of the hindlimb, each nerve was cut distally to facilitate the resolution of the compound action potentials.

102 of 173 (59%) units responded (with excitation and/or inhibition) to stimulation of all three nerves. Most of these responded to low levels of stimulation with short duration bursts of activity. Many responded further with late discharges of long duration to levels of stimulation invoking activity in Aδ and C fibers. Very few units responded exclusively to high levels of stimulation. Histological verification of recording sites with iontophoretically applied pontomine sky blue showed that the convergent units lay in laminae IV-VIII, the majority being located in VII and VIII.

Other units were characterized as responding only to SN and MGN (11%), SN and PAN (5.8%), MGN and PAN (1.7%), SN (20.2%) and PAN (2.3%). No units responded only to stimulation of MGN.

The receptive fields remaining after nerve section were mapped for many convergent units in response to natural stimulation. The resultant complex and enlarged receptive fields is suggestive of an "unmasking" effect which reveals peripheral influences extending over several segments.

The great degree of convergence between different peripheral nerves and fiber diameters within each nerve reveals synaptic connections not easily demonstrated by natural stimulation. Because of the convergence of cutaneous, muscular and joint input onto single neurons, it is suggested that ascending sensory and local reflexive pathways may share common interneuronal pools. (Supported in part by NIH grant AM16716)

1816 THE DEVELOPMENT OF SPINAL MONOAMINE SYSTEMS IN THE NORTH AMERICAN OPOSSUM. Albert O. Humbertson, Jr. and George F. Martin. Dept. Anat., Sch. Med., The Ohio State Univ., Columbus, Ohio, 43210.

Pouch-young opossums ranging in size from 15-105mm snout-rump length were subjected to the Falck-Hillarp technique or to glyoxylic acid perfusion and freeze drying (Loren et al., Histochemistry, 49: 177-192, 1976). Observations were made on cervical, thoracic and lumbosacral levels utilizing both techniques. In the youngest animals (15-30mm) there is evidence (fluorescence) for monoamine transport in axons located within the dorsolateral marginal zone. Such axons extend throughout the length of the cord. A few fluorescent varicosities are present also in the ventral marginal zone, but none have invaded the intermediate zone at any level. There is a cranial to caudal sequence to the growth of fluorescent neurites into their definitive terminal territories. At 35mm they have penetrated the dorsolateral intermediate zone at cervical levels and some have reached the area dorsal to the central canal. By 45mm comparable growth has taken place at lumbosacral levels. The fluorescence increases progressively in the intermediate zone at all levels of the cord, and by 55mm it is found in most of the areas expected from adult material. Such areas include: the dorsolateral intermediate zone, the region dorsal to the central canal, the periphery of the ventral horn and the region capping the dorsal horn (presumptive lamina I). In the oldest animals studied (60-105mm) the pattern of fluorescence is like that found in the adult with distinct varicosities. Supported by U.S.P.H.S. Grants NS-07410 and NS-10165.

1817 2 DEOXYGLUCOSE MAPPING OF THE PLANTAR CUSHION REFLEX.
John S. Kauer, Eric Proshansky*, William B. Stewart and M. David Egger. Depts. of Neurosurgery and Physiology, Yale Univ. Sch. of Med., New Haven, Conn. 06510 and Dept. of Anatomy, CMDNJ-Rutgers Med. Sch., Piscataway, N.J. 08854.

We have used the method of 2-deoxyglucose(2-DG)autoradiography for mapping metabolic activity in the pathway underlying the plantar cushion (PC) reflex in the cat spinal cord. In four adult cats anesthetized with pentobarbital, the tibial nerve was dissected free of surrounding tissue, left intact, and mounted on bipolar recording electrodes. Following administration of 100 μC/kg of 2-DG, the PC reflex was elicited electrically using 0.5 msec. pulses at 5 or 10 times threshold for 45 min. at 1,3, or 10 Hz. through needle electrodes inserted into the skin of the pad. By varying the frequency parameters of stimulation we were able to examine the pattern of 2-DG uptake in animals in which the reflex was present for the duration of the stimulation and in one animal in which the reflex was habituated prior to injection of the 2-DG. The animals were sacrificed at the conclusion of the stimulation and the tissue processed immediately for 2-DG autoradiography. In three animals in which reflex output was maintained for the duration of the stimulus a discrete, ipsilateral region of increased 2-DG uptake was observed only at the most medial edge of the dorsal horn within Rexed's laminae I-IV in the lumbar enlargement. This uptake pattern was also present in the animal in which reflex activity habituated. No increase in uptake was observed in the S_1 motor nucleus where motorneurons activated during the PC reflex are located. In one control animal prepared identically to the experimental cases, but without stimulation, no focal changes in 2-DG uptake were observed within the spinal gray matter.

The area of increased autoradiographic density at the most medial edge of laminae I-IV following electrical stimulation, likely represents increased activity associated with the termination of primary afferents from the PC. The area of labelling lies within the central distribution of the plantar nerve, in which PC afferents are included, and in part overlaps the region in which dorsal horn neurons activated by PC stimulation are found(Egger & Wall, J.PHYSIOL.(LOND) 216:483, 1971). These results indicate that the 2-DG technique is useful for the localization of the central terminations of primary afferent fibers innervating discrete peripheral sites.

1818 MORPHINE ANALGESIA, SUPRASPINAL INFLUENCE ON SPINAL MECHANISM.
Luke M. Kitahata, K. Hanaoka* and A. Taub*. Dept. Anesth. Yale Univ. Sch. Med. New Haven, Conn. 06517.

Recent evidence has delineated both spinal (Anesth. 41: 39, 1974) and supraspinal (Sci. Sinica 13: 1099, 1964) sites for the pharmacological action of morphine analgesia. The interaction between these sites is of major significance for the ultimate understanding of the mechanisms of morphine analgesia. Electrical stimulation in the region of the periaqueductal gray in the rat (Science 164: 444, 1969; Pain 1: 51, 1975) produces behavioral changes comparable to surgical analgesia in man. Such stimulation, particularly in the region of the dorsal raphe nucleus (Exp. Brain Res. 20: 32, 1974) inhibits activity in cells of Rexed Lamina V evoked by noxious stimulation of the skin. Morphine injected in microgram quantities into the region of the periaqueductal gray (Sci. Sinica 13: 1099, 1964) produces an analgesic effect in animals comparable to a 500-fold greater systemic dose. Taken together, these studies suggest that morphine may activate mechanisms in the periaqueductal gray region which, in turn, are suppressive of the activity of cells in Rexed Lamina V of the spinal cord, thus leading to analgesia (Pain 1: 51, 1975). The present study was undertaken to test the hypothesis that intravenous morphine activates supraspinal descending mechanisms which modulate the activity of those spinal ascending mechanisms mediating nociception. A dose-dependent suppression of the activity of Lamina V nociceptive neurons following morphine administration (0.5, 1.0 and 2.0 mg/kg) was demonstrated confirming the work of Kitahata et al. (Anesth. 41: 39, 1974). It was further demonstrated that the degree and duration of this suppression was greater in those animals with an intact spinal cord than in those animals whose spinal cord has been transected and was greater for evoked than for spontaneous activity. The effect was reversed by naloxone. The observation in this study supports the hypothesis that morphine activates brain stem structures, which, in turn, inhibit the activity of nociceptive neurons in Rexed Lamina V of the lumbar spinal cord.

1819 EFFECTS OF SOMATOSENSORY STIMULUS MODALITIES ON SINGLE SPINAL UNITS IN RATS; IMPLICATIONS FOR LORDOSIS BEHAVIOR. Lee-Ming Kow, Frank P. Zemlan*, and Donald W. Pfaff. The Rockefeller Univ., New York, NY 10021.

From behavioral (Kow & Pfaff, Brain Res., 1976; Kow et al., in prep.) and dorsal root ganglion (DRG) single unit (Kow & Pfaff, Fed. Proc., 1978) studies, it has been found that the sensory input from pressure stimulation on skin innervated by the lower lumbar spinal cord is necessary and sufficient for triggering lordosis in rats. In the present study, single unit activity (N= 353) was recorded from the spinal cord between lower L_5 and upper S_1 in urethane-anesthetized rats, and unit responses to a series of somatosensory stimuli were studied. 54% of the units did not respond to pressure, but responded to brushing, muscle-joint, and/or visceral stimulation, or none at all. 15% of the units responded only to pressure. The remaining 31% responded to pressure as well as other stimuli. Although the majority of pressure-responsive units were excited by pressure stimulation, a small percentage were inhibited or responded differently depending on the site stimulated. Within the spinal cord most of the units were recorded from laminae IV through VIII. The units responding only to brushing were confined to dorsal horn (laminae IV and V). Those responding only to muscle-joint or visceral stimulation were in the ventral horn. Pressure-responsive units were primarily found at intermediate depths. In contrast to DRG units (Kow & Pfaff, 1978), spinal units have larger receptive fields, higher resting activity, additional and more complex response types, and show greater variability of response. These comparisons indicate convergence of primary sensory information on the units recorded.

We assume that excitation of units responding only to pressure is centrally involved in triggering the lordosis reflex. Those units not responding to pressure are probably irrelevant for this behavior. Presently undetermined are the roles of units with complex or mixed response types.

1820 SYNAPTIC POTENTIALS IN SPINAL MOTONEURONS: EFFECTS OF EXTRA- AND INTRACELLULAR INJECTIONS OF SOME IONS. K. Krnjević, Y. Lamour*, J.F. MacDonald and A. Nistri*. Anaesthesia Res., McGill U, 3655 Drummond, Montreal.

PSPs were evoked in lumbosacral spinal motoneurons of cats (under Dial anaesthesia) by electrical stimulation of dorsal or ventral roots and various peripheral nerves. Extracellular injections of Co or Mn which were sufficient to depress the post-spike hyperpolarization also clearly reduced the amplitude of PSPs. Although the injection sometimes had a depolarizing effect, this was usually too small to account for the depression of EPSPs. Moreover, the EPSPs were clearly diminished even in the presence of no significant change in resting potential or a small hyperpolarization. Under stable conditions of recording this effect of the divalent cations was reversible. Unless these cations can interfere specifically with the ionic movements generated by synaptic activity, the observations suggest that these PSPs are generated mainly by chemical, rather than electrical transmission, although some degree of electrical transmission is not totally excluded.

In contrast to spike potentials, EPSPs were not markedly depressed by intracellular injections of procaine. On the other hand, they proved to be surprisingly sensitive to changes in the internal pH; intracellular injections of protons had a sharply depressant effect. This was probably not secondary to a change in membrane potential and was unexpectedly associated with a fall in cell input conductance. In this respect, it differs from the depressant action of intracellular injections of calcium or strontium. It is not clear whether the effect of protons represents a specific interference with the mechanism of generation of PSPs or whether it may indicate some degree of synaptic uncoupling.

Intracellular injections of Mn and Co were sometimes followed by a marked reversal of IPSPs (or increase in depolarizing IPSPs), but these changes could be ascribed to the concurrent injection of anions that can permeate the IPSP ionic channels.

1821 BRANCHING OF AXONS IN THE L_6, S_1 AND S_2 DORSAL ROOTS OF THE RAT. Lauren A. Langford* and Richard E. Coggeshall, Depts. of Anatomy and Physiology and Biophysics, and The Marine Biomedical Institute, The University of Texas Medical Branch, Galveston, Texas 77550.

In a previous abstract we reported that there were more dorsal root axons in the L_6, S_1 or S_2 dorsal roots of the rat than there were ganglion cells in the corresponding dorsal root ganglia. Our explanation for these data was that many of the dorsal root axons branch in the ganglion or in the dorsal root before they reach the spinal cord. Alternative explanations for the preponderance of axons over ganglion cells are: 1) that there are a number of dorsal root efferent fibers whose cell bodies are located within the spinal cord or 2) that there are a number of postganglionic sympathetic fibers that innervate the blood vessels of the dorsal root in addition to the dorsal root fibers. To control for the possibility of dorsal root efferents, the dorsal root ganglion was removed and the root was then examined in the electron microscope. Any fibers whose cell body is in the spinal cord would survive in the dorsal root whereas those fibers whose cell bodies are in the dorsal root ganglion would die. In one animal 3 days after ganglionectomy, no normal myelinated fibers were found but approximately 290 cell processes that might be unmyelinated fibers were observed in the dorsal root. In another animal which survived 10 days no myelinated fibers were seen but 20 processes that might be unmyelinated fibers were observed. Further studies to provide statistical validity and to determine whether or not the unmyelinated cell processes are unmyelinated axons are underway. For the present argument, however, it is clear that there are not enough dorsal root efferents to explain the discrepancy in axon and ganglion cell numbers. To control for the possibility that there are sympathetic fibers in the dorsal root, a sympathectomy was done and the dorsal root was examined after allowing time for degeneration of postganglionic fibers. In the one rat examined to date, there were 4757 dorsal root ganglion cells and 7422 dorsal root axons.

If further studies support these preliminary observations, the conclusion would be that there are more dorsal root axons than ganglion cells for segments L_6, S_1 and S_2 in the rat, even when dorsal root efferents and sympathetic fibers are excluded. Accordingly it seems that dorsal root axons branch in the ganglion or the dorsal root itself, a conclusion that is at variance with textbook descriptions that indicate that each dorsal root ganglion cell sends a single axon into spinal cord through the dorsal root.

1822 MORPHOLOGY OF PHYSIOLOGICALLY IDENTIFIED NEURONS IN THE SPINAL MARGINAL ZONE AND SUBSTANTIA GELATINOSA. A. R. Light, D. L. Trevino and E. R. Perl. Dept. Physiol., Univ. N. Carolina Chapel Hill, NC 27514

Differing physiological properties have been ascribed to neurons presumably indigenous to the dorsal horn marginal zone (lamina I), the substantia gelatinosa (lamina II) and the nucleus proprius on the basis of extracellularly recorded unitary discharges, which may be derived from a neuron's axon, soma or dendrites. Conventional microelectrodes do not reliably differentiate between these in a dense neuropil. Therefore, pipette electrodes containing horseradish peroxidase (HRP) were used to record unitary activity in lower sacral and coccygeal spinal cords of cats, unanesthetized after decerebration and spinal transection. After functional characterization, HRP was deposited intracellularly by iontophoresis: HRP staining provides a Golgi-like picture of the cell. No cells with somata in lamina I or II responded to afferent volleys confined to fibers conducting over 45 m/sec. Three main classes of neurons with perikarya in lamina I and lamina II responding to afferent input have been identified: 1) Neurons with dominant input from Aδ mechanical nociceptors had small to medium (10-30 μ diam.) somata in lamina I or the immediately subjacent part of lamina II: their predominant dendritic projection was in lamina I. 2) Neurons excited by innocuous thermal changes responded only to volleys containing C fibers: they had somata located in the marginal zone with dendritic projections mainly in the immediately subjacent (dorsal part) lamina II. The thermoreceptive neurons were the only group that consistently had significant spontaneous activity. 3) Two kinds of neurons had a dominant excitatory input from low threshold mechanoreceptors. One type was excited principally by input from the Aδ, "D" hair follicle receptors and had small somata located in the deeper portion of lamina II or the most dorsal part of nucleus proprius (lamina III) with dendrites which ramified extensively rostrocaudally in the same laminae. The second type appeared to receive predominant excitation from the low threshold C mechanoreceptors and had somata located within lamina II: their dendritic extensions were principally within the central part of lamina II. Units dominated by cutaneous receptors with rapidly conducting myelinated fibers had somata located deep to lamina II, however, some were found to have dendrites extending into lamina II and evidenced an excitatory input from low threshold C mechanoreceptors. Units responding inconsistently to primary afferent input or only showing inhibitory postsynaptic potentials were also observed superficially in the dorsal horn. Supported by USPHS, NINCDS grants 10321 & 11132 and a fellowship (NS05526) to ARL.

1823 EPSPs ELICITED BY SINGLE IMPULSES IN LARGE POPULATIONS OF MOTONEURONS. Hans-R. Lüscher*[1], Eberhard Fetz, Paul Ruenzel* and Elwood Henneman. Dept. of Physiology, Harvard Medical School, Boston.

The number of terminals given off by an axon of a motoneuron is a function of its diameter (McPhedran et al. J. Neurophysiol. 28:71, 1965). Furthermore, evidence has been presented that the amplitude of an individual stretch evoked EPSP in a motoneuron is related to the diameter of the I_A fiber conducting the afferent impulses (Mendell et al. J. Neurophysiol. 34:171, 1971). This suggests that the number of terminals from a I_A fiber to a motoneuron is also a function of its diameter. It is uncertain whether this inference is correct, however, because the amplitude of an individual EPSP is also strongly influenced by the input resistance of the motoneuron and the location of the synaptic terminals. If the influence of such variables could be minimized by averaging the EPSPs caused by single I_A impulses in a large number of motoneurons, the total synaptic effect of a I_A impulse could be determined and related to the number of its terminals.

By infiltrating a ventral root with isotonic sucrose solution so that its extracellular resistance is extremely high, the interiors of its axons can be used as wick electrodes to record voltage changes in all the motoneurons of that spinal segment. With an averaging computer triggered by the action potentials from a single, functionally isolated but intact afferent, the synaptic effect of a I_A impulse upon the whole population of motoneurons can be extracted from the physiological and electrical "noise" in the recording system. Potentials with the general waveform of EPSPs but of somewhat longer duration can be recorded under these conditions. They may be referred to as individual "post-synaptic population potentials" (PSPPs).

Individual PSPPs were recorded from S_1 ventral roots of cats under chloralose anaesthesia. The conduction velocity of the afferent impulses, all originating in the triceps surae muscles, covered the range for group I_A and group II afferents. The amplitude of these PSPPs showed a consistent and significant relationship to the conduction velocity of the afferent fibers. Impulses in slowly conducting I_A fibers yielded small PSPPs, while fast fibers were associated with larger PSPPs. Group II impulses elicited very small PSPPs.

These findings confirm the hypothesis that the number of terminals given off by an afferent fiber is a direct function of its diameter and suggest that the size principle applies also to primary sensory neurons in the stretch reflex.

1824 THE ORGANIZATION OF RETICULOSPINAL PROJECTIONS IN THE NORTH AMERICAN OPOSSUM. George F. Martin, Michael Panneton and Irene Tschismadia. Dept. Anat., Sch. Med., The Ohio State Univ., Columbus, Ohio, 43210.

Injections of ^{3}H-leucine were placed into each of the cell groups revealed by the HRP technique to be the origin of reticulospinal projections. The developed autoradiograms reveal that the nucleus cuneiformis projects by the ipsilateral sulcomarginal and ventral funiculi to laminae VII and VIII of the cord and that medially situated neurons throughout the nucleus retilaris pontis (RP) relay through the same routes to comparable targets. The rostral nucleus magnus raphe (RaM) distributes bilaterally through dorsolateral tracts to lamina I. When injections involve specific neurons in the ventrolateral part of the rostral RP there is additional labelling of axons which interdigitate with rubrospinal fibers within the contralateral cord and which also distribute to lateral parts of laminae IV through VI. Deposits of ^{3}H-leucine which cover the nucleus locus coeruleus and/or subjacent areas produce labelling within the ventral, lateral and dorsolateral white matter, ipsilaterally, as well as labelling of axons in the dorsolateral white matter contralaterally. Many of the contralateral axons course among rubral axons. Some of the cases with injections of the dorsolateral pons show light label within lamina I and lateral parts of laminae V and VI, bilaterally, as well as within laminae VII and VIII (mainly ipsilaterally) and lamina X. Injections of the nucleus reticularis gigantocellularis (RG) and/or the nucleus reticularis gigantocellularis, pars ventralis (RGcv) produce labelling within the ventral, lateral and dorsolateral white matter, bilaterally, as well as terminal label within lateral parts of lamina V and VI, ipsilaterally, and over laminae VII and VIII, mainly ipsilaterally. If serotonin containing neurons of the RaM and the RGcv are included in the injection there is evidence of a strong projection to laminae I and X, bilaterally. A somewhat different pattern of spinal label is produced by injections lateral to RG. Injections which include paramedian areas of the medulla, as well as the nucleus obscurus of the raphe, produce labelling of axons within both the ventral and lateral funiculi and terminal label within laminae VII through X. Label is especially heavy within laminae IX and X. Injections limited to more lateral areas of the medulla also result in spinal labelling and those which cover the rostral lateral reticular nucleus elicit labelling of terminals, bilaterally, within the intermediolateral cell column at thoracic levels. The nucleus retroambiguus projects mainly via the contralateral ventral funiculus to laminae VIII and VII.

1825 SPINAL CORD TRANSECTION: A QUANTITATIVE ANALYSIS OF REACTIVE EVENTS WITHIN THE SITE OF LESION FOLLOWING ADMINISTRATION OF PIROMEN, CYTOXAN OR TRYPSIN. M. A. Matthews, M. F. St. Onge, C. L. Faciane, J. B. Gelderd. Dept. Anat., LSU Med. Ctr., New Orleans, LA 70119.

Long-Evans hooded rats were cordotomized at the T-5 level and given: 1) cyclophosphamide, an immunosuppressive agent; 2) Piromen, a bacterial polysaccharide-nucleic acid complex; 3) topical and systemic trypsin; 4) no further specific treatment. Because of past and present controversy surrounding the proposed ability of these agents to promote spinal cord regeneration, a systematic study, employing light and electron microscopy, and quantitative methodology in a single animal model, was done in order to re-evaluate the effects of such treatment.

After an initial inflammatory reaction during the first week following surgery, the lesion zone is characterized either by areas of dense collagenous connective tissue with occasional fibroblasts and macrophages, or a loose, areolar tissue with numerous sheets and cords of mesodermal cellular elements but minimal collagen. By 45 days postoperative (dpo), axons supported by Schwann cells, invade and become entangled in the loose connective tissue matrix. With longer postoperative survival, cysts appear cranial and caudal to the lesion and erode much of the scar together with viable neural tissue. Administration of Cytoxan and Piromen did not result in any qualitative alteration of the scar matrix as evidenced by electron microscopy. Quantitative analysis revealed a slight reduction in the fibrous connective tissue component of the scar at 45-90 dpo associated with an elevated incidence of axons in this zone but this proved to be a transient occurrence as longer postoperative periods were studied. The use of trypsin resulted in significant reduction of the amount of fibrous connective tissue with a concomitant increase in loose connective tissue and the appearance of a few distinctive, compact bundles of unmyelinated axons lacking Schwann cells.

Consistent behavioral modifications were not observed in any of the treatment groups which would significantly distinguish them from controls. Our results appear to contradict the findings of Matinian and Andreasian (1976) who reported return of normal sensori-motor function in 80% of their animals treated with topical and systemic trypsin.

It is concluded that a major impediment to whatever long term regenerative potential exists within the spinal cord is the lack of axonal guiding elements within the scar, but more importantly, the severe erosion of the remaining spinal cord due to cyst enlargement.

Supported by a grant from the Edward G. Schlieder Foundation.

1826 EVALUATION OF ETHACRYNIC ACID AS A THERAPEUTIC AGENT IN EXPERIMENTAL SPINAL CORD TRAUMA. J.T. Molt, D.A. Poulos, H.K. Kimelberg*, and R.S. Bourke. Div. of Neurosurgery and Dept. of Physiology, Albany Medical College, Albany, N.Y. 12208

Hemorrhagic necrosis resulting from blunt trauma to the spinal cord is a progressive destructive process which radiates from gray matter into surrounding white matter. Recent evidence has shown that an early event following traumatic injury to the cord is astroglial swelling. Such swelling may be important in the spread of the hemorrhagic lesion due to the following mechanism. It is known that during trauma-induced hypoxia and ischemia, intracellular K^+ is released into the extracellular compartment of the spinal cord reaching concentrations of up to 70 mM. Swelling may be due to 1) uptake of K^+ plus Cl^- in accordance with Donnan equilibrium and 2) an extra component of HCO_3^--stimulated swelling involving the uptake of Na^+ and Cl^- into glia and possibly other cells. When swelling occurs in perivascular astroglia it may compress or occlude the microvasculature. This may reduce blood flow and increase intercapillary distances which will increase the diffusion path for oxygen resulting in a hypoxic insult to intact neurons. We have suggested that swelling by mechanism 2) above involves mediated Cl^- transport which can be inhibited by an unsaturated ketone derivative of aryloxyacetic acid (ethacrynic acid) among other agents. We tested the hypothesis that the K^+-dependent, HCO_3^--stimulated component of astroglial swelling is an important factor in the evolution of spinal cord injury and that its inhibition by ethacrynic acid might improve recovery from such an injury. Anesthetized cats were injured by dropping a 25 gm weight 20 cm onto an impounder and strain gauge centered on the exposed dural surface of the cord at the L2 segment. The impulse of the blow was recorded. Animals were treated with saline or ethacrynic acid 5 min following injury. Cats were evaluated 48 hrs post injury using a clinical examination and an electrophysiological test. The extent of the cord injury was then assessed histologically. All three methods of assessment revealed a significant improvement in animals treated with ethacrynic acid when compared with saline-treated control cats. Although unable to walk, the treated animals showed significantly better leg movement than untreated cats. Electrophysiologically, the descending tracts which modulate spontaneous spinal cord activity were shown to be more viable in treated animals than in controls. Histologically an average cross-sectional area of 85% of the untreated cords appeared injured compared to an average of 60% of the area in the cords of treated animals. These results indicate that inhibition of astroglial swelling by ethacrynic acid may be useful as a treatment modality for spinal cord injuries due to blunt trauma. (Supported by Grant NS13042 from NINCDS).

1827 PROPERTIES OF CENTRAL Ia AFFERENT FIBERS PROJECTING TO MOTONEURONS. J.B. Munson and G.W. Sypert, Univ. of Fla. Coll. of Med. and VA Hospital, Gainesville, FL 32610

Physiological studies of single medial gastrocnemius (MG) Ia afferents were made to determine their rostro-caudal distributions, branching patterns, terminal distributions, conduction velocities and EPSP generating properties in the cat spinal cord. Through the use of signal averaging techniques, field potentials ("branch potentials") and EPSPs occurring synchronously with action potentials in single MG Ia dorsal root afferents were studied in the region of the triceps surae motoneuron pool.

MG Ia afferents bifurcate upon entering the spinal cord and conduct both caudally (at 22 M/S) and rostrally (at 38 M/S). At intervals of 200μ to 1800μ ($\bar{x}$ = 1267μ), 6-8 major collateral branches conduct ventrally at 8-19 M/S. Prominent branch potentials and signs of synaptic activity can be distinguished in the regions of lamina VI (intermediate region) and lamina IX (motoneuronal pool). Mean amplitude of EPSPs generated by some major collateral branches is significantly larger or smaller than the mean for all EPSPs generated by that afferent. Branch potentials in the motoneuronal pool were recorded over a 8600μ maximum rostro-caudal extent.

These physiological results are integrated with previous anatomical studies to resolve inconsistencies and depict clearly the morphology of central MG Ia afferents projecting to motoneurons. (Supported by EY 01264 and VA Hospital Medical Research Service.)

1828 ELECTROPHYSIOLOGY OF ACUTE SPINAL TRAUMA. A.C. NACIMIENTO, M. BARTELS and H.-D. HERRMANN, Dept. Physiology I, and Dept. Neurosurgery, Saar University, School of Medicine, 6650 Homburg (Saar) G.F.R.

An exposed, otherwise intact spinal L7 segment in the cat was subjected to a sudden, short-lasting compression by an electromagnetically driven metal rod. Pathophysiological events at different degrees of compression were highly reproducible, allowing quantification. The following functions were monitored before, during and up to 6 hr after injury; a) polysynaptic reflex discharges (PRD); b) cortical evoked potentials (CEP) in response to the same afferent volley triggering PRD; c) conduction through the injured segment by recording from a S3 dorsal rootlet antidromic impulses set up by dorsal column stimulation at L1. With a compression of 1 mm there was initially little change in PRD and CEP; conduction was reversibly diminished for a few min. At 2 hr a decrease of PRD ensued, with no changes in CEP or conduction. PRD decreased further with time and disappeared 4-5 hr after injury. A compression of 2 mm caused an immediate loss of both PRD and conduction, leaving CEP unimpaired. At 30 min there was some degree of recovery of PRD and conduction, with a subsequent decline setting in after 60-90 min, and disappearance in 3 hr. At 3 mm there was immediate loss of PRD and conduction, delayed (after 60-120 min) signs of recovery, and final abolition. CEP were decreased by about 40% 10 min after injury followed by complete recovery. At 4 mm all responses were lost, with CEP recovering slowly after 10 min, to reach pre-lesion levels in 3-4 hr. No recovery of PRD or conduction was observed. Light microscopy of the injured segment displayed hemorrhages in the central grey matter, edema and axonal swelling in the white matter, well correlated with the degree of compression. These results show: 1) a differential sensitivity of spinal functions to injury, reflex activity being most susceptible; 2) a relative resistance and clear recovery tendency of CEP; 3) that post-traumatic changes in reflex activity and conduction set in immediately following injury, in the face of an essentially normal morphology.

1829 EFFECT OF DORSAL RHIZOTOMY ON THE SYNAPTIC POPULATION IN THE SACRAL SECONDARY VISCERAL GRAY. Michael F. Nolan and H. Keith Brown. Dept. of Anat., University of South Florida, Tampa, FL 33612.

Afferent impulses from pelvic visceral structures are relayed rostrally to brainstem levels via the sacrobulbar pathway. The cellular origin of this fiber tract is the secondary visceral gray located in the lateral funiculus at mid-sacral levels immediately dorsolateral to the sacral parasympathetic nucleus. This study was undertaken to identify the types and characteristics of synapses in this neuropil arising from ipsilateral dorsal root fibers. Adult male and female cats were anesthetized with pentobarbital sodium and subjected to unilateral intradural section of the S1, S2 and S3 dorsal roots. On the fifth postoperative day, the animals were reanesthetized and killed by transcardiac perfusion with buffered saline followed by 2% paraformaldehyde - 3% glutaraldehyde in 0.1M cacodylate buffer, pH 7.3. Sacral spinal segments were removed, osmicated and processed for transmission electron microscopy. The sacral secondary visceral gray was identified in 1μm toluidine blue cross sections. At the E.M. level, a heavy concentration of dense core vesicles both in axons and in terminal boutons clearly distinguishes this nuclear region from the nearby substantia gelatinosa. Both myelinated and unmyelinated degenerating fibers were observed throughout the extent of the sacral secondary visceral gray. In addition, degeneration was noted in the ipsilateral dorsal funiculus, Lissauer's tract and superficially in the dorsal part of the lateral funiculus. Synaptic terminals undergoing degenerative changes were found at all levels of this nucleus. The majority of degenerating boutons contained clear spherical vesicles and were found in association with dendrites of various sizes. These terminals were sometimes surrounded by glial elements and characteristically contained a tight clump of electron dense material consisting of synaptic vesicles and mitochondria. Boutons containing predominantly dense core vesicles did not appear to be affected by dorsal rhizotomy. These results suggest that dorsal root influence over neurons in the sacral secondary visceral gray is mediated by terminals containing clear spherical vesicles. Boutons containing dense core vesicles appear to originate from nerve cells other than those in sacral dorsal root ganglia. Possibly, these latter terminals are part of a descending bulbospinal tract system. This work was supported in part by NIH/BRSG RR5749-05.

1830 CENTRAL TERMINAL EXCITABILITY CHANGES OF SINGLE TYPE I AFFERENT FIBERS. Ronald E. Paul* and Daniel N. Tapper. Sch. of Elec. Eng.; Sect. of Physiol., N.Y. State Coll. Vet. Med.; Cornell U., Ithaca, N.Y. 14853.

Changes in activation threshold of central terminals of single Type I afferent fibers of hairy skin of cat, induced by small input conditioning stimuli, were studied in the sacral dorsal spinal gray matter. Conditioning stimuli, consisting of either single or short trains of action potentials, produced by electrical stimulation of the Type I terminal on the skin (the touch dome), were induced in either the fiber whose central terminal was to be tested or in the afferent of another adjacent Type I terminal. Central excitability of the test fiber was determined by Wall's technique of antidromic activation of the intraspinal terminals, using a tungsten microelectrode inserted in the spinal cord in proximity to the central terminal in upper lamina IV.

When a conditioning stimulus consisting of a single impulse was applied to the test fiber, a bimodal change in central excitability lasting up to 50 msec was observed. It consisted of a depolarization with a major peak at 8 msec and a second peak at 25 msec. The central delay for this effect was found to be less than 2.5 msec. When such a conditioning stimulus was applied to a Type I fiber other than the test fiber (spatial interaction), in some cases a similar change in central excitability of the test fiber was observed. In some other cases, a train of impulses (5 action potentials, 100 Hz) was required to produce the effect. The excitability change in the test fiber produced by such spatial interaction was observed to have a duration of up to 50 msec and a central delay of approximately 4-5 msec.

Work currently in progress using a GABA antagonist, bicuculline (dose range: 1-2 mg/kg) indicates that the reduction in activation threshold of the central terminals is due in large part to GABA activity. These results suggest that in addition to a possible intrinsic component to the post-conditioning threshold reduction (e.g. afterdepolarization), a presynaptic inhibitory process, such as primary afferent depolarization (PAD), is evoked by small scale input, both in the case where the conditioning impulse is applied directly to the test fiber and that where the conditioning pulse is applied to an adjacent fiber (spatial interaction).

By inserting this data into models of the transfer function between presynaptic membrane depolarization and transmitter release, it is possible to predict the time course of PSP size modulation caused by the calculated presynaptic potential changes. These results are important for understanding the role of PAD in information processing in central neural networks. (Supported by USPHS Grant 07505).

1831 THE COERULEOSPINAL PATHWAY: AN ANATOMICAL, NEUROCHEMICAL AND ELECTROPHYSIOLOGICAL STUDY. J.A. Pearson. Dept. of Physiology, University of British Columbia, Vancouver, B.C., Canada, V6T 1W5.

Large bilateral injections (2.0 µl) of a 30% solution of horseradish peroxidase (HRP) were placed in the lumbar enlargement of the spinal cord of Nembutal-anaesthetized rats. After a survival period of 48 hrs retrograde transport of HRP to neuronal cell bodies in the brainstem was determined using the procedure described by Mesulam. Labelled neurones were present in the ventral division of the caudal region of the locus coeruleus (LC) and the subcoeruleus area. Following hemisection of the cord, at the mid-thoracic level, HRP-positive cells were situated only in the LC contralateral to the lesion. Labelled cells were also found in the nucleus reticularis gigantocellularis, pontis caudalis and oralis, raphe magnus, pallidus and obscurus.

To confirm that the axonal transport of HRP to the LC had occurred in catecholamine containing neurones, the effect of 6-OHDA (12 µg in 4.0 µl) injected bilaterally into the caudal brainstem (5.5 mm posterior to lambda, 1.5 mm lateral, 7.5 mm from dura) was investigated. After 14 days, HRP was injected into the cord as described above. The number of labelled cells in the LC was markedly reduced (less than 10%) in comparison to the untreated controls. The extent to which cells in the adjacent reticular formation and in the raphe nuclei were labelled was unchanged.

Noradrenaline levels in the lumbar cord were determined by a radioenzymatic assay based upon the technique of Coyle and Henry. 6-OHDA treatment resulted in an almost complete depletion of noradrenaline (0.292±SE 0.010 µg/g in control animals, 0.030±SE 0.015 µg/g after 6-OHDA).

The effect of stimulation of LC upon the activity of spinal interneurones was investigated in urethane-anaesthetized rats. The type of neurone which was of particular interest responded to both non-noxious and noxious levels of cutaneous stimulation. Both types of response were inhibited by trains of stimuli applied to the LC. This effect could not be demonstrated in rats pretreated with 6-OHDA.

These results indicate that the LC gives rise to an ipsilateral, noradrenergic, inhibitory pathway to the lumbar spinal cord. The possibility exists that this system might be involved in modulation of nociception.

1832 ELECTRON MICROSCOPIC OBSERVATIONS ON THE SPINAL TERMINATION OF PHYSIOLOGICALLY IDENTIFIED DORSAL ROOT AXONS. Henry J. Ralston, III, Alan R. Light, and Edward R. Perl. Dept. Anat., Univ. of Calif. San Francisco, CA 94143 and Univ. N. Carolina, Chapel Hill, NC 27514.

Single primary afferent fibers in sacral and coccygeal segments were characterized functionally by electrophysiological recording with microelectrodes; subsequently they were stained by the iontophoretic, intracellular injection of horseradish peroxidase (HRP) from a solution contained within the micropipette. The HRP is transported, from the point of injection in the dorsal root, centrally for several millimeters and after fixation and reaction provided a Golgi-like picture of the central distributions. Myelinated fiber receptive units (Type I cutaneous and G-2 hair follicle) were selected for study and were identified on the basis of conduction velocity and their response to a variety of graded mechanical stimuli applied to the skin. After reaction to develop the HRP product, thick serial sections containing the stained axon were treated with osmium and imbedded in epoxy resins. The arborization of the axon was reconstructed with camera lucida. Selected axonal branches were prepared for serial thin sections for electron microscopy. The extensive branches of a single dorsal root axon from a Type I receptor made hundreds of synaptic contacts as they distributed in the dorsal horn. All synaptic contacts of this type of receptor were deep to the substantia gelatinosa (lamina II). All of the observed synaptic profiles contained round vesicles. The various synaptic profiles from a single Type I axon have differing morphologies: simple axodendritic contacts as well as complex "central" terminals which had multiple axodendritic and axoaxonal synapses. Other axoaxonal synapses were also observed; in all axoaxonal synapses the labeled primary afferent axon was post-synaptic to other profiles. G-2 hair receptor axons in cat distribute throughout the nucleus proprius (lamina III and IV) in a fashion generally similar to that for the Type I receptor. The fiber from a cat G-2 hair follicle receptor also showed myriads of synaptic contacts; to date simple axodendritic and the "central" terminal with multiple axodendritic synaptic contacts have been identified. (Supported by USPHS, NINCDS research grants NS11614, NS10321, and NS11132 and a fellowship NS05526 to A.R.L.)

1833 LYSOSOMAL AUTOLYSIS OF CONTUSED SPINAL CORDS. D. Rigamonti J. Wrathall* and C.C. Kao* Department of Anatomy, Georgetown Univ. Schools of Medicine and Dentistry, Washington, D.C.20007.

The time course change of the spinal cord after contusion can be dramatically demonstrated by the following model. Eighteen adult female dogs were used. The 7mm diameter spinal cord was compressed to 1mm for 2 seconds between the blades of a pair of hemostatic forceps at T10 cord level. Immediate findings after this mode of injury were a few petechial hemorrhages with no disruption of the spinal cord. Nevertheless, at one week after the contusion, a cavity extending throughout the entire cross-sectional area of the spinal cord was found. Apparently, this spinal cord cavitation was not due to the contusion, but was the result of "secondary destructive processes" which develope after the contusion.

We have previously reported massive mobilization and accumulation of neuronal lysosomes and release of lysosomal hydrolases near the plane of spinal cord transection which was associated with autolysis of the spinal cord tissue bordering the cut ends of the spinal cord stumps (J.Neurosurg. 46: 197, 1977).

We now report a correlated histological, histochemical and electron microscopic study in the contusion model, and identify that lysosome mediated spinal cord autolysis is one of the "secondary destructive processes" which cause spinal cord cavitation after spinal cord contusion.

Acid phosphatase (APase), used as the marker for lysosomes, was demonstrated by Gomori's and azo-dye methods and by electron microscopy. In a normal spinal cord, APase is positive in the meninges, in the blood vessel wall, and in nerve cell bodies of the grey matter, but not in the white matter tracts. At 3 to 6 hours after contusion, large quantities of lysosomes accumulate within short segments of axons in otherwise normal-appearing white matter about 2mm from the area of petechial hemorrhage proximal and distal to the injury. At 12 hours, the lysosome-filled axons form club-shaped axonal terminals (terminal clubs) which always pointed to the area of injury. At one day, the terminal clubs may reach 100µ in diameter and begin to leak APase into the surrounding tissue. Electron microscopic study revealed rupture of the terminal club with subsequent release of lysosomes into the interstitial space. The injured area subsequently became necrotic and detached from the spinal cord at the level where the lysosomes were released.

Since electron microscopy revealed the localization of the lysosomes within the axons and terminal clubs, it is unlikely that the APase originated from the circulation or from macrophages. We therefore propose that the lysosomes that accumulated in the spinal cord following spinal cord contusion originated within the nervous system. (Supported by:NIH NS14413-01)

1834 DENDRITES IN WHITE MATTER OF THE UPPER CERVICAL CORD OF THE ADULT CAT. P.K. Rose and F.J.R. Richmond.* (SPON: J.V. Milligan). Department of Physiology, Queen's University, Kingston, Ontario. Canada. K7L 3N6.

Both anatomical and electrophysiological studies have shown that descending spinal and propriospinal systems terminate on neurons at several spinal levels via short axon collaterals arising from parent axons in white matter. Yet some cells in the lumbrosacral cord have dendrites which extend into white matter raising the possibility that descending and propriospinal systems could synapse on spinal neurons without sending collaterals to the grey matter. The dendritic arrangement of cells in the upper cervical ventral horn of adult cats have therefore been examined with particular emphasis on their extensions into the surrounding white matter. Using either Golgi staining methods or intracellular injection of horseradish peroxidase (HRP), dendrites of ventral horn neurons were found to extend into all funiculi surrounding the ventral horn. Cells located close to the interface between grey and white matter often had a substantial part of their dendritic trees in the white matter. These dendrites typically had smooth surfaces even when they originated from cells whose dendrites in grey matter were covered by spines and intricate surface specializations.

Using intracellular injections of HRP we found that some white matter dendrites originated from neck muscle motoneurons. These HRP-filled dendrites, as well as unlabelled white matter dendrites, have been further examined at the electron microscopic level. In the ventrolateral and ventromedial funiculi dendrites formed horizontal bands which extended, at right angles, between the long myelinated fibre tracts running rostrally and caudally. Within these bands axodendritic synapses were found which may have been formed by the many small myelinated and unmyelinated axons running parallel to the dendrites. These results indicate that the white matter surrounding the upper cervical ventral horn must be considered as another site of synaptic integration.

1835 PRESYNAPTIC DEPOLARIZATION OF CORTICO-SPINAL AND RUBRO-SPINAL TERMINAL ARBORIZATIONS PRODUCED BY CONDITIONING VOLLEYS TO SENSORY NERVES. P. Rudomín, E. Jankowska+ and J. Madrid+. Department of Physiology and Biophysics, Centro de Investigación del IPN. México 14, D.F. and Department of Physiology, University of Göteborg, Sweden.

Studies on presynaptic depolarization (PD) in the cat spinal cord have been limited to the terminal arborizations of primary afferents. However, there is indirect evidence suggesting that vestibulo-spinal (VS) fibers synapsing with motoneurons are not subjected to PD. This lack of PD could be a general feature of descending fibers in the spinal cord. On the other hand, it is known that stimulation of sensory nerves increases the extracellular K^+ concentration mainly in the dorsal horn (DH) and intermediate nucleus (IN). If (K^+) were the main factor in evoking PD, the fact that VS fibers do not end or course through the DH and IN could explain why the VS fibers are not depolarized by conditioning volleys to sensory nerves. Present experiments were made to analyze PD of other descending fibers and in particular the specificity of its mechanism. We found that the excitability of cortico-spinal (CS) fiber terminals was significantly increased by conditioning volleys to cutaneous nerves, although practically unaffected by volleys to group I muscle afferents. Changes in the excitability of rubro-spinal (RS) fiber terminals showed the same pattern. The excitability of group Ia muscle afferents of extensor muscles terminating in that same neighborhood was markedly increased by conditioning volleys to group I afferents of flexor muscles but not so much by cutaneous volleys, as previously described. Such a differential action speaks of a highly specific organization of the mechanisms leading to PD of RS and Ia axon terminals within the IN. It is more consistent with the idea of a specific transmitter being responsible for the PD rather than electrical field interactions or K^+ accumulation. The latency of the excitability increase of the CS fibers in the DH could be as short as 2.7 ms after cutaneous conditioning and lasted up to 100 ms. The PD of RS terminals in the IN appeared to have a longer latency (7 to 9 ms), suggesting mediation by a greater number of interposed interneurons. The PD of CS fiber terminals in the DH may be explained by a dual mechanism: an early depolarization resulting either from electric field interactions (or K^+ accumulation) and a delayed PD probably resulting from transmitter action.

1836 THE SPECIAL RELATIONSHIPS OF CHICKEN EPENDYMAL CELLS IN THE SPINAL CORD AND CERTAIN BRAINSTEM AREAS. Frances M. Sansone, Dept. of Anat. Sci., Sch. Med., State University of New York at Buffalo, Buffalo, N.Y. 14214

An earlier investigation has shown that glycogen-rich cells surround ependymal cells throughout the entire chicken spinal cord and lower medulla. When the canal opens into the fourth ventricle, these cells assume a ventral midline position immediately deep to the ependymal cells and persist up to the level of the oculomotor nucleus (Sansone, J. Morph. 153:87, 1977). It was observed in that study, that the ventricular ependyma (VE) dorsal to the glycogen area retained the columnar appearance of spinal cord ependyma (SCE). Additional studies were therefore undertaken on the histology, histochemistry and ultrastructure of VE and SCE in young (8-14 day) and adult (1.5 yr.) chickens. SCE are tall columnar cells with basally placed nuclei. These nuclei form two to three layers giving the appearance of a subventricular or stratified epithelium. They are bounded by small basophilic neurons, so one is indeed struck by the similarity to the developing spinal cord. However, no mitotic figures are seen. Toluidine blue semithin sections and alkaline phosphatase studies show capillaries to be present just beneath the ependymal cells. At the ultrastructural level both the VE and SCE cells display basally located spherical or ovoid nuclei and the apical portions are filled with an elaborate Golgi apparatus, many smooth vesicles and large numbers of lysosomes. Rough endoplasmic reticulum and gliofilaments are sparse. A few polysomes are scattered about. Some of the SCE also contain rather large amounts of beta glycogen particles. Rare cilia and irregular margins characterize the luminal surfaces. Below the apical junctional complexes, their lateral borders are replete with complex invaginations very similar to the pattern seen in mammalian tanycytes (Millhouse, Brain-Endocrine Interaction II:3, 1974). A Golgi-Cox impregnation of some of the ependymal cells show them to have a radially oriented tail process which ends around blood vessels in the glycogen areas. These cells seem to fit the classification of ependymal tanycytes (Tennyson and Pappas, J. Comp. Neurol. 123: 379, 1964). Because of the unique arrangement of chicken ependymal cells, it seems plausible to postulate that they either release a substance into the cerebrospinal fluid or transport substances from the fluid to the blood.

Neural processes containing clear synaptic vesicles have been found between ependymal cells of the sacral cord region, but no definitive type synapses have been found. It is assumed that these axons arise from the contiguous small neurons. (Supported by the University of Buffalo Foundation).

1837 RESPONSE OF PRIMARY AFFERENTS TO CHANGES IN EXTRACELLULAR POTASSIUM CONCENTRATION IN THE BULLFROG SPINAL CORD. Sarah A. Shefner and Richard A. Levy. Dept. Pharmacol., Univ. Ill. Med. Ctr., Chicago, IL 60612.

Upon afferent stimulation, K^+ accumulates specifically around primary afferent terminals. This increase in extracellular K^+ concentration ($[K^+]_o$) has been proposed as a mechanism for generation of the dorsal root potential (DRP). This hypothesis assumes that increases in $[K^+]_o$ will substantially depolarize primary afferent terminals. However, measurements on other neuronal preparations show their membrane potentials to be rather insensitive to changes in $[K^+]_o$ comparable to those occurring around primary afferent terminals upon afferent stimulation. It was of interest, therefore, to measure the response of primary afferent terminals to known changes in $[K^+]_o$.

K^+-rich Ringer solutions were superfused over an isolated, hemisected portion of bullfrog spinal cord. Each K^+ concentration was applied until the resulting depolarization of primary afferents reached steady state. This depolarization was recorded with Ag-AgCl hook electrodes on a lumbar dorsal root. The same electrodes were used to record DRP's evoked by stimulation of an adjacent dorsal root.

K^+ dose-response curves showed that only at $[K^+]_o$ values greater than 25 mM did depolarizations approach those predicted by the Nernst equation. At $[K^+]_o$ values below 25 mM, depolarizations were smaller than those predicted by the Nernst equation, with changes in $[K^+]_o$ near rest levels causing only very small depolarizations. Addition of 20 mM Mg^{++} to the superfusate to block any K^+-induced transmitter release, decreased the K^+-induced depolarizations. This suggests that the direct depolarizing effect of physiologically occurring K^+ accumulation around primary afferents may be amplified by K^+-induced transmitter release from nearby neurons. Even in the Mg^{++}-free condition, where both direct and indirect effects of K^+ were present, we found the $[K^+]_o$ required to cause a depolarization equal to the DRP height was significantly larger than the amount of K^+ found (Sykova et al. Brain Res. 106:413, 1976) to accumulate around frog afferent terminals, upon a single afferent volley. However, these workers found high-frequency afferent stimulation could cause K^+ accumulations of up to 9 mM. In our preparation, a change in $[K^+]_o$ of this magnitude causes a large depolarization of the primary afferents, similar in amplitude to the DRP. Taken together, these data indicate that K^+ accumulation is not the sole mechanism for generation of the DRP, but may supplement PAD induced by GABA released at axo-axonic synapses onto the afferent terminal. The contribution of K^+-mediated PAD would be expected to be small for single afferent volleys, but much more significant upon high-frequency afferent activity.

1838 CORRELATIVE STUDIES OF INDIVIDUAL Ia-MOTONEURON PRESYNAPTIC TERMINAL SPIKES AND EPSPs. G.W. Sypert and J.B. Munson. Univ. of Fla. Coll. of Med. and VA Hospital, Gainesville, FL 32610

Electrical potentials in the triceps surae motoneuron pool generated synchronously with action potentials in single medial gastrocnemius (MG) Ia dorsal root afferents were studied in cats, using low impedence bevelled microelectrodes and signal averaging techniques. These potentials were of several types, including 1) presynaptic terminal spikes and 2) EPSPs. Presynaptic terminal spikes were usually a positive-negative sinusoid less than 20 μV peak-to-peak amplitude and about 400 μsec total duration. They were readily recorded in extracellular space and within motoneurons. EPSPs were recorded in 85% of 116 MG motoneurons and in 74% of 65 LG/S motoneurons.

Simultaneous recording of presynaptic terminal spikes and EPSPs permitted correlative studies of these two events. We have been particularly interested in correlates of EPSP latency from the presynaptic terminal spike. This latency is composed of synaptic delay plus electrotonic conduction time from synaptic site to recording site in the motoneuron soma, and thus should relate directly to electrotonic distance from generation to recording site. Also related to this electrotonic distance are dimensions of the EPSP: half width (HW), rise time (RT), amplitude and slope.

Latency was measured from the positive peak of the presynaptic terminal spike to the onset of the EPSP. Mean homonymous latency was 448 μsec (range 260-840); mean heteronymous latency was 463 μsec (range 320-640). Significant linear correlations were found between latency and RT and between latency and HW. Significant logarithmic correlations were found between latency and amplitude and between latency and slope (defined as 10-50% dv/dt). The latency-slope correlation was most powerful (homonymous $r=.65$ $p<.001$); heteronymous $r=.87$ ($p<.0001$). Thus, EPSP latency and slope should provide useful approximations of synaptic location on the some-dendritic membrane, in addition to the widely used parameters of RT, HW and amplitude. These data are also relevant to the possibility of electrical transmission at the Ia-motoneuron synapse. (Supported by VA Hospital Medical Research Service and EY 01264).

1839 PROJECTIONS OF AREA 4 TO THE SPINAL CORD IN SQUIRREL MONKEY (SAIMIRI). Johannes Tigges, Shiro Nakagawa* and Margarete Tigges. Yerkes Regional Primate Res. Ctr. and Dept. Anat., Emory Univ., Atlanta, GA 30322; and Dept. Anat., Wakayama Medical College, Wakayama-shi, Japan.

A single injection of either tritiated proline or a mixture of proline and leucine was made in area 4 of 9 squirrel monkeys. The locus of injections was systematically varied from medial to lateral among animals. The injected volume was 0.2-0.9 µl with a constant ^{3}H concentration of 100 µCi/µl. Following survival times of 2 days, the monkeys were perfused with 10% formalin. Transverse sections of the spinal cords were processed according to routine autoradiographic procedures (Cowan et al., '72). Counts of developed silver grains were made over segments of the lower cervical, lower lumbar and upper sacral cord at a magnification of 1000 X with the aid of a reticule (128 x 128 µm). The majority of silver grains was found over the contralateral side of the spinal cord; however, in sacral segments, the number of grains ipsilaterally to the injected side was also considerably above background level. On the contralateral side, the grains were concentrated over Rexed's laminae V, VI and VII; fewer grains were located over laminae IV and VIII. The number of grains over layer IX was slightly above background. No grains above background level were seen over laminae I, II and III. In cervical and lumbar segments, the ipsilateral projection was restricted to lamina VIII, whereas the termination in ipsilateral sacral segments was more widespread. There were only few direct corticospinal projections to lamina IX, which contained large α-motoneurons. This sparseness of contacts in lamina IX may be indicative of a relatively low degree of skilled manipulative capacities of hands and feet in squirrel monkey. Based on the distribution of silver grains over the white matter of the cord, the efferents of area 4 coursed mainly within the contralateral corticospinal tract; some fibers of this tract apparently recrossed at the level of their termination. The number of radioactively labelled fibers in the ipsilateral tract was small; these fibers seemed to terminate ipsilaterally. In one animal, there was evidence of an anterior tract ipsilateral to the injection. (Supported by USPHS Grant RR-00165 to the Yerkes Regional Primate Research Center.)

1840 TEMPORAL ANALYSIS OF POST TETANIC DEPRESSION OF ANTIDROMICALLY ACTIVATED RENSHAW CELLS: William G. Van Meter. Department of Veterinary Anatomy, Pharmacology & Physiology, Iowa State University, Ames, Iowa 50011

Adult mongrel cats of both sexes were anaesthetised with Dial; a laminectomy performed (S-1 to L-13); the spinal cord transected at L-1/T-13 and preparation made for extracellular recording of Renshaw cell bursts evoked by supramaximal antidromic stimulation of isolated ventral roots (L-7, primarily).

On-line computer analyses of Renshaw cell discharges (1st and Oth order PST histograms) were made. Stimulation rates varied from 10Hz to 50 Hz for durations of 30, 60 and 120 seconds. Post tetanic responses were recorded during the first 60 seconds following tetanic stimulation (recovery stimulation rate of 2Hz).

Post-tetanic potentiation was not seen during these early recovery periods. Depression of bursts was found to be directly related to the duration of tetany at a given frequency, for example at 20Hz for 30 seconds a slight depression of a few seconds was noted while 20 Hz for 60 seconds resulted in depressions of 15-30 seconds. Depression of the post tetanic discharges was also found to be directly related to the degree of inhibition of Renshaw cells during the tetanic stimulation. Recovery of depressed Renshaw cell discharges subsequent to tetany began after a delay of 20-30 seconds and responses to individual stimuli (at 2Hz) began after delays of 50 msec. or greater, again directly dependent on the duration and frequency of stimulation.

1841 STRUCTURE OF THE MICROVASCULATURE IN THE DORSAL ROOT GANGLION OF THE CAT. L.E. Wittmers, Jr.*, R.S. Pozos, and K. Stocker* (SPON: D.J. Forbes). Dept. of Physiology, UMD Med. Sch. & Dept. of Biol., College of St. Scholastica, Duluth, MN 55811.

The rate at which substances reach a given group of cells in a multicellular organism depends upon a multiplicity of factors, a specialized circulation, membrane permeability, circulation flow rates and geometric arrangement of the capillary vessels. The mammalian nervous system is highly sensitive to changes in its supply-removal system by way of the circulation. The present studies are aimed at quantitating the vascular geometry of the dorsal root ganglion (DRG) in an attempt to assist in the estimates of transport to and from this tissue. Colony raised mongrel cats were anesthetized and perfused with Microfil (Canton Biomedical Products) via aortic cannulation. The systemic arterial pressure was maintained within physiologic limits during the Microfil perfusion. The entire spinal cord and associated dorsal root ganglion were removed in block and prepared for light microscopy (formalin fixed, paraffin embedded) and three dimensional visualization (cleared in ethanol-methyl salicylate). Cells and Microfilled vessels were counted on paraffin sections employing an eyepiece grid. Three dimensional vascular casts were photographed through a dissecting microscope. Number of cells and vessels per unit field in the DRG were obtained for cervical (C), thoracic (T), lumbar (L) and sacral (S) cord levels. The data is presented in the following table.

	C (51)#	T (63)	L (300)	S (250)
C/F	73 ± 3 ##	94 ± 4	95 ± 2	51 ± 1
V/F	30 ± 1	22 ± 1	26 ± 1	29 ± 0.5
C/V	2.5 ± 0.1	4.7 ± 0.3	3.0 ± 1	1.8 ± .04

C/F = number of cell per field, V/F = number of vessels per field and C/V = cell to vessel ratio.

\# number of (n) indicates number of fields counted; entries are M ± SEM

± number indicates standard error of the mean

Idealized models for capillary-cell density and arrangement compatible with the above data will be presented along with three dimensional views of the DRG circulation.

1842 ULTRASTRUCTURAL CHANGES CAUSED BY SPINAL CORD ISCHEMIA. Shokei Yamada*, Robert L. Schultz*, (SPON: G.M. Austin) Sect. of Neuros., & Dept. of Anatomy, Loma Linda Univ., Loma Linda, CA., 92350

It is well known that ischemia of the spinal cord results in paraplegia in humans. Experimental paraplegia in animals has been produced by occlusion of the descending aorta by, Yamada, et al.* They reported changes in cytochrome a,a_3 and spinal cord potentials in response to posterior root stimulation in experimental cat spinal cord ischemia. The authors conducted electron microscopic studies on the spinal cord which had undergone ischemia produced by occlusion of the descending aorta for periods of 3, 5, 10, and 15 minutes. The spinal cord was perfused with a cacodylate-buffered mixture of glutaraldehyde, formaldehyde, and acrolein, through the descending aorta 30 minutes after the completion of the occlusion. There were minimum changes in the mitochondria and dendrites in the cord which underwent 10 minute occlusion. However, after the 15 minute occlusion there were marked changes in mitochondria, neurotubules, and endoplasmic reticulum. These changes involved the findings of abnormally shaped mitochondria and myelin figure formation from mitochondria. Neurotubules were decreased in amount and this was most obvious in the larger dendrites. The cisternae of the endoplasmic reticulum were obliterated in some areas, and the membranes close together. However, 3 and 5 minute ischemic cords showed little change in ultra structure. After 10 minute occlusion detectable changes were sometimes observed in mitochondrial structure and in the quantity of neurotubules present. It is noteworthy that no changes were seen in endothelial tight junctions at any time. These changes are confirmative of *in vivo* experiments involving marked changes in redox level of cytochrome a,a_3 and in interneuron activity of the spinal cord produced by 15 minute occlusion of the descending aorta.

* S. Yamada, et al.: Metabolic and functional changes of spinal cord in experimental ischemia. Abstract # 1635, Society for Neuroscience, 7th Annual Meeting, Anaheim, CA., Nov. 6-10, 1977.

1843 Online, real-time computer monitoring of single unit activity in the mammalian spinal cord. Robert P. Yezierski, Richard T. Gumbel* and Paul B. Brown. Dept. of Physiology and Biophysics, West Virginia University Medical Center, Morgantown, WV 26506.

Monitoring the activity of small neurons in the mammalian central nervous system is a difficult task due to the small amplitude spikes produced by these cells. Conventional recording techniques used in combination with averagers, special electrodes and off-line data analysis have been used with some success in characterizing the functional importance of small neurons in the spinal cord. In an attempt to simplify the process of characterizing peripheral input influencing small neuronal elements in the dorsal horn an online, real-time, computer aided wave form recognition technique has been developed. This technique uses a FORTRAN program running on a PDP-12 computer to automatically select template wave forms from digitized multi-unit data. Values representing sequential analog voltages of a single template are then used by an assembler program for real time wave form matching with incoming data. The initial application of this technique has been the tracking of spike amplitudes as a function of depth along an electrode track. In this process templates representing spikes of single units are obtained at different dorsoventral levels. Templates at adjacent electrode depths which possess similar shapes and similar physiological characteristics, e.g. receptive field and afferent input, are compared to determine the level at which the amplitude reaches a maximum. The depth at which a template attains maximum amplitude is marked by the deposition of ferric ions. Amplitude profiles have been obtained in the lumbar cord for neurons in laminae I-V. Results indicate that neurons in deeper laminae can be reliably tracked for greater distances than neurons in more superficial laminae, suggesting that the amplitude profile for a given unit provides an indication of cell size.

This work was supported by USPHS grant #NS12076 awarded to P. B. Brown.

1844 EVALUATION OF DORSAL COLUMN STIMULATION IN THE TREATMENT OF CHRONIC PAIN. Ronald F. Young, Division of Neurosurgery, UCLA School of Medicine, Harbor General Hospital Campus, Torrance, CA 90509.

The proposal of the gate theory as a neurophysiological mechanism of pain perception stirred considerable enthusiasm for the clinical treatment of patients with chronic pain. Further study indicated inhibition of some cells in laminae I, IV and V of the dorsal horn, thought to be involved in nociception, by dorsal spinal cord stimulation. The idea that electrical stimulation of inhibitory portions of the nervous system might abolish pain without altering normal sensory function led to the use of dorsal spinal cord stimulation (DCS) in humans for the treatment of chronic intractable pain.

This report reviews fifty-one patients with chronic pain who underwent dorsal spinal cord stimulation between 1972-1977 and have been followed for a mean of 38 months (range 12-67 months). Chronic pain in these patients was related to lumbar disc disease, previous surgical procedures, multiple sclerosis, spinal cord injury, cancer, and peripheral vascular disease. Thorough neurological evaluation, psychological testing, transcutaneous electrical stimulation and in some cases temporary dorsal spinal cord stimulation via percutaneously implanted leads were employed in selection of these patients from a much larger group with chronic pain.

Immediately after DCS implantation 47% of patients reported that they had essentially complete pain relief but by three years this had decreased to 8%. No patient followed four years or longer reported complete pain relief. Thirty-three% of patients were able to discontinue regular narcotics usage for pain relief after DCS. Only 16% of patients were able to return to gainful employment or full physical activity after DCS. Although no major complications occurred a total of thirty-three operative procedures were required in 21 patients to correct relatively minor problems related to stimulator implants. The conclusion is proposed that dorsal spinal cord stimulation is a relatively ineffective method for treatment of chronic pain. The relationship of this low success rate to the treatment of chronic pain in general and to the theories on which it was originally based will be discussed.

SYNAPTIC TRANSMISSION

1845 EFFECT OF AMMONIUM IONS ON IPSPS IN THE HIPPOCAMPAL SLICE
B. E. Alger and R. A. Nicoll, University of California, San Francisco

Ammonium (NH_4^+) acetate and chloride have been shown to reduce or eliminate hyperpolarizing IPSPs in several systems, including spinal motoneurons (MNs) (Lux 1972), trochlear MNs (Llinas, et al. 1974), neocortical cells (Raabe and Gumnit, 1975) and crayfish stretch receptor neurons (Meyer and Lux, 1974). However, doses of NH_4^+ effective on these neurons (i. e., 1-4mM/Kg) have little effect on hippocampal IPSPs in vivo (Eccles, et al. 1977). We have reexamined the action of NH_4^+ on hippocampal pyramidal cell IPSPs using the in vitro hippocampal slice preparation. Direct measurements demonstrated turnover times in the slice chamber are 95% complete in about 2 min and equilibration within the slice itself occurs at about 3 min. After impaling a CA1 neuron with a potassium methysulfate filled electrode, NH_4^+ was applied by perfusion at concentrations from 4-8mM. E_{IPSP} was determined by applying hyperpolarizing current pulses through the electrode. Because the presence of EPSPs can complicate measurements of E_{IPSP}, pentobarbital (10^{-4}mM) was used to prolong the IPSP and permit IPSP measurements to be made at times when EPSPs would be minimal. Pentobarbital also reduced the seizure activity occasionally seen in NH_4^+. All doses of NH_4^+ had a generalized depressant action on excitability in pentobarbital, resulting in abolition of the field potential population spike within 8 min at 8mM. Perfusion with 4mM NH_4^+ for at least 10 min had little effect on E_{IPSP}, while perfusion for 20 min caused a slight and variable reduction (ca.10-20%). 8mM NH_4^+ caused a rapid (<5min) and reversible depolarization (ca. 5 mV) and a reduction of about 50% in E_{IPSP}. A similiar depression of double shock inhibition of field potentials, which has the same time course as the IPSP recorded intracellularly, was not seen with 8mM NH_4^+ at times when NH_4^+ had reduced the original population spike amplitude by 75%. In conclusion these results indicate that doses of NH_4^+ which virtually abolish hyperpolarizing IPSPs in other systems (e.g. 5mM in stretch receptor causes a 90% block) have little effect on hippocampal IPSPs. However, considerably higher doses can reversibly reduce E_{IPSP} in this system. The failure of NH_4^+ to alter double shock inhibition of the field potentials suggests that either the conductance increase during the IPSP, rather than the hyperpolarization, is responsible for the inhibition, or that IPSPs in unimpaled cells are not hyperpolarizing.

1846 BIOCHEMICAL CHARACTERIZATION OF CYTOCHEMICALLY LOCALIZED CYCLIC NUCLEOTIDE PHOSPHODIESTERASE.
Marjorie A. Ariano and M. Michael Appleman*. Molecular Biology, Ahmanson Center for Biological Research, U.S.C., Los Angeles, CA 90007.

Cyclic nucleotide phosphodiesterase (PDE) activity has been cytochemically visualized at postsynaptic sites of asymmetrical terminals within the neuropil of rat corpus striatum and cerebral cortex. Formation of an electron-dense PDE reaction product occurs following incubation of 100 µM tissue slices of aldehyde-fixed brain with cyclic 3',5'-guanosine monophosphate (cyclic GMP) or cyclic 3',5'-adenosine monophosphate (cyclic AMP) as substrates. Visualization of the cyclic GMP PDE activity requires the addition of calcium and a heat-stable protein activator factor to the incubation medium.

PDE has been shown to exist in multiple forms which have different substrate specificities and kinetic properties, and can be differentially modulated. DEAE cellulose chromatography of extracts of both cortex and caudate, prepared by homogenization, sonication, and centrifugation shows the presence of three discrete active fractions. The first active fraction is a cyclic GMP-specific phosphodiesterase, requiring calcium and a protein activator for full activity. This enzyme is selectively inhibited by the phenothiazine, trifluoperazine, but the inhibition can be overcome by increasing the amount of protein activator. The second active DEAE fraction is a cyclic GMP-stimulated cyclic AMP PDE and the third is cyclic AMP-specific. Neither the second nor the third PDE fractions are activated by calcium and protein activator or significantly inhibited by trifluoperazine.

Kinetic analysis of tissues processed for electron cytochemistry demonstrates the presence of only one PDE form, with properties similar to the first DEAE fraction of fresh cortical or striatal homogenates. The surviving PDE form is stimulated by protein activator and calcium, and is inhibited by trifluoperazine.

Localization of phosphodiesterase activity at synaptic terminals supports the contention that cyclic nucleotides are involved in neurotransmission. Biochemical demonstration that this enzyme preferentially hydrolyzes cyclic GMP suggests that the guanosine nucleotide may have an important function in this neural process.

1847 FACILITATION OF TRANSMITTER RELEASE AT CRUSTACEAN SYNAPSES
G. D. Bittner, J. P. Segundo, and D. A. Baxter*
Dept. of Zoology, Univ. of Texas, Austin, Texas (78712)
and Dept. of Anatomy, UCLA, L.A., Calif. (90024)

We find that restricted sets of synaptic terminals made by the excitor axon on crayfish (Procambarus clarkii) opener muscles of the cheliped show very different amounts of facilitation for different stimulus rates and for different stimulus patterns at a given rate. Furthermore, the amount of facilitation at a given set of synapses varies according to the way in which "facilitation" is measured. For example, very different values for "facilitation" may be obtained if one measures

(1) the amplitude of the nth pulse with respect to the amplitude of the first pulse in a train; or
(2) the mean amount of transmitter released per impulse in a train of pulses compared to the amount released by 1Hz stimulation; or,
(3) the peak depolarization produced by a given patterned train compared to the peak produced by 1Hz stimulation or by a constant interval train at any given frequency.

Finally, a single inhibitor axon may greatly reduce transmitter release and facilitation of the excitor axon via its pre-synaptic effect on the excitor axon. However, if the inhibitor and excitor axons are stimulated together at an optimum timing for pre-synaptic inhibition and the inhibitor stimulation is suddenly stopped, the excitor axon at the next pulse in the train often releases the same amount of transmitter it would have released if only the excitor alone had previously been stimulated. This result implies that facilitation process is much more dependent upon the pattern than the amplitude of the pre-synaptic stimulation. This result is in agreement with facilitation at squid synapses (Charlton and Bittner, J. Gen. Physiol., in press).

1848 DEPOLARIZATION-RELEASE COUPLING AT A SYNAPSE LACKING REGENERATIVE SPIKES.
A. R. Blight and R. Llinás. Dept. Physiology and Biophysics, N.Y. Univ. Med. Ctr., 550 First Ave., New York 10016.

An investigation was made of the interaction between the "non-spiking" stretch receptor neurons of the crab (Callinectes) and the coxal promotor motoneurons which are activated in the stretch reflex. A parallel ultrastructural study demonstrated that the sensory fiber (T fiber) establishes synaptic junctions with the motoneuron dendrites within the thoracic ganglion, the presynaptic region being a simple cylinder 40-60µ in diameter and c. 200µ in length, with large stores of synaptic vesicles at its periphery, opposite the postsynaptic complex of motoneuron dendrites. These synapses are capable of continuous transmission over many seconds without depletion or desensitization, thus allowing the study of the functional linkage between the stretch reflex and the depolarization-release coupling at the junction. Analysis of transmission characteristics with simultaneous intracellular pre- and postsynaptic recording and presynaptic current-injection showed the depolarization-release coupling to be similar to that in the squid giant synapse. The relationship between pre- and postsynaptic levels of depolarization (with or without TTX poisoning of the voltage-dependent sodium conductance) follows the same bell-shaped curve, with quantitatively similar levels to those in the squid of onset, peak-release, and suppression-potential (Llinás et al., Proc. Natl. Acad. Sci. USA 73: 2918-2922, 1976). Also, in agreement with these findings, a maintained, low-level, presynaptic depolarization was found to give a linearly rising post-response. Peripheral conduction in the sensory fiber has been thought to occur with simple decremental conduction, but a graded sodium-dependent voltage transient in the fiber to step-depolarization may serve to compensate the capacitative distortion of the signal which arrives at the synapse. A voltage-dependent calcium conductance at the synaptic terminal was revealed by the intracellular injection of tetraethylammonium which allowed the development of regenerative calcium spikes with large depolarizing current-pulses. (Supported by USPHS Research Grant NS-13742 from NINCDS and by a NATO fellowship from the Science Research Council).

1849 MODIFICATION OF SYNAPTIC TRANSMISSION AND BURSTING PATTERNS IN APLYSIA CALIFORNICA BY AIR PRESSURE TO 10 ATMOSPHERES. Howard J. Bryant and James E. Blankenship. Marine Biomedical Institute and Department of Physiology and Biophysics. University of Texas Medical Branch, Galveston, TX 77550.

The onset of the symptoms of neurological dysfunction in man can occur at hyperbaric air pressures from 2 to 6.4 atmospheres absolute (ATA). These readily observable symptoms, such as those of nitrogen narcosis, may be ultimately related to alteration in the passive or active properties of the excitable membrane.

To determine if 10 ATA of air pressure can alter behavior at the cellular level we examined the unitary excitatory post synaptic potential (EPSP) produced in cell R15 of Aplysia californica when the right pleurovisceral connective is stimulated. The cell was hyperpolarized to -100 mV by passing current through one of two intracellular microelectrodes to supress its characteristic bursting pattern. Trains of 100 stimuli at 2 Hz were presented to the right connective and EPSP amplitudes were measured in the soma. Facilitation ratios were calculated as the ratio of the amplitude of the 2nd EPSP to that of the first ($f_2 = EPSP_2/EPSP_1$) and the 100th to that of the first ($f_{100} = EPSP_{100}/EPSP_1$). These experiments were repeated at 10 ATA of air pressure, in a 2% oxygen 98% nitrogen gas mixture, and in a 1/3 Ca^{++} solution. Application of pressure had no effect on the initial facilitation f_2. However, the facilitation of the 100th EPSP, f_{100}, was increased by 17 ± 5% ($\bar{X}$ + SE). Similar results were obtained with pressure in 1/3 Ca^{++} solutions and with 2% oxygen 98% nitrogen as the pressure medium. Time to peak of all the EPSP's was unaltered by pressure.

The bursting behavior of R15 was also altered by the application of pressure. The cell was penetrated with one microelectrode and allowed to produce its characteristic bursting pattern without stimulation or artificial polarization. The number of action potentials per burst was reduced by 25 ± 4% ($\bar{X}$ ± SE) at 7.8 ATA of air. Concurrently, the duration of the burst was reduced 31 ± 4%. The interval between bursts was also reduced 29 ± 4%. These parameters returned to control values upon lowering the pressure to 1 ATA.

1850 INCREASE IN CYCLIC AMP IN RAT HYPOTHALAMUS FOLLOWING THE ADMINISTRATION OF 5-HYDROXYTRYPTOPHAN. M. C. Bundman* and R. A. Browning (SPON: R. P. Lehr, Jr.). Southern Illinois University School of Medicine, Carbondale, Ill. 62901.

In recent years considerable evidence has accumulated implicating cyclic AMP in the post-junctional receptor events of several neurotransmitters including norepinephrine and dopamine. In the case of serotonin, however, the evidence is far less conclusive. Most studies have shown little or no stimulation of cyclic AMP production in response to serotonin, although a recent study demonstrated the presence of serotonin sensitive adenylate cyclase activity in some synaptosomes (Pagel et al., Life Sci. 19, 819, 1976). The present study was undertaken to further investigate the potential role of cyclic AMP in the serotonin mediated post-junctional events.

Animals were made supersensitive to serotonin in order to increase the likelihood of detecting changes in cyclic AMP levels. Trulson et al. (J. Pharmacol. Exp. Ther. 198, 28, 1976) demonstrated a marked supersensitivity of central serotonin receptors in response to low doses of 5-hydroxytryptophan (5-HTP) following destruction of serotonergic nerve terminals by 5,7-dihydroxytryptamine (5,7-DHT).

Two hours following pretreatment with the catecholamine uptake inhibitor, protriptyline (20mg/kg, i.p.), male Sprague-Dawley rats (190-200g) were treated intraventricularly with 5,7-DHT (150µg) or vehicle. Ten to twelve days later animals were given an intraperitoneal injection of either 5-HTP (100mg/kg) or saline and sacrificed by focused microwave irradiation to the head. Endogenous cyclic AMP levels were measured by a modification of the ^{125}I radioimmunoassay of Steiner et al. (J. Biol. Chem. 249, 1121, 1972).

When compared with controls, 5,7-DHT treated rats exhibited a 100% increase ($p<0.001$) in hypothalamic cyclic AMP 15 min after the administration of 5-HTP. This increase was associated with a time dependent, concomitant increase in brain serotonin. In contrast, 5-HTP failed to produce an increase in the concentration of cyclic AMP in the caudate nucleus (an area with fewer serotonergic nerve endings). Moreover, rats not treated with 5,7-DHT failed to exhibit an increase in cyclic AMP in either hypothalamus or caudate nucleus. These findings show that 5-HTP increases cyclic AMP in the hypothalamus. However, further studies are needed to establish whether this is due to a direct effect of serotonin on its receptors.

1851 EFFECTS OF HALOTHANE ON SYNAPTIC TRANSMISSION IN A MAMMALIAN SUPERIOR CERVICAL GANGLION. Daryl Christ* (SPON: T.W. Schoultz). Dept. Pharmacology, University of Arkansas for Medical Sciences, Little Rock, AR 72201.

The mechanism of action of halothane on single ganglion cells in the rabbit superior cervical ganglion, in vitro, was explored with microelectrode techniques. Halothane (0.1 - 1 mM) reduced the amplitude of subthreshold excitatory postsynaptic potentials (e.p.s.p.s) with no significant changes in the times of rise or half-decay of the e.p.s.p.s. If the e.p.s.p. was suprathreshold, halothane reduced the e.p.s.p. to subthreshold amplitudes; although the concentration required depended on the safety factor of transmission at that synapse. At the concentration range which reduced the e.p.s.p., halothane had no effect on the amplitude or time-course of the action potential which was evoked by direct stimulation through the recording electrode. Also, there were no changes in the hyperpolarizing electrotonic potential, indicating that halothane had no effect on the time-constant or effective membrane resistance of the postganglionic cell membrane. Changes in the resting membrane potential did occur, but they were small and inconsistent. Even at concentrations of halothane in the range of 1 to 5 mM, there were only small changes in the properties of the ganglion cell membrane.

Acetylcholine, which was added to the physiological solution, produced a depolarization which was concentration dependent. Halothane in concentrations which reduced the e.p.s.p., also reduced the amplitude of the depolarization by ACh, but prolonged the duration of the response. If the depolarization by ACh was large, it was followed by a hyperpolarization. Halothane also reduced the hyperpolarizing phase of the ACh action.

These results indicate that the effects of halothane on the superior cervical ganglion are due to alterations of the processes of synaptic transmission. One effect would appear to be a depression of the postsynaptic sensitivity to the neurotransmitter. (Supported by NIH Grant NS-10393.)

1852 PURIFICATION OF A SYNAPTIC VESICLE-BOUND PROTEIN MEDIATING CALCIUM DEPENDENT VESICLE NEUROTRANSMITTER RELEASE AND PROTEIN PHOSPHORYLATION. Robert J. DeLorenzo, Steven D. Freedman*and Wendy B. Yohe*. Dept. of Neurol., Yale Med. Sch ., New Haven, CT. 06510.

An isolation procedure was developed in this laboratory for obtaining highly enriched, more physiologically active synaptic vesicles that could be maintained in vitro for biochemical or physiologic studies (BBRC 80: 183, 1978). This preparation was employed to demonstrate that calcium simultaneously stimulated synaptic vesicle release of neurotransmitters and phosphorylation of specific vesicle proteins, especially proteins DPH-L and DPH-M (Neurol. 28: 367, 1978; BBRC 80: 183, 1978; Epilepsia 18: 357, 1977). The results suggested that calcium-dependent vesicle protein phosphorylation may play a role in mediating neurotransmitter release and other aspects of vesicle function. This investigation was initiated to study how different preparation conditions could affect calcium's ability to stimulate neurotransmitter release and protein phosphorylation in synaptic vesicle preparations. Washed vesicle fractions were treated under numerous conditions to attempt to dissociate calcium's ability to stimulate release and phosphorylation from the vesicles. Treating the vesicles with EDTA and homogenization and isolating them by centrifugation removed the ability of calcium to stimulate release and phosphorylation without significantly affecting the norepinephrine concentration of the treated vesicles. When the solubilized vesicle fraction was added back to the treated vesicle preparation, the ability of calcium to stimulate release and phosphorylation was restored. A highly purified activator protein was isolated from the solubilized fraction by column chromatography. This protein restored the ability of calcium to stimulate neurotransmitter release and protein phosphorylation when added to the treated vesicle preparation. The binding of this activator protein to the vesicles was dependent upon the presence of physiologic intracellular concentrations of magnesium ions in the isolation media, accounting for the variable degree of removal of this protein from vesicles prepared by conventional techniques. The calcium and activator protein-dependent stimulation of protein phosphorylation was shown to be mediated by the activation of a vesicle-bound protein kinase that had essentially identical substrate requirements for activation as those for initiating norepinephrine release. The results of this investigation are consistent with and expand the initial hypothesis from this laboratory that the calcium and vesicle-bound activator protein dependent phosphorylation of specific vesicle-associated proteins may be the underlying biochemical mechanism mediating some of the physiologic effects of calcium on neurotransmitter release and synaptic vesicle function.

1853 INHIBITORY TRANSMISSION IN RAT CORTICAL NEURONS IN CULTURE. Marc A. Dichter and Bernard Biales*. Department of Neurology, Beth Israel Hospital and Harvard Medical School, Boston, Mass. 02215.

Rat embryo cortical neurons maintained for 3 - 8 weeks in dissociated cell culture form abundant inhibitory (as well as excitatory) synaptic connections with one another. IPSPs are associated with an increased conductance to Cl and can be inverted by neuronal hyperpolarization to beyond approximately -70 to -80 mV. GABA applied by iontophoresis or mini-perfusion also causes an increased Cl conductance in all neurons tested. Threshold GABA concentration appears to be ca. 2 - 4 uM. Near saturation (exceeding the limits of measurement) occurs at ca. 50 uM. Glycine produces a similar effect at 20 - 50 times higher concentrations but with much greater variability. Some neurons are insensitive to even 1 mM, although neurons insensitive to glycine may still exhibit large IPSPs.

IPSPs are inhibited by 1 uM bicuculline or 10 uM picrotoxin, but are also markedly reduced by 10 uM strychnine. Bicuculline blocks GABA effects but not glycine. Strychnine, at a level which blocks IPSPs, blocks GABA effects on these cells.

Bathing the neurons in 10 uM GABA reversibly abolishes synaptic activity, although neurons may have high resting potentials and good action potentials. Bathing the cells in 100 - 1000 uM glycine did not abolish synaptic potentials.

Our physiological and pharmacological data, in conjunction with the autoradiographic and biochemical support for the GABA system (Snodgrass et al, this meeting) indicate that GABA is the predominant inhibitory transmitter utilized by mammalian cortical neurons in vitro.

1854 ELECTROPHYSIOLOGICAL AND PHARMACOLOGICAL CHARACTERIZATION OF THE DISYNATIC MEDIATION OF THE SLOW INHIBITORY POSTSYNAPTIC POTENTIAL IN THE SYMPATHETIC GANGLIA OF RABBITS. N. J. Dun and A. G. Karczmar, Dept. Pharmacol., Loyola Univ. Stritch Sch. Med., Maywood, Ill 60153.

Acetylcholine (ACh) was applied electrophoretically to cells of isolated rabbit superior cervical ganglia, and the response was recorded by means of intracellular recording techniques. In the presence of d-tubocurarine (5 μM), ACh applied by repetitive current pulses (10-20 Hz, 10 msec/pulse, 1-2 sec) elicited three distinct membrane potential changes: a slow depolarization, a slow hyperpolarization, or a biphasic response consisting of an initial hyperpolarization followed by a depolarization. Atropine (1 μM) blocked both the depolarizing and hyperpolarizing response to ACh. On the other hand, superfusion with a low Ca/high Mg solution, tetrodotoxin (0.1 μM), haloperidol (0.1 μM) or phenoxybenzamine (1 μM) selectively and reversibly abolished ACh-induced hyperpolarization without appreciably affecting the depolarization. The membrane resistance remained relatively constant during the course of hyperpolarization. Application of steady depolarizing and hyperpolarizing currents decreased and increased, respectively, the amplitude of hyperpolarization. These results demonstrate that hyperpolarization elicited by iontophoretic application of ACh is electrophysiologically and pharmacologically similar to the slow inhibitory postsynaptic potential (slow ipsp) induced by nerve stimulation. Furthermore, the results provide evidence that the slow ipsp is mediated by a cholinoceptive adrenergic interneuron interposed between the preganglionic fibers and principal ganglion cells; when activated muscarinically by cholinergic fibers the interneuron liberates a catecholamine, possibly dopamine, which then acts postsynaptically in the production of slow ipsp.

This study is supported in part by NIH Grant NS 6455.

1855 PURINERGIC MODULATION OF MONOSYNAPTIC RESPONSES IN RAT HIPPOCAMPAL SLICES. T. Dunwiddie, B. Hoffer* and G. Lynch. Dept. Pharm., Univ. Colorado Med. Center, Denver, CO 80262 and Dept. Psychobio., Univ. California, Irvine, CA 92717

The electrophysiological actions of purine nucleotides and nucleosides were studied utilizing the in vitro hippocampal slice preparation. Adenosine and related agonists were found to inhibit both the spontaneous and evoked unit activity of CA1 pyramidal cells. A marked reduction in the amplitude of synaptically evoked responses, evoked via stimulation of the Schaffer collateral-commissural afferents to CA1, was produced by these same drugs. The stereospecificity of these effects corresponds to that observed in biochemical studies, in that the ℓ-enantiomer of N^6-phenylisopropyl adenosine was considerably more potent than the corresponding d-form. Superfusion of methylxanthines, which block adenosine receptors, or adenosine deaminase, which catabolizes extracellular adenosine, profoundly antagonizes depressant adenosine responses. Both methylxanthines and adenosine deaminase augment the amplitude of the evoked field potentials when administered alone. Hexobendine, a putative adenosine uptake blocker, had little effect on synaptically evoked responses. In contrast to the depressant effects of adenosine superfusion, 8-parachlorophenylthio- or 8-bromo-cylic 3'5' guanosine monophosphate reliably and reversibly increased the amplitude of evoked field potentials. None of the agents listed above appeared to alter long-term potentiation induced by tetanization of the Schaffer collateral pathway at 400 Hz.

It is concluded that inhibitory "adenosine" receptors are present in the monosynaptic Shaffer-commissural system, and that endogenous release of adenosine or adenine nucleotides may serve to reduce the efficacy of synaptic transmission along this central pathway. Cyclic guanine nucleotides may mediate another type of modulation which results in increased amplitude of synaptic responses. However, the mechanisms whereby these modulatory influences are brought about remain to be determined.

1856 RESPECTIVE ROLES OF ELECTRICAL AND CHEMICAL FEEDFORWARD INHIBITIONS IN REGULATING RESPONSES OF THE GOLDFISH MAUTHNER CELL TO EXCITATORY AFFERENTS. Donald S. Faber and Henri Korn. N.Y.S. Res. Inst. on Alcoholism and Dept. of Physiology, SUNYAB, Buffalo, N.Y. and INSERM U3, CHU Pitie-Salpetriere, Paris, France.

Field effect and chemical inhibitions of the goldfish Mauthner cell (M-cell) are mediated by impulses in the same interneurons (PHP cells) of its recurrent collateral network (Science, 1976, 194: 1166). The hypothesis that these interneurons also exert a feedforward inhibition of the M-cell has been confirmed by comparing their intracellularly recorded responses to stimulations of the ipsilateral posterior eighth nerve, which has well-established electrotonic and chemically mediated excitatory inputs to the latter. For standardization, stimulus strengths were normalized with respect to that required for M-cell orthodromic activation (1.0T).

Eighth nerve stimuli evoked both electrical and chemical inhibitions of the M-cell: i) the electrical component is a short latency (0.25 msec) extrinsic hyperpolarizing potential (EHP) recorded extracellularly in the M-cell axon cap. Its threshold was at 0.2-0.25T, and it was maximal in amplitude (6-8 mV) with stimulus strengths of 1.0T or less. ii) the later chemically mediated inhibitory postsynaptic potential (IPSP) had a similarly low threshold, but its stimulus-response characteristics were not determined as it was masked by the simultaneously occurring monosynaptic EPSPs. Threshold intensity for the excitatory responses was also comparable to that of the inhibitory ones, but with greater stimulus strengths, EHP amplitude increased more sharply. Since EHP peak time (0.65 msec) is intermediate between those measured for the electrotonic and chemical excitatory components (0.35 and 1.0 msec, respectively), the field effect inhibition truncates M-cell excitation at intensities below 1.0T and may even produce a transient net membrane hyperpolarization. During the same experiments 80% of the PHP cells recorded intracellularly fired at a much lower stimulus (0.3-0.6T) than did the M-cell, and the latency of their activation corresponded to that of the EHP, a finding consistent with the postulate that their orthodromic impulses mediate at least a portion of the afferent inhibitions. Finally, simultaneous intracellular recordings from the M-cell and these presynaptic neurons provide evidence that common afferent fibers excite both: auditory stimuli subthreshold for M-cell activation frequently evoke repetitive firing in the interneurons. In conclusion, these findings suggest a functional role for the feedforward inhibitory network. The M-cell initiates a high threshold and extremely rapid startle response to auditory stimuli. The electrical and chemical afferent inhibitions would both contribute to this high threshold property, with the speed of the first component balancing that of the electrotonic excitation of the M-cell

(Supported in part by NIH Grant No. NS-12132).

1857 IONIC BASIS OF PRESYNAPTIC INHIBITION AT THE CRAYFISH CLAW OPENER. Paul A. Fuchs. Neuroscience Program, Stanford University, Stanford, California 94305.

The opener muscle of the crayfish claw is innervated by only two axons, an excitor and an inhibitor. The inhibitor axon innervates not only the opener muscle fiber, but the terminals of the excitor axon as well; thus providing both post- and presynaptic inhibition. Intracellular recording from the excitor axon on the surface of the opener muscle reveals hyperpolarizing IPSPs of 100 μV amplitude and 80 msec duration in response to action potentials in the inhibitor. The membrane potential of the axon can be varied by passing current through a suction electrode placed over the opener nerve near the intracellular electrode. Using this technique, it is possible to obtain a reversal potential for the IPSP in the excitor axon. For 20 cells the reversal potential was 5.37 ± 1.68 mV (mean ± s.d.) hyperpolarized to the 80 mV rest potential. To learn the ionic basis of the IPSP, the reversal potential was determined while bathing the claw in saline containing varied concentrations of potassium and chloride. Reducing external chloride from 240 to 10 mM caused a 10 mV depolarizing shift in the reversal potential, bringing it above rest. A 10-fold change in extracellular potassium (from 1 to 10 mM) produced a 25 mV depolarizing shift in the reversal potential. Thus the reversal potential of the presynaptic IPSP depends on external potassium as well as chloride, suggesting that GABA (the inhibitory transmitter) activates both conductances during inhibition of the excitor. In contrast, the reversal potential of the postsynaptic IPSP shows a 35 mV depolarizing shift for the same chloride concentration change, and little or no dependence on the extracellular potassium concentration. This confirms previous descriptions of the postsynaptic IPSP as primarily a chloride conductance increase. It is intriguing that the opener inhibitor produces different synaptic responses on two different cells. There is an interesting correlation between this ionic differentiation and pharmacological differences between pre- and postsynaptic inhibition at this junction. (Dudel and Hatt, Pflügers Arch. 364: 217-222, 1976.; Marder and Paupardin-Tritsch, J. Physiol in press, 1978.)

1858 MEMBRANE POTENTIAL EFFECT ON INHIBITORY POSTSYNAPTIC CURRENTS OF APLYSIA. Daniel Gardner. Dept. of Physiology, Cornell Univ. Medical College, New York, N.Y. 10021.

Gardner and Stevens have previously reported that postsynaptic currents (PSC) underlying a class of inhibitory synapses in the buccal ganglia of Aplysia californica decay as a single exponential which is invariant with membrane potential (V_m) from -150 to -40mV. We ascribed the PSC decay to voltage-independent relaxation of open postsynaptic channels. Adams et al have recently reported smooth logarithmic voltage-dependence of PSC decay from -80 to -10mV in A. juliana and dactylomela. To reconcile these data, I have re-examined PSC decay over the range -150 to 0mV in A. californica. Two-electrode clamp currents were Bessel filtered at 1 kHz and fitted to exponentials to determine PSC decay time constant τ. From -150 to -40mV, τ =19±7msec (n=57) did not vary with V_m. At more depolarized V_m, input resistance decreased dramatically. In addition, many cells showed a) faster PSC decay b) decay faster than exponential, in some cases with undershoot, and/or c) decreased peak conductance. Three sets of experiments were performed to see whether these effects represented either V_m-dependent PSC relaxation, or else an artifact of remote membrane poorly clamped at the low R_{in} of depolarized levels: 1) Current pulses were injected into the cell, causing voltage relaxations which decayed faster (including undershoot), at -15 and -25mV than at -135mV. 2) TEA was injected into the postsynaptic neuron to block delayed rectification which might be activated by a poorly-controlled remote synapse; TEA reduced the decrease in R_{in} with only slight effect on PSC τ. 3) The decay seen at hyperpolarized V_m might represent uncontrolled slow axonal charging from a fast remote synaptic current. To test this, step commands across the reversal potential were given during PSC. Currents reversed direction and relaxed consistent with the new V_m, showing that recorded current decay represents PSC relaxation, rather than charging of intervening membrane. I conclude that the PSC decay seen at hyperpolarized V_m shows the true time course of the synaptic conductance. At depolarized V_m, clamp control is poor due to decreased R_{in}, and the faster non-exponential decay seen includes superimposed non-synaptic inward current, perhaps resulting from IPSP-induced removal of Na-inactivation. Supported by NIH-NINCDS grant NS11555 and RCDA NS00003.

1859 STIMULUS-SECRETION COUPLING: ELECTROPHYSIOLOGICAL AND MICROSCOPIC STUDIES OF GIANT EXOCRINE GLAND CELLS. James M. Goldring* and Stanley B. Kater. Dept. Zool, Univ. of Iowa, Iowa City, Iowa 52242.

We have studied stimulus-secretion coupling in the salivary gland of the slug, Ariolimax californicus. Histological examination of the gland has demonstrated at least four secretory cell types based on cell size and secretory granule size and staining characteristics. Of particular interest is the finding that many of the cells are 80-120 μm in diameter and contain 6-10 μm secretory granules, thus allowing optical and electrophysiological techniques to be applied simultaneously. Cells in the intact gland have been studied with standard electrophysiologic techniques. Many cells have resting potentials of 60-80 mV and generate all or none, over shooting action potentials. Action potentials are maintained in media containing Ca ions but not Na and are abolished in media containing Na but not Ca. In addition, the spike is reversibly abolished when 10 mM Co is added to normal Ringer (both Na and Ca present). These data suggest that during the rising phase of the action potential Ca ions are the predominant current carrier.

We have also isolated single cells by enzymatic digestion of the gland. Isolated cells have been impaled with microelectrodes while being observed through an inverted microscope equipped with Nomarski optics. These cells also maintain deep resting potentials and generate overshooting action potentials. In addition, action potentials cause distinct morphological changes which may be related to the secretory process.

1860 GLUTAMATE AND SYNAPTIC DEPOLARIZATION OF CEREBELLAR PURKINJE CELLS J.T. Hackett, S.M. Hou, and S.L. Cochran. Dept. Physiology, Univ. of Virginia Medical School, Charlottesville, Va. 22901.

Purkinje cells (PC's) have two easily recognizable excitatory inputs, the parallel fibers (PF's) and the climbing fibers (CF's). A third input, presumably from stellate cells (SC's), is inhibitory. Each of these inputs evokes a postsynaptic potentials (PSP's) in PC's, which can be reversed with extrinsic polarization through the recording electrode, suggesting a chemical intermediary at all three synapses. The PC-PSP's evoked by electrical stimulation of PF's usually have a more negative reversal potential than that of PSP's elicited by CF activation. This difference in reversal potentials provides a basis for characterizing agonists of the PC subsynaptic receptors. Accordingly, we have investigated the excitatory action of glutamate (Glu) on frog PC's. The entire cerebellum and adjacent brainstem were quickly removed from frogs *(Rana pipiens)* and maintained in a bath with superfused Ringer solution. Glu added to the bath in concentrations from 0.2 to 2 mM, increased the frequency of PC action potentials within 5 sec. Intracellular recordings, with beveled glass microelectrodes (less than 0.2 μm tip outer diameter; 4 M K citrate), revealed that Glu acts by an increase in ionic conductance which reduces the membrane potential. This action was rapidly blocked by 2 mM GABA. The GABA selectively increased PC ionic conductance that blocked PF-PC transmission with little or no effect upon intracellular recorded CF-PSP's. Three types of synaptic contacts upon the PC were seen at the electronmicroscope level: 1) PF's contacted spines on the spiny branchlet units of the distal dendrites tree; 2) the CF contacted thorns emitted from the soma and proximal dendrites; and 3) presumed SC terminals contacted directly PC axon hillock, soma, and dendrites. The geometric distribution of these contacts suggests that GABA may act upon the PC dendrite where these SC contacts occur. The resulting increase in conductance would tend to shunt distal excitation, and thus restrict PF synaptic current to the molecular layer, while the CF evoked excitation near the PC soma remains relatively unaffected. The PC depolarizations elicited by Glu and PF stimulation had similar reversal potentials while CF-PSP's inverted at a lower membrane potential, though in some PC's the values apparently overlap. The negative value of the reversal potential indicates that there are both sodium and potassium ionic conductance channels opened by the activation of PC subsynaptic receptors. These results are consistent with the hypothesis that Glu and PF transmitter act on the same PC subsynaptic receptor, suggesting in fact that Glu may be the PF neurotransmitter.

1861 **EFFECTS OF CHRONIC EXPOSURE TO A 60-Hz ELECTRIC FIELD ON SYNAPTIC TRANSMISSION AND PERIPHERAL NERVE FUNCTION IN THE RAT.** Richard A. Jaffe, Richard D. Phillips* and William T. Kaune,* Biology Department, Battelle Memorial Institute, Pacific Northwest Laboratories, Richland, WA 99352.

There is considerable national concern over the possible biological effects of exposure to 60-Hz electromagnetic fields from extra-high-voltage (EHV) transmission lines. Reports in the literature on biological effects of electric fields have suggested that the nervous system can be affected by exposure to electric fields and that these effects may have detrimental health consequences for the exposed organism. The purpose of this study was to investigate the effects of chronic (30-day) exposure of rats to a 60-Hz, 100-kV/m electric field on synaptic transmission and peripheral nerve function.

A system has been built which is capable of simultaneously exposing 144 rats, housed in individual plastic (lexan) cages, to uniform vertical, 60-Hz electric fields. Extensive tests have been made, and document that the exposure systems are free of corona discharge and ozone formation and that the animals do not receive spark discharges or other shocks in the housing system during exposure to electric fields. The systems are free of significant levels of harmonic distortion and vibration. Electric field measurements showed that the electric field strength within a cage varies by about 7%, due to the effects of the lexan cage material, and that the differences among fields in different cages are less than 3%.

Superior cervical sympathetic ganglia, vagus and sciatic nerves were removed from rats anesthetized with urethan, placed in a temperature-controlled chamber (37.5±0.4°C) and continuously superfused with a modified mammalian Ringer's solution equilibrated with 95% O_2 and 5% CO_2. Several parameters and tests were used to characterize synaptic transmission and peripheral nerve function. These included amplitude, area, and configuration of the postsynaptic or whole nerve compound action potential; conduction velocity and synaptic delay; accommodation; refractory period; strength-duration curves; conditioning-test response, frequency response; post-tetanic response; and high-frequency-induced fatigue. The results of all of the neurophysiologic tests and measurements so far completed indicate that synaptic transmission and peripheral nerve function are not significantly affected by chronic (30-day) exposure to a 60-Hz, high-voltage electric field. There are trends in the data, however, that suggest increased neuronal excitability in exposed animals. Replicate studies are currently underway. (This study was supported by the U.S. Department of Energy under contract EY-76-C-06-1830)

1862 RELEASE OF ACh FROM GANGLIONIC NEURON CELL SOMAS. David A.Johnson* and Guillermo Pilar (SPON: W. Wilson). Physiology Section, Biological Sciences Group, Univ. of Connecticut, Storrs, CT 06268.

Acetylcholine (ACh) release from neuronal cell somas was examined using the chick ciliary ganglia. Cell bodies in this ganglion are known to synthesize ACh (Suszkiw et al, 1976). The complications caused by the presence of presynaptic cholinergic elements was eliminated by using denervated preparations.

Ganglia in 3-5 day old chicks were denervated preganglionically by surgical section of the oculomotor nerve at its entrance into the orbit. At various times after nerve section birds were perfused by aortic injection of glutaraldehyde and post-fixed with osmium for electron microscopic examination.

Presynaptic nerve endings underwent progressive degeneration following operation and by 3 days, no ganglion cells could be found which possessed presynaptic terminals. Therefore, birds chosen for biochemical studies had been denervated 3-4 days.

Additional animals were used to measure ACh release in response to various stimulation parameters. Both the denervated ganglion and its contralateral control were incubated in μM ^{3}H-Ch at 37 C. ^{3}H-Ch taken up from the incubation medium is synthesized into ^{3}H-ACh. ^{3}H-ACh released in response to stimulation was separated from ^{3}H-Ch in the effluent by extraction into tetraphenyl boron in acetonitrile: toluene fluor following conversion of ^{3}H-Ch to ^{3}H-PhCh by choline kinase. Labelled ACh remaining in the ganglion at the conclusion of stimulation experiments was determined by high voltage electrophoresis.

In response to a 3 min. exposure to 55 mM K^+, denervated ganglia showed significant release of ^{3}H-ACh in amounts approximately 15% of those of the contralateral control. No measurable release was observed in Ca^{++}-free solutions. Antidromic electrical stimulation of the ciliary nerve for 3 min. at 20 Hz results in increased amounts of ^{3}H-ACh in ganglionic effluents. Control experiments were conducted with acetylcholinesterase added to the collected samples. No ACh was recovered in the extracted phase.

This evidence shows that ^{3}H-Ch taken up from the incubation medium can be synthesized into ^{3}H-ACh by denervated ganglion cell bodies. This ACh can then be released in response to stimulation. That this release is Ca^{++}-denendent and can be evoked by antidromic electrical stimulation suggests that it is not attributable to release of transmitter from glial elements. Therefore, it appears that denervated ciliary ganglion neurons can release ACh from their cell somas. Supported by NIGMS 1-732-GN-07219, NS 10-388 and the Univ. of Connecticut Research Foundation.

1863 **POLYPEPTIDE NEUROTOXINS FROM SCORPION AND SEA ANEMONE ACTIVATE NEURONAL SODIUM CHANNELS BY SIMILAR MECHANISMS.** Bruce K. Krueger and Mordecai P. Blaustein. Dept. Physiology and Biophysics, Washington University School of Medicine, St. Louis, MO 63110.

Polypeptide toxins from the scorpion Leiurus quinquestriatus (LqTX) and the sea anemones Anthopleura xanthogrammica (AxTX) and Anemonia sulcata (AsTX), as well as the steroid batrachotoxin (BTX), a sodium channel activator, were examined for their effects on sodium channels in pinched-off nerve endings (synaptosomes) from rat brain. Toxin-induced increases in sodium permeability resulted in membrane depolarization which was detected with the fluorescent probe CC_5 (J. Physiol. 247, 589, 1975). None of the polypeptide toxins alone had a significant effect on synaptosome membrane potential; all of the polypeptides potentiated the effect of BTX. Catterall has reported similar results for LqTX in neuroblastoma (J. Biol. Chem. 251, 5528, 1976). BTX alone, at maximally-effective concentrations (30 uM), depolarized the synaptosomes to the same extent as did increasing $[K]_o$ from 5 mM to 150 mM. The concentration of BTX which produced half-maximal depolarization (K_{BTX}) was about 2 uM (see table, below). In the presence of maximally effective concentrations of AxTX and LqTX, K_{BTX} was found to be 80 nM and 30 nM, respectively. In the presence of a just-subthreshold concentration (0.2 uM) of BTX, half-maximal depolarization by polypeptide toxins (K_{TX}) was observed at 40 nM AxTX and 4 nM LqTX. Three A. sulcata toxins ($AsTX_I$, MW 4700; $AsTX_{II}$, MW 4800; $AsTX_{III}$, MW 2700) each depolarized synaptosomes in the presence of 0.2 uM BTX. Preliminary results indicate that LqTX also potentiates the depolarization of synaptosomes by the alkaloid, veratridine. Depolarization by BTX, both in the presence and absence of the polypeptide toxins, was completely abolished by the sodium channel blocker, tetrodotoxin (10 uM), indicating that both BTX and polypeptide toxins interact with sodium channels, possibly at different sites. Recent reports indicate that these polypeptides may have different amino acid compositions and in some cases very different primary structures. This raises the possibility that widely different organisms have different polypeptide toxins all of which bind with high affinity to sodium channels in nerve and muscle, and which act by a common mechanism.

Polypeptide Toxin (TX)	K_{TX} (nM)	K_{BTX} (nM)
None	—	2000
AxTX (MW 5500)	40	80
LqTX (MW 6700)	4	30

1864 LOCAL SYNAPTIC CIRCUITS IN RAT HIPPOCAMPAL SLICES: INTERACTIONS BETWEEN PYRAMIDAL CELLS. B.A. MacVicar and F.E. Dudek Department of Zoology and Erindale College, University of Toronto.

Electrophysiological studies of the mammalian brain have begun to emphasize the importance of local synaptic circuits. Direct analysis of neuronal interactions in these systems requires intracellular techniques for stimulating one cell and recording from another. Synaptic physiology of intrinsic hippocampal pathways was studied in vitro with simultaneous intracellular recordings. Concurrent neuronal impalements with KCl and K citrate microelectrodes were obtained from pairs of CA3 pyramidal cells separated by <200 μm. Extracellular stimulation of the mossy fibres (MF) evoked an excitatory postsynaptic potential (EPSP) and/or spikes; these responses were typically followed by a recurrent inhibitory postsynaptic potential (IPSP). Spontaneous depolarizing and hyperpolarizing potentials were not present in some cells; in other cells they ranged from asynchronous to highly synchronous. The amplitude of these spontaneous depolarizations and the MF EPSPs could both be increased with weak hyperpolarizing current injection. Spontaneous hyperpolarizations and recurrent IPSPs both reversed with Cl^- leak from the microelectrode. These spontaneous responses had the properties of synaptic potentials. Since reciprocal current injection experiments showed that most of these cells were not electrotonically coupled to each other, the close synchrony often observed for the spontaneous EPSPs and IPSPs indicates that some pyramidal cells have very similar synaptic input.

In a few pairs of pyramidal cells, spikes from depolarizing current injection in one cell caused EPSPs and spikes in the other cell. The EPSPs had a latency and time course consistent with chemical synaptic transmission and increased amplitude with hyperpolarizing current injection. These results directly demonstrate excitatory synaptic interactions between CA3 pyramidal cells. More often then excitatory interactions, spikes evoked in one pyramidal cell via intracellular current injection caused inhibition in nearby pyramidal cells. Therefore, action potentials in a single pyramidal cell can activate the recurrent inhibitory system, which synapses on many other pyramidal cells. Future analysis of pyramidal cell interactions may allow a precise description of their involvement in potentiation and seizure in the hippocampus.

1865 SYNAPTIC DISSECTION AND THE EFFECTS OF LITHIUM ON SYNAPTIC TRANSMISSION IN THE CENTRAL NERVOUS SYSTEM. Lawrence E. Mallach. Dept. Anat. and Biomath., Sch. Med., UCLA, Los Angeles, CA 90024

In the last twenty-five years, studies of biochemical and pharmacological correlates of affective disorders have yielded and impressive body of data. However, not only are the etiology and pathogenesis of affective disorders unknown, but the mechanisms by which pharmacological agents are able to ameliorate the symptoms remain obscure. Lithium salts are successfully being employed in the treatment of bipolar disease, and the ability of lithium to substitute for sodium is well known. Several hypotheses for the mechanism of action of lithium have been advanced, and include altered resting potential, competition with other important ions (eg. calcium), and involvement with transmitter metabolism (serotonin and noradrenaline). Intra and extra cellular recording is in progress in the invitro hippocampal slice preparation and provides evidence for the relative importance of the several components mentioned above, as well as information regarding the site of activity. Theoretical modeling which treats the synapse formally as a series of coupled chemical reactions has demonstrated the feasibility of partially decoupling the synapse by inducing oscillatory behavior which is characteristic of reaction schemes with simple nonlinearities such as the sigmoidal dependence of neurotransmitter release on calcium influx. This technique, which is currently being developed, may provide information on the reaction rates as well as characterizing the nonlinearities generating the oscillatory behavior. It is also suggested that in combination with pharmacological agents whose site and mode of action is known, may provide an effective technique in dissecting the synapse.

1866 MODULATION OF THE ACTION OF L-GLUTAMATE ON APLYSIA NEURONS. M. J. McCreery* and D. O. Carpenter (SPON: D. E. Evans). Neurobiol. Dept., Armed Forces Radiobiol. Res. Inst., Bethesda MD 20014.

At crustacean neuromuscular junction, the excitatory response of the muscle to glutamate is markedly potentiated by aspartate which has only a small effect when applied alone. We have found a similar modulation of glutamate responses by aspartate on Aplysia neurons. However, these glutamate responses are due to either Cl- or K+ conductance increases rather than a Na+ conductance increase as in the crustacean muscle. Most of our recordings were made from unidentified neurons in the buccal ganglion and some from the abdominal ganglion. Cells were penetrated with two independent microelectrodes for recording and current passing, respectively. Drugs were passed ionophoretically from 3- or 5-barrelled extracellular electrodes or from two single-barrelled electrodes whose tips were placed together microscopically. Most receptors were located in the neuropile.

On different neurons, glutamate may cause no response or specific conductance increases to Na+, Cl-, or K+, and on some cells there are biphasic responses to Cl- and K+. The Na+ responses are rare, and we have not investigated those in detail. For most Cl- and K+ responses, aspartate is very much less effective than glutamate and must be applied at 2-50 times the concentration of glutamate for an equal response. However, when a control ionophoretic pulse of glutamate is preceded by an ionophoretic pulse of aspartate, the glutamate response may be potentiated by as much as fivefold. As the number of preconditioning aspartate pulses is increased, the glutamate responses are first facilitated and then depressed. This suggests that aspartate can interact with and desensitize the glutamate receptor but that the modulatory action is through a different action. The potentiation is similar for Cl- and K+ responses and is also not affected by the membrane potential at which the cell is tested. The potentiation is abolished in Na+ free seawater even though both the Cl- and K+ responses may actually increase in size under these circumstances. In addition to causing an increase in amplitude, Na+ free seawater results in an increase in the time-to-peak of the glutamate response and a depression rather than facilitation when aspartate is applied with glutamate. Although in some experiments cooling depresses the modulation, in most the modulation is still present at temperatures as low as 5^{o}C. Cysteate, a sulfonic acid analogue of aspartate, also causes modulation of the glutamate response and is about equally effective as aspartate. It is of interest that homocysteate, the sulfonic acid analogue of glutamate, blocks the glutamate responses and inhibits the facilitation by aspartate.

Others have ascribed the modulation of the glutamate response by aspartate to a conformational change of the receptor, an inhibition of the glutamate uptake system, or an induced alteration of the rate of onset and recovery of receptor desensitization. Our results are most consistent with an inhibition of Na+ dependent glutamate uptake, although we cannot explain the ineffectiveness of temperature in blocking the modulation by this mechanism.

1867 ACTIONS OF GABA, GLYCINE AND BACLOFEN ON AFFERENT FIBRES AND THEIR CENTRAL SYNAPSES. M. E. Morris, G. Di Costanzo*, S. Fox*, J. F. MacDonald, and R. Werman. Department of Research in Anaesthesia, McGill University, Montreal, Quebec, Canada.

The effects of γ-aminobutyric acid (GABA), glycine, and β-(4-chlorophenyl)-γ-aminobutyric acid (Baclofen) were observed on (i) the excitability of primary afferent fibres, and (ii) the transmission through cuneate synapses of the decerebrate cat. 1 Hz stimulation of a forelimb nerve or micro-electrode excitation of presynaptic terminals evoked antidromic and orthodromic potentials which were respectively recorded for estimate of synaptic input and output from the nerve and medial lemniscus. Transmission efficiency was assessed from input-output curves, constructed from integrals of the simultaneously evoked responses to regularly repeating cycles of varying intensities of either central or peripheral stimulation (Krnjevic & Morris 1976, J. Physiol. 257: 791; Morris 1978, J. Physiol. *IN PRESS*). Glycine (0.1-0.2 g/kg I-V) decreased synaptic transmission and did not alter the resting excitability of the afferent fibres. Baclofen (0.1-2.0 mg/kg I-V) produced a more marked depression of transmission, and a small but distinct decrease in both presynaptic and peripheral nerve excitability. GABA administration (0.1-0.2 g/kg I-V or 10^{-2}M superfusion of the medulla) caused large, reversible increases in afferent terminal and peripheral fibre excitability; synaptic efficiency either fell or was enhanced. During the GABA-evoked changes corresponding increases in both the extracellular K^{+} level (to <4mM) and the negative tissue potential were measured in the cuneate with ion-selective microelectrodes. GABA's direct action on peripheral fibres was confirmed in experiments with the isolated, desheathed frog sciatic nerve, by observing changes in compound action potentials, which were evoked by 1 Hz stimulus intensities which were submaximal for A fibres. Graded, reversible increases in excitability occurred during applications of 10^{-7}-10^{-2}M GABA to the site of stimulation; they could be blocked by picrotoxin. The depression of cuneate transmission which glycine causes appears to be entirely post-synaptic. A component of Baclofen's mainly presynaptic action (Fox *et al.* 1978, Neuroscience *IN PRESS*) may be a decrease in afferent activity reaching the CNS. In contrast are GABA's more complex excitatory and inhibitory effects - the depolarization of afferent fibres, and both depression and facilitation of synaptic efficacy - which suggest extra-terminal receptor distributions, and may be due in part to extracellular K^{+} accumulation, arising either from a direct membrane action and/or glial uptake of GABA.

1868 THE "CALCIUM BLOCKERS", VERAPAMIL AND D-600, BLOCK BOTH SODIUM AND CALCIUM CHANNELS IN VERTEBRATE NEURONS. Daniel A. Nachshen* and Mordecai P. Blaustein, Dept. Physiol. and Biophys., Washington U. Med. Sch., St. Louis, MO 63110.

The effects of the putative calcium channel blockers, verapamil (VPL) and D-600, were tested on pinched off presynaptic nerve terminals from rat brain and on the frog sartorius neuromuscular junction (n.m.j). ^{45}Ca uptake (J. Physiol. 247: 617, 1975) was measured in synaptosomes which were depolarized either with veratridine, an alkaloid that opens sodium channels, or with high external potassium concentrations. The extent of synaptosome depolarization was determined indirectly with the voltage-sensitive fluorescent dye, di-pentyl oxacarbocyanine (J. Physiol. 247: 589, 1975). VPL or D-600 (40-60 μM) inhibited the potassium-induced ^{45}Ca uptake by about 40%, but had no effect on the potassium-induced depolarization of the synaptosomes; this inhibition of Ca uptake by VPL and D-600 is, presumably, due to blockage of Ca channels. Veratridine-induced ^{45}Ca influx was inhibited by about 70% by 40-60 μM VPL or D-600, and veratridine-induced depolarization of the synaptosomes was reduced by about 50%; the latter observation indicates that Na channels are also blocked by VPL and D-600.

Microelectrode recordings of end-plate potentials (epp's) and minature end-plate potentials (mepp's) were used to evaluate the actions of VPL and D-600 at the frog n.m.j. Low concentrations of VPL (40-50 μM) or D-600 (10 μM) had no effect on mepp amplitude, and either slightly decreased (<25% change) or had no effect on the epp amplitude. These concentrations of drug did, however, increase the threshold for nerve stimulation. These findings suggest that the VPL and D-600 can block sodium channels in the nerve. In preparations where mepp frequency had been made sensitive to changes in the bathing calcium concentration by raising the external potassium, VPL (40-50 μM) and D-600 (10 μM) did not depress mepp frequency. Although VPL and D-600 appear to be highly specific blockers of inward calcium currents in mammalian myocardum (Kohlhardt et al., Pflugers Arch. 335: 309, 1972) our data indicate that these drugs block both sodium and calcium channels in vertebrate neurons. Moreover, calcium channels in vertebrate neurons appear to be much less sensitive to VPL and D-600, than are calcium channels in mammalian myocardial cells. [Supported by USPHS grant NS-08442.]

1869 AMINE MODULATION OF RATE OF DECAY OF POST-TETANIC POTENTIATION IS MEDIATED BY A CYCLIC NUCLEOTIDE. S.A. Newlin, W.T. Schiapfer, and S.H. Barondes. Div. of Physiology and Pharmacology, Dept. of Medicine, and Dept. of Psychiatry, UCSD, La Jolla, CA 92093; and Psychiatry Research, VAH, San Diego, CA 92161.

We have previously presented evidence for serotonergic and dopaminergic heterosynaptic modulation of the rate of decay of post-tetanic potentiation (PTP) at an identified cholinergic synapse (RC1-R15) in the abdominal ganglion of Aplysia californica (i.e. amines speed the rate at which the potentiated epsp falls to its resting value following repetitive stimulation) (Newlin et al., Soc. Neurosci. Abstracts 3, #1654, 1977). Serotonin antagonists SQ10,631 (10^{-4}M) antagonizes the effects of perfused serotonin (10^{-7}M) but not the effects of perfused dopamine; and, conversely, dopaminergic antagonist d-Butaclamol (10^{-5}M) antagonizes the effect on PTP decay rate of perfused dopamine (5x 10^{-7}M) without antagonizing the serotonin effect. Thus, we can conclude that the serotonergic and dopaminergic modulation of PTP decay occur through parallel channels, and not in tandem. Stimulation of neural pathways on the right parieto-visceral connective and the branchial nerve mimic the effects of perfused amines.

Amine effects on PTP decay rate are potentiated by phosphodiesterase inhibitors, isobutylmethylxanthine (5x10^{-4}M) and RO 20-1724 (10^{-4}M). Perfused 8-benzylthioadenosine 3',5'-cyclic phosphate, a cyclic AMP analogue shown to be effective in Aplysia preparations (Treistman and Levitan, Nature 261: 62, 1976), mimics the effect on PTP decay of perfused amines or neuronal activation. (A large, i.e. twofold, increase in post synaptic (R15) input resistance can also be observed in the presence of the cAMP analogue. This effect is distinguishable from the presynaptic effect on PTP decay rate). Effects of the amines as well as the cAMP analogue are completely reversible within one-half hour of washing.

These data are consistent with the hypothesis that presynaptic amine modulation of the decay rate of PTP resembles other effects of biogenic amines in that a cyclic nucleotide appears to be involved. It is notable that two different amines may use the same final common mechanism. What is novel is that the object of modulation is the duration of a long-lasting synaptic plasticity, PTP.

1870 COLICIN-LIKE EFFECTS OF β-BUNGAROTOXIN. Ronald H. Ng, Keith Terasaki* and Bruce D. Howard. Dept. of Biological Chemistry, UCLA School of Medicine, Los Angeles, Calif. 90024.

β-Bungarotoxin (M.W. 22,000) is a presynaptically acting, neurotoxic, protein from snake vemon. It causes neuromuscular blockade and exhibits phospholipase A activity. Colicins K and E_1 are protein toxins made by Escherichia coli. These colicins are known to interfere with several bacterial transport processes, decrease membrane potential and lower ATP levels (1,2). It is believed that the primary effect of the colicins is a de-energization (in the form of depolarization) of the bacterial membrane. Secondarily, ATP is utilized in an attempt by the cell to increase its membrane potential. Under conditions in which the membrane Ca^{2+}/Mg^{2+}-ATPase is made inactive, the membranes of the colicin-treated cells become deenergized without an accompanying decrease in ATP levels (1,3). We have obtained extensive evidence that β-bungarotoxin acts on synaptosomes in a manner similar to that of colicins K and E_1 on bacterial cells. β-Bungarotoxin interferes with synaptosomal transport of several neurotransmitters and nontransmitter compounds. It also decreases the membrane potential and the ATP level of synaptosomes. Our studies indicate that the β-bungarotoxin-induced interference with synaptosomal transport processes and reduction in ATP levels are secondary to membrane depolarization by the toxin. We suggest that the toxin inhibits transmitter release by a combination of depolarization of axonal terminals and a depletion of ATP stores in the terminals. (Supported by NIH Grant NS 12873 and NIH postdoctoral fellowship NS 05706.)

1871 ELECTROPHYSIOLOGICAL STUDIES IN THE ISOLATED TURTLE BRAIN. M.C. Nowycky*, U. Waldow* and G.M. Shepherd. Dept. Physiol., Yale Univ. Sch. Med., New Haven, Ct. 06510

Isolated preparations of several regions of the vertebrate nervous system have been introduced in recent years to aid in electrophysiological analysis of neuronal properties under more controlled conditions than are found in vivo. We report here preliminary results from a study of the isolated brain of the turtle, Pseudemys scripta. The animals were decapitated, and the entire brain, from medulla to olfactory nerves, was carefully removed, placed in a chamber, and superfused with oxygenated Ringer at room temperature. The parts of the brain of interest were dissected from the rest. Our initial focus has been on the olfactory bulb. The olfactory nerves were stimulated with single or paired shocks, and the responses in the olfactory bulb were recorded with a penetrating micropipette. The field potential responses to orthodromic volleys consist of three successive periods of activity, related to the impulse volley in the olfactory nerves, synaptic responses of the mitral cells, and synaptic responses of the granule cells. The laminar localization of the field potentials was in accord with previous in vivo studies. In paired volley experiments, the olfactory nerve potentials were found to undergo periods of refractoriness and supernormality similar to those previously reported in the in vitro olfactory nerve of tortoise (Bliss, T.V.P. and M.E. Rosenberg, J. Physiol. 239:60-61P, 1974), and the in vivo rabbit olfactory bulb (Getchell, T.V. and G.M. Shepherd, J. Physiol. 251: 523-548, 1975). The synaptically-evoked potentials typically undergo long-lasting suppression, for periods of up to several seconds. Extracellular single unit recordings also reveal long-lasting suppression of test responses. These results are similar to those obtained in the in vivo rabbit bulb (Getchell and Shepherd, 1975), where it has been postulated that the suppression is due to dendrodendritic synaptic interactions between mitral cells and interneurons. The present results suggest that these interneuronal synaptic systems are powerfully active in the isolated preparation. This is an important criterion for the viability of the preparation, and its validity for the analysis of local circuit properties. Intracellular responses have also been obtained, showing impulse generation in presumed mitral cells in response to synaptic input to their dendritic tufts in the olfactory glomeruli. Other parts of the brain appear to retain their viability, as evidenced by the recording of evoked potentials and unitary spikes in regions of the telencephalon in response to volleys in related fiber tracts.

1872 EXTREME SENSITIVITY OF OLFACTORY CORTICAL NEURONS TO KAINIC ACID TOXICITY. J.W. Olney, T. de Gubareff* and T. Fuller.* Wash. Univ. Sch. Med., St. Louis, MO 63110.

Several years ago we reported the neuron-necrotizing but axon-sparing action of kainic acid (KA) when microinjected directly into the rat diencephalon. Many neurons in the injected area were sensitive to the toxic action of KA but some, e.g., magnocellular neurons of the paraventricular hypothalamic nucleus (PVH) were quite resistant. We have now explored the neurotoxicity of KA following various routes of administration - intradiencephalic, intrastriatal, intraventricular and systemic - and are impressed that, although the pattern of brain damage following each route is different, there are definite repeating features, a potentially important one being that the olfactory cortex (OC) is destroyed by any of the above modes of KA administration.

To explore the apparent differential sensitivity of PVH and OC neurons to KA toxicity, we injected KA (3-4 nmoles in 0.5-1 µl) unilaterally into the diencephalon about 1 mm from PVH but much farther (> 5 mm) from OC. Histopathological analysis of the brains at various post-injection intervals revealed complete sparing of magnocellular PVH neurons but widespread destruction of OC neurons bilaterally. In other experiments, 65% of 52 brains examined after intrastriatal injection of KA (1.5-10 nmoles) revealed extensive OC damage. As will be described elsewhere (Schwb etal. NS. Abs.1978),OC neurons are among the most sensitive in the brain to degeneration following systemic administration of KA (10-12 mg/kg i.p.) and small doses of KA (< 1 nmole) administered intraventricularly sometimes cause OC lesions. The observation that KA induces degeneration of OC neurons following various modes of administration, including systemic or direct injection into brain regions quite distant from OC, implies not only extreme sensitivity of OC neurons to KA toxicity, but a remarkable tendency of KA to penetrate barrier interfaces and travel long distances within brain tissue. This underscores the need for histological controls in KA lesioning experiments and for caution in interpreting such studies.

The extreme sensitivity of OC neurons to KA toxicity is of particular interest because these neurons are thought to be glutamergically innervated, there being evidence that olfactory bulb axons which synapse upon OC neurons use Glu as excitatory transmitter. The relative simplicity of the olfactory system and ready accessibility of its components to experimental manipulation coupled with its possible use of Glu as excitatory transmitter and its extreme sensitivity to KA toxicity makes this system a promising target for future KA studies. Supported by USPH grants NS-09156, DA-00259, ES-07066 and RSD Award MH-38894 (J.W.O).

1873 LEPTINOTARSIN: QUANTIZED RELEASE OF ACETYLCHOLINE AT THE RAT NEUROMUSCULAR JUNCTION. L. S. Satin*, A. Siger*, B. C. Abbott, T. H. Hsiao* and W. O. McClure. (SPON: G. P. Moore). Section of Cellular Biology, University of Southern California, Los Angeles, CA 90007, and the Department of Biology, Utah State University, Logan, UT 84322.

Hsiao and Fraenkel have described a toxic protein, leptinotarsin (LPT), which occurs in the hemolymph of Leptinotarsa haldemani (Hsiao, In: Toxins: Animal, Plant and Microbial, ed., P. Rosenberg, Pergamon Press, 1978). We have improved the original fly lethality assay for the toxin, and have studied a number of the properties of LPT using a phrenic nerve-diaphragm preparation from the rat. Intracellular recordings with conventional 3 megohm microelectrodes filled with KCl show that treatment with partially purified LPT (G-200 fraction; Hsiao and Fraenkel, Toxicon 7, 119, 1969) produces a massive outpouring of miniature end plate potentials (mepps) reminiscent of the action of black widow venom gland homogenates (BWGH). Unlike BWGH, LPT induces a biphasic release: about 10% of the total store of releasable mepps are seen in an initial "pulse" of activity which lasts only about a minute, and is followed by a second release which lasts 10-15 minutes before the frequency of mepps falls to zero. The maximum frequency of mepps is also different in the two phases, reaching $>$800 Hz in the first phase, but only 300-400 Hz in the longer, second phase.

Several experiments have been carried out further to study this phenomenon. Impaling either the usual upper layer of cells or the underlying layer yields the same results, indicating that the biphasic release does not come from these two different cell layers. Removing Ca++ from the bathing solution abolishes the first phase, but has very little effect upon the second phase. Heating the toxin (60°, 5 min) completely destroys both its fly killing activity and its ability to stimulate release from the neuromuscular junction.

The data indicate that purification of the toxin, and further study of the homogeneous protein, is worthwhile. Despite the fact that only partially purified material was used in these experiments, the results suggest the possibility that either (a) two different pools of presynaptic ACh can be released in a quantized manner, or (b) release from a single pool can be stimulated by two different mechanisms, both of which yield quantized release. Studies with the purified toxin should be of value in our understanding of the synaptic mechanisms which control release of ACh. Supported in part by the National Science Foundation (BNS 76-80657) and the Nelson Research and Development Co.

1874 DISTRIBUTION AND PHYSIOLOGICAL PROPERTIES OF IVN THROUGH-FIBER SYNAPSES IN THE STOMATOGASTRIC GANGLION. Karen A. Sigvardt and Brian Mulloney. Dept. of Zoology, University of California at Davis, Davis, CA 95616.

The gastric and pyloric motor patterns generated by the neurons of the stomatogastric ganglion of the spiny lobster are disrupted in a characteristic way by a burst in the IVN through-fibers. The change in the motor pattern results from the particular distribution of synapses of the IVN fibers onto neurons of the ganglion and the characteristics of each of these synapses. Two types of synapses have been characterized: excitatory and biphasic. The PSP in VD is excitatory and results in 1:1 spikes in VD at frequencies of IVN stimulation up to 50 Hz. The PSP in PD is biphasic, consisting of a fast excitatory component and a slower inhibitory component. The excitatory component predominates at low frequencies but is less effective at frequencies above 25 Hz. At higher frequencies the slower inhibitory component dominates. The IPSP involves a mixed Cl^- and K^+ conductance increase. Its reversal potential is -74 mV and is changed in the depolarizing direction by increasing external K^+ concentration or internal Cl^- concentration. Inhibitory synapses have been observed but at this writing have not been characterized. A description of the properties of each of the IVN synapses will provide a basis for understanding the changes in the motor pattern which occur during an IVN burst.

1875 CHEMICAL STUDIES OF GABA NEURONS IN TISSUE CULTURE. S.R. Snodgrass, Marc A. Dichter, W.F. White and Bernard Biales*. Dept. Neurology & Neuroscience, Children's Hospital and Harvard Medical School, Boston, Mass. 02115.

Biochemical characteristics of GABA neuronal function were studied in low density dissociated rat cortical cell cultures (Dichter, Brain Res., 1978). Physiological and pharmacological data suggest that GABA neurons are present and that GABA is the major inhibitory transmitter, as is thought to be true in vivo. GABA and GAD activity were detected in all cultures and increased in parallel as cultures matured and synapses formed. In contrast, ChAc, though present, does not always increase with time. The cultures also contain a sodium dependent, high affinity GABA uptake system which can be inhibited by DABA. Parallel autoradiographic studies show a dense uptake of GABA over the somata and processes of many but not all neurons. Exogenous GABA or GABA made from 14C-glucose can be released from the cultures in a calcium dependent manner. Specific binding of 3H-bicuculline has been found and increases as the cultures mature. Additional receptor studies, including autoradiography, are being done with the GABA agonist muscimol.

The cultures contain glycine in concentrations similar to that found for GABA, but the uptake of glycine is less than that of GABA and we have been unable to demonstrate autoradiographic labelling of neurons with glycine. We do not believe that glycine is functioning as a major transmitter. Tyrosine hydroxylase activity is not detectable in the cultures, in keeping with the presumed absence of monoamine cell bodies from cerebral cortex.

Our biochemical demonstration of GABA synthesis, release and uptake together with the physiological and pharmacological evidence that GABA mimics the inhibitory transmitter (Dichter and Biales, this meeting) indicates that GABA is most likely the inhibitory transmitter utilized by mammalian cortical neurons in vitro.

1876 VESICLE CYCLING AND STORAGE OF ACh IN TORPEDO ELECTROPLAQUE SYNAPSES. J. B. Suszkiw*, (spon. T. L. Schwartz) Physiology Section, Biological Sciences Group, Univ. of Conn., Storrs, CT 06268.

Recycling of synaptic vesicles in the electromotor nerve terminals of Torpedo was studied on the ultrastructural and biochemical level. When isolated electric organs were stimulated electrically (1 Hz, 1200-1500 total pulses) in the absence of choline (Ch^+), the number of vesicles in the terminals, total tissue acetylcholine (ACh), and vesicular ACh all were reduced to 30-40% of control. During subsequent recovery in Ringer solution containing 0.1 mM Ch^+, the number of vesicles in the terminals returned to 80% of control after 3 hours and to 97% of control after 5 hours. Over the same time period, the ultrastructural morphology of the terminals returned to normal. The recovery of the vesicular content of ACh was slower than was the return to normal of vesicle numbers, suggesting that: 1) Reformation of vesicles is not contingent upon the supply of ACh. 2) Reformation of morphologically identifiable synaptic vesicles may precede the recovery of the capability for ACh storage by reformed vesicles.

When an extracellular tracer, dextran, was included in the incubation medium during the reformation of vesicles, no entrapment of the dextran in the reformed vesicles could be demonstrated. This and other morphological evidence suggest that after intensified vesicle usage, new vesicles may originate from cytoplasmic membraneous precursor structures rather than by direct retrieval from plasmalemma. The present results, when compared with results obtained by Zimmerman and Denston (Neuroscience 2, 695, 1977) during low frequency (0.1 Hz) stimulation, when vesicle numbers are conserved, and incorporation of dextran into vesicles can be demonstrated, suggest that vesicle cycling during states of low and high vesicle usage may not follow the same pathway. Part of this work was performed in Max Planck Institut, Goettingen, W. Germany. Supported by Max Planck Fellowship and in part by NIH grant NS10388.

1877 EFFECTS OF SEROTONIN (5-HT) ON CALCIUM CURRENT AND CALCIUM DEPENDENT SYNAPTIC PROCESSES IN PRESENCE OF REMOVAL OF FREE INTRACELLULAR CALCIUM WITH VARIOUS SPEED. Clara Torda. N.Y.Center PA. Training, N.Y.,N.Y.,10028.

Iontophoretically administered 5-HT increases spike generation in lateral (LG) and medial (MG) geniculate neurons having low frequency spontaneous activity and inhibit LG and MG neurons with high frequency spontaneous activity (Torda, Gen.Pharmacol.,1978) and cortical neurons (Szabadi, Bradshaw & Bevan, Brain Res., 1977 126:580). In low concentrations 5-HT increased postsynaptic activity and in high concentrations 5-HT decreased postsynaptic activity. Woolley (The Biochemical Bases of Psychosis, or the Serotonin Hypothesis of Mental Disease, Wiley, N.Y., 1961) observed that 5-HT significantly increased the inward flux of Ca^{++}. Since administration of Mn or Lanthanium may prevent 5-HT potentiation of pre- and postsynaptic excitatory or inhibitory activity, the observed effects of 5-HT may be, at least in part, calcium-dependent. The here presented work addresses the problem whether the speed of removal of intracellular (intraneuronal) free Ca^{++} affects the nature of the effect of 5-HT on synaptic activity. -- The effects of iontophoretically administered 5-HT on presynaptic currents and postsynaptic activity has been studied in squid stellate ganglion following the method described by Llinas, Steinberg & Walton, Proc. Natl. Acad. Sci., U.S.A., 1976, 73: 2918). In low concentrations 5-HT increased inward flux of Ca ion into the presynaptic terminal and its cholinergic storage vesicles resulting in increased release of acetylcholine, and increased postsynaptic activity, including increase of the calcium current. In higher concentrations (preferably after a few second exposure) 5-HT inhibited the previously activated processes (e.g. neurotransmitter release, postsynaptic activity, etc.). After having ascertained for each preparation the critical concentration of 5-HT that started to generate inhibitory effects, several substances with Ca++ binding ability (including polypeptides and proteins with small molecular weight) were introduced into the presynaptic neuron. Some of these agents reversed the inhibitory effects of 5-HT to potentiation of excitatory processes. It seems, therefore, that 5-HT dependent effects result, at least in part, from the combined effects of increased inward flux of Ca^{++} and the availability of intracellular (intraneuronal) processes involved with the removal of the incoming free Ca^{++}. Intracellular concentrations of free Ca^{++} below a critical level seems to promote excitation. Free Ca^{++} concentrations exceeding this critical level promote inhibition of activity.

1878 PHYSIOLOGICAL STUDIES OF POSTNATAL RAT SYMPATHETIC NEURONS AND SKELETAL MUSCLE CELLS IN VITRO. E. Wakshull*, M. Johnson and H. Burton, (SPON: A.L. Perlman). Depts. Phys. & Biophys. and of Anat. & Neurobiol., Wash. Univ. Sch. Med., St. Louis, MO 63110.

Dissociated embryonic rat superior cervical ganglion neurons (scgn) form cholinergic synaptic connections on each other (O'Lague et al., PNAS 71: 3602, '74; Ko et al., Br. Res., 117: 461, '76), as well as on co-cultured skeletal muscle (Nurse and O'Lague, PNAS 72: 1955, '75). Hexamethonium (C-6), a ganglionic blocking agent, antagonizes the former synaptic potentials more effectively than the latter, while the reverse is true for d-tubocurare (d-tc) (Nurse and O'Lague, '75). Evidence from our laboratory has indicated that normally adrenergic scgn acquire the ability to synthesize and release acetylcholine in vitro (Johnson et al., Nature, 262: 308, '76). Recent work on explants of scg taken from progressively older postnatal rats has suggested the existence of a critical period for the expression of this transmitter "plasticity" (Ross et al., Nature, 267: 536, '77). We have extended this investigation to the study of postnatal dissociated scgn cultures with and without skeletal muscle cells present. The results show that scgn taken from up to 12 week old rats still form cholinergic connections with each other and with skeletal muscle.

The methods for establishing these cultures are described elsewhere (M. Johnson, this volume). Standard electrophysiological techniques were used to study over 900 neurons. Excitatory post synaptic potentials (epsps) were found between scgn even when taken from 12 week old rats. The epsps were Ca^{++}-dependent and were blocked by C-6; a few potentials could be blocked by the β-adrenergic antagonist propranolol. In some cultures, as many as 80% of the neurons penetrated were synaptically interconnected. SCGN from 5 and 10 week old rats elicited d-tc (1 μM) sensitive junctional potentials with skeletal muscle; these were often suprathreshold. Several scgn formed neuromuscular junctions and an autapse. Autaptic potentials were not effectively blocked by 1 μM d-tc. These data suggest that either the small subpopulation of cholinergic sympathetic neurons selectively survive in these cultures, or that, in contrast to explanted scg, dissociated scgn retain a certain degree of transmitter "plasticity" into adulthood. Studies are in progress to differentiate these two possibilities. (Supported by NIH grants 11888 and NS 09809)

1879 EVIDENCE FOR THE LACK OF INVOLVEMENT OF CYCLIC AMP IN MODULATION OF GANGLIONIC TRANSMISSION IN THE GUINEA PIG SUPERIOR CERVICAL GANGLION. James K. Wamsley*, Asa C. Black, Jr., James R. West, and Terence H. Williams. Department of Anatomy, University of Iowa College of Medicine, Iowa City, Iowa 52242.

The effects of stimulation of guinea pig superior cervical ganglia (SCG) in vitro at 37 C with 50 μM concentrations of dopamine, L-norepinephrine, or L-isoproterenol in Eagle's Medium containing 5 mM theophylline were determined. 50 μM dopamine produced no stimulation of cyclic AMP levels, 50 μM norepinephrine produced a doubling of cyclic AMP levels, while 50 μM isoproterenol produced a 6-fold increase in cyclic AMP levels over control values. The increases were blocked by propranolol, indicating that they were due to stimulation of a β-adrenergic receptor--adenylate cyclase complex. In the rabbit SCG, by contrast, 50 μM dopamine produced an increase in cyclic AMP levels of 60% over control values. The possible involvement of the β-receptor complex in the modulation of ganglionic transmission was tested by stimulating ganglia at 10 Hz for 8 minutes. No elevations of cyclic AMP levels were produced in guinea pig SCG, but a doubling of cyclic AMP levels in rabbit SCG was noted. Current concepts of the function of cyclic AMP in neural transmission in the SCG involve a dopaminergic SIF cell, dopamine receptor--adenylate cyclase complex, and the generation of a slow inhibitory postsynaptic potential (s-IPSP). Previous research has indicated that the guinea pig SCG lacks a s-IPSP, and its SIF cells contain norepinephrine rather than dopamine. Since preganglionic stimulation of the guinea pig SCG has now been shown not to cause increased cyclic AMP levels, and since the guinea pig SCG lacks a dopamine receptor--adenylate cyclase complex, we conclude that cyclic AMP is apparently not involved in the modulation of neural transmission in the guinea pig SCG (unlike the rabbit SCG, where it has been shown to have this function). Supported in part by National Research Service Award PHS 1T-32MH15172-01 to J.K.W., a Pharmaceutical Manufacturer's Association Foundation, Inc., Research Starter Grant to A.C.B., and by NS-11650 to T.H.W. from the National Institutes of Health.

1780 EVIDENCE FOR A ROLE OF CYCLIC GMP IN NEURAL TRANSMISSION IN THE GUINEA PIG SUPERIOR CERVICAL GANGLION (SCG). James R. West, James K. Wamsley*, Asa C. Black, Jr., and Terence H. Williams. Dept. Anatomy, Univ. Iowa Coll. Med., Iowa City, Iowa 52242.

Muscarinic cholinergic receptors regulate cyclic GMP levels in bovine SCG, where muscarinic agonists increase cyclic GMP levels of principal ganglionic neurons (PGNs) (1,2). Current thinking suggests that acetylcholine released from preganglionic terminals interacts with muscarinic receptors, causing increased cyclic GMP levels in PGNS, resulting in generation of a slow excitatory postsynaptic potential (s-EPSP) (2). Cyclic GMP may have a role in the potentiation of the s-EPSP in rabbit SCG (3). Since Libet has shown that the guinea pig SCG has a prominent s-EPSP, we determined the effect of pharmacological and physiological stimulation on cyclic GMP levels in this ganglion. Guinea pig SCG were pre-incubated in Eagle's Medium (EM) for 20 min. at 37 C., then transferred to EM containing 5 mM theophylline, 2.2 mM $CaCl_2$, and agonist. SCG were incubated for 2 min. and frozen in liquid N_2. Preganglionic physiological stimulation was performed at 37 C in EM containing 5 mM theophylline and 2.2 mM $CaCl_2$ for 8 min. at 10 Hz using a 0.5 ms rectangular pulse width. Frozen SCG were homogenized in 6% TCA and centrifuged at 12,000 x g for 30 min. at 4 C, extracted 6X with diethyl ether and assayed for cyclic GMP by the Steiner method. Precipitates were analyzed for protein by the Lowry technique.

2 min.	500 μM Carbachol	2.97 ± 0.52 (6)*
2 min.	500 μM Carbachol + 300 μM Atropine	0.60 ± 0.02 (4)*
2 min.	100 μM L-Norepinephrine	0.36 ± 0.12 (6)*
2 min.	Incubation Control	0.47 ± 0.14 (8)*
8 min.	Preganglionic Stimulation (10 Hz)	1.40 ± 0.17 (10)*
8 min.	Stimulation Control	0.50 ± 0.09 (10)*

*Picomoles Cyclic GMP ± Standard Error (Number Ganglia).

We conclude that both muscarinic agonists and preganglionic stimulation increase cyclic GMP levels in guinea pig SCG. Norepinephrine has no apparent effect on the accumulation. We suggest that these data are consistent with a role for cyclic GMP in synaptic transmission in the guinea pig SCG. (1) Bartfai, Study, and Greengard, Adv. Behavioral. Biol., 24:285-295 (1977). 1881 FUNCTIONAL SIGNIFICANCE OF SLOW EPSPs IN MYENTERIC GANGLION CELLS. J. D. Wood and C. J. Mayer*. Physiol. Dept., Univ. Kansas Med. Ctr., Kansas City, KN 66103 and Physiologisches Institut, der Universität München, 8 München 2, Federal Republic of Germany.

Electrical activity was recorded intracellularly from myenteric ganglion cells of guinea-pig small intestine in vitro. Electrical stimulation of interganglionic connectives evoked a slowly rising excitatory postsynaptic potential (slow EPSP) that was prolonged for several seconds after termination of the stimulus in these cells. The slow EPSP was associated with increased input resistance and augmented excitability of the somal membrane. Microiontophoresis of 5-hydroxytryptamine (5-HT) onto these neurons mimicked the slow EPSP. The 5-HT antagonist, methysergide, blocked both the slow EPSP and the action of 5-HT. Focal mapping with a stimulating electrode indicated that the neurons were multipolar. In the absence of the excitatory transmitter substance, the somal membranes either could not be activated to spike discharge by intrasomatic injection of depolarizing current or the spike threshold was high and the cells did not discharge repetitively to depolarizing current. During the slow EPSP, the characteristic postspike hyperpolarizing potentials of these cells were eliminated and the cells discharged continuously at a frequency that was directly dependent upon the intensity of injected depolarizing current. Electrical stimulation of the cell's processes elicited spikes which electrotonically invaded the soma. Spontaneously occurring spike patterns in the processes were also observed as electrotonic potentials in the soma. It was obvious that the excitability of the soma was much lower than that of its processes under these conditions. The probability that the passive current flow from the axonal or dendritic spikes would trigger a somal spike was greatly increased during the slow EPSP. Spike activity appeared to be restricted to the dendritic tree in the absence of the slow EPSP; whereas during the EPSP, when the membrane time constant, space constant and excitability were increased, the soma functioned to relay dendritic information to the axon at the opposite pole of the soma. These axons project to adjacent ganglia. The functional significance of the slow EPSP appears to be provision of a mechanism by which the soma gates the transmission of information between its processes and thereby regulates the spread of excitation within the neural plexus.

1882 LEPTINOTARSIN: NEUROCHEMICAL STUDIES OF THE RELEASE OF ACETYLCHOLINE FROM RAT BRAIN SYNAPTOSOMES. J. Yoshino*, D. Baxter*, T. Hsiao* and W. O. McClure. Section of Cellular Biology, University of Southern California, Los Angeles, CA 90007, and Department of Biology, Utah State University, Logan, UT 84322.

Presynaptic neurotoxins which influence the spontaneous release of neurotransmitter, such as black widow spider toxin and β bungarotoxin, are of importance as possible mechanistic probes in examining the process of neurotransmission. Recently we have described (Satin, et al., these Abstracts) the action at the neuromuscular junction of a new presynaptic neurotoxin, leptinotarsin (LPT). LPT is a protein which was discovered by Hsiao and Fraenkel (Toxicon 7, 119, 1969) in the hemolymph of the Colorado potato beetle, Leptinotarsa sp. We have now examined the ability of the partially purified toxin from L. haldemani to stimulate release of acetylcholine (ACh) from rat brain synaptosomal preparations. Synaptosomes were incubated with [^{3}H] choline to label internal stores of both choline and ACh, and were immobilized and washed on Millipore filters. Solutions of LPT were applied to the washed bed of synaptosomes, and the filtrate collected for analysis. In this system LPT induces the release of radioactive material. Fractionation of the released radioactivity indicates that the release of both choline and ACh is stimulated, and that relatively more ACh is released. Heating the LPT abolishes releasing activity. Removing Ca^{++} from both the washing solution and the solution of LPT reduces activity, but does not eliminate it entirely. The data suggest that LPT is a specific stimulant of release of ACh in synaptosomes, as it is at the neuromuscular junction.

Other properties of the release have been defined. Release of radioactivity follows first order kinetics in time. Increasing the concentration of the toxin yields a saturation in the rate of release.

Before being studied in more detail, however, the toxin must be purified to homogeneity. Using the assay described above, isolation of the toxin is now being carried out. Supported by the National Science Foundation (BNS 76-80657), the National Institute of Health (NIH 5 SO7 RR07012), and the Nelson Research and Development Co.

TISSUE CULTURE

1883 IN VITRO SYSTEMS FOR THE STUDY OF EMBRYONIC VISUAL NEURONS. Ruben Adler, Marston Manthorpe* and Silvio Varon. Dept. Biol., Sch. Med., U. Ca. San Diego, La Jolla, CA 92093.

Development and regeneration of neural components of the visual system have been the objects of intensive investigation in vivo. In vitro, aggregate cultures of visual cells have been studied in several aspects, including the increase in choline acetyltransferase (CAT) in co-aggregates of neural retina (NR) and optic lobe (OL) from the chick embryo. However, there is little or no description of retinal or optic lobe neurons in monolayer cultures, the availability of which could permit detailed investigations on trophic influences required for neuronal survival, the interactions between NR and OL cells, and directional instructions for the elongation of NR neurites.

We report here that defined manipulations of the environment in which OL cells are grown make it possible to achieve cultures containing either: (1) an enriched population of neurons in the virtual absence of nonneuronal ("flat") cells; or (2) a purified population of flat nonneuronal cells, free of neurons; or (3) a combined culture containing both cell types. A combination of substrates of higher adhesiveness (polyornithine, unwashed collagen) with a horse serum-containing culture medium tends to produce sparser cultures in which no development of flat cells takes place. On the contrary, substrates of lower adhesiveness (washed collagen, plastic), together with the supplementation of the medium with fetal calf serum produce "clumped" cultures and promote extensive development of nonneuronal cells underlying the neurons. Mechanical removal of the latter makes it possible to obtain purified nonneuronal populations. Preliminary experiments indicate that similar cultures of NR cells can also be obtained. (Supported by USPHS grant NS-07606.)

1884 ULTRASTRUCTURAL CYTOCHEMISTRY OF PLASMALEMMA OF CULTURED HUMAN MUSCLE. Valerie Askanas and W. K. Engel. NIH, Bethesda, MD 20014.

Tissue culture of human muscle provides a valuable tool to study neuromuscular diseases. Since a plasmalemmal defect might be a basic abnormality in some neuromuscular disorders, we used the membrane probes concanavalin A (Con A), ruthenium red α-bungarotoxin, and tannic acid to describe the ultrastructural cytochemistry of the plasmalemma of normal human muscle cells in vitro during different stages of growth. Single spindle-shaped myoblasts have a globular pattern of peroxidase-post-coupled DAB-reacted Con A staining of the plasmalemma, indicating the presence of α-D-glucoside and/or α-D-mannoside groups. After myoblast fusion, the young myotubes and later mature cultured muscle fibers have uniform Con A staining on the entire surface of the plasmalemma. Variation in the staining intensity appeared due to irregularities of the plasmalemma or to obliquity of the section. Penetration of the staining into the cell was not observed when integrity of the plasmalemma was preserved. Omitting the Con A from the incubating medium or pretreatment with α-methyl-glucoside prevented staining. Addition of 25 μg/ml of Con A to the culture medium at day 0 caused agglutination of the myoblasts, but after myoblast fusion addition of Con A did not seem to have an influence on muscle differentiation. Ruthenium red binds to membrane acid mucopolysaccharides. It gave strong uniform staining of the of the plasmalemma at all stages of muscle-cell development. α-bungarotoxin binding, with the immuno-peroxidase technique, identifying acetylcholine nicotinic receptors in the cultured muscle, stained the plasma diffusely and evenly (without hot-spots) at all stages of muscle-cell development, as previously reported (V. Askanas et al., Neurology, 27, 1019-1022, 1977). Tannic acid did not bind to the plasmalemma of single myoblasts or of young myotubes. However, mature cultured muscle fibers had intensive staining of the plasmalemma and of saccular membranes (? t-tubules or plasmalemmal precursors or postcursors) within the muscle fibers (clearly recognized t-tubules do not form in cultured human muscle). (Cultured embryonic chick and rat muscle showed the same differentiation of plasmalemmal tannic-acid stainability with muscle fiber maturity; in addition, the clearly identifiable t-tubules of those mature fibers were darkly stained, as were the t-tubule-originating "lace" of the cultured chick-embryo fibers; an outer layer of the avian leucosis-sarcoma viral C-particles in the cultured chick-embryo was also stained.) Therefore, tannic-acid appears to be a very good probe for studying muscle cell maturation in culture. The described cytochemical staining of normal human muscle during development now provides the basis for seeking plasmalemmal abnormalities in cultured abnormal human muscle.

1885 LABELING CHOLINERGIC NEURONS IN CELL CULTURE. Kate Barald and Darwin Berg. Dept. of Biology, UCSD, La Jolla, CA 92093.

We have previously shown that dissociated chick spinal cord (SC) cells in culture express high affinity choline uptake that has many of the properties expected for cholinergic neurons in vivo. We now report an autoradiographic procedure for selectively labeling neurons that display high affinity choline uptake. The labeled population includes cholinergic neurons both in SC and in ganglionic cultures, while at least some neuronal populations known to be non-cholinergic remain unlabeled.

The success of the autoradiographic procedure depends on the fact that much of the choline taken up by the high affinity system by cells in culture is converted to compounds such as membrane lipids that are retained by conventional fixation methods. Cultures of SC, ciliary ganglion (CG), or dorsal root ganglion (DRG) cells grown with skeletal myotubes were incubated for 1 hr in 0.1 μM (^{3}H)choline (10.1 Ci/mmol) followed by 1 hr in 10 mM unlabeled choline. The cultures were then fixed in glutaraldehyde, post-fixed in osmium, rinsed, coated with photographic emulsion, and developed after 7-11 days.

CG neurons are cholinergic, and in CG-myotube cultures 99% of the neurons labeled. DRG neurons are thought to be non-cholinergic, and in DRG-myotube cultures none of the neurons labeled. Myotubes also remained unlabeled. SC neurons prepared from 4-day embryos displayed a spectrum of labeling when grown with myotubes for 1 wk. About half (56 ± 4%, SEM, 7 expts) labeled substantially. To show that labeled SC cells included cholinergic neurons, extracellular stimulation and intracellular recording were used to identify neurons that had innervated myotubes. The cells were then examined by (^{3}H)choline autoradiography. Out of 17 cases, 16 were clearly labeled. By comparing the number of labeled neurons in cultures incubated with (^{3}H)choline, (^{3}H)γ-amino butyric acid (GABA), or both, it was concluded that most neurons that exhibited little or no (^{3}H)choline labeling could instead be labeled by (^{3}H)GABA, and vice versa. Thus different populations of neurons appeared to be distinguished by the labeling procedures.

In some SC cultures (^{3}H)choline labeling may not be restricted to cholinergic neurons. For example, cultures prepared with SC cells from 7-day embryos are thought from previous work to have many fewer cholinergic neurons than SC cultures from 4-day embryos, yet they appear to have as many (^{3}H)choline labeled neurons, some of which may also label with (^{3}H)GABA. In all cases (^{3}H)choline labeling was blocked by Na^+ deprivation or 10 μM hemicholinium-3. Thus, in addition to cholinergic neurons, the procedure may also label other select populations of neurons, perhaps in rapid growth or in a multi-functional precursor state.

These labeling methods will be useful for distinguishing different neuronal populations and following their development. (Supp. by USPHS Grant #12601, Muscular Dystrophy Assoc., & Am. Heart.)

1886 EFFECT OF GLIAL CONDITIONED MEDIUM ON SURVIVAL AND FIBRE OUTGROWTH FROM CHICK SENSORY NEURONS. Yves A. Barde*, Ronald M.Lindsay*, Denis Monard* and Hans Thoenen, Dept. of Pharmacology, Biocenter of the University, Basel, Switzerland

Process formation can be induced in clonal neuroblastoma cells by a macromolecule termed "glial factor" which has been identified in the medium conditioned by culture C-6 glioma cells. Fibre ougrowth can also be elicited in cultures of peripheral sensory neurons by the well-characterized mouse submaxillary gland nerve growth factor (NGF). We report here that glial conditioned medium (GCM), the source of the "glial factor", can support both survival and fibre formation of isolated chick sensory neurons and that neither NGF nor "glial factor" are responsible for this effect.

Dorsal root ganglia from 10-12 day old chick embryos were dissociated and plated on collagen coated dishes and surviving neurons counted after 48 hours. In the absence of either NGF or GCM, less than 5% of the cells plated survived. The addition of either GCM or NGF led to a marked increase in the number of surviving neurons. The effect of NGF could be completely abolished by specific antibodies to NGF. In contrast, the increased survival of neurons promoted by GCM was not blocked by the NGF antibodies, even when the concentration of antibody used was 100-fold higher than that required to block the effect of NGF. Partially purified "glial factor" did not support the growth of the isolated sensory neurons despite a 100 to 150-fold increase in specific activity determined by the neuroblastoma bioassay. Therefore, it may be concluded that the support of survival and induction of fibre outgrowth in sensory neurons were brought about by a factor other than that which is responsible for neuroblastoma cell process formation, i.e. "glial factor". Digestion of GCM with pronase or chymotrypsin markedly reduced the ability of GCM to support the survival of the sensory neurons, suggesting that this factor might be a polypeptide. Further characterization is now in progress. We are also examining the possibility that this factor might be influencing the survival of sympathetic cells in culture.

1887 MUSCARINIC RECEPTOR BINDING IN SPINAL CORD CELL CULTURES: EFFECT OF MUSCLE-CONDITIONED MEDIUM. Neville Brookes, David R. Burt and Alan M. Goldberg. Dept. Pharmacol. and Exptl. Therap., U. Maryland Sch. Med., and Dept. Envirn. Hlth. Sci., Johns Hopkins U., Sch. Hygiene, Baltimore, MD.

The specific activity of choline acetyltransferase (CAT) in surface cultures of dissociated murine spinal cord (SC cultures) is greatly increased when the cultures are maintained in medium which has been conditioned by murine skeletal muscle cells (Giller et al., J. Cell Biol. 74:16, 1977). Protein content, neuronal cell count and activities of cholinesterase (ChE), glutamic acid decarboxylase and other enzymes are not similarly increased by conditioned medium (CM). It is not known whether this induction of CAT activity is associated with changes in other parameters of cholinergic neurotransmission. The present experiments examine the effect of skeletal muscle CM on the binding of [^{3}H]quinuclidinyl benzilate ([^{3}H]QNB) to muscarinic receptors in SC cultures.

Cultures were prepared by mechanically dissociating spinal cords from 13-day-old mouse embryos and then seeding aliquots of the cell suspension onto collagen-coated dishes at a cell density of approx. $2x10^5/cm^2$. [^{3}H]QNB binding was detectable in control SC cultures after 5 days of incubation and it had increased by an average factor of 6.6 times at 21 days, when the specific binding was 340±80 pmole/g protein (mean ± SEM, N=8). Specific [^{3}H]QNB binding was still increasing at 28 days of SC culture. CM-treated SC cultures were fed from day 4 onward with medium which had previously been conditioned by muscle cell cultures for 2-3 days. CAT specific activity in CM-treated SC cultures was increased by a factor of 2.7±0.5 (N=3) times control values at 14-15 days, and 4.2±0.8 (N=3) times at 18-21 days. The corresponding factor for ChE specific activity at 18-21 days was 1.3±0.1 (N=3). In parallel experiments, [^{3}H]QNB specific binding increased only by a factor of 1.6±0.2 (N=8) times control values at 20-21 days. Thus, the effect of muscle CM on muscarinic receptor binding was comparable to the modest effect on ChE activity and did not approach the scale of the marked influence on CAT activity.

1888 DOES THE SAME COMPONENT OF CONDITIONED MEDIUM INDUCE NEURITE OUTGROWTH FROM BOTH SYMPATHETIC AND PARASYMPATHETIC NEURONS? Frank Collins* (SPON: L. Mathers) Dept. Bio. Sci., Stanford Univ., Stanford, CA 94305

Individual ciliary ganglion (parasympathetic) and lumbar chain (sympathetic) neurons from chick embryos extend neurites in heart-cell conditioned medium, but not in unconditioned medium. Nerve growth factor (NGF) will not substitute for conditioned medium under our culture conditions, nor is the activity of conditioned medium affected by antiserum to NGF. Since conditioned medium supports outgrowth both from neurons which are considered to be NGF-dependent (sympathetic) and from those considered to be NGF-independent (parasympathetic), it is important to know whether the same or different components of conditioned medium are involved.

An active component of conditioned medium, which is apparently negatively charged, binds to the positively charged polyornithine-coated culture substratum, so that culture dishes pretreated with conditioned medium will support neurite outgrowth in unconditioned medium. The conditioned medium activity which binds to the culture substratum supports neurite outgrowth from both the sympathetic and parasympathetic neurons. The activity is sensitive to trypsin, but not to collagenase, RNase, or DNase. An ammonium sulfate fraction, which contains a very low percentage of the total protein in conditioned medium, contains the material which binds to the substratum and which supports neurite outgrowth from both classes of neuron.

These results suggest that identical or very closely related components of conditioned medium induce neurite outgrowth from both sympathetic and parasympathetic neurons.

1889 ELECTROPHYSIOLOGY AND PHARMACOLOGY OF STRIATED MUSCLE FIBERS CULTURED FROM DISSOCIATED NEONATAL RAT PINEAL GLANDS. Joseph E. Freschi*, Andrew G. Parfitt* and William G. Shain (SPON: L. H. Masukawa). Armed Forces Radiobiol. Res. Inst., Bethesda, Md. 20014.

Striated muscle fibers have been observed within the pineal glands of several mammalian species including man. We found striated muscle fibers in each of twenty consecutive pineal glands cultured from individual neonatal (2 day) rats. Subsequent experiments were done with dissociated cultures of pineal glands pooled from several litters. Myotubes were first visible after about one week in culture. During the next several weeks the myotubes increased in size, developed cross-striations, and began to twitch spontaneously. The resting membrane potential (RMP) increased with age in culture. All myotubes studied showed delayed rectification. Action potentials either occurred spontaneously or could be evoked if the membrane were sufficiently polarized. No spontaneous end plate potentials were seen. Acetylcholine (ACh) produced a brief, monophasic depolarizing response. Norepinephrine (NE), serotonin (5HT), dopamine (DA), melatonin (MEL), and γ-aminobutyric acid had no effect on the RMP when applied iontophoretically. The ACh response was reversibly blocked by 10^{-6}M d-tubocurarine and irreversibly blocked by 10^{-6}M α-bungarotoxin. Atropine at 10^{-4}M reduced the amplitude and shortened the time course of the ACh response, and 10^{-3}M produced complete but reversible inhibition.

It is concluded that myogenic cells of unknown origin occur within the neonatal rat pineal gland. These pineal muscle fibers are electrophysiologically and pharmacologically identical with peripheral skeletal muscle cells in vitro. Although the pineal gland is devoid of ACh, these striated muscle fibers develop ACh receptors but do not develop receptors mediating electrophysiological responses for NE, 5HT, DA, MEL, or GABA which are known to be present in the pineal. A comparison of the developmental properties of these cells in culture with other systems such as striated muscle fibers in dissociated thymus (Wekerle, et. al. Nature 256: 493-494, 1975) suggests the possibility that these pineal striated muscle fibers may arise from pluripotential stem cells.

1890 **PRECISE NEURITE TRANSECTION AND DE-INSULATION OF PHOTOETCHED MULTI-MICROELECTRODES WITH UV-LASER MICROBEAM TECHNIQUES.** **Guenter W. Gross*, M. Louise Higgins*, and Marilyn Smith* (SPON. J.E. Hines). Dept. Biology Texas Woman's University, Denton, Texas 76204.**

A UV-laser microbeam system is being utilized to a) transect neurites of nerve cells in culture, b) create adhesion patterns on glass or plastic surfaces and c) de-insulate end regions of photoetched gold conductors on the floor of tissue culture chambers. These techniques are being developed to influence the ordered neuronal growth of networks in vitro and to develop a long-term simultaneous single unit recording capability from more than 30 neurons in a network. The three micromanipulations can be easily carried out with a 1 μm resolution by firing UV laser pulses of 8 ns duration and 337 nm wavelength through a microscope objective. This achieves a minimum focus of 0.7 μm and a maximum power density of 10^{12} Watts/cm^2. Successful transections depend on the power density utilized, the exact position of the focus relative to the plane of the neurite, the distance of the transection from the cell body and the size of the neurite. Scattered UV radiation appears to have little immediate effect on neurons and is being investigated on the ultrastructural level. EM studies also reveal blebbing and ultrastructural disruption resulting from shock waves produced by excessive energy densities or vaporization of substrate. Electrode de-insulation is achieved by the laser-induced vaporization of minute amounts of gold from the flat conductor and the concomitant pressure-removal of the overlying insulation. A 10 μm diameter crater in a 3 to 4 μm thick insulation layer has an impedance of approximately 3 megohm at 1 kHz. These recessed gold surfaces have recorded single unit activity from snail brain ganglia resting against the recording matrix in a shallow pool of saline. Giant cells produce 3 mV signals that can be seen by several electrodes simultaneously. The more abundant 40 μm diameter cells produce spike amplitudes of 300 to 500 μV that are seen by only one electrode. With this recessed tip design, simultaneous single unit recording from smaller neurons appears assured if electrode impedances remain below 4 megohm, shunt impedances are above 30 megohm and glia cells are not allowed to re-insulate the electrode craters.

1891 HRP CHARACTERIZATION OF NEURONS IN ORGANIZED CULTURES OF CEREBELLUM. W.J. Hendelman and K.C. Marshall, Depts. of Anat. and Physiol., University of Ottawa, Ottawa, Canada, K1N 9A9.

Organotypic (Maximow) cultures of newborn mouse cerebellum have 3 different regions: the cortical area with its Purkinje neurons (PN), the deep cerebellar nuclear neurons (DN), and a group of cells derived from the brain stem in the peduncular region (BS). Clearly identified neurons were visualized in select mature cultures and injected intracellularly with horseradish peroxidase (HRP, Sigma type VI), using depolarizing pulses equivalent to about 100-120 x 10^{-9}Amp.-minutes of steady current. Perfusion of the cultures in BSS (supplemented with glucose) at 35°C was continued for 4-6 hours, and followed by aldehyde fixation. The reaction in Hanker-Yates solution was monitored microscopically for up to 2½ hours. It was generally observed that the soma and dendrites of smaller neurons (25μ or less) were not stained, though the axons were well filled. The PN axon had a constant diameter of 1-2μ and followed a relatively direct course to the DN area. Most axons emitted a single recurrent collateral. In the DN region the axon arborized in a narrow field (appr. 60 x 150μ) and terminated in knobs (2-5μ);some axon branches had "terminals-en-passant". The DN axons were seen to bifurcate several times, and the diameter of the branches varied in size but was usually 1μ or less. After injection of a single neuron many axon branches were seen entering the cortical region. Several axons followed a sweeping trajectory along the margin, though others coursed directly through the explant. Some had a long, sometimes looping pathway through the cortex, often exhibiting abrupt changes in direction. Evidence of terminals consisted of smooth or beaded excrescences along the axons or along slender side branches. BS neurons: These large cells (~30μ) have 2-4 dendrites which are broad at their origins and emit spines. They taper gradually and often seem to continue as axon-like neurites which may extend for some distance. Some neurons appear to give rise to multiple axons emanating from soma and dendrites. The axons are thin, and characterized by small varicosities along their course. There is usually an extensive plexus of local collaterals, but the longer branches meander erratically into the cortical and the non-neuronal outgrowth regions. This technique has proven useful to demonstrate the axonal branches of a single neuron. These projections corroborate our electrophysiological data on the interconnections in these cultures. Further studies are intended to define the synaptic connections electron microscopically. (Supported by the Medical Research Council of Canada).

1892 SYNAPSE FORMATION BY NEUROBLASTOMA AND HYBRID CELL LINES. Haruhiro Higashida*, Steven P. Wilson, Michael Adler and Marshall Nirenberg. Laboratory of Biochemical Genetics, NHLBI, NIH, Bethesda, MD 20014.

Nineteen neuroblastoma or hybrid cell lines that synthesize acetylcholine (ACh) were cultured with rat striated muscle cells. Myotubes were tested for synapses by intracellular recording using the presence of spontaneous miniature endplate potentials and evoked responses as criteria for functional innervation. Rates of ACh synthesis were 35-460 pmol ACh formed/min/mg homogenate protein. Cells incubated with 100 μM [^{3}H]-choline released 80-6,370 fmol [^{3}H]-ACh/min/mg protein into the medium and contained 38-540 pmol [^{3}H]-ACh/mg protein (Wilson, et al., Fed. Proc. 37, 1784, [1978]). Six cell lines formed synapses with high frequency (Syn^+ lines) (14-63% of myotubes tested were innervated); whereas 13 cell lines formed few or no synapses (Syn^- lines). Some, but not all, Syn^- lines exhibited defects in the coupling of K^+-dependent depolarization with ACh release. Four additional cell lines lack choline acetyltransferase activity and also were unable to form functional synapses with myotubes. Syn^+ cell lines that were examined formed synapses with myotubes rapidly, 20-30 min after cells were added to myotubes. These cells also formed synapses with clonal G8-1 mouse striated muscle cells.

Some Syn^+ cell lines undergo depolarization when activated by ACh, serotonin, or dopamine. Addition of neurotensin, angiotensin-II, bradykinin, or somatastatin by iontophoresis or by diffusion from blunt pipettes resulted in slow hyperpolarization (usually 10 to 20 mV, 10-20 sec) followed by prolonged depolarization (2 to 10 mV, 30-80 sec). The effects of activating these and other species of receptors on synapse formation and function thus can be studied.

Treatment of Syn^+ hybrid cells with dibutyrl-cAMP (Bt_2cAMP) for > 5 days increased markedly the number of synapses formed, the frequency of spontaneous muscle synaptic responses, and K^+-dependent release of [^{3}H]-ACh from cells. These results show that stimulus-dependent ACh release is regulated by Bt_2cAMP, thereby regulating synapse formation and efficiency, and that clonal cell lines can be generated with defects in depolarization-ACh-release coupling and other presynaptic functions.

1893 BULK ISOLATION FROM RAT CEREBRAL CORTEX OF VIABLE NEURONS WHICH RETAIN SYNAPTIC COMPLEXES. W. B. Huttner*, R. Meyermann*, V. Neuhoff* and H.-H. Althaus* (SPON: P. Greengard).
Max-Planck-Institut Exp. Med., 34 Goettingen, FR Germany.

A new approach to the bulk isolation of rat cerebral neurons has been introduced (1). In the present study, the principles of this isolation procedure were investigated, and EM examinations of the isolated nerve cells were carried out (2). The basis of this procedure is the predisaggregation of the neurons in situ brought about by perfusion of the brain under specialized conditions: 1) a hyperosmolar concentration of hexoses in the perfusate; 2) the presence of collagenase and hyaluronidase; and 3) an elevated capillary pressure of the perfusate. The first condition is a prerequisite for the isolation of neurons whereas the other two conditions improve the morphological integrity of the neurons. Histological and TEM studies of the perfused brain reveal that after perfusion most of the glial cells surrounding the neurons are destroyed. This predisaggregation of the nerve cells in situ, together with the damaging effect of the perfusion on the capillary network, greatly facilitates the subsequent mechanical dissociation of the brain tissue. The cell suspension obtained contains virtually no neuronal nuclei, and 70% of the neurons retain the proximal parts of their processes. Using a Ficoll density gradient with a liquid fluorocarbon as a cushion, a neuronal fraction of 90% purity is obtained yielding 20 x 10^6 nerve cells/g cortex. Upon SEM and TEM examination of the isolated neurons, various cell types can be distinguished, and the plasma membranes and intracellular structures appear well preserved. A novel feature of the isolated, viable neurons is that they still retain some of their synaptic complexes. Having attached presynaptic buttons including mitochondria and vesicles, as well as pre- and postsynaptic membranes and densities, the cells represent neurons retaining synaptosomes on their plasma membranes. Preliminary experiments have determined that the nerve cells can be maintained in culture (Althaus, Neuhoff, Huttner, Monzain and Shahar).

1894 ION TRANSPORT AND MEMBRANE POTENTIAL PROPERTIES OF CULTURED RAT BRAIN ASTROCYTES. H.K. Kimelberg*, C. Bowman* and R.S. Bourke. Div. Neurosurg., Albany Med. Coll. and Neurobiology Research Center, State Univ. of N.Y. at Albany, Albany, N.Y.

Primary astrocyte cultures were grown from 1-3 day old rat brains (Booher and Sensenbrenner, Neurobiol. 2, 97, 1972), and were studied after 2-3 weeks in culture. The initial rate of K^+ influx (as $^{86}Rb^+$) at an external $[K^+]_o$ of 4.5 mM under equilibrium conditions at 37°C, was 0.02 to 0.03 μmoles K^+/min/mg protein. Efflux rates calculated from a first order rate constant of 0.03 min^{-1} and a K^+ content of 0.9 μmoles/mg protein were similar. Active ouabain-inhibited uptake of K^+ was 0.006 to 0.01 μmoles K^+/min/mg protein, balancing a Na^+ efflux (based on Na^+ influx) of 0.007 μmoles/min/mg protein. Since $[Na^+]_o$=130 mM this data suggests that the permeability of the membrane to Na^+ is considerably less than for K^+. (Na^++K^+) ATPase activity was 0.016-0.05 μmoles ATP hydrolyzed/min/mg total cell protein. Cl^- influx and efflux (as $^{36}Cl^-$) were both in the range of 0.04 to 0.05 μmoles/min/mg protein and were partially inhibited by the anion inhibitor,4 acetamido-4'-isothiocyanostilbene-2,2'-disulfonate (SITS), suggesting that Cl^- transport in these cells was both passive and mediated. Also the cells lose Cl^- in low Cl^- medium.

The membrane potentials of these cells were measured at 25°C using microelectrodes. Untreated cells were too flat to be impaled but after treatment with DBcAMP the cell bodies rounded up and were easily impaled. Addition of DBcAMP had little effect on transport rates. A number of the cells had membrane potentials (E) of around -70 mV, similar to astroglia in vivo. Groups of cells were pre-equilibrated with media of increasing $[K^+]_o$ at constant $[Cl^-]_o$, and the slope of a plot of the data was 53 mV/10 fold change in $[K^+]_o$ at $[K^+]_o$ values > 35 mM. Extrapolation to E=0 gave a value for $[K^+]_i$ of 150 mM. Below 35 mM $[K^+]_o$ the E values diverged from a straight line, and a permeability ratio (α) for Na:K of 0.04 was calculated. However cells with less negative potentials, due either to heterogeneity or impalement injury, were also found, giving a mean value for E of -51±18 mV (+S.D. n=43) at $[K^+]_o$=4.5 mM. The results from perfusion of impaled cells with media of varying $[K^+]_o$ but constant KxCl product, also showed a slope of 55 mV/10 fold change in $[K^+]_o$. From this a $[K^+]_i$ of 170 mM and α=0.03 was obtained.

Thus these astrocyte cultures, like mammalian astroglia in vivo, show high negative potentials of -70 mV largely determined by K^+, and a (Na+K) pump sufficient to maintain a K:Na ratio of ≥ 10, which makes them suitable as in vitro models. In addition, these cells seem to show both passive Cl^- transport and a mediated, SITS-inhibitable Cl^- exchange component. (Supported by Grant NS 13042 from NINCDS).

1895 PARALLEL CHANGES IN ELECTRICAL AND CONTRACTILE ACTIVITY IN CULTURED MYOCARDIAL CELLS. M. Kitzes* and M. W. Berns* (SPON: J. Sassin). Dept. Dev. & Cell Biol., UC Irvine, Irvine, CA 92717.

Intracellular study of spontaneous activity of over 800 neonatal rat (1-2 day old) ventricular cells in culture provided consistent data to establish normal patterns of spontaneous electrical activity under controlled conditions of the surrounding standard medium. Our results indicate that a certain percentage of the cells showed resting membrane potentials (total range -40mV to -98mV), overshoot and total spike amplitude values comparable to those normally found in neonatal and adult rat heart. A relatively low ratio of pacemaker (40%) to non-pacemaker cells (60%) and low incidence of hyperpolarizing afterpotentials (35%) were found. These findings indicate that reversion of the cultured cells to a younger state may only be partial in our cultures.

Our results show that La^{+++} (.1mM to 3mM) administration always results in diminished contraction frequency and strength with complete block of spontaneous contractility at higher concentrations. These changes, however, were paralleled by marked alteration of electrical activity. Intracellular recordings during this trend towards complete block of contractility show a concomitant progressive cell depolarization, diminished discharge frequency and marked increase in action potential duration with alteration of normal configuration. Action potentials from cells showing slow rhythmic spontaneous contractions in an otherwise immobile monolayer achieved durations of up to 2.5 sec. All cells which showed complete block of contractility after exposure showed resting membrane potentials which ranged from -25mV to -55mV and no action potentials. In all cases, complete recovery of contractility, resting membrane potential and normal action potentials followed replacement of experimental medium by normal medium. Recovery to increased strength and contraction frequency paralleled by increased action potential discharge frequency and levels of membrane polarization was observed frequently.

Our results indicate that in the neonatal rat monolayer culture, La^{+++} is not a specific E-C uncoupler as has been reported previously but has multiple effects upon the normal electrical characteristics of the cultured cells.

This research was supported by NIH grants HL15740, GM23445 and GM22754, and by U.S. Air Force grant AFOSR-77-3136.

1896 GROWTH CHARACTERISTICS OF ISOLATED ADRENAL MEDULLARY CELLS IN CULTURE. Bruce G. Livett, Deanne M. Dean* and Garth M. Bray. Division of Neurology, Montreal General Hospital and McGill University, Montréal, Québec, Canada, H3G 1A4

Peripheral adrenergic neurons and adrenal medullary cells both originate from the neural crest. Adrenal medullary cells, obtained in high yield (10^7 cells/gland) from bovine adrenal medullae by retrograde perfusion with collagenase[1], provide a convenient system for studying adrenergic function and development in-vitro. Cells rich in adrenaline or noradrenaline have been obtained by fractionation on Percoll gradients and plated in DMEM with serum supplements. By two days in culture, most cells had flattened out and developed short processes, some of which had terminal expansions resembling growth cones. By 6 days these processes had extended up to 250μ in length and displayed a varicose appearance. Examination of the cultures by the Faglu fluorescence method[2] revealed high concentrations of catecholamines in the varicosities and growth cones of the cell processes. Transmission electron microscopy confirmed that the processes contained either adrenaline or noradrenaline vesicles. Chemical analysis of the cells after 6 days in culture showed that they contained principally noradrenaline (NA) (NA/A 21.94 ± 0.07, n=5) in contrast to the cells which, when first plated, contained mostly adrenaline (A) (NA/A 0.23 ± 0.07, n=9). Long-lasting contacts were made by the adrenergic processes with the soma and processes of other chromaffin cells.

We conclude that under appropriate conditions, adrenal chromaffin cells can undergo process formation resulting in varicose fiber networks similar to those of adrenergic neurons.

1897 MORPHOLOGY AND GFA-IMMUNOFLUORESCENCE OF ASTROGLIA-CONTAINING MONOLAYER CULTURES FROM RAT CEREBRUM. Marston Manthorpe*, Ruben Adler and Silvio Varon (SPON: S.A. Hillyard). Dept. Biol., Sch. Med., U. Ca. San Diego, La Jolla, CA 92093.

Reactive gliosis in response to damage in the CNS leads to scar tissue which is thought to present a barrier to the regenerating neurite. Regulation of proliferation, hypertrophy or fibrotization of astroglial cells, the three main components of gliosis, could be most conveniently analyzed under the control conditions of a monolayer cell culture, particularly if the latter could be made available as a purified, homotypic population. Cell suspensions were obtained from neonatal rat cerebrum by trituration after trypsin treatment. The cells were cultured on glass coverslips, in CO_2/air with fetal calf serum-supplemented medium. Cultures were inspected periodically under phase contrast microscopy for morphology and numerical analyses, and examined at selected time intervals by an indirect immunofluorescence test for the presence of Glial Fibrillary Acidic protein (GFA). The early cultures displayed two readily distinguishable cell categories, each susceptible of further, though less sharp, subdivisions.

(1) Flat cells (thinly spread, phase-light elements, with grossly polygonal contours and no processes) were responsible for practically all of the culture growth, and became the nearly exclusive population in 2 week-old cultures started at appropriate seeding densities. A combined treatment of serum withdrawal and dibutyryl cyclic AMP (DBcA, 1 mM) causes these cells to assume typical astrocytic morphologies, as already described by other investigators. In our hands, this morphological conversion was i) massive, ii) rapid, iii) reversible, and iv) imposable on early and/or sparse cultures, as well as 2-week old confluent ones. Each treatment component, applied separately, appears to elicit distinctive morphological changes. GFA was found to be present in most flat cells before, as well as after, the treatments.

(2) Process-bearing (PB) cells were present as early as the cultures could be analyzed, when they equaled or outnumbered the flat cells, but showed no propensity to proliferate. PB cells were characterized by: i) small, well-contained bodies with either a phase-dark or a phase-bright appearance, ii) discrete, thin processes varying in number and branching patterns, iii) no gross morphological responses to the above treatments, and iv) no detectable GFA antigen, thus far.

Attempts are underway to alter behavior and/or relative numbers of the two cell classes by use of different culture conditions, with the ultimate aim to obtain them as separate subpopulations of cerebral cells. (Supported by USPHS grant NS-07606).

1898 Morphology and electrophysiology of cerebellar neurons in cell culture. E.A. Neale, G. Moonen*, R.L. Macdonald, W. Gibbs*, and P.G. Nelson. LDN, NICHD, NIH, Bethesda, MD 20014

The cerebellar cortex has been used as a model for the study of neuronal development and synaptic specificity. To further examine the morphology and synaptic physiology of specific neurons, it is desirable to grow cerebellar tissue in a monolayer cell culture system where anatomic complexity is reduced and neurons are more readily accessible for intracellular recording and structural tracing. We have obtained, from 17-19 da fetal rat cerebella, long-term (>8 wk) cell cultures which contain several types of neurons. Intact cerebella were passed through Nytex 215 nylon mesh to obtain small clusters of cells which, when plated, spread to form networks of neurons. Neuronal survival in these cultures was greater than in cultures prepared from single cell suspensions, with or without subsequent reaggregation before plating.

Intracellular recordings were obtained from >100 neurons with soma diameters >15 μm. Although membrane potentials were low (20-30 mV), spontaneous action potentials were usually seen. Synaptic activity was recorded in most cells (>90%) and both excitatory and inhibitory postsynaptic potentials were observed.

More than 20 neurons were injected with horseradish peroxidase (HRP) so that entire selected cells might be structurally analyzed. The most common large neuron had a 20 μm rounded soma, one or more dendritic shafts with blunt-ended, spine laden branches, and a single axon that bifurcated several times, but showed few swellings in contact with other neurons. With the electron microscope, these swellings were seen to contain pleomorphic vesicles. Morphologic features of such neurons suggest that they are Purkinje cells whose dendritic arborizations are considerably less complex than in vivo. A second type of large neuron showed a 20 μm rounded soma, long slender dendrites, and an axon with many delicate branches forming numerous contacts on processes of nearby cells. Similar cells, not injected with HRP, displayed nuclear rodlets and subjunctional dense bodies beneath impinging synaptic terminals, features associated with Golgi cells. A third neuronal type was characterized by a 6 μm soma occupied mostly by its nucleus, rich in condensed chromatin, similar to cerebellar granule cells.

Several distinct varieties of synaptic boutons were found in these cultures. It appeared that the shafts of the presumed Purkinje cell dendrites received primarily large boutons marked by pleomorphic vesicles, while smaller boutons filled with rounded vesicles were commonly associated with dendritic spines.

Cerebellar neurons, possessing active membrane properties, can thus be maintained in long-term cultures. The neurons display morphologic features characteristic of in vivo cerebellar neurons, and develop extensive synaptic connectivity.

1899 QUANTITATIVE LONG-TERM SURVIVAL AND DEVELOPMENT OF CHICK CILIARY GANGLION NEURONS GROWN ALONE IN DISSOCIATED CELL CULTURE. Rae Nishi and Darwin Berg. Dept. of Biology, UCSD, La Jolla, CA 92093.

Cell death between embryonic days 8 and 13 in the normally developing chick ciliary ganglion reduces the number of neurons from 6500 to 3200. We have previously shown that quantitative long-term survival of the neurons, including those destined to die in ovo, can be obtained in cell culture when 8-day embryonic ganglia are dissociated and grown with skeletal myotubes. We now report that equivalent survival can be obtained when CG neurons are grown alone in appropriately conditioned medium, and that they develop high levels of choline acetyltransferase (CAT) activity under these conditions.

Ciliary ganglia from 7-8 day chick embryos were removed, gently dissociated, and plated with or without skeletal myotubes or heart cells at a density of ca. 6 x 10^3 neurons (1 ganglion equivalent) per 16 mm collagen-coated Falcon tissue culture well. Culture medium consisted of Eagle's MEM supplemented with 5% chick embryo extract and 10% horse serum. Neurons grown alone received medium diluted 1:1 with conditioned medium obtained from myotube or heart cell cultures. Culture extracts were prepared and assayed for CAT activity by following the conversion of radioactivity from (^{3}H)acetyl Co-A to (^{3}H)acetylcholine, as determined by extraction with tetraphenylboron in heptanone. Surviving neurons were counted with phase contrast optics before extract preparation in each case.

When grown alone in conditioned medium, the number of surviving neurons per culture remained constant for at least 3 weeks. The mean number, per ganglion equivalent used to prepare the cultures, was 6370 ± 170 (SEM, 37 cultures counted) over the entire period. Comparable survival was obtained in conditioned medium lacking embryo extract; no survival was observed for unconditioned medium supplemented only with horse serum. For neuron-myotube cultures, in which we have previously shown that most of the neurons innervate myotubes, levels of CAT activity increased from 25 ± 1.2 fmoles ACh/neuron/hr at 3 days in vitro to 404 ± 36 at 15 days (mean ± SEM, 3 experiments). Neurons grown with heart cells displayed a similar development of CAT activity. CAT activity for neurons grown alone in conditioned medium with embryo extract increased from 29 ± 3.6 fmoles ACh/neuron/hr to 347 ± 12 over the same time period (3 experiments).

Thus factors present in the medium can promote the survival of CG neurons in dissociated cell culture, including those neurons destined to die in ovo. Direct contact with myotubes or heart cells is not necessary for the survival, and the neurons continue to develop under these conditions as indicated by the increases in levels of CAT activity. (Supported by USPHS Grant #12601, The Muscular Dystrophy Association, the The American Heart Association.)

1900 CHOLINERGIC AND NUCLEOTIDE RESPONSES IN CULTURED FROG SYMPATHETIC NEURONS. Ante L. Padjen, Donna L. Gruol, George R. Siggins, and David S. Forman. Dept. Pharmacol. Therap., McGill Univ., Montreal, Canada, LNP, NINCDS, NIH, Bethesda, Md., The Salk Institute, La Jolla, Calif., and NMRI, NNMC, Bethesda, Md.

Several purine and pyrimidine mononucleotides including ATP and UTP produce potential changes in cultured bullfrog sympathetic neurons which are similar to cholinergic muscarinic responses (Siggins et al., Nature 270:263,1977). In the present study we have analyzed the responses of these neurons to muscarine, a cholinergic agonist thought to act primarily at the muscarinic receptor, and compared them to nucleotide-evoked responses. Longterm (4-8 week) cultures of adult bullfrog sympathetic ganglia were studied using conventional intracellular recording techniques and superfusion of drugs (Padjen et al., Neurosci. Abs. 1:813, 1975). Neurons ($\bar{x}$=40x54 μm) displayed stable resting potentials (-35 to -58 mV; $\bar{x}$=45 mV) and generated single or repetitive overshooting action potentials when stimulated with intracellular current pulses. Input resistances calculated from hyperpolarizing I-V curves ranged from 14 to 41 MΩ($\bar{x}$=27 MΩ). Mean R_m, τ_m, and C_m were 1612 Ωcm^2, 5.2 msec, and 3.4 μF/cm^2 respectively. The response to a 15-60 second pulse of 10^{-4}M muscarine was most often (29 out of 40 cells) a slow depolarization ranging from 2-19 mV ($\bar{x}$=7 mV) which lasted several minutes. Occasionally this depolarization was followed by a prolonged secondary hyperpolarization (1-5 mV). In 11 cells there was little or no response (<2mV depolarization). The depolarizing and hyperpolarizing muscarinic responses were associated with either an increase or no change in input resistance. The nucleotide responses were similar to those seen with muscarine: prolonged depolarization sometimes followed by secondary hyperpolarization, both generally accompanied by an increase in input resistance. In 24 cells in which both muscarine and nucleotides were tested, 21 responded to both agents with UTP being the most potent, while 3 responded only to the nucleotides. However, atropine ($3x10^{-6}$-$1.3x10^{-5}$M) reversibly blocked the depolarizing responses to muscarine but had no effect on responses to nucleotides. Thus, the electrophysiological properties and muscarinic receptors of these cultured neurons are similar to those of acutely isolated sympathetic neurons. However, a unique response is seen in the cultured neurons. Research is in progress to test for nucleotide responses in acutely isolated ganglia.

1901 MORPHOLOGY AND ELECTROPHYSIOLOGY OF DISSOCIATED MOUSE HIPPOCAMPAL CULTURES. J. Peacock, D. Rush, and L. Mathers, Stanford University Medical School, Stanford, CA 94305

Dissociated hippocampal cultures from fetal mice (13-18 days gestational age) were grown for up to 2 months in culture. Neurons in mature cultures were round and small (maximal size, 15-20 μM). Their processes were extensively branched but difficult to see with phase contrast optics due to their growth among underlying nonneuronal cells. Processes could be identified with silver staining and by intracellular injection of the fluorescent dye, Lucifer Yellow. Some processes appeared to have spines and others to be beaded. Processes tended to emanate from one side of the soma in 22/28 fluorescent-stained cells either originating at the cell body (11 cells) or from a single trunk (11 cells). Commonly, there were 2-4 orders of branching, but up to 6 orders could occur (as counted centrifugally from the soma).

Spontaneously occurring action potentials (APs), postsynaptic potentials (PSPs), and burst potentials were recorded intracellularly in > 200 cells with K-acetate or Lucifer Yellow filled micropipettes. Repetitively firing APs were also elicited by intracellular stimulation and frequently were preceded by stereotyped prepotentials which suggested their sites of origin were on processes remote from the cell body. In some cells, the AP could trigger long duration depolarizing afterpotentials (0.3-2 sec) with superimposed action potentials.

APs in these highly electrogenic cells were short (0.6-1.2 ms) with peak rates of rise from 320-1333 v/s (mean 696 ± 300 v/s, 24 cells), and corresponding rates of fall from 107-667 v/s (mean 351 ± 167 v/s, 24 cells). Following the AP, the afterhyperpolarization was usually short (< 10 ms), but postburst afterhyperpolarization could last < 2.5 sec).

Synapse formation was demonstrated in the following ways: by spontaneous occurrence of PSPs which were inhibitory (50/72 consecutive cells) or excitatory leading to APs; by reversal of inhibitory PSPs (Vrev ∿-40 mV); by the detection of synaptically coupled cell pairs; and by ultrastructural identification of synaptic junctions. Electronmicroscopy further revealed multiple synaptic contacts on single processes with a predominance of asymmetric over symmetric junctions.

Neural networks which formed in these cultures demonstrated reciprocal innervation (3/19 synaptic pairs) and multiple innervation (2/19 pairs). Widespread synchronous bursting could occur with many cells participating in the bursting (up to 25 cells per microscopic field have been found).

These experiments show that a well developed branching morphology and a broad range of electrophysiologic phenomenology are found in hippocampal neurons which have been grown in culture for 1-2 months. (Supported by NIH Grant NS12151).

1902 CILIARY GANGLION NEURONS MAY FORM INEFFECTIVE SYNAPSES IN DISSOCIATED CELL CULTURE. Guillermo Pilar and Jeremy Tuttle.* Physiology Section, Biological Sciences Group, University of Connecticut, Storrs, Connecticut 06268.

Neurons in dissociated cell culture vary in their ability to form functional synapses. While synapses between sympathetic ganglion cells and among spinal cord cells seem common, functional synapses between dorsal root ganglion cells are either very rare or do not occur. This study examines synaptogenesis between dissociated ciliary ganglion neurons in cell culture.

Electron micrographs of ciliary ganglion neurons in culture include profiles with typical synaptic ultrastructure (bouton-like "endings" with aggregates of clear vesicles along the "presynaptic" membrane; evidence of "post-synaptic" electron density) and these profiles are often found on the cell soma as well as along neurites. However, intracellular recordings from over 100 neurons in these cultures have failed to detect synaptic potentials. Recordings were taken in growth medium, normal saline and high-Ca^{++} saline; and they include simultaneous recordings from cell pairs with direct intracellular stimulation of each in turn, and single-cell recordings using extracellular stimulation of other neurons and processes. The neurons in these cultures have adequate levels of choline-acetyltransferase activity, and will take up ^{3}H-choline from the medium and synthesize ^{3}H-acetylcholine (Ach). Thus the observed lack of synaptic interaction is probably not due to a defect in transmitter metabolism. Rather, the results suggest a defect in synaptic transmission such that the neuron-neuron contacts formed are ineffective.

This possibility was examined by measuring the sensitivity of dissociated ciliary ganglion neurons to iontophoretically applied Ach. When neurons from St. 36-37 embryoes were tested at 24 hrs. after dissociation, most of the cells depolarized and discharged in response to short (3 ms) pulses of Ach. However, only about half of the cells tested at 3 da. in culture were sensitive, and none of a small sample (n=8) tested at 5-11 da. in culture showed a depolarization to Ach. Ach was also iontophoresed onto myotubes co-cultured with some of these neurons, using the same iontophoretic micropipettes. All of the myotubes depolarized in response to much lower doses of Ach, whether or not they were contacted by nerve fibers. While we cannot at this time exclude a defect in the neuronal release of Ach, our findings suggest the failure to record synaptic potentials from these cultured neurons is due to a very low neuronal sensitivity to Ach. This lack of sensitivity to Ach may be a cellular response secondary to the trauma inherent in tissue isolation. Its basis, and the ability of these cells to release Ach is under study. Supported by NIH-NS10338, NS5382, and the Univ. of Conn. Research Foundation.

1903 FORMATION OF CHOLINERGIC SYNAPSES BETWEEN EMBRYONIC CHICK SYMPATHETIC NEURONS AND SKELETAL MYOTUBES DEVELOPING IN DISSOCIATED CELL CULTURE. Barbara Pope* and Paul H. O'Lague (SPON: William L. Byerly.) Dept. Biology, UCLA, Los Angeles, CA 90024.

Monolayer cultures of isolated sympathetic neurons and skeletal myotubes were made by dissociating the superior cervical ganglia of 13-14 day-old chick embryos and adding the resulting cell suspension containing primarily neurons and a small number of non-neuronal cells to the myotubes. These myotubes had formed from myoblasts isolated from 11 day-old chick embryonic pectoral muscle and plated onto collagen-coated coverslips (10^5 cells/cm^2) 4-7 days prior to the addition of the neurons. 10-31 days after the addition of the neurons, neuron-myotube pairs were tested with intracellular microelectrodes for synaptic interaction. In 27 of 150 pairs tested an action potential evoked in a neuron by an intracellular depolarizing current pulse gave rise after a latency (range 2 to 20 msecs) to an excitatory junction potential (e.j.p.) in a myotube. The amplitudes of the e.j.p.'s ranged from 3 to 25 mV. In the few cases tested, the e.j.p.'s were blocked by d-tubocurarine (1 μg/ml) and α-bungarotoxin (5 x 10^{-7} g/ml). The effect of these agents on the neuron-myotube interaction suggests that transmission was nicotinic-cholinergic. In a few experiments neuron-neuron pairs in the cultures were tested for interaction; excitatory synaptic potentials were found. The characteristics of this interaction are presently under investigation. Supported by USPHS Grants NS12901, 5-S07RR07009-12, and a Muscular Dystrophy Association postdoctoral fellowship to B.P.

1904 α-BUNGAROTOXIN BINDING SITES AND ACETYLCHOLINE RECEPTORS IN CHICK CILIARY GANGLION NEURONS IN CULTURE. Peter Ravdin*, Ralph Nitkin, and Darwin Berg. Dept. of Biology, UCSD, La Jolla, CA. 92093.

We have found that neurons from a parasympathetic source, the chick ciliary ganglion, bind α-bungarotoxin (α-Bgt) when grown in dissociated cell culture. Toxin concentrations adequate to saturate sites revealed by fluorescent toxin do not block the sensitivity of the neurons to iontophoretically applied acetylcholine (ACh).

Neurons obtained by trypsin dissociation of 8-day embryonic chick ciliary ganglia were grown for 1-2 weeks in cell culture with chick skeletal myotubes. Tetramethyl rhodamine-conjugated α-Bgt was used to visualize the distribution and relative site densities of toxin binding sites on the neurons. After 1 hour in 0.1 μM toxin, fluorescence microscopy revealed that both the neuron cell bodies and the processes had toxin binding sites. The labelling of individual cell bodies was generally uniform with occasional small clusters appearing on a few of the neurons. A wide range in the intensity of toxin labelling was found among different neurons in many of the culture dishes; some apparently morphologically normal neurons had no detectable labelling, while others in the immediate vicinity were labelled quite brightly. Fluorescent toxin binding could be blocked by 140 μM d-tubocurarine or excess unlabelled toxin. Prelabelling with 0.1 μM unlabelled toxin blocked most of the fluorescent toxin bindign, suggesting that the sites had been largely saturated. [^{125}I]α-Bgt binding studies indicated a mean site density of ca. 10^6 per neuron.

The neurons showed a wide variability in their sensitivities to iontophoretically applied ACh even after normalization for differences in resting potential (mean: 51 mV) and input impedance (mean: 45 MΩ). Preincubation with 0.1 μM α-Bgt for one hour followed by sensitivity measurements in the presence of toxin resulted in a complete blockade of ACh sensitivity on the myotubes but caused no significant change in the sensitivity of the neurons. The sensitivities for neurons in control cultures was 104 mV/nC (SEM=23, n=18) and in toxin treated cultures was 82 mV/nC (SEM=19, n=12).

Thus chick parasympathetic neurons have a high affinity binding site for α-Bgt that is distinct from the active site of the ACh receptor, as has been shown for sympathetic neurons (Carbonetto et al., PNAS 75: 1016 (1978)) and a pheochromocytoma cell line (Patrick and Stallcup, PNAS 74: 4689 (1977)). While the relationship between the toxin binding site and the ACh receptor in the membrane of ciliary ganglion neurons remains to be determined, it is clearly different from that observed for skeletal myotubes. 1905 IN VITRO MAMMALIAN PACEMAKER NEURONS. Michael S. Raybourn and Cornelius A. Tobias. Radiation Biophysics Group, Donner Lab/LBL, Univ. of California, Berkeley, Berkeley, Ca. 94720

We are currently investigating the cellular bioenergetics of neuronal pacemaker cells in mammalian tissue cultures. In our roller-tube cultured explants from rat cerebellum, we can record the spontaneous electrical activity of Purkinje cells during liquid and/or gas phase presentations of various agents. Application of synaptic blocking agents results in a complete cessation of spontaneous activity in about one-half of the Purkinje cells (non-PM). These cells presumedly derive their driving force from their synaptically-mediated inputs. The rest of the Purkinje cells revert from their normal stochastic firing patterns to a clock-like pacemaker (PM) rhythmicity. These latter cells must possess an endogenous pacemaker for such activity.

Using various agents to interrupt the intracellular electron transport chain activity (hypoxia, carbon monoxide), we are attempting to correlate the threshold sensitivity of a given Purkinje cell subtype (i.e. PM,non-PM) to these insults. Presumed differences in metabolic requirements due to the presence or absence of an endogenous pacemaker mechanism may well be resulting in significant differences in susceptibility to such insults. We have found dose-dependent effects on Purkinje cell spontaneous activity due to gas-phase hypoxic and carbon monoxide insults. These effects are generally photodisassociable and we are currently attempting to determine the action spectra for this in order to localize the site of direct cellular toxicity. In addition, we are using the protein synthesis inhibitor, Anisomycin, in order to ascertain what role, if any, that protein synthesis might play in determining the endogenous activity of pacemaker Purkinje cells.

1906 COORDINATE BIOCHEMICAL AND MORPHOLOGICAL CHANGES DURING PHENOTYPIC CONVERSION OF HUMAN NEUROBLASTOMA CELLS. R.A. Ross & D.J. Reis (Lab. Neurobiol.,Cornell Univ. Med. Coll., New York, NY) and B.A. Spengler* & J.L. Biedler* (Lab. of Cellular & Biochemical Genetics, Memorial Sloan-Kettering Cancer Center,New York, NY)

The continuously cultured human neuroblastoma cell line SK-N-SH was analyzed to study the relationship between its biochemical and morphological properties. Biochemically, the cell line is adrenergic, expressing activities for tyrosine hydroxylase (17.3 ± 2.2 pmol/hr/mg) and dopamine- -hydroxylase (DBH)(14.66 ± 0.42 nmol/hr/mg), but not choline acetyltransferase or glutamate decarboxylase. Morphologically, the line consists of two different cell types: a neuroblast-like cell with neuritic processes and a small rounded cell body and an epithelial-like cell without processes and with a flattened cell body. Biochemical analysis of clones of these two cell types shows a clear correlation between the cell's morphology and its DBH activity: a neuroblast-like clone (SH-SY5Y) having high DBH activity (11.13 ± 0.4 nmol/hr/mg) and an epithelial-like clone (SH-EP) having no DBH activity. A clone with intermediate morphology (SH-IN) has intermediate DBH activity (7.63 ± 0.4 nmol/hr/mg). During long-term culture of the neuroblast-like clone, a small proportion(5%) of the cells began to express an epithelial-like morphology, suggesting that these two cell types may interconvert in cell culture. To test this hypothesis, subclones were isolated from the SH-EP cells which had begun to show morphological divergence from their usual epithelial appearance. The presence of a unique chromosomal marker in SH-EP cells was used to confirm that the subclones were derived from the SH-EP cells. Nine subclones were isolated and all contained the unique chromosomal marker. All were assayed for DBH activity. The two epithelial-like subclones were without DBH activity while the 3 with neuroblast-like morphology expressed DBH activity (5.77 ± 0.14 nmol/ hr/mg). Four subclones with intermediate morphology expressed intermediate levels of DBH activity (3.67 ± 0.09 nmol/ hr/mg). Thus changes in cell morphology were directly correlated with changes in DBH activity.

Using morphological and biochemical markers for neuronal differentiation, we have shown that the two widely differing cell types of the human neuroblastoma cell line SK-N-SH show coordinate morphological and biochemical bidirectional interconversion in culture. We speculate that these two cell types may represent extremes in a spectrum of phenotypic expression , one representing a differentiated neuroblast with a small, rounded cell body, neurite-like processes, and neurotransmitter-synthesizing enzymes and the other an undifferentiated neuroepithelial cell with a flattened cell body and lacking neuritic processes and neurotransmitter-synthesizing enzyme activity. Supported by grants HL 18974, NS 03346, NS 06911, CA 08748, & CA 18856.

1907 PINEAL CELLS ENHANCE CHOLINE ACETYL TRANSFERASE ACTIVITY IN MONOLAYER COCULTURE WITH CELLS DERIVED FROM SUPERIOR CERVICAL GANGLIA. Vernon Rowe* and James Parr* (SPON: James Couch). Neurology Research Lab, VA Hospital, Kansas City, MO 64128 and Dept. of Neurology, Univ. of Kans. Med. Ctr., Kansas City, KS 66103.

Monolayer cultures of cells derived from neonated rat pineal glands and superior cervical ganglia (SCG's), by trypsinization and trituration, were plated in replicate fashion. The replicates contained cells derived from either pineal, or SCG, or both. All cultures were plated onto collagen, and were maintained in identical culture media containing 2.5S nerve growth factor under identical conditions. Tyrosine hydroxylase (TH), choline acetyltransferase (CAT), and serotonin N-acetyltransferase (NAT) activities were measured at 18 days of culture age. At this time, TH activity was very low in all replicates (0.2-0.3 nmoles/mg protein/hr). NAT activity did not vary markedly among the cultures (800 to 1300 pmoles/dish/hour). CAT activity in the cocultures, however, was up to 10 times that observed in the SCG's cultured alone (180 vs. 18 pmoles/mg protein/min). Pineals cultured alone did not contain detectable CAT activity.

These data are consistent with the interpretation that adrenergic target cell influence is insufficient, in itself, to develop and maintain adrenergic specification in the developing peripheral autonomic nervous system. Indeed, adrenergic target tissue, in the absence of presynaptic influences, can produce cholinergic specification in immature sympathetic neurons.

1908 ELECTROPHYSIOLOGIC PROPERTIES OF HUMAN DRG NEURONS IN CELL CULTURE:EFFECT OF POTASSIUM AND DEVELOPMENTAL STAGE.Brian S. Scott, Ted L. Petit and Lawrence E. Becker.* Surrey Place Centre, Toronto, Ontario, Canada M5S 2C2.

The electrical properties of human neurons have been characterized quantitatively through an extensive intracellular electrophysiologic investigation of cell cultures of dorsal root ganglia (DRG). In three cases, cultures were prepared from fetal DRG (13, 23 and 27 weeks of gestation) and in one case from more mature DRG (3 months post-natal). No neuropathology was detected in these cases.

The DRG were softened in collagenase, dissociated and plated on collagen coated coverslips. The culture medium consisted of 10% fetal calf serum in CMRL-1415 with both normal (4mM) and elevated (20mM) potassium (K). The later has been found to enhance neuron survival.

After periods in culture ranging from 6 to 62 days, cultures (both 4 and 20mM medium) were transferred to 4mM K and the following features examined:resting membrane potential (Vm); cell input resistance (Ri), specific membrane resistance (Rm), rheobase (Irh), voltage change at rheobase (Vrh=Irh x Ri), duration of the action potential (APt), time constant (TC, determined from strength duration data), and absolute refractory period (ARP). The table below illustrates the results obtained from all four specimens grouped according to the K concentration of the culture medium.

K	Vm**	Ri**	Rm	Irh**
mM	(mV)	(Mohm)	(ohm·cm^2)	(nAmp)
4	48.7±.79(222)	22.5±.79(178)	1074±.39(176)	.65±.03(167)
20	52.7±.60(307)	19.5±.81(205)	1008±.46(202)	.91±.04(206)

K	Vrh*	APt**	ARP**	TC**
mM	(mV)	(msec)	(msec)	(msec)
4	12.3±.55(156)	3.34±.13(135)	3.51±.12(126)	3.68±.14(164)
20	14.5±.74(171)	2.38±.11(152)	2.77±.11(143)	2.81±.12(192)

* P<.05, ** P<.01, $\bar{X}\pm$ S.E.M., N in brackets

The changes in Ri and Irh were due to an increase in cell size in elevated K. However analysis of variance with cell size as a covariate showed that K exerted a small but significant effect, independent of cell size, on the other significantly different variables.

The data, limited to four cases with respect to developmental stage, showed that cell size also increased with age. Rm, APt, ARP and the TC were also found to increase with age independent of cell size, but more cases are required to confirm this phenomenon.

Supported by a grant from the Physicians' Services Incorporated Foundation.

1909 PROLIFERATION OF GLIAL CELLS IN CONTINUOUS CELL CULTURES FOLLOWING KAINIC ACID LESIONS OF RAT STRIATUM. V.K. Singh, E.M. Bohn*, and D. Van Alstyne*. Immunology Unit, Children's Hospital, Vancouver, B.C. V5X 1X2, Canada.

Glial cells grow to confluency in vitro following their dissociation from kainic acid lesioned striatum of normal adult rat brain. The procedure involved the induction of a specific neuronal degeneration, achieved by stereotaxic injections of 5 nmoles of kainic acid into caudate-putamen nucleus (Singh et al., Brain Res. 147: 1978), dissection and mincing of the tissue in the presence of growth medium (MEM containing 0.2% glucose, 10% fetal calf serum 5 units/ml penicillin and 5 µg/ml streptomycin) and distribution of the dissociated tissue in glass tissue culture dishes.

The cells from kainic acid lesioned striatum proliferate to form complete monolayers within 4-5 days and exhibit contact inhibition. The cell growth, which is sensitive to actinomycin D and colchicin, is correlated with an active synthesis of DNA, RNA and protein. Morphologically several distinct cell populations, including astrocytes and oligodendrocytes, are observed. The cells are characterized by the presence of glial fibrillary acidic protein (GFAP) localized through immunofluorescent and immunoperoxidase techniques. This cell line appears to be more susceptible to lysis by rubella virus than are the more commonly used rabbit or baby hamster kidney cell lines.

(Supported by a grant from the Multiple Sclerosis Society of Canada).

1910 ACETYLCHOLINE RECEPTOR AND ESTERASE: EVIDENCE FOR DISTINCT PATHWAYS OF INTRACELLULAR TRANSPORT. Henry Smilowitz* (SPON: Yvonne Grimm-Jorgensen), Dept. Pharmacol., U. Conn. Health Ctr., Farmington, CT 06032.

Most of the acetylcholinesterase (ACHE) that is synthesized by chick embryo pectoral muscle cells in culture is released into the culture medium [Wilson B.W. et al., Dev. Biol., 33: 285-299, 1973]. We have found that ACHE release (measured as ACHE activity appearing in diisopropyl fluorophosphate (DFP) treated culture medium) can be stimulated 60% by 5×10^{-8}M of the calcium ionophore A23187 and can be inhibited by the carboxylic ionophores which transport monovalent cations. For example, release of ACHE is inhibited 50% by 4×10^{-8}M Monensin, or 1.6×10^{-8}M Nigericin or 7.5×10^{-8}M X537A [Smilowitz, H., Fed. Proc. 37: 788, 1978]. The inhibition of ACHE release by the ionophores is not due to an overall inhibition of protein synthesis. And both the inhibition of ACHE release and the accompanying accumulation of ACHE activity by the cells can be fully reversed within 2-4 hours after removal of the drug.

The rate of appearance of cell surface acetylcholine receptors (AChR) (measured as the rate of appearance of I^{125} α-bungarotoxin binding sites) is unchanged by concentrations of ionophore which maximally inhibit ACHE release. Experiments employing ACHE histochemistry and electron microscopy reveal intracellular membrane vesicles in ionophore treated cells which stain heavily for ACHE. Further, the ACHE of ionophore treated cells is less accessible to degradation by trypsin and collagenase. Preliminary cell fractionation experiments indicate that the ACHE which accumulates in ionophore treated muscle cells can be found on membranes that are distinct from plasma membrane. These experiments suggest that the ACHE accumulates on intracellular membranes in ionophore treated cells that are inaccessible to externally applied agents, while the acetylcholine receptor proceeds normally to the plasma membrane and remains accessible to externally applied α-bungarotoxin. We propose that the acetylcholinesterase and the acetylcholine receptor are transported intracellularly by distinct membranous pathways; one is profoundly inhibited by the monovalent ionophores, the other is unaffected. Supported by NIH NS13860.

1911 MODULATION OF cAMP-INDUCED PROCESS FORMATION AND ConA-INDUCED CAP FORMATION IN CULTURED GLIOMA CELL LINES. Barry H. Smith, Theodore M. Liszczak*, Rogers Pleasants*, and Paul L. Kornblith*. Neurosurgical Service, Massachusetts General Hospital, Boston, MA 02110

The molecular mechanisms of cyclic AMP-induced process formation as well as conconavalinA-induced cap formation have been studied in a cultured human glioma cell line (Mi) and four clones derived therefrom.

The parent cell line, as well as all derived clones, form processes in the presence of 10^{-3}M dibutyrl-cAMP, although the percentage of cells exhibiting such processes varies from clone to clone (i.e., from 50 to 80% of the population at 48 hrs.). Ultrastructurally such processes are characterized by prominent bundles of microfilaments as well as by microtubules all arrayed in the long axis of the process.

Local anesthetic agents (dibucaine 10^{-4}M, lidocaine 10^{-4}M, and procaine 10^{-4}) which are membrane-active agents as well as microfilament-active agents, block this process formation with dibucaine being the most effective (∿ 100%). The microtubule-active agent vincristine (.0005 mg/ml) also blocks such processes but cytochalasin B, (12.5 µg/ml), which interferes with microfilament function, results in very short, highly-branched processes, suggesting that microfilaments are important for elongation. Protein synthesis, as evidenced by the addition of 10^{-6}M puromycin, is not required for process formation. Metabolic inhibition (Na azide, 10^{-2}M), although it reduces the total number of cells as well as the proportion of cells with processes, allows process formation to occur. 10^{-3}M Ca^{++} in the medium results in the formation of extremely long processes. Phosphodiesterase inhibitors (theophylline, 10^{-3}M and papaverine, 10^{-3}M) enhance process formation when added with dibutyrl-cAMP. Papaverine alone produces bipolar cells with extremely long, wide processes, whereas theophylline alone is without effect. Relative movements of surface-bound molecules were monitored by binding with ConA (5-100µg/ml) which reliably produces patching and capping in this glioma line. Formation as well as internalization of the caps has been followed by light, scanning, and transmission (electron microscopy). Microfilaments (40-60 Å) appear necessary for cap formation and internalization, but microtubules, perhaps by virtue of a role in stabilizing the cytoskeleton, may be inhibitory. These postulates are supported by the fact that dibucaine (10^{-4}M) blocks cap formation as does dibutyrl cAMP, which has been associated with microtubule assembly. In the case of dibucaine treatment, aborted caps appear to form on short, microfilament-free processes.

We conclude that microfilaments, microtubules and associated membrane states are critical elements in cAMP-induced process formation, as well as conA-induced cap formation, in our glioma cell lines, although the two processes differ in their mechanisms.

1912 ELECTROPHYSIOLOGICAL PROPERTIES OF ISOLATED SYMPATHETIC NEURONS DEVELOPING IN MICROCULTURES. Trisha Suppes and Paul H. O'Lague. Dept. Anatomy and Dept. Biology, UCLA, Los Angeles, CA 90024.

Intracellular microelectrodes were used to study the electrophysiological properties of sympathetic neurons developing in microcultures. These cultures consisted of small (<300 microns in diameter) islands of cardiac myocytes and one or a few (<5) neurons isolated from mechanically dissociated superior cervical ganglia of newborn rats as described previously (Furshpan et al., PNAS 73: 4225, 1976). 18-90 days after plating the neurons, their electrophysiological properties were examined during continuous perfusion of the cultures (see above reference for methods and perfusion media); all neurons tested (>100) had resting potentials in the range -55 to -70 mV, action potential amplitudes of 65 to 90 mV, and maximum rates of rise of 200 to 480 V/sec. These values are comparable to those reported for the neurons in mass cultures (O'Lague, P.H., Potter, D.D., and E. J. Furshpan, Devel. Biol., in press) and for sympathetic neurons in superior cervical ganglia of adult rats (Perri et al., Pflugers Arch. 14:40, 1970). The ionic basis of the action potential in the neurons was studied with the pharmacological agents tetrodotoxin (TTX), a blocker of voltage-sensitive Na^+ channels, tetraethylammonium (TEA), a blocker of voltage-sensitive K^+ channels, and Co^{++} and Mn^{++}, both blockers of voltage-sensitive Ca^{++} channels. TTX (0.5-3 µM; 40 cases tested) abolished the action potential evoked by a current pulse; the remaining depolarization was graded with the strength of the current pulse and could be transformed into an all-or-none response by addition of TEA (5-25 mM) to the TTX perfusion media. This all-or-none response was dependent on extracellular Ca^{++} (16-20 mV per 10 fold change), was independent of changes in extracellular Na^+ and abolished by Co^{++} (2-5mM, 4 cases) or Mn^{++} (1mM, 2 cases). This evidence suggests that Na^{++} and Ca^{++} carry inward current during the action potential. In many neurons, usually in older cultures (>3 weeks), the action potential was followed by a long lasting (150-450 msec) afterhyperpolarization (LAH) of 5-15 mV peak amplitude. This LAH was due to an increase in K^+ permeability triggered by Ca^{++} ions entering during the action potential. Evidence for this is: 1) the LAH was accompanied by a substantial decrease in membrane resistance (in some cases up to 30%); 2) it reversed at the K^+ equilibrium potential; and 3) it was greatly reduced in amplitude and duration by lowering the extracellular Ca^{++} or by addition of Co^{++} and Mn^{++} at the same concentrations which block the Ca^{++} action potentials in these cells. Whether in a single neuron the expression of the above electrophysiological properties changes as it develops in culture and whether electrical activity affects this expression are presently under investigation.

1913 NEURONAL SURVIVAL AND CAT ACTIVITY IN DISSOCIATED CELL CULTURES OF CILIARY GANGLION. Jeremy Tuttle*, March Ard*, and Janusz Suszkiw*, (spon: J. Alanis). Physiology Section, Biological Sciences Group, Univ. of Connecticut, Storrs, Connecticut 06268.

This study intends to better define the culture conditions necessary for the survival and development of ciliary ganglion neurons, and to describe the developmental pattern of choline-acetyltransferase activity in culture.

All cultures were prepared from ganglia dissected at embryonic stage 29-32. The effect upon subsequent cell survival was determined for the following other variables: 1) Plating density. No effect of plating density was noted between 9000 and 30,000 neurons cm^2. 2) Basic medium. Cell growth was most rapid when supplemented MEM was used. Supplemented L-15, L-15, DMEM, and highly supplemented MEM were not as suitable. 3) Serum additions. Bovine serum (newborn and fetal), and human serum (from a single source and pooled), (10% V/V), were all unsatisfactory, for survival at 2-4 days in culture was <20% and zero at 1-2 weeks. Heat-inactivated horse serum (HS, 10% V/V) allowed neuronal survival at reduced levels for no more than ten days. 4) Chick embryo extract (CEE) was necessary for long-term survival. 10% (V/V) CEE in supplemented MEM without serum could support 30% survival for three weeks in culture. At 1% CEE, without serum, all cells died in 5 days. When 10% CEE was combined with 10% HS, up to 90% of the neurons plated could survive three or more weeks in culture. 5) 50% of plated neurons could survive at least one month in the absence of other cells in fresh 10HS10CEEMEM, but only 20% remained at 3 weeks in conditioned medium. Neurons survived best when grown on collagen along with myoblasts, for >80% survived at least one month.

The cholineacetyltransferase (CAT) activity in these cultures was also determined over three weeks in culture. CAT activity per cell increased 100-fold during the first two weeks in culture both with and without myoblasts. Cultures in conditioned medium showed a marked but lesser rise in CAT activity. This development of CAT activity in dissociated cell culture differs from that in vivo as follows: 1) CAT activity increases at a later time in cell culture. This may reflect a period of recovery after dissociation. 2) In vivo, the rise of CAT activity continues past embryonic stage 40 to much higher levels while the initial sharp rise in activity in vitro is followed by a slower increase or drop, depending upon the culture substrate used. These results suggest: 1) Some component of CEE is critical for the survival of ciliary neurons in culture. 2) Interactions with other cells or other unknown factors are necessary for the full expression of normal CAT development in vitro. Supported by NIH-NS10338, NS5382 and The Univ. of Conn. Research Foundation.

1914 TROPHIC AGENTS DIRECTED TO CILIARY GANGLIONIC CELLS IN MONOLAYER CULTURES. Silvio Varon, Ruben Adler and Marston Manthorpe* (SPON: A.L. Miller). Dept. Biol., Sch. Med., U. Ca. San Diego, La Jolla, CA 92093.

Neurons dissociated from 8-day chick embryo ciliary ganglia (CG) will not survive in monolayer cultures with medium supplemented only with serum. Other investigators have reported their survival on polyornithine substrata in the presence of heart-conditioned medium (Helfand et al, Dev. Biol. 50, 541, 1976), on pre-established cultures of myotubes (Nishi & Berg, PNAS 74, 5171, 1977), or on collagen in medium supplemented with embryo extract and horse serum (Tuttle, Soc. Neurosci. Abst., III, 529, 1977). We report here the detection of different trophic agents (directed to CG neurons) in chick embryo extract (CEE), heart-conditioned medium (HCM), and fetal calf or horse sera. CG's were dissociated after mild trypsin treatment, and seeded in dishes coated with either a highly adhesive collagen or poly-ornithine (P-ORN). One-day cultures were counted differentially for total and neurite-associated large phase-bright (LB) cells, and analyzed for choline acetyltransferase (CAT). CEE was produced from 12 day whole embryos. HCM was obtained by incubating serum-containing medium for 48 hr over 2-day old cultures of 8-day chick embryo heart cells.

CEE supplementation (25 µg protein/ml) provided: i) in the absence of serum, no survival of LB cells on either collagen or P-ORN, ii) in combination with 10% fetal calf, high numbers of LB cells on both substrata but some neuritic outgrowth only on collagen, or iii) in combination with 10% horse serum, high LB cell numbers on both substrata and high neurite production on collagen but not on P-ORN. HCM supplementation (at 50% dilution) yielded: i) with no serum present during conditioning, no LB support on either substratum even after serum addition, ii) with fetal calf serum (both before and after conditioning), high numbers of LB cells and extensive, elaborate neurites on P-ORN but lower numbers and no neurites on collagen, or iii) with horse serum throughout, slightly lower LB cell numbers than with fetal calf serum and the same neurite development on P-ORN but no neurites on collagen. The occurrence of different active agents in the two trophic sources (CEE and HCM) is indicated by their dependence on different substrata for neuritic promotion (even though both substrata are competent with the correct trophic source), as well as by their different serum requirements. In addition, serum constituents are necessary, though not sufficient, contributors to the trophic effectiveness of either source. Lastly, comparison of CAT activities in these several culture situations suggests that regulation of this enzyme may be partly independent from cell numbers and/or neurite production. (Supported by USPHS grant NS-07606).

1915 LARGE-SCALE CULTURE OF NON-NEURONAL CELLS AS AN ADJUNCT TO SPINAL CORD RECONSTRUCTION. J. Wrathall*, C.C. Kao* and D.Rigamonti (SPON: M. DeSantis). Department of Anatomy, Georgetown University Schools of Medicine & Dentistry, Washington, D.C. 20007.

In a previous report (Kao et al. J. Neurosurg. 46:757, 1977) on a delayed nerve grafting technique for spinal cord reconstruction, proliferation of Schwann cells and fibroblasts from the grafted nerve was observed one week after placement of the graft. These cells grew into the cut ends of the spinal cord and appeared to facilitate axonal outgrowth from the spinal cord and subsequent bridging of the transection. To attempt to enhance this process, we have prepared large-scale cultures of mitotically active non-neural cells from peripheral nervous tissue to be used as an adjunct to the reconstruction procedure.

Dorsal root ganglia, or segments of sciatic nerve, from the adult cat were minced, incubated with trypsin or trypsin-EDTA solutions, and dissociated by mechanical agitation with a vortex mixer. The cell suspensions obtained were plated on collagen-coated dishes and cultured in a medium consisting of Eagle's MEM, non-essential amino acids, 6 mg/ml glucose, 10% fetal calf serum and 50 µg/ml Gentamicin. The cultures were maintained at 36.5° in an atmosphere of 5% CO_2 - 95% air, and subcultured weekly with the aid of trypsin-EDTA solution. One cell line derived from sciatic nerve appears to consist of larger fibroblast-like cells and smaller, spindle-shaped, refractile cells with elongated oval nuclei. This mixture of cell types has been maintained over 10 subcultures to date. Two cell lines derived from dorsal root ganglia in separate experiments, were morphologically similar to one another. These cultures consist almost exclusively of small, spindle-shaped, refractile cells with elongated oval nuclei and resemble cultured Schwann cells described by others. Electron-microscopic examination of pellets of trypsinized cells showed that these cells have irregular nuclei, dilated rough endoplasmic reticulum containing material of a density that is similar to the cell matrix and well-developed Golgi. These cell lines, and that derived from sciatic nerve, have been successfully frozen in liquid nitrogen using 10% dimethyl sulfoxide. Cells derived from both tissue sources have been used individually, or in combination, in spinal cord reconstruction experiments. For this purpose, cultures were harvested using trypsin-EDTA solution, the cells counted in a hemocytometer and viability estimated by trypan-blue exclusion. Cells were washed with a balanced salt solution by centrifugation and pellets containing about 5×10^7 viable cells were prepared. Portions of the pellets have been applied to the cut ends of the spinal cord just prior to the placement of the nerve graft, in a cat transected cord model system.

1916 OUTGROWTH OF NEURONAL PROCESSES IN VITRO FROM THE RETINAL TISSUE INTO THE TECTAL TISSUE, EXPLANTED FROM THE ADULT GOLDFISH. Myong G. Yoon, Dept. of Psychology, Dalhousie Univ., Halifax, N. S., Canada, B3H 4J1.

The patterns of neuritic outgrowths from the retinal tissue into the tectal tissue are investigated in vitro under various experimental conditions by culturing the neural tissues, explanted from the visual pathways of the adult goldfish. A rectangular piece of the retinal tissue is dissected free and implanted on a culture dish in a predesignated orientation. Its topographically matching area of the optic tectum is also dissected from the same fish, and co-cultured with the retinal explant in various geometric configurations within the same culture dish. Under favorable culture conditions, the retinal tissue shows vigorous outgrowths of neuronal processes as early as 12 hrs after explantation. These retinal neurites have bush-like growth cones which contain several philopodia at the advancing tips. Autoradiographic examination reveals that if (H^3) L-proline is injected into the eyeball about 24 hrs before explantation of the retinal tissue, the sprouting neuronal processes from the retinal explant later show intense labelling throughout their entire extent, including the growth cones at their advancing tips. The labelling in the retinal neurites persists as long as the culture is maintained for up to 6 weeks. The direction of neuritic outgrowths from the retinal explant in vitro seems to follow the regularity in the embryonic development or regeneration of the axons of retinal ganglion cells in vivo: the retinal neurites tend to grow in the radial direction towards the optic disc at the center of the retina, especially at an early stage in culture. Some of the retinal neurites eventually grow into the co-cultured tectal tissue. It is not known as yet whether these retinal neurites would establish functional connections with appropriate visual neurons of the tectal tissue in vitro. In contrast to the retinal tissue, the tectal explant does not show any neuritic outgrowth in the same culture dish for a period up to 6 weeks.

TROPHIC FUNCTIONS

1917 ADVERSE EFFECTS OF TETRODOTOXIN ON EARLY DEVELOPMENT AND SURVIVAL OF POSTSYNAPTIC CELLS IN SPINAL CORD CULTURES. Gregory K. Bergey*, Robert L. Macdonald and Phillip G. Nelson. Laboratory of Development Neurobiology, NICHD, NIH, Bethesda, Md. 20014.

Dissociated fetal mouse spinal cord cultures were used to assess the effects of chronic action potential blockade on neuronal survival. Dorsal root ganglion (DRG) cells and spinal cord (SC) cells in culture are easily distinguished morphologically and electrophysiologically. Intracellular recordings show that SC cells commonly exhibit ongoing action potentials and postsynaptic potentials, whereas DRG cells, while electrically excitable and capable of establishing synapses with SC cells, are electrically quiescent and receive no synaptic input when grown in culture. Previous electron microscopic examination has shown cultured SC somata to be heavily invested with synaptic terminals; DRG somata appear devoid of innervation.

Exposing combined SC-DRG cell cultures to 10^{-6}M or 10^{-7}M tetrodotoxin (TTX), a specific blocker of sodium conductance channels in neurons, completely blocked all spontaneous electrical activity. When cultures were grown in medium containing these concentrations of TTX from day 1 or day 8, examination of the cultures at 5 weeks revealed a marked reduction in the number of SC neurons while DRG cell counts were unaffected. SC cells larger than 30μ were reduced in number to less than 9% of controls ($p<.001$) while DRG cell counts were not significantly different from controls. If treatment with TTX was delayed until 10 weeks in culture no significant diminution of either SC or DRG cell counts was evident. Tetrodotoxin treatment did not affect the electrical characteristics of the DRG cells; resting membrane potentials and input resistances did not differ from the control values. The remaining SC cells were fragile and had lower resting membrane potentials than normal, but some surviving SC cells revealed evidence of synapse formation in TTX with both IPSPs and EPSPs being recorded. TTX is reported not to affect axoplasmic transport and no non-specific toxic effects have been reported at the concentrations used in these experiments. The specificity seen in the present experiments with regard to cell type and age of culture argues against such non-specific effects.

These results indicate that blockade of electrical activity in co-cultured mammalian DRG and SC neurons markedly affects the development and survival of neurons that normally receive synaptic inputs in culture. This suggests that action potentials and synaptic activity play crucial roles in central neuronal development during early stages of differentiation and synapse formation; at later states neuronal survival is less affected by blockade of electrical activity.

1918 RAPID LOSS OF JUNCTIONAL ACETYLCHOLINE RECEPTORS AFTER DENERVATION OF RAT SKELETAL MUSCLE. R. S. Brett* and S. G. Younkin. Dept. Pharmacology, Case Western Reserve University School of Medicine, Cleveland, Ohio 44106.

Previous studies of the mouse diaphragm (Porter & Barnard; Exp. Neurol. 48:542, 1975) and the rat soleus (Frank et al.; Cold Spr. Harb. Symp. 4:275, 1976) have found no decrease in the number of junctional acetylcholine receptors (AChR) in the early period after denervation. In this study we examined junctional AChR after denervation of rat diaphragm and extensor digitorum longus (EDL) muscles by measuring the binding of (^{125}I)α-bungarotoxin. Junctional AChR were evaluated by one method in diaphragm and another in EDL. Innervated and denervated (1,2,3,5 and 7-9 days) left hemidiaphragm muscles were labelled with toxin in vitro and dissected into a piece containing end-plates and several 1-mm wide pieces adjacent to the piece containing end-plates. The number of extrajunctional AChR in the end-plate-containing piece was estimated on the basis of the extrajunctional AChR found in the immediately adjacent end-plate-free piece and junctional AChR were calculated by subtracting this number from the total number of AChR in the end-plate containing piece. Junctional AChR were significantly ($P = 0.01$) decreased by day 5 and at 7-9 days after denervation were reduced to 58% of the innervated level. EDL muscles were denervated unilaterally and 7-8 days later AChR in denervated and contralateral innervated muscles were labelled in situ using the tibialis muscle to construct a pool which held a small volume of rat Ringer's solution containing 2.0 μg/ml (^{125}I) α-bungarotoxin. Rats were allowed to recover and 5 days later the radioactivity in each muscle was measured. At this time virtually all extrajunctional receptors have been degraded so residual radioactive toxin is bound almost exclusively to junctional AChR. In these experiments denervated muscles contained only 65% of the radioactivity measured in contralateral innervated muscles ($P = 0.001$ by the paired t-test). Using the methods described, we find decreases of 35% and 42%, respectively, in the number of junctional AChR in rat EDL and diaphragm muscles denervated for 7-9 days. The apparent discrepancy between this and earlier reports may be related to differing experimental conditions or may reflect a difference between slow (mouse diaphragm, rat soleus) and mixed or fast (rat diaphragm and EDL) muscles. Our results support the concept that innervation plays a significant role in maintaining the normal high concentration of junctional AChR as well as in suppressing extrajunctional AChR. (Supported by USPHS NIH grant NS 13027.)

1919 REGULATION OF ACETYLCHOLINE RECEPTOR METABOLISM BY DIRECT ELECTRICAL STIMULATION. Diana J. Card* and Douglas M. Fambrough. Carnegie Institution of Washington, Baltimore, MD 21210

As a result of denervation skeletal muscle synthesizes large numbers of extrajunctional acetylcholine receptors. Many studies have shown that extrajunctional ACh receptor numbers (or ACh sensitivity) are regulated by the contractile activity of the muscle. The aim of this study is to identify the mechanism by which electrical stimulation regulates ACh receptor metabolism. We have measured the effect of electrical stimulation on the synthesis (appearance in the extrajunctional muscle membrane) of ACh receptors and their subsequent degradation (or removal) from membranes of denervated rat skeletal muscles maintained in organ culture. ACh receptors were measured by specific and irreversible binding with radioactive α-bungarotoxin.

The rate of de novo biosynthesis was measured by determining the rate of appearance of ^{2}H, ^{13}C, ^{15}N-containing ACh receptors when muscles were cultured in medium containing ^{2}H, ^{13}C, ^{15}N-amino acids. Cultured 5-day denervated extensor digitorum longus (EDL) and soleus muscles were found to synthesize new receptors for several days in organ culture. Stimulation at 100 Hz for 1 sec every 80 sec, producing visible contraction, but not maximal tetanic tension, barely altered the rate of incorporation of new ACh receptors into extrajunctional plasma membrane of EDL and soleus muscles, even when applied for 5 days. Supra-maximal stimulation with the same stimulation pattern produced a rapid decline of 10-20% in rate of new receptor production and a corresponding decline in overall protein synthesis. Stimulation beyond 18-24 hr (up to 68 hr) resulted in a further decrease in new receptor production to about 30% of control rate, but no more. Stimulation for longer than 16 hr produced less than 5-10% decrease in overall protein synthesis compared with control muscles.

The degradation rate of extrajunctional ACh receptors was estimated by irreversibly labeling ACh receptors with radioactive iodinated α-bungarotoxin and measuring the rate of release into the culture medium of mono- and diiodo-tyrosine, breakdown products of the radioactive α-bungarotoxin. The rate of this proteolytic process which reflects the average ACh receptor lifetime was 22 hr. Electrical stimulation at 100 Hz for 1 sec was applied every 80 sec for up to 30 hr to produce maximal tetanic tension and had no effect on the apparent degradation rate of receptors in denervated EDL muslces.

Strong electrical stimulation, producing frequent tetanic contractions, may therefore, decrease receptor biosynthesis and thereby contribute to previously reported reduced ACh sensitivity.

1920 NGF-INDEPENDENT DEVELOPMENT OF MOUSE EMBRYO SYMPATHETIC NEURONS IN CELL CULTURE. Michael D. Coughlin and Ira B. Black, Dept. of Neurology, Cornell University Med. Coll., N.Y.,N.Y.10021.

The superior cervical ganglion (SCG) of the 14 gestational day (E14) mouse embryo extends neurites and differentiates biochemically when cultured in the absence of added nerve growth factor (NGF). In contrast, ganglia from newborn mice (NB) require added NGF for survival in culture. Co-culture of the E14 ganglion with target submandibular gland radically alters nerve growth fiber outgrowth and development of tyrosine hydroxylase (T-OH) activity in the ganglion. By 5 days in culture, ganglia grown with target tissue, even in the presence of anti-serum to NGF (Anti-NGF), exhibit a 2-fold increase in T-OH activity over ganglia grown alone or with non-target tissues. Ganglia grown with target salivary glands exhibit increased elaboration and directionality of nerve fiber outgrowth, even in the presence of Anti-NGF.

In the above experiments, ganglion support cells and/or target tissue may have transferred NGF to neurons through an antibody-resistant mechanism. To determine whether E14 and NB ganglion neurons are intrinsically different, ganglia were trypsin-dissociated and neurons were grown in single cell culture. E14 neurons, in medium without added NGF, attached to poly-ornithine coated culture dishes and extended neurites within 4 hours. Approximately 20% of the neurons plated survived for 24 hours. In direct contrast, NB neurons exhibited neurite extension only in the presence of added NGF. Heart cell conditioned medium (CM) enhanced survival and neurite extension in both E14 and NB neurons; the mechanisms involved, however, differed. In CM, 50% of the E14 neurons exhibited neurite extension at 24 hours and survival was not significantly affected by Anti-NGF. A similar percentage of NB neurons survived in CM, but this effect was abolished by Anti-NGF. Thus, E14 neurons, unlike NB neurons, are capable of surviving in cell culture without added NGF and without support cells. Moreover, E14 neurons, unlike NB neurons, respond to CM factor(s) which are insensitive to Anti-NGF.

1921 A FACTOR RELEASED FROM NERVE BY STIMULATION PREFERENTIALLY INCREASES END-PLATE ACETYLCHOLINESTERASE. B. Davey*, S. G. Younkin, and L. H. Younkin. Dept. Pharmacology, Case Western Reserve University School of Medicine, Cleveland, Ohio 44106.

Supramaximal neural stimulation of a single sciatic nerve-extensor digitorum longus (EDL) muscle preparation at 7 Hz for 30-60 min releases a factor which causes a significant increase in the cholinesterase (ChE) activity of EDL muscles denervated in vivo for 3 days and then maintained in organ culture for 1 day. The release of this factor is not diminished when d-tubocurarine is used to block muscle contraction in the neurally stimulated preparation, but its release is diminished after presynaptic block with magnesium (Younkin et al., Science, in press). In this study we show (1) that the increase in ChE caused by this factor is virtually completely due to an increase in true acetylcholinesterase (AChE), (2) that the factor has a preferential effect on end-plate AChE, and (3) that protein synthesis is not required for the factor to be effective. To show that the increase in ChE caused by this factor is due to an increase in AChE the ChE of organ-cultured EDL muscles was measured without inhibitors present as described by Davey and Younkin (Exp. Neurol. 59, 168-175, 1978) and with either iso-OMPA (10^{-4} M), which selectively inhibits butyrylcholinesterase, or BW284C51 (10^{-5} M), which selectively inhibits AChE, present. The increase in total ChE (no inhibitors present) caused by the factor released by neural stimulation was 0.70 ± 0.11 umoles acetylthiocholine hydrolyzed per min per g muscle. Virtually all of this increase was due to an increase in AChE because the increase in iso-OMPA resistant ChE was 0.75 ± 0.05 and the increase in BW284C51 sensitive ChE was 0.64 ± 0.17. To assess the effect of the factor on end-plate and background AChE we examined segments of hemidiaphragm which were denervated in vivo for 3 days and then cultured for 1 day in control medium or in medium conditioned with neurally stimulated EDL muscle. In these experiments the factor released by nerve stimulation caused a dramatic (102%) and highly significant ($P<0.001$) increase in end-plate AChE but had essentially no effect on background AChE. Cycloheximide (10^{-5} M) was added to control medium and to medium conditioned with neurally stimulated EDL muscles to determine the extent to which the effect of the factor released by neural stimulation is dependent on protein synthesis. Cycloheximide decreased the AChE of 3-day denervated muscles cultured for 1 day in control or supplemented medium to about 60% of normal, but muscles cultured in the presence of factor continued to have an AChE which was significantly ($P<0.05$) higher (20-30%) than that of muscles cultured in the corresponding control medium. (Supported by USPHS NIH grant NS 13027.)

1922 ANATOMY AND PHYSIOLOGY OF AXOTOMIZED CAT ABDUCENS MOTONEURONS. J. M. Delgado-Garcia*, R. Baker, K. Alley and R. McCrea. Dept. Physiol. & Biophys., New York Univ. Med. Ctr., 550 First Ave., N.Y. 10016; Case West. Reserve Univ. Med. Ctr., Cleveland 44106.

During experiments designed to study internuclear neurons in the abducens nucleus (Abd.n.), it was observed in Nissl material that either intracranial or peripheral section of the VIth nerve did not produce retrograde chromatolysis and degeneration of Abd. motoneurons (Mn). Subsequently, a study was implemented to follow activity of Abd Mns from onset of axotomy to reinnervation. The results complement, but more often contrast with, the classical picture provided in other axotomized Mns. Experimentally, stimulating electrodes were placed bilaterally and intracranially on the VIth nerve. The magnetic search coil technique was used to record eye movement. In two experiments tungsten microelectrodes were implanted in the Abd.n. to chronically record antidromically-elicited field potentials following axotomy. Four to seven days following axotomy, the antidromic field potential was reduced by more than 90%. This reduction remained until reinnervation of the muscle (16-25 days) at which time the field potential returned to normal amplitude. During either eccentric lateral gaze or natural vestibular stimulation, the field potential amplitude could be facilitated up to 50%, but it never reached control level. In acute electrophysiological experiments carried out 10 days after axotomy, the antidromic field potential was also depressed. Intracellular recording from Abd Mns exhibited the presence of an M spike; however, unless the cell was depolarized, an IS-SD invasion did not occur. Preliminary studies indicate that failure of antidromic invasion is likely due to a decrease in membrane resistance including the axon hillock area most prominently. In similarity with synaptic deafferentation in spinal Mns, the somatically located vestibular IPSP was either completely, or nearly completely, removed in all axotomized Mns; however, the contralateral vestibular EPSP always remained with only moderate modification in time course and amplitude. Large changes in dendritic excitability were not observed. To corroborate the above findings, we injected HRP intracellularly in axotomized and normal Mns for light and electron microscopy. To date, the dendritic spread of reconstructed axotomized Mns does not differ from that of normal Mns nor is there evidence for any other unusual dendritic morphology. The soma and proximal dendritic tree of the axotomized Mns are covered with fibrillar astrocytic processes and the number of synapses is reduced 50-60% from normal. We conclude that the classical chromatolysis picture as ascertained in other mammalian Mns is not without exception and that Abd Mns may be a useful model for study of trophic relationships in the mammalian CNS. (Supported by USPHS grants NS-13742, EY-02007 and NS-00147)

1923 ALTERATION OF SKELETAL MUSCLE MEMBRANE BY SUBPERINEURAL INJECTIONS OF BATRACHOTOXIN - FURTHER EVIDENCE FOR NEUROTROPHIC CONTROL OF MUSCLE. S.S. Deshpande*, R.J. Boegman, and E.X. Albuquerque. Dept. Pharm. & Exp. Ther., Sch. Med., Univ. MD., Baltimore, MD. 21201.

Substances that block axonal transport such as batrachotoxin (Ochs, Science 187:1087, 1975) are of interest to further understand axonal transport of trophic factors and their effect on the muscles. Although BTX increases Na^+ permeability and instantaneously blocks axoplasmic transport, the mechanism is poorly understood. BTX (2.0-10 mM) was injected subperineurally into peroneal nerves about 10 mm (close site) or 35 mm (distant site) away from the entrance of nerve into extensor digitorum longus (extensor) muscle of the female Wistar rats. The radial front of bulk concentration of toxin at either site was ± 5 mm. The vehicle, 10% dextrose in 0.9% saline, was injected at similar sites on the contralateral side. The muscle membrane was significantly depolarized (5-10 mV) at the endplate at 50 min after BTX injection at close site; distant site required about 160 min. Neither MEPP frequency nor amplitude were affected at this time or even up to 6 hrs when muscles were still paralyzed. The observed membrane depolarization was not a result of direct depolarization by BTX on the muscle membrane nor was it reversible with bath applied tetrodotoxin (TTX 3 µM). Similar injections of TTX (2 µg) into nerve which failed to block axonal transport also failed to cause membrane depolarization up to 24 hrs although muscles were paralyzed and the normal transmitter release was still present. Therefore early depolarization seen at the endplate region with BTX injections was not due to muscle inactivity. There was total cessation of spontaneous and evoked transmitter release in muscles studied at 18 hrs when almost complete recovery of membrane potential and partial recovery of axonal transport had occurred. At 48 hrs and 5 days after BTX injection no transmitter activity was evident but endplates were significantly depolarized. Thus, possible interpretations for these findings are: 1) block of the trophic factor(s) responsible for maintenance of membrane potential and transmitter activity occurs simultaneously but the effect on the latter is only evident when available stores of transmitter are depleted. 2) Although recovery of transport resulting in membrane repolarization occurs, depletion of transmitter could possibly trigger proliferation of Schwann cells and nerve terminal degeneration. 3) Early depolarization seen with BTX injections at two sites and the onset of its occurence that is related to the site of injection positively support neurotrophic hypothesis. (Supported by NIH grants NS-12063, and funds from Muscular Dystrophy Association and the Paralyzed Veterans of America.)

1924 ENHANCEMENT OF AXONAL OUTGROWTH FROM SPINAL CORD EXPLANTS BY CONDITIONED MEDIUM. Lori B. Dribin, and John N. Barrett. Dept. Physiol. and Biophys., Univ. of Miami Med. Sch., Miami, Fla. 33152.

Results indicate that a large molecule(s) (molecular weight greater than 20,000 daltons) produced by rat muscle, lung, or fibroblast cells in tissue culture is capable of enhancing neurite outgrowth from rat spinal cord slices.

Slices of 15 to 16 day fetal rat spinal cord, freed from all spinal ganglia and meninges were plated on collagen plus poly-L-lysine coated glass coverslips. 5-Fluorodeoxyuridine was sometimes included in the culture medium (modification of Hams F12) to reduce non-neuronal cell outgrowth. Twenty four hours after explantation, medium previously conditioned 3 to 4 days by dissociated fetal or newborn rat muscle, lung, or fibroblast cultures was added to the spinal cord slices. Medium conditioned in the presence or absence of 10% fetal calf serum was effective in increasing the area covered by fiber outgrowth by more than 100% over control values. The maximal effect of the conditioned medium was observed one week after plating.

In order to determine the approximate molecular weight of the factor, the conditioned medium was filtered with Pellicon molecular filters PTHK or PTGC (nominal molecular weight cutoffs 100,000 and 10,000 respectively). The neurite growth enhancing activity was found exclusively in the higher molecular weight fractions. Controls consisted of fresh, non-conditioned medium filtered in the same manner as the conditioned medium. Since the neurite growth promoting activity was retained in the higher molecular weight fractions even after 2 washes with serum free fresh medium using the PTHK filter, the molecular weight of the active fraction must be at least 20,000 daltons.

The molecule(s) involved is probably not the classical Nerve Growth Factor (NGF), since spinal cord slices cultured in 5, 10, 15 or 30 biological units of NGF per milliliter of medium were similar to controls. Supported by NIH grants NS12207 and NS07044.

1925 NEUROTROPHIC CONTROL OF CHLORIDE CONDUCTANCE IN CULTURED MUSCLE. J. K. Engelhardt, K. Ishikawa*, and Y. Shimabukuro*. Grant Neuroscience Laboratories, Dept. of Neurology, USC School of Medicine, Los Angeles, Ca. 90033.

A neurotrophic factor is known to reduce the membrane resistance (R_m) of cultured chick skeletal muscle while leaving the membrane capacitance ($C_m \simeq 10\ \mu F/cm^2$) unchanged (Engelhardt et al., Brain Research 126: 172-175, 1977). The product $R_m \times C_m$ is equal to the electrical time constant (τ_m) of the muscle fiber; therefore, τ_m measurements can be used to estimate membrane conductance ($G_m = C_m/\tau_m$). When τ_m measurements are made in Normal Cl^- and Low Cl^- bathing solutions, component ionic conductances of the resting muscle membrane can be estimated using the following relations:

$$G_m(\text{in Normal } Cl^-) = C_m/\tau_m(\text{Normal}) \simeq G_K + G_{Cl}$$
$$G_m(\text{in Low } Cl^-) = C_m/\tau_m(\text{Low } Cl^-) \simeq G_K$$
$$G_{Cl} \simeq G_m(\text{Normal}) - G_m(\text{Low } Cl^-)$$

When τ_m measurements from pure muscle cultures are compared with those from muscles that have been co-cultured with spinal cord explants, the above assumptions result in the conductance values (in μsiemens/cm^2) tabulated below:

	G_m	G_K	G_{Cl}
Pure Muscle	575	510	65
Muscle + Nerve	1020	518	502

These results indicate that the neurotrophic factor is reducing R_m (increasing G_m) through an increase in G_{Cl}.

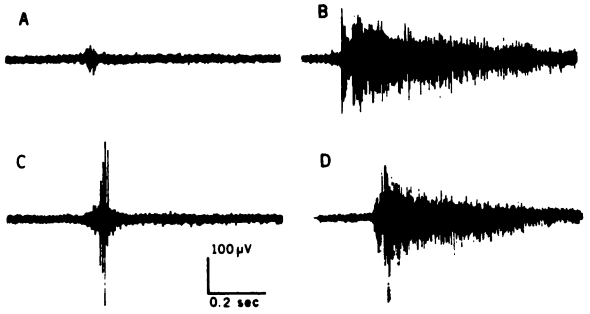
1926 MYOTONIA IN NORMAL COMPLEXUS MUSCLE AND MUSCULAR DYSTROPHY OF THE CHICKEN. Richard K. Entrikin, William R. Randall** and Barry W. Wilson. Depts. Pharmacol. and Avian Sciences, Univ. California, Davis, CA 95616

Abnormal EMG (electromyographic) activity, similar to that in various forms of myotonia, is a characteristic of pectoralis major muscles of genetically dystrophic chickens. We have observed similar activity in complexus ("hatching") muscles of normal chicks at 5 days ex ovo. "Insertional" activity was elicited from pectoralis major and complexus muscles by slight movement of a 31 gauge concentric needle electrode inserted into muscles of anesthetized (pentobarbital, 30 mg/Kg, i.p.) chicks. The activity in A below was recorded from the pectoralis major of a 5-day-old normal chick. This short duration, low amplitude, "immature" pattern contrasts markedly with the prolonged "myotonic" pattern recorded from the complexus muscle of a 5 day normal chick (B). The short duration, high amplitude pattern from the pectoralis major of a 28-day-old normal chicken is shown in C, and the prolonged "myotonic" pattern from the pectoralis of a 28-day-old dystrophic chicken is shown in D. The results show that insertional EMG activity in the normal complexus at 5 days ex ovo (B) is very similar to the "mature" dystrophic pattern (D), and is markedly different from both "immature" (A) and "mature" (C) normal activity. Another important feature of normal complexus muscles is the hypertrophy of fibers on days 16-20 in ovo, followed by atrophy until day 7 ex ovo (Ashmore et al., J. Histochem Cytochem. 21:266-278, 1973). The complexus muscle of the normal chick appears to offer unique possibilities for studying the relationship between myotonic EMG activity and skeletal muscle development. (Supported by the MDA).



1927 NEUROTROPHIC CONTROL OF 16S ACETYLCHOLINESTERASE AT THE NEUROMUSCULAR JUNCTION. Hugo L. Fernandez and Barry W. Festoff. Neurobiology Research Lab, VA Hospital, Kansas City, MO 64128 and Dept. Neurology, Univ. of Kansas Med. Ctr.

The mechanism(s) underlying neural control of skeletal muscle acetylcholinesterase (AChE) is not fully understood, but nerve-evoked muscle activity, ACh and regulatory substances released by nerves have all been proposed. The precise role and relative importance of these factors are unclear, partly because some might be involved in the control of junctional AChE and others of non-junctional AChE. Junctional versus non-junctional AChE may now be clearly distinguished, since of three AChE molecular forms in skeletal muscle only one (16S, sedimentation coefficient) is associated with endplates. Neurotrophic influences which are exerted independent of nerve-evoked muscle activity may be demonstrated by showing that denervation changes develop sooner if the nerve is cut close to, rather than far from, the muscle. The present work was undertaken in an effort to determine which factor(s) is involved in "trophic" regulation of junctional 16S AChE.

Obturator nerves of male Sprague-Dawley rats (150-200g) were transected on one side either at their point of entrance to anterior gracilis muscle (short stump) or 3.5-4cm central to that point (long stump), leaving the contralateral nerve intact (control). At varying postoperative times gracilis endplates, which are localized in two well-defined regions (3-4mm wide), were separated from non-innervated muscle regions and processed for AChE molecular forms (sensitive to BW284C51) on sucrose gradients. Endplate enriched zones of control gracilis contained 16,10 and 4S AChE, while muscle regions devoid of endplates had only 10 and 4S AChE. The amount of 16S AChE (% of control) gradually decreased in both long and short stump preparations, reaching the same level (10-20% of control) 6 days after denervation. The time of onset of these effects, however, was different; enzymatic decay started considerably earlier in short stump (12-24h) as compared to long stump (3-4d) preparations.

These and other results indicate that the time of onset of 16S AChE decrease, induced by denervation, is dependent on the length of nerve stump that remains attached to the muscle. In as much as muscle becomes inactive at the time of nerve section, regardless of nerve stump length, our findings cannot be attributed to muscle disuse. Rather, they imply that "trophic" regulation of 16S AChE primarily involves a neurogenic factor(s) which is independent of nerve-evoked muscle activity. Whether such a factor(s) is 16S AChE itself, also found in peripheral nerve, other axoplasmic molecule(s), or even ACh, is currently under investigation.

1928 EXCHANGE OF PROTEIN BETWEEN GLIA AND NERVE CELL AXONS IN CRAYFISH R.M. Grossfeld and G.D. Bittner. Zool. Dept., University of Texas, Austin, TX 78712.

In crayfish peripheral nerves, the distal stumps of cut motor axons undergo relatively few ultrastructural and physiological changes for long periods after separation from their cell bodies. The glial cells surrounding these axons exhibit a progressive hypertrophy and hyperplasia, as well as a prolonged increase in incorporation of radioactive leucine. Parallel histological results have been obtained for the medial giant axons and their adjacent glial sheaths in the crayfish central nervous system. We hypothesize that the long-term survival of severed motor axons and certain CNS axons depends, in part, upon their exchange of essential macromolecules with adjacent glial cells. We have, therefore, investigated the transfer of newly synthesized proteins from glia to adjacent axons.

Central nerve cords or limb nerves were isolated. These tissues were incubated in van Harreveld's solution containing H^3-leucine and then in a comparable ("chase") solution in which non-radioactive leucine replaced radioactive leucine ("normal incubation conditions"). Tissues were fixed with formaldehyde and autoradiographs were prepared from plastic-embedded sections. The autoradiographic grains overlying glial sheaths and the axoplasm of adjacent axons were quantified. Axonal areas were measured by planimetry.

Protein synthesis was linear for at least 2 hours. The washout of unincorporated radioisotope from the tissues attained 75% of the maximal value by 10 minutes and reached the maximal value by 40 minutes in the "chase" solution. Addition of puromycin, cycloheximide, and chloramphenicol to the labeling and "chase" solutions gave a 99% inhibition of protein synthesis without significantly altering the uptake of radiochemical. Under these conditions of protein synthesis inhibition, the grain counts for areas overlying the tissues were reduced to background. We have performed experiments, under normal incubation conditions, in which we varied only the time in the "chase" solution or the calcium concentration of this solution. Preliminary results indicate that there is a transfer of protein from glia to adjacent axons and that this transfer is sensitive to the extracellular calcium concentration.

1929 ALTERATIONS IN THE IN VITRO PHOSPHORYLATION OF NUCLEAR PROTEINS AFTER DENERVATION OF SKELETAL MUSCLES. Irene R. Held and Hock C. Yeoh*. Neuroscience Research Laboratory, VA Hospital, Hines, IL 60141 and Loyola Univ. Med. Ctr., Maywood, IL 60153.

Previously, we reported that the endogenous activities of nuclear protein kinases are stimulated in skeletal muscles which have been denervated for 48 hours. In this report, the changes occurring after denervation in the differential phosphorylation of nuclear proteins from two different types of skeletal muscle are demonstrated.

Nuclei are isolated as previously described by us from soleus and EDL (extensor digitorum longus) muscles which have been denervated for 48 hours by cutting the sciatic nerve in the mid-thigh of the rat. The sham-operated, contralateral muscles are used as the source of "control" nuclei. Intact nuclei (100-400 µg nuclear protein) are incubated for 10 minutes at 37°C. in a phosphorylation media (0.25 ml) consisting of 50mM Tris:HCl, pH 7.5, 0.1M NaCl, 2mM $MgCl_2$, 20 µCi γ - ^{32}P-ATP and 1uM cyclic AMP, when added. After termination of the reaction with excess, cold ATP and $Na_2P_2O_7$, aliquots are taken for determination of the levels of endogenous protein kinase activities by measuring the specific radioactivities (dpm/µg nuclear protein) of TCA-precipitable protein and also for the evaluation of the differential phosphorylation of hot, SDS-solubilized, nuclear proteins resolved by SDS-acrylamide electrophoresis and identified by assays of the radioactivity of gel slices.

When the gel electrophoregrams of the SDS-solubilized nuclear proteins from soleus and EDL muscles of the rat are compared, marked quantitative and qualitative differences are seen in the 10-12 discrete, protein-staining bands that are resolved. In addition, the phosphorylation profile also differs. At least four of the major protein bands of soleus nuclear proteins have high levels of ^{32}P radioactivity. The endogenous nuclear protein kinase activity of EDL muscle, however, appears to be more than fivefold lower than that of soleus muscle. After a denervation period of 48 hours, the nuclear protein kinase activity (dpm/µg protein) is significantly stimulated in both muscles and an increased radiolabeling of several discrete protein bands is found. No change is observed in the protein pattern after denervation. Alterations in phosphorylation induced by pre-incubation of skeletal muscle nuclei with cyclic AMP are being studied.

The factors responsible for the mediation of the observed alterations in the phosphorylation of nuclear proteins after denervation of skeletal muscles remain unidentified. Supported by NINCDS Grant NS-11755 and by the Medical Research Service of the Veterans Administration.

1930 I-125-αBUNGAROTOXIN BINDING TO DENERVATED MUSCLE: A SURVEY STUDY USING LIGHT AND EM AUTORADIOGRAPHY. R. H. Loring and M. M. Salpeter. Cornell Univ., Ithaca, N.Y., 14853.

The appearance of extrajunctional acetylcholine receptor following denervation of a muscle has commonly been studied by measuring the increase in I-125--αBungarotoxin (αBGT) binding to the muscle. It is often assumed that most of the increased binding of labeled toxin to denervated muscle represents binding to acetylcholine receptors in the plasma membrane. This study was undertaken to test this assumption by localizing αBGT binding at both the light and electron microscope levels by autoradiography.

Labeling was performed in vivo, by bathing the exposed sternomastoid muscle of a mouse in αBGT (Fertuck et al, J. Cell Biol. 1975: 66, 209). αBGT was used at $3x10^{-6}$ M for 2 to 3 hrs, which was found to fully inactivate receptors. Three mouse sternomastoid muscles denervated for eight days were compared with two normal sternomastoid muscles. Non-saturable binding was determined on two eight-day-denervate muscles that were bathed for 3 hrs in $3x10^{-6}$ M unlabeled toxin before bathing for 3 hrs in labeled toxin. All the muscles were prepared for both light and EM autoradiography.

We find that: 1) αBGT binding to the postjunctional membrane (PJM) of the denervated endplate is not significantly different from that at the innervated PJM, and is decreased more than 90% by pretreatment with unlabeled toxin; 2) Denervated muscle shows a large fiber to fiber variability in the label on the extrajunctional plasma membrane (EJM). The site density on the EJM of adjacent fibers may differ by as much as 10-fold; 3) The average αBGT density at the denervated EJM is 200 sites/μ^2 (compared with the normal EJM site density of less than 40 sites/μ^2) and these αBGT binding sites are evenly distributed with no "hot spots" in areas of the muscle within 5 mm of the endplate; 4) A fraction of αBGT is bound in the "cytoplasm" of denervated muscle. Preliminary EM autoradiographic analyses, corrected for radiation spread, suggest that more than 50% of the internal sites are associated with the muscle triads, presumably representing sites on the T-system. If this assumption is correct then the actual site density of T-system membrane is probably only about 1/3 the site density at the EJM; 5) Prelabeling with cold toxin eliminates 90% of both the cytoplasmic and EJM label; 6) In denervated muscle, αBGT is also bound to collagen and invading non-muscle cells. This binding is not saturated by pretreatment with unlabeled toxin. These results indicate that care should be taken to show that αBGT is actually bound to muscle acetylcholine receptors when interpreting experiments designed to study receptor spread following denervation.

1931 NERVE GROWTH FACTOR IN THE SERUM AND SUBMANDIBULAR GLANDS OF MICE WITH MUSCULAR DYSTROPHY. Richard A. Murphy, Nicholas J. Pantazis* Dept. Anat., Harvard Med. Sch., Boston, MA 02115.

Nerve growth factor (NGF) is present in high concentrations in the submandibular glands of adult mice but the reason for this is not understood. Removal of the salivary gland, for example, has no effect on serum levels of NGF so the gland does not appear to be secreting this protein into the circulation. On the other hand, high levels of NGF are present in saliva and this result suggests that the gland is an exocrine organ with respect to NGF. In spite of this information, however, we still have no clue as to what role NGF plays in the gland or in saliva.

Recently, Furukawa et al. (BBRC 76:1202, 1977) have shown that extracts of salivary glands from mice with muscular dystrophy are less active in the bioassay for NGF (biological units/mg protein) than are extracts from control animals. This result could arise for several reasons: 1) there may be less NGF than in the salivary glands of dystrophic mice than in glands from normal animals; 2) the structure of the NGF molecule in the dystrophic gland may be altered and therefore less active biologically; 3) there may be substances in the submandibular gland which inhibit NGF's actions in the bioassay. In this study, we have begun to examine these alternatives.

Submandibular glands from sexually mature 129 B6/f_1/Jdy mice were frozen and subsequently homogenized and the supernatant fractions examined using a radioimmunoassay made against 2.5S NGF. The data indicate that glands from male dystrophics contain less NGF (2.21±.29µg/mg protein) than glands from unafflicted littermates (4.58±.38µg/mg) ($p<0.001$). Female dystrophic mice show even greater differences in gland NGF levels (0.021±.01µg/mg) when compared to control animals (0.25±.06µg/mg). Serum levels of NGF, however, are not altered in the afflicted animals of either sex. Furthermore, the deficit in the glands is not limited to NGF. Concentrations of epidermal growth factor (EGF) measured by RIA are reduced by amounts comparable to that for NGF. On the other hand, β amylase, a digestive enzyme in the submandibular gland, is normal in dystrophic animals.

The molecular properties of NGF from the salivary glands was analyzed by gel filtration. The NGF from normal and dystrophic animals (male and female) eluted identically as a single peak (m.w. approx. 140,000) on two different resins. Furthermore, NGF from dystrophic glands is biologically active at concentrations which are similar to those of the NGF from normal animals. Hence, we are unable to detect any differences in the chemical and biological properties of the NGF from the glands of normal and dystrophic animals. We conclude, therefore, that submandibular glands from dystrophic mice indeed contain less NGF (and EGF) than do glands from normal animals, for reasons unknown.

1932 THE EFFECT OF PROPYLTHIOURACIL ON THE DEVELOPMENTAL MORPHOLOGY OF THE MESENCEPHALIC NUCLEUS OF DUCK EMBRYOS. Y. Narayanan* and C.H. Narayanan (SPON: R.B. Malloy). Dept. Anat., LSU Sch. Med., New Orleans, LA 70119.

This report deals with the effects of propylthiouracil (PTU) on the development of the mesencephalic nucleus of the trigeminal nerve of duck embryos from eight to twenty-six days of incubation age. Embryos were made hypothyroid by the in vivo injection through membrane blood vessels of single or multiple doses of 0.2 to 0.5 cc of 0.2% PTU beginning from the eighth day of incubation. PTU treated embryos and a corresponding number of saline injected control embryos were examined at one day intervals until hatching. Recordings of the frequency of beak movements showed a significant reduction in the treated embryos at all stages of development. Thyroid follicles in the treated embryos had very little or no colloid in them, and the follicular epithelial cells were enlarged as determined by mean acinar heights. In a previous study on the normal development of the mesencephalic nucleus, based on the morphological changes observed, the cells have been classified into three stages from early appearance until hatching. We have followed the same sequence of changes in the present study in our evaluation of the effects of PTU on the neurons of the mesencephalic nucleus during (a) the midincubation period, 13 to 18 days; (b) the last phase, from day 19 to hatching. The neurons of the mesencephalic nucleus in the treated embryos showed a general retardation of structural development. This was particularly reflected in a reduction of the Nissl and neurofilaments. A reduction in the size of neuronal somata and a reduction in the number of cells were observed. Our results suggest that thyroid hormone is essential for the normal development of structure and functional relations of the mesencephalic nucleus of the trigeminal nerve.

1933 IMMUNOLOGICAL DETECTION OF A NERVE GROWTH FACTOR-LIKE MOLECULE IN MOUSE MILK. Nicholas J. Pantazis*, Richard A. Murphy and Michael Young*. (Spon. Barry G.W. Arnason) Dept. Anatomy, Harvard Med. Sch., Boston, MA 02115, and Lab. of Physical Biochemistry, Mass. Gen. Hospital, Boston, MA 02114.

The submandibular glands and saliva of adult mice contain large amounts of nerve growth factor (NGF). High concentrations of the protein are secreted via saliva into the digestive tract of the adult animal, and it is reasonable to suspect that the protein's presence there is of biological importance. If this is true, however, then intriguing questions arise concerning the newborn animal. It is known that NGF does not appear in abundance in the salivary gland or saliva until puberty, so the newborn may require NGF from other sources. This reasoning led us to question whether or not the diet of the newborn mouse could provide this protein. Consequently we have examined mouse milk to determine if it contains NGF.

Using a radioimmunoassay for 2.5S-NGF, we have detected in milk a molecule which is immunologically indistinguishable from salivary gland NGF. The material is present in concentrations ranging from 100-600 ng/ml, and it is detectable in milk collected from mothers nursing from 3 to 16 days postpartum. Over this time period, no consistent differences in the concentration of this material in milk were noted.

The chemical properties of the immunoreactive molecule were studied on columns of Sepharose 6B. The material elutes from the column as a large molecular weight species (500,000-600,000 daltons) and it does not dissociate at low concentrations (ng/ml). In solvents containing guanidine hydrochloride, the material displays a molecular weight of 40,000-50,000. This value differs significantly from the molecular weight of the immunoreactive component of salivary gland NGF (13,000) determined under identical experimental conditions.

Thus far we have been unable to obtain a positive response in the ganglion bioassay with the NGF-like molecule detected in milk. Several explanations could account for this result. It is possible that the molecule measured by radioimmunoassay is not NGF but rather an immunochemically cross reacting species. Alternatively, the NGF we detect in milk may be present in a biologically inactive form. Finally, milk may contain other factors which interfer with neurite outgrowth in the ganglion assay. These alternatives are presently under study.

Supported by a grant from the National Foundation, March of Dimes to RAM and NIH grants to RAM and MY.

1934 SODIUM-STIMULATED, NERVE GROWTH FACTOR DEPENDENT HEXOSE UPTAKE BY CHICK EMBRYO GANGLIONIC NEURONS. Stephen D. Skaper* and Silvio Varon. Dept. Biol., Sch. Med., U. Ca. San Diego, La Jolla, CA 92093.

Nerve Growth Factor (NGF) is essential for development of sympathetic and sensory neurons. Dorsal root ganglionic (DRG) cells, when incubated in vitro in the absence of NGF undergo a general metabolic degeneration which is preceded by certain changes in permeation properties. To determine whether NGF deprivation could affect the capacity of these cells to take up an important energy source, namely glucose, cells were incubated with or without NGF for different times, and then presented with the factor and tested for uptake of [^{3}H]labeled 2-deoxy-D-glucose (2DG). The pulsed cells were collected on moist glass fiber filters under vacuum suction. The filters were washed with ice-cold incubation medium, dried and counted via liquid scintillation techniques. The standard incubation medium consisted of 40mM Hepes or Tris-Hepes pH 7.4, 140mM NaCl, 5mM KCl, 1mM $MgCl_2$, 0.1mM $CaCl_2$, and 1% bovine serum albumin.

2-Deoxy-D-glucose uptake by DRG cells was reduced by NGF deprivation and restored by delayed NGF administration (up to 6-hr). Calculation of apparent uptake constant (K_t) and maximal velocity (V_{max}) in NGF-maintained and -deprived cells showed about 2-fold differences between NGF-controlled and NGF-independent hexose uptakes. This NGF-dependent portion (about one-third) of the total specific hexose uptake was also dependent on the presence of Na^+ ions, with the apparent K_t for 2DG varying inversely with the Na^+ concentration (V_{max} was unaffected). Preincubation of DRG cells with 1mM ouabain for 30 min, followed by a pulse with [^{3}H] labeled 2DG, also resulted in a 53-63% reduction of the NGF sensitive uptake. The NGF-controlled hexose uptake was also energy dependent, being inhibited 47-67% by a 30 min preincubation with 1-2mM 2,4-dinitrophenol. Other transport substrate activities (α-amino-isobutyric acid, uridine) for DRG cells which exhibited NGF regulation were likewise Na^+ sensitive. These results indicate that NGF may provide for the maintenance and development of its embryonic target neurons by modulating permeation properties which regulate the availability of major energy substrates (and other nutrients), and may conceivably do so by acting through a sodium gradient across the cell membrane.

(Supported by U.S. Public Health Service grant NS-07606.)

1935 A NEUROTROPHIC INFLUENCE ON ADULT MUSCLE WHICH IS INDEPENDENT OF ELECTRICAL ACTIVITY. L. Ziskind* and A.J. Harris*(SPON: J.I. Korenbrot). Dept. Physiology, Otago University Medical School, Dunedin, New Zealand.

Strips of denervated adult mouse diaphragm and segments of embryonic spinal cord were pinned to collagen-coated dishes and immersed in 0.2 ml of culture medium enriched with foetal calf serum, human plancental serum and chick embryo extract.

1-2 weeks after explanting spinal cord segments spontaneous depolarising potentials were recorded in some muscle fibres. These were reversibly blocked by d-tubocurarine (dTC, 5 x 10^{-6} gm/ml) but were not affected by tetrodotoxin (TTX, 2 x 10^{-7} gm/ml). In denervated muscle fibres action potentials were insensitive to TTX, whereas sensitivity to the toxin was restored upon reinnervation of the cultured muscles. Such TTX-sensitive action potentials were detected only in fibres which showed miniature end-plate potentials (m.e.p.p.'s), indicating that a spinal cord explant in the bath was not sufficient to initiate the restoration of toxin sensitivity.

Strips of denervated diaphragm which were chronically stimulated for 4 days did not regain TTX sensitivity. In contrast, the action potential mechanism became sensitive to TTX in muscle fibres which had developed synapses in the continual presence of dTC (5 x 10^{-6} gm/ml). The observations indicate that restoration of TTX sensitivity in reinnervated adult muscle results from some trophic influence of the nerve which is independent of both muscle activity and the action of transmitter on postsynaptic receptors.

VESTIBULAR SYSTEM

1936 NECK MOTOR RESPONSES TO VERTICAL ROTATIONS IN THE ALERT CAT. John H. Anderson and Costas Pappas*. Lab.Neurophysiol.,Dept.Physiol., U.Minn., Mpls., Minn. 55455

Vestibular reflexes involving the neck musculature play an important role in controlling posture and mediating eye-head coordination. Due to the mechanical linkage of the head and neck, one important aspect is for the control of head position in the vertical planes. Therefore, as part of our efforts at determining the dynamic characteristics of the vestibulo-nuchal reflexes, we have examined those initiated by roll (lateral) and pitch (forward-backward) rotations, in which cases both vertical semicircular canal and otolith inputs are present. The motor outputs measured were the EMG activities of the sternomastoid (a head rotator and ventral flexor) and biventer cervicus (dorsal flexor) muscles. These were chosen since they can function either synergistically (during roll) or antagonistically (during pitch) and therefore might demonstrate the reciprocal organization of vestibular reflexes involving flexor and extensor motoneurons.

Alert cats, whose heads and spinal vertebrae (C_{7-8}) were rigidly fixed, were subjected to sinusoidal rotations in the frequency range 0.04-4.0 Hz. In this situation there was a modulation of the tonic activity in the biventer cervicus which, if the head were free to move, would have subserved compensatory movements: during roll the responses lagged the contralateral angular acceleration and during pitch they lagged downward acceleration. The phases showed lags of 140 to 150 degrees at the lowest frequencies tested, whereas at the higher frequencies this became less: about 120 deg. at 1.0 Hz and only 50-85 deg. at 4.0 Hz. Since the sternomastoid muscle was usually silent in the alert situation, for some recording sessions the cats were given small doses of ketamine hydrochloride (5-8 mg/kg). There was then a background level of activity in the sternomastoid. The phase of the modulated activity was largely in agreement with that of the biventer.

From these results we conclude that the otolith inputs make important contributions to the neck motor outputs at the lower frequencies, whereas the canal inputs are more significant at the higher frequencies. Furthermore, the rising phase curves and rather small phase lags for frequencies above 1.0 Hz suggest that in addition to "indirect" pathways involving integration of the vestibular inputs, there is likely to be also a significant contribution to the motor outputs by the direct pathways at the higher frequencies. This is most probably necessary to prevent large phase lags in head position which would otherwise be introduced by the viscoelastic properties of the head-neck system in the freely moving animal.

1937 FREEZE-FRACTURE STUDIES ON THE SYNAPSE OF THE TYPE I HAIR CELL IN THE VESTIBULAR SYSTEM OF THE GUINEA PIG. D. Bagger-Sjöbäck* and R. L. Gulley. Illinois Eye and Ear Infirmary, University of Illinois, Chicago, Illinois and Department of Anatomy, Case Western Reserve University, Cleveland, Ohio.

Synapses of type I hair cells with calyceal terminals of dendrites of vestibular ganglion cells were studied in the maculae and cristae using thin section and freeze-fracture techniques. In thin sections, very few synaptic junctions are found along the apposition of these cells. Infrequently, synaptic bodies are adjacent to the hair cell plasmalemma, and the opposed calyceal plasmalemma is lined by a prominent postsynaptic density. In freeze-fracture replicas, the plasmalemmae at these junctions are identical to those of the ribbon synapse in the inner hair cell of the organ of Corti (Gulley and Reese, '77). Our failure to find such junctions in replicas of most type I hair cells, many of which had very large areas of their membrane exposed, suggests that very few of these junctions are present in these hair cells, and that some type I hair cells may even lack this junctional structure. The apposition of the hair cell and dendrite, however, is specialized. The hair cell is invaginated by cytoplasmic protrusions of the dendritic calyx. The number, shape and depth of these invaginations varies between different cells. These variations are not related to the location of the hair cell in the sense organ. In non-invaginated regions of the apposition, the plasmalemmae are separated by a 25-30 nm extracellular space. The extracellular space narrows at the invaginations, where the apposed plasmalemmae are separated by 6 to 7 nm. A thin paramembranous density lines the plasmalemmae along the region of widened extracellular space adjacent to the invagination. In freeze-fracture replicas, neither the hair cell nor the calyceal plasmalemma within the invaginations have a special distribution of intramembranous particles on either membrane leaflet. However, at the base of the invaginations of the hair cell, a large aggregate of widely-spaced, large, angular particles surrounds the invagination on the external membrane leaflet. The corresponding region of the calyx has no special distribution of particles on either membrane leaflet. Typically, chemical and electrical junctions are characterized by a special distribution of intramembranous particles at the junctional region. The regions of the type I hair cell where the plasmalemma is most closely opposed to the calyx, have no particle specialization, but instead are surrounded by large intramembranous particles. The scarcity, or lack, of chemical synaptic junctions along this calyceal apposition and the unique arrangement of particles around a region of plasmalemma closely apposed to the postsynaptic cell may indicate an unusual mode of conduction between the hair cell and ganglion cell dendrite.

1938 VESTIBULAR AND OPTOKINETIC PROPERTIES OF NEURONS IN THE VESTIBULAR NUCLEI OF RABBITS. N. H. Barmack and V. E. Pettorossi*. Neurological Sciences Inst., Good Samaritan Hosp. & Med. Ctnr., Portland, OR. 97209

The vestibular nuclei receive a direct projection from primary otolithic and semicircular canal afferents. In addition these nuclei receive indirect visual projections from the cerebellar flocculus, as well as extracerebellar visual projections of unknown origin. We have examined how these classes of afferent information converge on single cells in the vestibular nuclei in paralyzed and unanesthetized rabbits. Rabbits were mounted with heads placed near the center of a biaxial rate table, which could be sinusoidally oscillated about the vertical axis activating the horizontal semicircular canals, and about the longitudinal axis, activating the anterior semicircular canals and utricles. Monocular optokinetic stimulation in the horizontal and vertical planes was delivered, by projecting a random dot pattern off two mirrors mounted on galvonometers and onto a rear projection tangent screen subtending 72 x 72 deg. All vestibular units tested evinced both a vestibular and visual responsiveness. Most cells which were primarily sensitive to rotation in the vertical plane differed from cells which were sensitive to rotation in the horizontal plane, in that the discharge rate of vertically sensitive cells could be modulated at low frequencies of stimulation (.001-.02 Hz), as well as at higher frequencies of stimulation (.02-.8 Hz); indicating that vertically responsive cells receive convergent otolith and semicircular canal inputs. Cells which had a type I vestibular response also had a visual directional selectivity for ipsilateral optokinetic stimulation which was synergistic. For example, type I cells in the medial vestibular nucleus were excited by ipsilateral horizontal acceleration and by posterior-anterior optokinetic stimulation of the ipsilateral eye. The effect of optokinetic stimulation of the contralateral eye was always weaker and sometimes not synergistic. The vestibular and optokinetic interactions of type II cells were less predictable, and some type II cells were more strongly driven by optokinetic stimulation of the contralateral eye. The optokinetic velocity sensitivity for vestibular cells had a broad range, extending from .25 deg/sec to 50 deg/sec. This broad range far excedes the range of neurons in one of the possible sources of indirect visual input to the vestibular nuclei; the dorsal cap of the inferior olive. Electrolytic lesions of the dorsal cap made during recording from optokinetically modulated type I vestibular nuclei neurons, reduce the overall level of activity of these cells but do not abolish their directional selectivity. We conclude that the immediate visual responsiveness of vestibular nuclei neurons originates from extraolivary sources. (Supported by PHS Grant EY-00848 and The Oregon Lions Sight Foundation).

1939 VESTIBULO-SPINAL SYSTEM ADAPTATION TO SUDDEN UNILATERAL VESTIBULAR LESIONS. F. Owen Black and Conrad Wall III. Department of Otolaryngology, Eye and Ear Hospital, University of Pittsburgh, Pittsburgh, Pennsylvania 15213, USA.

Otherwise normal patients with sudden unilateral vestibular disturbances develop a characteristic nystagmus and ataxia which gradually improves. In contrast to the vestibulo-ocular system, quantitative characteristics of the compensating vestibulo-spinal system have received very little attention. We are presently investigating vestibulo-spinal system adaptation using a computerized force platform to record and analyze patients' postural stability. (Black, et al. 1977).

Serial force platform recordings from two groups of patients will be presented: 1) patients with temporary vestibular disturbances as a consequence of otosclerosis surgery (stapedectomy) and 2) patients with sudden, complete loss of peripheral vestibular function (labyrinthectomy). Data analysis was accomplished by 1) x-y displacement amplitude plots, 2) polar vector amplitude and angle fluctuations, 3) phase plane plots and 4) power spectral analysis. Preliminary results indicate that the two groups of patients recover at significantly different rates, (and probably by different mechanisms) when account is taken of patient age at the time of the lesion. General inferences regarding possible adaptive mechanisms will be presented.

1940 VESTIBULAR, AUDITORY, AND SOMATOSENSORY RESPONSES OF NEURONS IN VENTRAL BASAL AND POSTERIOR THALAMUS OF THE CAT. Paul Blum and Sid Gilman. Dept. Neurol., Columbia Univ., New York, NY 10032 and Dept. Physiol., Thomas Jefferson Univ., Phila., PA 19107.

Investigations of the rostral projections from the vestibular system in the cat using evoked potential techniques have shown that activity originating in the vestibular nerve reaches the ventral basal (VB) and posterior (PO) nuclei of the thalamus. In this study, investigations were undertaken of the responses of single units in VB and PO to: 1) electrical stimulation of the vestibular nerve; 2) electrical and natural stimulation of the auditory nerve; 3) electrical stimulation of the ipsilateral forepaw and contralateral forepaw (CFP); and 4) natural stimulation of cutaneous, muscle, and joint receptors throughout the body surface. Forty-two percent of 333 units recorded were responsive to these sensory stimuli. Units that were activated at short latency (<30 msec) following CFP stimulation or with receptive fields confined to the contralateral body surface were termed "somatic non-convergent units." These units (38% of responsive units) were found preferentially in VB. Units responding exclusively to auditory stimuli were termed "auditory non-convergent units" (4% of responsive units) and were found in the medial geniculate nucleus. A third class of units were termed "convergent" (43% of responsive units). These units either: 1) responded to auditory and somatic stimuli; 2) responded to CFP stimulation at excessive latency (>30 msec); or 3) had a bilateral receptive field. Convergent units were located throughout PO. Fourteen percent of the responsive units were activated by vestibular nerve stimulation. Seven of these units were activated by stimulation of the vestibular nerve at a stimulus intensity that was low enough so that the stimulus did not spread and activate fibers in the cochlear nerve. Another group (13 units) was activated at higher intensity vestibular nerve stimulation. There was no differences that could be identified between the two groups of vestibular-activated units on the basis of location or characteristics of the response to sensory stimuli. Vestibular-activated units were found throughout PO and along the border between PO and VB. The range of latencies following vestibular nerve stimulation was from 4 to 25 msec, and 71% of these units also were activated by auditory or somatosensory stimuli. This data suggests that vestibular activity is processed by the thalamus in PO. This data also shows that there is considerable convergence of vestibular information with somatosensory and auditory information at the level of the thalamus.

1941 A METRIC SPACE DERIVED FROM NEURONAL FIRING PATTERNS. W. Bouris and A. A. Perachio. Yerkes Reg. Primate Res. Ctr., Emory Univ., Atlanta, GA 30322.

Recordings from second-order cells of the vestibular system that were responsive to linear acceleration (translational motion) were examined for dynamics in their responses that would reflect adaptation to repetitive stimulation and for quantitative comparisons among such cells. Since these cells can exhibit nonlinear responses, such as rectification, the requirements for linear analysis of the data cannot be met satisfactorily. Also, the experimental conditions that would allow for the linearization of such nonlinear data are extremely difficult to achieve for this type of vestibular stimulus (French, A.S., et.al., Kybernet. 11(1972), 15-23; Gardner, E.P. and Fuchs, A.F., J. Neurophysiol. 38(1975), 627-650; Spekreijse, H. and Oosting, H., Kybernet. 7(1970), 22-31).

An alternative method is developed which is based on first deriving a geometric space in which a point is an unambiguous representation of a cell's firing pattern, and conversely any observed firing pattern is a unique point in this space. First, consider the interval of time taken to observe a cell's response to a stimulus. This interval is a subspace of the X-axis. The list of firing times that occur in this interval is a finite subset of it. Any such finite subset has a maximum number of firing times, determined by the length of the interval and the maximum firing rate possible. The collection of all such finite subsets forms the space we are interested in.

Next, consider the metric of the X-axis. The distance between two times of firing is simply the length of interval between them. (This is the usual notion of distance for one-dimensional space.) A new metric is derived from this one whose units are the same (msecs) with which, given two firing trains, A and B, the distance between A and B can be measured. The calculation of this distance requires the operations subtraction, minimum of a list and maximum of a list. It satisfies the definition of a metric: $d(A,B) = d(B,A)$, $d(A,B) + d(B,C) \geq d(A,C)$, if $d(A,B) = 0$, then A is B; and if A is B, then $d(A,B) = 0$. Suppose A is 50 msecs from B. One way to view this is that a clock whose resolution is finer than 50 msecs would be required in order to distinguish A from B.

Programs have been written for the LINC-8 Computer to calculate these distances. Algorithms are also utilized to compute a new pattern that is in some sense minimally distant from a given population of observed firings, i.e., a kind of "typical" pattern.

1942 THE VESTIBULAR CORTEX IN THE ALERT MONKEY: NEURONAL ACTIVITY IN AREA 2v DURING ROTATION IN THE DARK AND OPTOKINETIC STIMULATION.
U.Büttner*, U.W.Buettner* and V.Henn* (SPON: T.T. Kennedy). Dept. of Neurology, University of Zürich, CH 8091 Zürich (Switzerland).

Single unit activity was recorded from the lower end of the intraparietal sulcus (area 2v) of the rhesus monkey seated on a turntable with his head fixed. For vestibular stimulation the monkey was rotated sinusoidally around a vertical axis in complete darkness at frequencies between 0.005 and 1 Hz. During optokinetic stimulation a cylinder covered with vertical black and white stripes, which completely surrounded the monkey, was rotated sinusoidally at frequencies between 0.01-1 Hz around the stationary animal. Horizontal and vertical eye position was recorded with chronically implanted DC silver-silver chloride electrodes. For quantitative analysis phase and gain of neuronal activity relative to turntable velocity was determined using a Fourier analysis program.

About half of the neurons responding to vestibular stimulation were classified as type I neurons, since they were activated during rotation to the ipsilateral side and inhibited during rotation in the opposite direction. The remaining half were type II neurons with a mirror-like behavior. At frequencies between 0.1 and 1 Hz cortical neurons showed a phase advance of 0-20° relative to turntable velocity. At lower frequencies the phase advance increased and reached about 90° at 0.005 Hz. The phase characteristics were compared with the phase advance of the simultaneously recorded nystagmus.

Nearly all vestibular cortex neurons responded also to optokinetic stimulation. In order to obtain similar responses the cylinder, or the turntable, had to move in opposite directions, which elicits nystagmus into the same direction. The response to optokinetic stimulation was instantaneous and often as strong as for a comparable vestibular stimulus. It was noticed that neurons still responded at high frequencies (0.5-1 Hz) with small cylinder displacements.

1943 VARYING COMBINATIONS OF VISUAL AND VESTIBULAR INPUTS ALTER RESPONSES OF OTOLITH UNITS IN CAT VESTIBULAR NUCLEI. N.G. Daunton, D.D. Thomsen*, and C.A. Christensen*. NASA-Ames Research Center, Moffett Field, CA 94035 and Vassar College, Poughkeepsie, NY 12601.

Many neurons in the cat vestibular nuclei which are sensitive to linear acceleration are also influenced by moving visual stimuli (Daunton and Thomsen, Neurosci. Abstr. II, 2, 1526, 1976). The majority of units which respond to linear acceleration in a given direction also respond to visual stimulation in the opposite direction. These two inputs provide congruent information about the cat's linear self-movement.

The present study examined the response of otolith units in the vestibular nuclei to stimulus configurations which differ from the naturally occurring condition of congruent visual and vestibular stimulation. Chronically prepared cats were relaxed with Flaxedil and artificially ventilated. Single units responsive to linear acceleration in the dark were tested for visual sensitivity. Units responsive to sinusoidal visual and vestibular stimulation in the same axis were tested in three conditions of combined visual and vestibular stimulation: 1) congruent stimulation obtained by moving the animal in the lighted, but stationary visual enclosure; 2) visual and vestibular stimulation applied in opposite directions resulting in twice the image displacement of congruent stimulation; 3) coupled visual-vestibular stimulation resulting in no seen visual movement relative to the animal.

The results show that, compared with vestibular stimulation in the dark, almost all cells displayed increased gain to linear acceleration when they were stimulated in the light, even in the condition in which there was no seen movement. This finding conflicts with the results of Waespe, et al. (Pflug. Arch., S373, R87, 1978) who noted that in monkey sensitivity to angular acceleration was decreased by the coupling of visual and vestibular inputs. In the present study the majority of units showed a greater increase in gain when the visual stimulation was congruent with the linear acceleration than when the visual stimulation provided no image displacement. There was also a tendency for the gain of units to be greater for congruent stimulation than for the double displacement condition. These results are similar to those reported by Berthoz, et al. (Exp. Br. Res., 23, 471-489, 1975) for human observers tested in conditions resembling those studied here. Within-unit analyses of phase relationships showed minimal changes in phase under the coupled stimulus condition relative to the vestibular, dark condition. However, with congruent stimulation, detectable phase shifts were observed. These data suggest that vision can provide both a specific and non-specific influence on units responding to linear acceleration in the vestibular nuclei, and that visual and vestibular inputs about self-motion do not combine additively.

1944 VESTIBULAR AND NECK SENSORY INPUT TO UNITS IN THE VESTIBULAR NUCLEUS OF ALERT CATS. James H. Fuller. Biol. Sci. Group, Univ. Connecticut, Storrs, CT 06268.

Single units in the vestibular nucleus having a semicircular canal and neck sensory input were recorded in cats executing an eye-head movement task. The cats were trained to align their heads and/or eyes with a target and to maintain this alignment within $\pm 2.5^{o}$. In the experiments to be presented, the target was stepped from one side to the other, with an excursion of 20 to 60 degrees in the horizontal plane. Proper alignment was determined by a rotary potentiometer connected to the shaft restraining the head or by the oculogram. Canal input was identified by passive rotation of the whole animal about the vertical axis, and by latency measurements of firing rate changes following a $2,000^{o}/sec^{2}$ deceleration of the head during active movements; latencies were 5-10 msec. Neck sensory input was characterized by fixing the animal's head in space and passively rotating the body about the head. Firing rate modulation was both dynamic and static in most units; latency to rapid pulses of the body was approximately 20 msec.

Spindle, joint, or tendon sensory discharge may be influenced by internally generated muscle contraction as well as by passive movement of the neck; furthermore, direct, internally generated inputs can influence unit firing rate independent of neck muscle activity. Two basic procedures were employed to segregate these sources of firing rate modulation. During active head movements, static friction loads were randomly applied to the rotary shaft. In the other procedure, the animal's head was fixed, and the horizontal head torque (measuring attempted head movement) signal was substituted for the rotary potentiometer signal. The gain of the torque signal was randomly adjusted to require greater effort on some trials while the animal performed the task in one of three paradigms: 1) head fixed to the stationary platform; 2) head fixed to the platform, which was moved by the servo system, with the torque signal serving as the input; and 3) head fixed in space, with the body moved about the head by the servo system as in item 2. Individual trials in which a greater effort was required were segregated and analyzed for qualitative and temporal differences in onset or offset of firing rate changes. Preliminary data indicate that the input to these neurons, located on the medial-descending border of the vestibular nuclei 1-2 mm caudal to the abducens nucleus, is mainly of vestibular and neck sensory origin.

1945 TRANSFER FUNCTION ANALYSIS OF RHESUS MONKEY HORIZONTAL VESTIBULOOCULAR REFLEX USING PSEUDORANDOM BINARY SEQUENCE AND SINUSOIDAL ROTATIONAL STIMULATION. Joseph M. Furman, Dennis P. O'Leary. Dept. Otolaryngology, Div. of Vestibular Disorders, Univ. of Pittsburgh, Sch. of Med., Pittsburgh, PA 15213 and James W. Wolfe. USAF School of Aerospace Medicine, Brooks AFB, San Antonio, Texas 78235.

A transfer function analysis of the alert rhesus monkey horizontal vestibuloocular reflex (VOR) was determined using pseudorandom binary sequence (PRBS) rotational acceleration about the vertical axis in the dark. The PRBS period length and state duration were chosen to deliver vestibular stimuli at frequencies from 0.008 Hz to 0.66 Hz simultaneously. Eye movements were recorded with chronically implanted electrooculographic electrodes which were connected to a DC coupled amplifier. The electrooculogram was sampled at 100 Hz by a PDP 11/40 computer using a 12 bit analog to digital converter. The nystagmoid eye position data was then analyzed by a software algorithm which replaced saccadic movements with estimated slow phase eye position. The transfer function of the VOR was then estimated using a cross-spectral analysis technique. Single frequency sinusoidal vestibular stimulation was also used to calculate gain and phase.

The PRBS technique has the advantage of allowing a characterization of the monkey's VOR at many frequencies simultaneously during a short time interval (about 5 minutes). This minimizes the effects of physiological nonstationarities on the estimate of the VOR transfer function.

Preliminary results using the PRBS technique reveal that response decline is minimal even after an hour of stimulation. Also, response variability cycle to cycle using sine wave stimulation exceeds response variability during PRBS stimulation.

1946 RHYTHM GENERATION IN TONICALLY ACTIVE LABYRINTHINE PRIMARY AFFERENTS OF THE TOADFISH, OPSANUS TAU. S. Highstein & A. Politoff. Dept. of Neurosci. A. Einstein Coll. Med., Bronx, N.Y. & Dept. of Physiol., Boston U. Sch. Med., Boston, Mass.

Action potentials (AP) were recorded with a hook electrode from physiologically identified tonically active posterior semicircular canal primary afferents, in vitro. Recording sites were less than 1mm from the labyrinthine sensory epithelium. >200 units were studied. Following each AP a baseline hyperpolarization-depolarization sequence (H-DS) leading to the subsequent spike is seen. H-DSs are stereotyped for a given unit firing at a stable frequency. However, ramp-like depolarization does not invariably lead to spiking as an occasional AP is dropped. Notable in these cases of dropped APs is the absence of an H-DS at the predicted interval of AP occurrence. Tetrodotoxin (TTX, 1µm bath applied) blocks the APs; H-DSs at the frequency of spiking before TTX application are never observed. Thus, H-DSs are invariably associated with APs and are absent if APs are absent.

Frequency of spontaneous APs and H-DSs are increased by de- and decreased by hyperpolarizing currents applied directly to the recorded nerve filament. These currents almost certainly modulate frequency directly by flowing in an antidromic direction thru the afferent fiber into the extracellular space. Changes in frequency are also produced by currents passed across the ampullary wall. As transmission between Type II hair cells and primary afferents is chemical, lumen positive or negative transepithelial pulses presumably act directly on presynaptic secretory membrane to increase or decrease transmitter release respectively, thus modulating discharge frequency orthodromically. In regular units changes in frequency of APs and H-DSs increase and decrease in parallel whether they are caused by direct or transsynaptically applied polarization.

In speculation upon the mechanism of rhythm generation in tonic primary afferents, Calvin's relaxation oscillator model is compatible with the experimental results. Tonically active primary afferents have fine highly branched dendrites which should be subject to ongoing transmitter release from numerous hair cells simultaneously. This electrotonically remote depolarization will be passively conducted towards the spike initiation region producing a steady depolarization at rest. When threshold is exceeded, a spike will be initiated and will spread passively back into the dendritic tree causing hyperpolarization at the spike initiation region of the primary afferent. As the hyperpolarization dies away, the membrane potential will rise again because of the steady synaptic depolarization, and another spike will occur. Polarizing currents passed directly into the nerve are presumably acting on this same spike initiation region to affect spontaneous frequency.

1947 EFFECTS OF IPSI AND CONTRA-LATERAL CALORIC STIMULATION ON THE 8th NERVE RESPONSE IN ALERT MONKEYS. A.W. Louie* and J. Kimm. Depts. of Physiology and Biophysics and Otolaryngology, Uni. of WA., Sch. Med., Seattle, WA 98195.

Activity of single nerve fibers of the vestibular nerve in alert monkeys were recorded during ipsi-lateral and contra-lateral caloric stimulation. Eye movements were recorded simultaneously with these single fiber recordings. Caloric stimulation of the ipsi-lateral canal increased the firing rate of the units when the stimulus was above core body temperature and decreased the firing rate when the stimulus was below core body temperature. Concurrent with these changes in the firing rate of the unit, nystagmic eye movement responses were recorded. As expected, with an increased firing rate of the nerve, the fast phase of nystagmus was toward the stimulated side, the converse was seen when the nerve firing rate was decreased below the resting rate. Contrary to what was expected, nystagmic eye movements were not closely coupled with the firing rate of the 8th nerve. In many cases, the nystagmus would stop and then reverse its direction before the nerve fiber returned to its pre-stimulated resting rate. To a contra-lateral caloric stimulation, the 8th nerve firing rate could also be altered from its resting rate. Irrigations of 20^{o} C of the contra-lateral ear caused a change in firing rate in 22 of the 24 fibers observed. In response to irrigation of 52^{o} C, 12 of 22 units also showed a change in their firing rate. Those fibers which were affected by the contra-lateral caloric stimulation also showed a high correlation to those units which exhibited a diminished phase lag re-acceleration with an increased frequency of oscillation.

Supported in part by NIH Grant RR-00166. Special acknowledgment to LIFE TECH INSTRUMENTS for the use of the Air Caloric Stimulator used in this study.

1948 DIFFERENTIAL RESPONSE OF THE CRISTA TO SINUSOIDAL ROTATION. Jay W. McLaren and Dean E. Hillman, Dept. Physiol. and Biophys., The University of Iowa, Iowa City, IA. (Present addresses: Dept. Physiol. and Biophys., Mayo Clinic, Rochester, MN 55901 and Dept. Physiol. and Biophys., New York University Med. Sch., New York, NY 10016)

The horizontal semicircular canal crista is approximately three times as wide at its dorsal end as at its ventral end, while the cupula's thickness conforms to this asymetric shape. Recent studies have shown that during rotation the thin region of the cupula is displaced through about 50% greater distance than thicker regions (McLaren and Hillman, Neurosci. Abst. 3: 544, 1977). One might expect afferent ampullary nerve fibers to also show response characteristics that are dependent on the position of their associated receptor cells along the length of the crista. In this study, electrophysiological characteristics of single unit afferent fibers from bullfrog horizontal ampullary nerve were examined during rotation and correlated with their site of innervation. Single fibers were dissected from the surface of the main nerve bundle with steel hook electrodes and their action potentials recorded during sinusoidal rotation (rotation amplitude: 0°-40°; frequency: .2-.8 Hz). Fibers were classified as belonging to one of three groups according to their projection into the crista. The first group innervated receptor cells on the narrow end of the crista, adjacent to the thin portion of the cupula, the second group innervated a section of the crista just to the center of the broad end, while the third group innervated the broad end. Fibers that projected to the narrow crista (group 1) showed: 1) high maximal firing rate per unit angular velocity, 2) low angular velocity thresholds, 3) peak firing rates that reached a maximum and leveled off or decreased as peak angular velocity increased from 0 to 150°/sec, and 4) mean phase lead of about 33° relative to angular velocity. In contrast, fibers that innervated the opposite end of the crista showed: 1) relatively low peak firing rates per unit angular velocity, 2) high angular velocity thresholds, 3) firing rates that increased linearly with peak angular velocity (between 0 and 150°/sec), and 4) a mean phase lag of about 17° relative to angular velocity. Characteristics measured from fibers of group 2 were generally between those of groups 1 and 3. The spatial distribution of these response characteristics along the crista is consistent with the distribution of the cupula's mechanical response as measured during similar rotation. It is concluded that separate channels of information carried by the ampullary nerve arise at least in part from the differential mechanical response of the cupula. (Supported by USPHS, grant NS-13742 from NINCDS).

1949 VISUAL "CONTEXT" DETERMINES THE OCULAR RESPONSE TO HIGH FREQUENCY (3 HZ) HEAD OSCILLATION IN SUBJECTS ADAPTED TO PROLONGED VISION REVERSAL. G. Melvill Jones, P.R.T. Davies* and A. Gonshor*. Aviation Medical Research Unit, Dept. of Physiol., McGill University, Montreal, Quebec, Canada.

Previous work has shown that prolonged optical reversal of vision produces large adaptive changes in the vestibulo-ocular reflex (VOR) as tested by low frequency sinusoidal head rotation in the dark. The present results indicate that vision much improves the adapted ocular response to head rotation, even at an oscillatory frequency which exceeds the upper limit of purely visual following. For example, when the one-year adapted cat was oscillated in the dark at 3.0 Hz and 8°/sec amp. (peak to peak), the smooth component of ocular response had a gain (eye vel./head vel.) of 0.44 and phase of +20° (relative to normal compensation). The same head oscillation with lights on and reversed vision produced markedly different values of gain and phase, namely 0.94 and +149° respectively. With head stationary, the same relative oscillatory movement of the visual field produced no measurable ocular response. In all cases, the visual field had approximately the same angular constraint as that provided by the reversing optical system.

A similar, but not identical, phenomenon has been observed in man. When an adapted human subject oscillated his head at 3.0 Hz and 3° amp. in the light, the ocular response was quite different according to whether the reversing prisms were off or on. With prisms off, the eyes moved in approximately the normal direction at about half gain (gain≈0.4; phase≈ +10°). With prisms on they moved in an approximately reversed direction (gain≈0.4; phase≈ +145°). Therefore, in the adapted subject the oculomotor response was substantially affected by vision according to whether it was normal or reversed. Yet, at this frequency (3.0 Hz), but at approximately half the amplitude of movement of the visual field relative to the stationary head, no eye movements were produced in the same adapted subject. Significantly, the unadapted subject always produced non-reversed ocular responses of gain 1.0 and phase zero, independently of whether the prisms were off or on.

It seems that in both cat and man the adaptive process includes modifications which permit the visual "context" to influence the Visual-Vestibular-Interactive-System at frequencies that are beyond the normal visual tracking capabilities, and in ways which are not available to the unadapted subject.

1950 ROTATION EFFECTS ON BEHAVIOR DEVELOPMENT AND RECOVERY OF FUNCTION FOLLOWING LESIONS OF LATERAL VESTIBULAR NUCLEUS IN RATS. D. Modianos, T. McCormack*, L. Garrett,* W. McLauchlan*, and R. Catera*. Psych. Dept., Fordham Univ., Bronx, N.Y. 10458.

The lateral vestibular nucleus (LVN) is the origin of the lateral vestibulospinal tract. This tract has been extensively studied neuroanatomically and neurophysiologically. Lesions in LVN produce severe deficits in tests of posture and movement in adult rats (Modianos and Pfaff, Brain Res.106:31, 1976). Since Thoman and Korner (Dev.Psychobiol.,5:92, 1971) have shown that vestibular stimulation affects behavior development in infant rats, the present study investigated (1) effects of rotation upon recovery of performance on several motor tasks following unilateral LVN lesions in weanling rats, and (2) development of, and effects of rotation upon, the acquisition of the same tasks used to evaluate recovery of performance following lesions. One group of rats was rotated for twenty minutes each day beginning at birth, while the second group was identically handled but not rotated. Between day 10 and weaning, each rat was evaluated for ability to balance and traverse a beam, for occurrence of the righting reflex, and for the ability to regain an upright position after being suspended upside-down from a wire grid ("climb over" task). After weaning, all rats received unilateral electrolytic lesions in LVN. One group consisted of rats rotated since birth and after lesions, one group was rotated after lesions only, and a third group was never rotated. Developmentally, rotation significantly facilitated performance on the righting reflex task, had a slight (but statistically significant) effect on the climb over task, and did notaffect ability to balance on or traverse a beam. Following unilateral LVN lesions, rotation significantly facilitated recovery of performance, but only on some tasks and only in rats which had been rotated since birth. Rats rotated since birth recovered righting reflex ability quickly following lesions. Rotation,either since birth or after lesions only, did not affect time spent on the balance beam. However, rats rotated since birth were more able to traverse the balance beam and less resorted to balancing by clinging in an inverted position than either rats rotated only after lesions or rats which were never rotated. There was no effect of rotation upon recovery of performance in the climb over task. We conclude that (1) rotational stimulation has effects on both behavior development and recovery of function following vestibular lesions,(2) knowledge of rotation effects on development does not always predict rotation effects on recovery of function and (3)facilitation by rotational stimulation of recovery of function following vestibular lesions is evident only in animals rotated since birth.

1951 STROBE LIGHT PREVENTS SHORT-TERM VOR ADAPTATION TO VISION-REVERSAL IN CAT. R. Notkin*, O. Panyszak*, G. Melvill Jones, and G. Mandl. (SPON: R. Capek).
Aviation Medical Research Unit, Department of Physiology, McGill University, Montreal, Quebec, Canada.

Exposure of the alert, initially unadapted, but vision-reversed cat to 4 hours forced oscillation in normal light produced marked (over 50%) and highly significant ($P < 0.001$) attenuation of the vestibulo-ocular reflex (VOR) as tested by sinusoidal rotation in the dark at 1/4 Hz and 20°/sec amp (peak to peak).

Identical forcing stimuli performed on the unadapted animal with vision reversal, but in strobe light of 3 μsec flash duration at 4 Hz flash frequency, produced an insignificant ($P > 0.2$) adaptive change in the dark-tested VOR. Thus, prevention of continuous image slip on the retina by means of strobe light was associated with prevention of short-term VOR adaptation to vision reversal. This finding suggests that, unlike in man (Melvill Jones & Mandl, 1977, Neurosci. Abst. Vol. III, No. 1726), retinal image slip is necessary for activation of the short-term adaptive process in cat.

Interestingly, in contrast to humans (Mandl & Melvill Jones, 1977, Neurosci. Abst. Vol. III, No. 1812), the unadapted vision-reversed cat showed no evidence of reverse tracking episodes during head oscillation in strobe light. Thus, an alternative explanation for the absence of adaptation in cats exposed to strobe light may be the absence of reversed, i.e. VOR opposing, eye movements during adaptation.

1952 NONLINEAR AFFERENT RESPONSE PROPERTIES FROM THE ISOLATED GUITARFISH SEMICIRCULAR CANAL. Dennis P. O'Leary and Conrad Wall, III. Dept. Otolaryngology, Div. of Vestibular Disorders, Univ. of Pittsburgh, Sch. of Med., Pittsburgh, PA 15213.

Investigations of receptor mechanisms of the semicircular canal have been aided in previous studies by the use of linear system analysis of afferent responses to controlled rotational acceleration. These studies have resulted in models in the form of differential equations or linear transfer functions. However, it is possible that receptor transduction and subsequent spike train modulation are influenced by intrinsic nonlinearities, such as those resulting from viscoelasticity and spike generating mechanisms, that are reflected in the observed afferent response dynamics.

We tested for the presence of certain nonlinear afferent response components by applying a high frequency rotational acceleration signal in combination with a low frequency modulation stimulus. Such dual inputs have been used successfully for identifying certain nonlinearities in engineering control systems (e.g. Atherton, D.P., Nonlinear Control Engineering, Van Nostrand, New York, 1975). Low-amplitude rotational acceleration of frequencies $\geq$ 30 Hz were combined with either (1) single frequency sinusoidal oscillations of frequencies $\leq$ 1 Hz, or (2) pseudorandom binary sequence rotational acceleration spanning bandwidths from 0.04 to 4.0 Hz. Responses to the dual inputs were compared with those resulting from only the lower frequency inputs, in the same horizontal canal afferents. Time domain cross-correlation and frequency domain complex spectral analyses techniques were used to obtain system descriptors.

Results showed that the afferent response dynamics were modifiable reversibly and systematically by application of dual inputs, indicating significant nonlinear effects. Specific effects noted included: (1) reduction of the dominant time constant of afferent responses, (2) enhancement of response "adaptation", (3) systematic changes in low-frequency gain and phase, and (4) changed patterns of background (unmodulated) activity toward lower coefficients of variation. These results form the basis for an extended model of semicircular canal transduction, which, in addition to linear mechanics, includes specific types of nonlinear mechanisms.

1953 RESPONSES OF SECOND-ORDER VESTIBULAR NEURONS DURING LINEAR ACCELERATION ALONG HORIZONTAL AXES IN RAT AND SQUIRREL MONKEY. A. A. Perachio, W. Bouris, S. Anschel, and D. H. Rice. Yerkes Reg. Primate Res. Ctr., Emory Univ., Atlanta, GA 30322.

The response of neurons, in and around the vestibular nuclei of anesthetized rats, to sinusoidal linear acceleration along a vertical (Z) axis is sinusoidally modulated (Perachio, A. A., et. al., Soc. for Neurosci., Abst. 1733, 1977). A nearly linear gain relationship between that response and the input acceleration over a limited (0.2-0.5 Hz) frequency range is indicated by a decrease in gain as acceleration increases. A similar finding has been reported for forelimb muscle (EMG) activity in decerebrate cats accelerated along the fore-and-aft (X), side-to-side (Y) and vertical axes (Anderson, J. H., et. al., Brain Res., 120 (1977), 1-15).

The activity of neurons in the region of the vestibular nuclei was recorded, in both anesthetized rats and alert squirrel monkeys, while the animals were subjected to sinusoidal translational motion along their longitudinal or transverse axes. Head orientation was fixed, pitched nose down 22° from the stereotaxic horizontal plane. Neurons responded either to one direction of movement alone or exhibited some degree of sensitivity to acceleration along either axis. Most neurons, responsive to acceleration along both horizontal axes, were sensitive either to forward and ipsilateral (x^+, y^+) or backward, contralateral (x^-, y^-) motion, indicating a resultant direction of maximum sensitivity.

A relatively small number of neurons was encountered whose activity modulated with oscillating visual stimuli. In general, linear acceleration sensitive neurons did not appear to respond during spontaneous eye movements. In cases where sensitivity was tested, gain appeared to decrease with increasing stimulus frequency (acceleration) resembling previous findings for Z-axis-sensitive neurons.

1954 TRANSFER FUNCTIONS OF CAT SEMICIRCULAR CANAL EIGHTH NERVE AFFERENTS. Robert J. Peterka*, Dennis P. O'Leary and David L. Tomko. (SPON: R.F. Dunn). Depts. Otolaryngology & Pharmacology, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA 15213.

Responses to yaw rotation of 94 primary afferent neurons innervating the horizontal semicircular canal were recorded with micropipettes in barbiturate anesthetized cats. Pseudorandom binary sequences (PRBSs) of rotational acceleration (bandwidth 0.0078 to 3.70 Hz) were delivered to a rate-of-turn table under computer control. The transfer function observed at each first order afferent (i.e., gain and phase) was determined using a cross spectral analysis between the input PRBS and the output neural response. Since implementation of the cross spectral analysis required that an estimate of the firing rate of the neuron be specified in equally spaced time intervals, a digital filter, the French-Holden algorithm (French & Holden, Kybernetik, 1971, 8, 165-171) was used. In addition to the transfer function estimates, cross spectral analysis provided a determination of the coherence function, a measure of the linear correlation between the stimulus and the response. Typically, the coherence function at frequencies less than 0.1 Hz had values near unity, indicating a linear response to the PRBS stimulus. At higher frequencies, coherence was generally less than 0.5 indicating either the presence of noise or a nonlinear response to the stimulus.

Results indicated that gain and phase varied widely for different cells at the same test frequencies. Because others have noted a correlation of response dynamics with the degree of regularity of discharge of a cell, we have divided the population into two groups based on the coefficient of variation (CV) of the unit at rest. Cells with resting CVs greater than 10% in general showed an average of two to four times higher gain across the bandwidth tested and 10 to 20 degrees less phase lag (re acceleration) than cells with CVs less than 10%. The differences in gain and phase between the two subpopulations were more pronounced at frequencies above 0.5 Hz. Gains and phases computed from application of sinusoids were in agreement with those obtained from the PRBS stimulus application in the same cells.

Analytic transfer functions of various forms were fit to the averaged gain and phase data for the two populations to provide a quantitative data summary. Neurons with CVs less than 10% were best fit by a two pole, one zero transfer function similar in form to that obtained for this type of unit in the squirrel monkey by Goldberg and Fernandez (J. Neurophysiol., 1971, 34, 681). Irregularly discharging *neurons (CV greater than 10%) on the other hand, were best fit by a transfer function with a fractional exponent term.*

1955 ACTIVATION OF VESTIBULAR AND RETICULAR NEURONS DURING VESTIBULAR REFLEXES INDUCED BY SINUSOIDAL POLARIZATION OF SEMICIRCULAR CANAL AFFERENTS. B.W. Peterson, K. Fukushima, N. Hirai*, R.H. Schor, V.J. Wilson. Rockefeller Univ., New York, N.Y. 10021.

When labyrinthine afferents are activated by sinusoidal horizontal rotation in decerebrate cats, vestibular reflex activation of neck[1] and limb[2] muscles lags 40-80° behind the discharge of second order (2°) vestibular neurons. Thus 2° neuron activity is not sufficient to produce the reflex activation. To investigate the role of vestibulospinal and reticulospinal neurons in vestibular reflexes we have developed a technique for inducing these reflexes by sinusoidal electrical polarization of single semicircular canal nerves. In decerebrate, partially cerebellectomized cats fine wires were implanted at locations near horizontal or anterior canal ampullae where stimuli evoked pure horizontal or vertical eye movements. Modulated, continuous currents were applied monopolarly to polarize canal nerve terminals. The modulating waveform was either a single sinusoid at 0.01-5 Hz or nine superimposed sinusoids covering the range 0.018-6.1 Hz. (To minimize interactions between them, the nine frequencies were all relatively prime, odd multiples of the same fundamental frequency). Action potentials of vestibular or reticular neurons were recorded with micropipettes, discriminated and processed by computer to obtain cycle histograms at each of the applied frequencies. Fourier analysis was used to determine the gain and phase of the neural response at each frequency plus the amount of harmonic distortion and noise.

Responses were typically sinusoidal, except where discharge was cut off at threshold, and response amplitude was related to stimulus amplitude indicating that the responses were linear. Responses of 2° neurons were all similar regardless of whether the neuron projected to the spinal cord. Peak discharge was approximately in phase with peak stimulus negativity at frequencies below 0.2 Hz. Above 0.2 Hz the gain increased and a phase lead developed which reached 40-50° at 6 Hz. This behavior probably reflects accomodation in the nerve terminals which makes them sensitive to rate of change of stimulus current. Higher order vestibulospinal and reticulospinal neurons were also modulated by sinusoidal polarization. Some behaved like 2° neurons but for others the response lagged 30-80° behind the 2° response and the gain fell over the frequency range 0.18-1.5 Hz. Responses of these neurons thus resemble those of neck muscles described by Wilson et al.[3] Supported by N.I.H. NS 02619 and EY 02249.

1956 THE INFLUENCE OF BILATERAL PLUGGING OF THE ANTERIOR OR LATERAL SEMICIRCULAR CANALS ON VERTICAL AND HORIZONTAL VESTIBULOOCULAR REFLEXES IN THE RABBIT. V. E. Pettorossi* and M. H. Barmack, (SPON: R. S. Dow) Neurological Sciences Inst., Good Samaritan Hosp. & Med. Cntr., Portland, OR.

In contrast to the horizontal vestibuloocular reflex (HVOR), the vertical vestibuloocular reflex (VVOR) of the rabbit has a higher gain (eye velocity/head velocity) and a smaller phase lead (eye position +180° re: head position), at low frequencies of sinusoidal angular accelerations (± 10 deg, .005-.05 Hz). That the low frequency gain of the VVOR can be attributed to a utricular input can be demonstrated by turning the rabbit 90 deg, "nose-up" so that its longitudinal axis is parallel with rather than orthogonal to the linear acceleration of gravity. Under this condition the gravity vector is orthogonal to the plane of polarization of hair cells of the utricular maculae, and the gain and phase of the VVOR are similar to the phase and gain of the HVOR. It is possible to derive a contribution of the utricle to the VVOR by subtracting the VVOR obtained when the rabbit is "nose-up" from the VVOR obtained when the rabbit is prone; assuming a linear combination of the canal and otolith signals. In the present report we examine this assumption by plugging the anterior canals bilaterally and thereby obtaining a direct measurement of the residual contribution of the utricle to the VVOR. The anterior semicircular canals were plugged with bone wax or with wires which compressed a portion of the membranous canal. This bilateral plugging caused a decreased VVOR gain and an increased phase lag at higher stimulus frequencies (.05-.8 Hz). The magnitudes of the reduced gain and increased phase lag, were dependent on the proximity of the canal plugs to the ampullae. When the anterior canal plug was greater than 500 μ from the ampulla, there was residual anterior canal function. The gain and phase of the VVOR following bilateral anterior canal plugging are consistent with the prediction which assumed a linear combination of utricular and anterior canal inputs. Plugging the anterior canals also reduced the gain and increased the phase lead of the HVOR. Conversely plugging the horizontal canals, although eliminating the HVOR, did not cause as big a reduction in the VVOR. We conclude that the blockage of the free flow of endolymph in one of the canals, impedes the flow of endolymph in all canals. The extent of this impedance is different for the lateral and anterior canals. It might be attributed to the different spatial relationships of these canals to the membranous duct which joins their ampullae to the utricle, thereby comoleting their endolymph "circuits". 1957 ABSENCE OF STRUCTURAL CHANGES IN GRAVISTATIC RECEPTORS DURING VESTIBULAR COMPENSATION. Christopher Platt & Earl Y. Jew*. Dept. Biological Sci., Univ. Southern California, Los Angeles, CA 90007.

Plasticity of vestibular function is shown by vestibular compensation, in which recovery of symmetrical upright posture is restored some time after a unilateral vestibular lesion. Partly because of the relatively short time course of compensation, it has been considered a central phenomenon. However, whether peripheral changes might be necessary along with the central changes has not been tested directly.

Fishes were used for this study because their known capability for both growth and reorganization of adult afferent sensory systems suggests they might have greater structural plasticity in their peripheral vestibular systems than most other vertebrates. Conversely, if such plasticity is not present in fishes, it seems far less likely to be a mechanism used by higher vertebrates.

The gravistatic organ, the utricle, was removed from one side of an anesthetized goldfish's head to provide the control specimen. After plugging the wound with saline agar, each fish was allowed to recover. Motor behavior, including body tilt, swimming attitude and eye-roll, was monitored to evaluate the degree of compensation after the initial grossly asymmetrical disorientation. Animals were sacrificed at intervals from 1 to 14 days after the operation, and the remaining utricle prepared for scanning electron microscopy (SEM), as were the controls.

Compensation was largely complete within 5 days. SEM observations on the control and "compensated" utricular sensory maculae showed no changes in a) morphological orientation of hair cell ciliary bundles, which indicate directional sensitivity; b) distribution of the different forms of hair cell ciliary bundles; nor c) relative proportions of macular area covered by outward versus inward-facing hair cells, which are not 1:1 but asymmetrical in the normal utricle.

We conclude that structural changes in the asymmetrically organized gravistatic receptors of one side are not necessary for restoration of symmetrical postural motor output after a contralateral vestibular lesion. Instead, the central processes involved in vestibular compensation must be both sufficient and necessary.

1958 MAUTHNER CELL OF THE BULLFROG TADPOLE MEDIATES RAPID ACTIVATION OF CONTRALATERAL TAIL MUSCULATURE. Michael K. Rock. Department of Physiology and Biophysics, Washington University School of Medicine, St. Louis, MO 63110.

The Mauthner cell of the bullfrog tadpole (Rana catesbeiana) is a large nerve cell located in the medulla at the level of the VIII nerve as in other species. Stimulation of the anterior branch of the ipsilateral VIII nerve produced short latency EPSP's and firing of the M-cell. An action potential in the M-cell was followed by extracellularly recorded activity in contralateral tail muscle with a latency of about 10 msec (Fig. A). A similar tail response was elicited after direct intracellular stimulation of the M-cell. Variability in the latency and amplitude of the tail response was observed with VIII nerve and intracellular stimulation. Repetitive intracellular stimulation at a frequency of 1 Hz evoked a tail response to the initial M-cell spike with no response to subsequent M-cell activity (Fig. B). The characteristic response in the contralateral tail to VIII nerve stimulation could not be elicited after the M-cell was damaged and inactivated. Stimulation of the contralateral VIII nerve produced depolarizing PSP's in the M-cell soma. However, the tail response elicited by VIII nerve stimulation was eliminated by prior stimulation of the opposite VIII nerve. These results indicate that the tadpole Mauthner cell mediates a rapid activation of contralateral tail musculature in response to ipsilateral VIII nerve stimulation as in teleost fish. 1959 VESTIBULAR EFFERENT NEURONS OF PIGEONS INNERVATE SEVERAL CRISTAE AMPULLARES WITH AXON COLLATERALS. Dietrich W.F. Schwarz, Irmgard E. Schwarz* and R.David Tomlinson*. Lab. Otoneurol., Depts. Otolaryngology and Physiology, University of Toronto, Toronto, Canada.

Retrograde axonal transport of either ^{3}H-adenosine or horse radish peroxidase (HRP) injected into cristae ampullares of semicircular canals in pigeons, identified perikarya of efferent vestibular neurons. These are located bilaterally within less than 1/2 mm^3 in the nucleus reticularis pontis caudalis just ventro-latero-caudally to the abducens nucleus. Neurons projecting to each of the six canal cristae appaered to be not topographically seperated and neurons projecting to either the utricular or lagenar macula were found at the same location, whereas cochlear efferent neurons are located within and medio-ventral to the superior olivary nucleus. Numbers of cells found labelled after injection of individual cristae were remarkably constant, although cell counts after anterior canal crista injections were lower than for lateral and posterior canals (range 95 to 150 cells per crista). Injections into all three canal cristae of one side yielded similar cell counts, whereas the numbers of cells labelled by injections into all six cristae were increased by ca. 50%. Injections into the lateral canal perilymph yielded no labelled cells which suggests that no effective diffusion of marker from one crista to an other one has occured. Thus our data suggest that efferent cells send collateralizing axons to more than one crista. This conclusion is corroborated by the fact that a few neurons could be shown to be labelled with both, ^{3}H-adenosine and HRP when one crista was injected with the first and an other one with the second marker. It can be concluded that activity of efferent neurons is unlikely to provide a control on afferent vestibular input which is specific for head movement parameters.

1960 LOSS OF BOTH THE QUICK COMPONENT OF HEAD NYSTAGMUS AND THE ABILITY TO RIGHT IN THE AIR FOLLOWING PONTINE LESIONS IN THE RAT. David W. Sirkin, Timothy Schallert*, and Philip Teitelbaum. Program in Neural and Behavioral Biol., and Dept. Psychol., Univ. of Illinois at Urbana-Champaign, Champaign, IL 61820.

Vestibular compensation for passive angular motion is very marked in lower vertebrates. A fish swimming in a rotating bowl circles in the opposite direction to that in which the bowl is turned. A frog sitting on a turntable turns its head to the left if the turntable is rotated clockwise. These responses tend to stabilize the orientation of the animal's head in space. A vestibular response can also be elicited by spinning an animal many times quickly, and then stopping the motion abruptly. In this case, the animal turns in the same direction as the original motion. These vestibular responses to angular motion, shown by the eyes as well as the head and body, are modified in mammals by quick movements of the eyes and head in the direction opposite to that of the vestibular compensatory response. These "anticompensatory" movements are normally triggered before the vestibular response has progressed very far. During a rotation, and following an abrupt stop of a series of rapid rotations, compensatory and anticompensatory movements typically alternate in a rhythm, or nystagmus. The compensatory movement is called the slow component, and the anticompensatory movement, the fast component.

It has long been known that paramedian pontine reticular formation (PPRF) lesions abolish the quick component of ocular nystagmus in monkeys and cats. We report here that lesions of a homologous region in the rat brain abolish the quick component of head nystagmus. (Preliminary observations indicate that the quick component of ocular nystagmus is also lost.) Our observations indicate that when anticompensatory mechanisms are abolished the vestibular compensatory responses of the head and body in the rat are at least as strong as in lower vertebrates. A rat with a right PPRF lesion, if grasped by an investigator and turned clockwise, turns its head to the left until its nose touches its left thigh. When stopped abruptly after rapid counter-clockwise spinning, the rat shows a steady turn of the head to the left, followed by tight counter-clockwise circling. Rats with bilateral lesions show these responses bilaterally. Strong responses are shown long after the lesions are made--at least 9 months in bilaterally lesioned rats--and are not affected by the application of visual occluders.

A second result of bilateral PPRF lesions in the rat is the complete loss of the ability of the animal to right when released in the air with dorsal surface down. Unilateral lesions result in a partial impairment of this reflex. It is interesting that a single lesion releases one vestibular reflex while abolishing another. 1962 DYNAMIC EVALUATION OF HUMAN VESTIBULO-OCULAR FUNCTION USING WHITE NOISE ROTATION STIMULUS AND LINEAR SYSTEM PARAMETER ESTIMATION TECHNIQUES. Conrad Wall III, F. Owen Black and Dennis P. O'Leary. Dept. of Otolaryngology, Div. of Vestibular Disorders, Univ. of Pittsburgh, Sch. of Med., Pittsburgh, PA 15213.

White noise rotational stimulation has previously been used to describe the response of first order vestibular afferents in animals and the vestibulo-ocular reflex (VOR) in normal humans (Wall, et al, 1978). The results from a cross spectral calculation give frequency domain dynamic response estimates of gain and phase which can serve as one form of inter test comparison.

A more compact form of system descriptor or model is provided by fitting linear system parameters (Eykhoff, 1975) to these experimentally determined gain and phase points. This method yields a small set of coefficients that can be directly related to mathematical models of the semicircular canal or of the VOR (Peterka, et al, 1978). We are applying these two techniques for identification of human vestibular abnormalities.

In the first approach, the data from a small group of patients having known vestibular disorders are compared to normal data. These comparisons provide the basis for initial decision criteria which are used to separate any new data into categories without other information concerning the patient. This prediction is then compared with an independent medical assessment which includes a vestibular test series and post-operative surgical information.

The second approach attempts to classify the fitted parameters of steady state gain and linear system time constants of patients having known disorders into groups which are outside the limits for normal human subjects. The results of these two approaches will be presented and discussed.

1961 EFFECT OF HEAD TILT ON RECEPTIVE FIELD ORIENTATION OF SIMPLE CELLS IN AREA 17 OF UNANESTHETIZED CATS. David L. Tomko, N. M. Barbaro* & F. N. Ali*. Dept. Pharmacology, Sch. Med., Univ. of Pittsburgh, Pittsburgh, PA 15261

Electrophysiological evidence for convergence of visual and vestibular information in visual cortical cells has existed since 1960 (Grüsser & Grüsser-Cornehls, Pfluger's Arch., 1960, 270, 227-238). Results in the past few years regarding the quantitative nature of such convergence have been to some extent contradictory, with some authors finding that the use of natural vestibular stimuli results in significant alterations in receptive field (RF) orientation of area 17 cells (c.f., Denny & Adorjani Exp. Brain Res., 1972, 14, 312-317), and others finding no effect (Schwartzkroin, Exp. Neurol., 1972, 36, 498-506).

The response properties of 28 single units with simple RF properties and histologically verified to lie in cytoarchitectural area 17 were determined in paralyzed, unanesthetized cats. RF properties were first mapped using a hand held ophthalmoscope to define the RF type, its boundaries, and center. Subsequently, they were determined quantitatively by presenting in random order for 0.6 seconds each, 18 different stationary slit orientations. The random order was repeated five times, and the stimulus was presented monocularly while recording the time of occurrence of action potentials. Then the animal was tilted 45^{0} around the naso-occipital axis and the procedure repeated. When possible (11 cells) the RF properties were redetermined when the animal was returned to the horizontal position. Ten of these 11 replications reproduced the original RF properties within 10^{0}. Data were averaged off-line for the five presentations of the 18 different orientations, the orientation giving the maximal response was determined, and three tuning curves were constructed with responses expressed as per cent of maximum. The tuning curves defined the orientation of the RF first with the animal horizontal, second with the animal tilted 45^{0}, and third after the return to the horizontal position. Comparison of the first two tuning curves enabled comparison of the actual amount of RF tilt with the expected amount of RF tilt due to head tilt (i.e., 45^{0}).

The RF orientation of 10 of the 23 cells (43.5%) after head tilt was within 5^{0} of the expected tilt of the RF due to the head tilt. Of the remaining 13 cells (56.5%), 7 RFs tilted from 15 to 35 degrees more than the expected 45^{0} tilt, and 6 RFs tilted from 15 to 45 degrees less than the expected 45^{0} tilt. These results are interpreted as an indication that the vestibular system exerts a tonic influence over the response properties of at least some of the neurons of the primary visual cortex. (Supported by NIH grant NS12308, and the University of Pittsburgh Medical Alumni Association).

1963 MEMBRANE VOLTAGE NOISE AND CILIARY MOTILITY IN THE APLYSIA STATOCYST. Michael L. Wiederhold. Neurobiology Dept. Armed Forces Radiobiology Research Institute, Bethesda, MD 20014.

The Aplysia statocyst is a spherical balance organ. The wall of the cyst consists mainly of 13 receptor cells with motile cilia projecting into the fluid filled cyst lumen. Dense statoconia settle to fill the bottom third of the cyst lumen, but are kept in continual random motion by the beating cilia. A receptor cell is excited when the preparation is tilted sufficiently to bring its cilia into contact with the statoconia. The excitation consists of a depolarization and an increase in membrane voltage noise.

An analysis of the membrane noise caused by excitation is presented, which indicates that the noise is a superposition of many discrete depolarizing events whose average amplitude is between 1.5 and 2.3 mV. These are interpreted as arising from collisions between the moving statoconia and the beating cilia. With a receptor cell positioned so that only occasional collisions between the statoconia and cilia would occur, isolated discrete events of the size predicted by the analysis are seen. The conductance change associated with these events is about 10 times larger than estimates of single ionic channel conductance from other studies.

When a preparation is treated with seawater containing 10 mM $NiCl_2$ (which has been used in other studies to paralyze the cilia of paramecium), the motility of these cilia is reduced or blocked, and both the depolarizing and noise-increase responses to tilting are either greatly reduced or abolished. Another agent which blocks ciliary motility is a factor in the serum of cystic fibrosis patients. When such serum was mixed with seawater, results similar to those with $NiCl_2$ treatment were obtained. The mechanisms by which the ciliary motility might contribute to the sensory function of these cells are discussed.

1964 ANALYSIS OF CENTRAL VESTIBULOCOLLIC PATHWAYS BY MEANS OF MODULATED POLARIZATION OF VESTIBULAR AFFERENTS. V.J. Wilson, K. Fukushima, N. Hirai*, B.W. Peterson and Y. Uchino*. Rockefeller University, New York, N.Y. 10021.

Sinusoidal stimulation of single ampullary nerves with modulated continuous current[1] has been used to evoke activity of contralateral dorsal neck muscles in decerebrate cats. The stimulus typically consisted of nine superimposed sine waves covering the range 0.018-6.1 Hz. Rectified EMG activity usually exhibited a considerable phase lag re input negativity at 0.18-0.37 Hz, with a phase advance at higher frequencies that sometimes resulted in a lead at 3-6 Hz. At frequencies below 0.18 Hz there was great variation and often little or no lag. Gain usually decreased with increasing frequency. Central phase lag was measured by recording simultaneously from second-order neurons and muscle, or by taking the mean difference between the two in many experiments. The magnitude of the lag, which may approach 60-70° at 0.18 Hz, shows that this method of stimulation activates complex neural circuitry, presumably the same circuitry activated by natural stimulation. The phase lag at lower frequencies is clearly not produced by second-order neurons, which in these preparations respond to the same stimulus with a phase lead, but it may be produced by vestibular and reticular neurons that project to the spinal cord but do not receive short-latency canal input[1].

The MVST, which contains the crossed disynaptic excitatory canal pathways, plays no essential role in producing the muscle response at low frequencies, but such a direct pathway may be a more important contributor to the phase advanced response at higher frequencies[2]. We have tested this hypothesis by evoking vestibular reflexes, with superimposed sine wave and square wave stimulation before and after transection of the MLF just rostral to the obex. This lesion, which interrupted the MVST, had minor, inconsistent effects. Therefore, pathways other than the disynaptic one are sufficient to produce all components of the response of the muscle, at least when the reflex is studied in the decerebrate cat with the head immobilized. Supported by N.I.H. and NSF grants NS 02619 and BMS 75-00487.

VISION

1965 EFFECT OF ACETYLCHOLINE DRUGS ON RECEPTIVE FIELD PROPERTIES OF RABBIT RETINAL GANGLION CELLS. Michael Ariel* and Nigel W. Daw, Dept. Physiol., Washington Univ. Sch. Med., St Louis, MO 63110.

We investigated the effects of the cholinergic nicotinic antagonist mecamylamine, and the acetylcholinesterase inhibitor physostigmine, on the activity of ganglion cells in the rabbit retina. The drugs were infused into the internal maxillary artery in the intact animal. Most types of ganglion cell were not much affected by mecamylamine, indicating that acetylcholine synapses represent a small fraction of their input. An exception was on center X cells, in agreement with the results of Masland and Ames (J. Neurophys., 39, 1220 (1976). We showed that both color coded X cells and on center X cells that are not color coded had their activity reduced by mecamylamine: this was true of both spontaneous activity and the response to light in either the center or the surround of the receptive field. Directionally sensitive cells also had their activity reduced by mecamylamine, but the response to a spot moved in the preferred direction was rarely reduced by more than 50%. Physostigmine, on the other hand, had a dramatic effect on directionally sensitive cells: the cells responded to movement in both preferred and null directions. The effect of physostigmine was indistinguishable from the effect of picrotoxin, and consistently occurred at one-fifth the concentration. Physostigmine and picrotoxin potentiated each other's effects. Mecamylamine reduced the effects of both physostigmine and picrotoxin on DS cells.

1966 MEMBRANE PROPERTIES OF SOLITARY ROD PHOTORECEPTORS. Charles R. Bader*, Peter R. MacLeish* and Eric A. Schwartz* (SPON: Ann E. Stuart). Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115 and Dept. of Pharmacological and Physiological Sciences, University of Chicago, Chicago, IL 60647.

Single, isolated (solitary) rod photoreceptors were obtained by enzymatic dissociation of the tiger salamander (Ambystoma tigrinum) retina. These solitary rods retained the morphological features of rods of the intact retina and could be maintained in vitro for several days. Solitary rods could be penetrated by one or two micropipettes under observation using infra-red illumination and an infra-red to visible light image converter. The dark-adapted solitary rods were isopotential, had a resting potential of approximately -45 mV and a steady-state slope resistance of 500 MΩ measured at the resting potential. Solitary rods responded to light with hyperpolarizations graded with light intensity; the change in potential produced by light often exceeded 25 mV. The time-course of the responses from solitary rods was similar to that from rods in the intact retina stimulated with large diameter spots of light. The current-voltage relationship, obtained by injecting extrinsic current through an impalling pipette, showed both inward- and outward-going rectification. The amplitude of the light response could be altered by changing the membrane potential of solitary rods. Depolarization, produced by injecting current, reduced the amplitude of the response; polarization beyond 0 mV reversed the polarity of the response. The same reversal potential was observed in both inner and outer segments.

The kinetics of the light-induced current and the voltage dependence of the light insensitive currents are being studied by the voltage-clamp technique.

1967 VISUAL DEFECTS IN THE MUTANT MOUSE PEARL. G. W. Balkema, Jr., U. C. Dräger, L. H. Pinto and J. W. Vanable, Jr.*. Dept. of Biol. Sci., Purdue Univ., West Lafayette, IN 47907 and Dept. of Neurobiol., Harvard Med. Sch., Boston, MA 02115.

When exposed to moving visual patterns normal mice display optokinetic nystagmus (OKN). By testing OKN we screened 52 mouse mutant stocks for visual defects. In pearl mice, a recessive coat color mutant, it was not possible to elicit an OKN either under low or high illumination test conditions. However, pearl's postrotatory nystagmus was normal. Furthermore, at the light microscope level we have not detected any morphological abnormalities, either in the retinas or the brains of pearl mice. The electroretinographic light response of pearl was similar to that of +/+; there were no detectable differences in either the waveforms or the illuminations for half-maximal amplitudes of a- and b-waves. Thus, pearl mice do not show morphological or electroretinographic signs of retinal degeneration.

We recorded the responses of cells in the primary visual cortex of pearl and +/+ mice to light stimuli projected onto the receptive fields; background illumination was in the upper scotopic/low photopic range. For equivalent responses the stimulus had to be 1-2 log units brighter for pearl cells than for cells of +/+ mice.

In recording from single cells in the superficial layers of the superior colliculus we determined intensity-response curves and plotted incremental threshold. At dim background levels (-5 to -3 log cd/m^2) the thresholds for pearl were on the average 2 log units higher than for +/+. For increasingly brighter backgrounds the mean thresholds for pearl approached the mean thresholds for +/+ (0.25 log units difference at 2.5 log cd/m^2). This threshold elevation in the dark for pearl does not seem to be caused by a prolonged time course of dark adaptation, since the rates of dark adaptation were similar in pearl and +/+: the mean time for 50% threshold recovery following 3 min light exposure at 3.8 log cd/m^2 was 16 min for pearl and 21 min for +/+.

Thus, we have found that pearl mutants show a decreased light sensitivity when measured in the primary visual cortex and the superior colliculus, but so far we are unable to explain how this defect is related to pearl's lack of OKN.

1968 ELECTRON MICROSCOPIC INVESTIGATION OF THE CAT SUPERIOR COLLICULUS. M. Behan*, J.T. Weber, M.F. Huerta and J.K. Harting. Department of Anatomy, University of Wisconsin, Madison, Wisc. 53706. (SPON: G.J. Royce).

Our findings to date relate primarily to the normal ultrastructural features of the stratum zonale (SZ) and the stratum griseum superficiale (SGS). Throughout the synapses examined, terminals with round or pleomorphic vesicles are clearly distinguished. There appears to be no correlation between pale or dark mitochondria and vesicle shape. In general, round and pleomorphic vesicles are associated with asymmetric and symmetric thickenings respectively. While most of the synapses within the SZ and the SGS are axodendritic, a few dendrodendritic contacts were most apparent in serial synapses.

The stratum zonale (20-25μm thick) contains numerous astrocytes arranged parallel to the pial surface. Astrocytic processes extend into the upper portion of the SGS. Many small myelinated axons (.4-4μm in diameter), are found in the SZ. The ratio of terminals containing round vesicles to those with pleomorphic vesicles is approximately 1:1.

Transition from the SZ to the SGS is well defined. The SGS can be subdivided into three layers. In the SGS1 (70-100μm thick) the number of myelinated profiles is greatly reduced. There is also an increase in the number of synapses in the dense neuropil. The ratio of round to pleomorphic vesicles in terminals is closer to 2:1. Frequently terminals end on dendritic spines.

The transition from the SGS1 to the SGS2, clearly seen in 1μm toluidine blue stained sections, is less apparent in the electron microscope. In contrast to the SGS1, the SGS2 (150-200μm thick) shows an increase in the number and size of myelinated axons, has larger dendritic profiles and fewer glial elements. The number of synapses in any measured area is approximately the same as the SGS1.

The SGS3 (150-200μm thick) is distinguished from the SGS2 by having larger cells (up to 30μm diameter) with very large dendritic profiles and a further increase in the number of myelinated axons. The ratio of terminals with round or pleomorphic vesicles is still approximately 1:1. The SGS3 merges gradually and almost indistinguishably into the stratum opticum.

1969 THALAMO-CORTICAL PROJECTIONS AND HISTOCHEMICAL IDENTIFICATION OF SUBDIVISIONS OF THE LP-PULVINAR COMPLEX IN THE CAT. David M. Berson* and Ann M. Graybiel, Dept. of Psychology, Mass. Institute of Psychology, Cambridge, MA 02139. (SPON: R.L.M. Faull).

The LP-pulvinar complex of the cat's thalamus contains a distinct medial zone receiving input from the superficial layers of the superior colliculus (LPm), a second zone receiving input from the striate cortex (LPℓ) and a third, lateral zone in the pulvinar (Pul) receiving input from the pretectal region. In an effort to identify these three zones in normal material, we studied the distribution of acetylcholinesterase in the caudal thalamus and found the LPm sharply defined by high AchE activity, the pretectorecipient Pul also rich in AchE, and LPℓ a pale AchE-poor band between the two.

Since it has been suggested that these vision-related subdivisions of the LP-pulvinar complex may also be dissociable on the basis of their patterns of thalamo-cortical projection (Brain Res.44, '72 & 147,'78), the ascending projections of LPm, LPℓ and Pul were studied autoradiographically. The distribution of cortical labelling in these autoradiographic experiments varied systematically with the location of the center of the thalamic injection site. Injections centered in the pretectorecipient zone (Pul) elicited heavy labelling in the cortex of the middle suprasylvian crown and in the fundus of the splenial sulcus, and variably labelled parts of area 19. Deposits centered in the striate corticorecipient zone (LPℓ) heavily labelled area 19, the medial bank of the middle suprasylvian sulcus and the caudo-medial bank of the posterior suprasylvian sulcus and produced sparse labelling of areas 17 and 18. Injections centered in the tectorecipient zone (LPm) labelled the ventral bank of the anterior ectosylvian sulcus; the fundus and, caudally, the lateral bank of the middle suprasylvian sulcus; and those parts of the posterior suprasylvian sulcus not labelled by LPℓ injections.

The finding that particular regions of the posterior neocortex receive projections from certain of the subdivisions of the caudal thalamus but not from others was confirmed in many cases by the fact that injections of HRP into circumscribed cortical areas produced one, or in some cases two bands of retrograde thalamic cell-labelling which respected the boundaries of LPm, LPℓ and Pul. While some degree of overlap in the thalamo-cortical projections of these thalamic zones thus seems likely, LPm, LPℓ and Pul nevertheless appear to be associated with distinct sets of cortical areas. Inasmuch as the inputs to these thalamic zones from cortical or subcortical elements of the visual mechanism are clearly distinct, it is concluded that the subdivisions of the LP-pulvinar complex may serve to forward different types of visual information to distinct targets within the posterior association cortex.

1970 CHANGING-DISPARITY AND CHANGING-SIZE INPUTS FEED THE SAME MOTION-IN-DEPTH STAGE. Kenneth I. Beverley and David Regan*. Psychology Dept., Dalhousie Univ., Halifax, N.S. B3H 4J1.

We have previously reported psychophysical evidence for the existence of neural filters specifically sensitive to changing object size (Regan & Beverley, Vision Res., 1978a,b, in press). We now report that these changing-size filters feed the same motion-in-depth stage that is fed by changing-disparity inputs.

Subjects viewed a bright adapting square, or mean side length 1°, with both eyes. All four sides (of the square) moved towards each other at a constant velocity of 0.3°/sec for 1.0 sec, then the square disappeared for 0.25 sec and the cycle repeated. After 20 min adaptation subjects reported the illusion that a static test square of 1° side appeared to move towards the head, whether the test square was viewed monocularly or binocularly, or was of positive or negative contrast. Our aftereffect data suggests that this motion-in-depth aftereffect can be attributed to unbalanced activity at a motion-in-depth stage fed by changing-size filters.

We then arranged that the test squares seen by the left and right eyes remained constant in size, but moved towards each other (i.e. the disparity was changed). Subjects found that they could cancel the motion-in-depth aftereffect by adjusting the rate of change of disparity of the squares. This can be explained if the changing-disparity signal feeds the motion-in-depth stage that mediated the aftereffect.

Further evidence that changing-disparity and changing-size inputs converge onto the same motion-in-depth stage is: (1) The time constant for the exponential decay of the motion-in-depth aftereffect was not significantly different whether measured by cancelling with a binocularly-viewed changing-size test square (24 sec, SE=2 sec) or by a changing-disparity test square (28 sec, SE=3 sec). (2) We were able to combine changing-size stimulation and changing-disparity stimulation so as to evoked antagonistic motion-in-depth responses. Subjects viewed identical 1° squares with the left and right eyes in binocular fusion. The two squares moved away from each other with a ramping waveform producing the compelling illusion of a single square moving in depth towards the head. We then arranged that the size of the squares decreased in the same manner as the disparity increased. Subjects reported that for small rates of size change the binocularly-fused square appeared to move towards the head, but for large rates of size change the square moved away from the head. For an intermediate rate of change the square did not move in depth at all.

We compared the effectiveness of changing-disparity and changing-size inputs by normalizing them in terms of the inputs that would be produced by a real square moving in depth. On this basis the changing-disparity input was 9 times more efficient than the changing-size input at our viewing distance of 145 cm.

1971 ADAPTATION TO A GRATING REVEALS SECOND HARMONIC COMPONENTS OF THE HUMAN VEP TO CONTRAST MODULATION. I. Bodis-Wollner and C.D. Hendley*. Dept. Neurology, Mt. Sinai Sch. Med., New York, N.Y. 10029.

Contrast of a 6 cycles/degree grating with sinusoidal luminance profile was modulated at the rate of 8 Hertz. Contrast modulation is the successive presentation of the same grating at higher and lower contrast. Analytically, a contrast modulated grating may be regarded as the sum of counterphase flicker and steady grating of equal spatial frequencies. 100% contrast modulation is the successive presentation of a grating and a blank field with the same mean luminance as the pattern--or simply it is pattern-on, pattern-off presentation. Analytically it is a pure counterphase grating having the same frequency but half the spatial contrast of the on-off grating.

Evoked potentials to contrast modulated gratings were recorded for four observers whose response was a single hump for a complete cycle of contrast modulation. Frequency analysis of the evoked potential of these observers showed that most of the response energy was concentrated at the fundamental frequency of modulation (8 Hertz). When stimulus presentation was interspersed for 3 second periods with an adapting high contrast steady grating of the same spatial frequency as the contrast modulated grating, its effect on the evoked potential was two-fold. While there was some reduction of peak to trough amplitude of the adapted EP to on-off presentation, its waveshape appeared as a double hump during the modulation period. Frequency analysis showed that most of the energy of the evoked potential was now concentrated at the second harmonic component. Apparently pattern adaptation caused a frequency shift in the EP spectrum of these observers. These results suggest that 1) a predominant first harmonic EP to on-off presentation of a grating is not simply a response to local luminance change (flicker), and 2) frequency doubling in the human VEP to counterphase grating presentation may be the response of visual pathways which are resilient to pattern adaptation.

This work was supported in part by Grant No. EY 01708 of the National Eye Institute.

1972 BEHAVIORAL MEASURES OF VISUAL RECOVERY IN MONOCULARLY DEPRIVED MONKEYS (MACACA NEMESTRINA) REARED WITH AND WITHOUT RETINAL LESIONS. John Boles, James R. Wilson and Anita Hendrickson. Dept. of Ophthalmology, Univ. Washington, Seattle, WA 98195.

Ten monkeys were deprived of binocular vision by suturing shut the lids of one eye (EYE 1) prior to the 24th postnatal day. EYE 1 was opened and EYE 2 closed (reverse suture) when the monkeys were between 10 & 12 mo old. The Early Lesion (EL,n=2) group received a laser lesion of the central 10° of the retina in EYE 2 when EYE 1 was sutured. Late Lesion (LL,n=4) animals received the same type of lesion in EYE 2 at the time of reverse suture. No Lesion (NL,n=4) animals had the initial and reverse suture only. Grating visual acuity was tested in a modified Wisconsin General Test Apparatus before and after reverse suture, using a two-alternative, forced choice procedure and food reinforcement. Each grating of a set of four was paired randomly with a control card (30cy/deg). The set of gratings was chosen to bracket a monkey's threshold between 50% and 90% correct response. Visual perimetry, visuo-motor tasks like reaching for objects and placing, and play behavior were assessed before and after reverse suture. The normal grating acuity threshold (72% correct) reached by Nl and LL using EYE 2 was about 10cy/deg. The thresholds of EL monkeys using EYE 2 was about 3.8cy/deg, which we take to be a measure of peripheral retinal acuity.

Continued testing for at least 6 mo after reverse suture has indicated:

1. EYE 1 of all animals showed improved visual acuity. The acuity threshold of the EL and LL monkeys reached 7.5-10cy/deg by 4 mo after reversal. The acuity of NL monkeys was as good as 2-4 cy/deg by 5-6 mo after reverse suture.
2. The onset of recovery occurred at different rates. LL and EL monkeys started to recover about 1 mo after reversal. NL animals did not begin until at least 4 mo after reverse suture.
3. The rate of recovery for all animals proceeded similarly once it began. Recovery of the EL monkeys was confounded by their having to overcome an "eccentric fixation" caused by the central lesion in EYE 2 during the critical period.
4. The perimetry tests showed that it was unlikely that only the monocular segment of EYE 1 was responsible for this recovery. Visuo-motor behavioral tests indicated that the EL and especially LL groups were indistinguishable from normals while NL animals were more handicapped in visual behavioral tests.

We conclude that laser lesions of an experiencing (EL) and experienced (LL) retina promote recovery of behaviorally useful vision in the central retina of a visually deprived eye.

1973 A ROLE FOR CYCLIC GMP IN VERTEBRATE PHOTORECEPTORS. M.D. Bownds, M.L. Woodruff, M.S. Biernbaum*, A.S. Polans, J. Hermolin*, P.R. Robinson and B.P. Abramson*. Department of Zoology and Laboratory of Molecular Biology, and Neurosciences Training Program, University of Wisconsin, Madison, Wisconsin 53706.

The molecular events that link light absorption to a sodium conductance decrease in vertebrate photoreceptors may involve a cyclic nucleotide system. Frog retinal rod outer segment (ROS) cyclic GMP levels (but not cyclic AMP levels) are reversibly decreased by illumination over the same range of light intensity that decreases ROS membrane permeability. The latency of the cyclic GMP decrease is less than 50 msec and $t_{\frac{1}{2}}$ for the decrease is about 125 msec. Cyclic GMP levels are reduced by 10^4 to 10^5 molecules per photopigment molecule bleached at illumination bleaching only a few photopigment molecules in each ROS. The light-induced decrease in cyclic GMP occurs on the same time scale and shows the same sensitivity as the light-induced conductance decrease that underlies the electrophysiological response of vertebrate rod cells.

The decrease in cyclic GMP levels is caused by an enhanced hydrolysis of cyclic GMP (phosphodiesterase: cyclic GMP→5'GMP), rather than a decrease in the rate of cyclic GMP synthesis (guanylate cyclase: GTP→cyclic GMP). Control of cyclic GMP levels is complex: GTP, both the precursor to cyclic GMP and a cofactor for the light activation of ROS phosphodiesterase, can be decreased 70% ($t_{\frac{1}{2}}$ = 7 sec) by low levels of illumination. ATP levels are not influenced by light.

Cyclic nucleotides have been shown to regulate cell physiology by stimulating the level of specific protein phosphorylations (protein kinase activity). Two small molecular weight proteins (M.W. 12,000 and 13,000) associated with ROS are phosphorylated in the dark and dephosphorylated in the light. Dephosphorylation of both proteins is graded with light intensity over the same range of intensity that decreases cyclic GMP levels and suppresses ROS permeability. The phosphorylation of both proteins is increased by cyclic nucleotide addition.

Several pharmacological agents affect cyclic GMP, the phosphorylation of the two small molecular weight proteins and outer segment permeability similarly. For example, phosphodiesterase inhibitors, that increase the level of cyclic GMP in ROS, increase both the level of protein phosphorylation and permeability. Calcium ions decrease the level of cyclic GMP (via inhibition of guanylate cyclase), the level of protein phosphorylation and permeability.

1974 A VISUAL CLIMBING FIBER INPUT TO THE VESTIBULOCEREBELLUM: AN ACCESSORY OPTIC-INFERIOR OLIVARY-VESTIBULOCEREBELLAR PROJECTION SYSTEM. N. Brecha and H.J. Karten. Dept. of Psychiatry, S.U.N.Y. Stony Brook, N.Y. 11794.

The avian accessory optic nucleus, the nucleus of the basal optic root (nBOR), receives a specfic projection from the displaced retinal ganglion cells. The nBOR has recently been reported to project bilaterally directly upon the oculomotor complex, trochlear nucleus and vestibulocerebellum. The cerebellar projection terminates as a mossy fiber system within a horizontal band upon the superficial regions of the granule cell layer adjacent to the Purkinje cell layer. These findings suggest this system is responsible for a fast visual input to the oculomotor neurons and the vestibulocerebellum.

Unilateral injections of ^{3}H-proline/^{3}H-leucine into the nBOR resulted in labeled fibers which join the brachium conjunctivum cerebellopetale(BCP). At the level of the nucleus semilunaris labeled fibers leave the BCP and either turn ventrally to join the ipsilateral ventral tegmental tract or to cross the midline and then turn ventrally to join the contralateral ventral tegmental tract. Labeled fibers course caudally to terminate bilaterally upon the medial division of the inferior olivary complex(OIm) and the labeling was somewhat heavier over the ipsilateral OIm. Unilateral HRP injections into the olivay complex have confirmed this projection system. Unilateral HRP injections into folia IXc, IXd or the paraflocculus of the vestibulocerebellum resulted in retrograde labeling of cells only within the contrlateral OIm.

These results thus demonstrate the OIm which receives a bilateral nBOR projection, gives rise to a climbing fiber projection upon those cerebellar regions which also receive a mossy fiber projection from the nBOR. Moreover, the OIm is likely to give rise to a visual climbing fiber input in view of its afferentation from the accessory optic system. The observations of the displaced ganglion cells of the retina giving rise to a specfic projection upon the avain accessory optic nucleus (nBOR) and the accessory optic nucleus projecting directly upon oculomotor neurons and both directly and indirectly upon the vestibulocerebellum further empasizes the specfic role this system may play in visual processes including oculomotor behavior.

1975 MIMICKING OF DARK ADAPTATION BY Ba^{2+} RECORDED IN OUTER SEGMENTS OF TOAD RODS. Kenneth T. Brown and Dale G. Flaming*. Dept. Physiol., Sch. Med., UCSF, San Francisco, CA 94143.

Intracellular recording was conducted in outer segments of red rods in the isolated, inverted and superfused retina of the toad, Bufo marinus. Recently developed microelectrode techniques were used to readily obtain high quality recordings in which the membrane potential and light response could be maintained stably for 2-3 hr. Effects of changing the extracellular concentration of both Ca^{2+} and Ba^{2+} were studied. Increasing $[Ba^{2+}]_o$ in the range from 0.0 - 2.0 mM was shown to mimic dark adaptation by depolarizing the cell, increasing the amplitude of the light response, increasing sensitivity, increasing the time-to-peak of the light response, and slowing decay of the light response. Lipton, Ostroy and Dowling (J. gen. Physiol. 70: 747, 1977) have reported that adaptation changes the values of both V_{max} and σ in the V-logI curves of red rods in the toad retina. The value of σ is the light intensity that elicits a light response of 1/2 the saturated amplitude, V_{max}. They also found that although changes of $[Ca^{2+}]_o$ altered V_{max}, the value of σ was unaffected. We maintained adaptation constant at slightly above the completely dark adapted level, and changed $[Ba^{2+}]_o$ from 0.0 to 2.0 mM. This increased V_{max} more than 50% and decreased the value of σ by about 0.7 log units. Thus Ba^{2+} can mimic adaptation even better than Ca^{2+}, since Ba^{2+} can control the value of σ. This makes Ba^{2+} of great interest in the ionic control of adaptation, expecially since barium has been reported by Bellhorn and Lewis (Exp. Eye Res. 22: 505, 1976) to be concentrated in the outer and inner segments of rods in the cat retina.

1976 DISSOCIATION OF MOVEMENT AND ATTENTION: NEURONAL CORRELATES IN POSTERIOR PARIETAL CORTEX. M. Catherine Bushnell*, David Lee Robinson, and Michael E. Goldberg. Armed Forces Radiobiology Research Institute, Bethesda, Maryland 20014.

Cells in monkey superior colliculus (SC), frontal cortex, and posterior parietal cortex (PP) have an enhanced response to a spot of light in their receptive field (RF) when the monkey uses the light as a target for a saccadic eye movement. This response facilitation is spatially selective; it does not occur when the animal makes a saccade to a stimulus outside of the RF. Thus this enhancement may be part of the neuronal mechanism of attention. Since attention can be dissociated from movement, we attempted to determine if the effect could likewise be separated. The facilitation in SC is dependent on an eye movement (Wurtz and Mohler, 1976).

Rhesus monkeys were trained to fixate a spot of light and release a lever when the spot dimmed. Peripheral visual stimuli were presented both within and without the RF, and the monkeys were trained to make one of several responses: continue to fixate the spot and ignore peripheral stimuli; make a saccade to a peripheral target; continue to fixate the spot, attend to the peripheral stimulus and release the level when it dimmed. Extracellular single-unit recordings were made while the animals performed their tasks.

Nearly half of the visually responsive neurons in both PP and frontal cortex showed more vigorous responses when the monkey was preparing to make a saccade to the RF stimulus. In PP all neurons tested showed similar enhancement when the monkey was attending to the RF stimulus but not preparing to make a saccade to it. This no-saccade enhancement was spatially specific; attention to stimuli outside of the RF did not result in enhancement. In contrast to PP data, frontal cortex neurons showed little or no enhancement when the monkey attended to a RF stimulus without making a saccade to it. In all cases, enhancement required the presence of a stimulus in the RF.

The enhancement phenomenon in PP is fundamentally different from that in SC and frontal cortex. SC and frontal cortex seem to participate only when the stimulus is the target for an eye movement and may be important in transferring visual information to the oculomotor system. In PP the enhancement seems to function as a general attention system when the stimulus is important to the animal regardless of the motor strategy the animal uses to handle the stimulus.

1977 THE ROLE OF THE MIDDLE TEMPORAL AREA (MT) IN THE RESIDUAL VISUAL CAPACITY OF THE STRIATE LESIONED BUSHBABY. Ruth B. Caldwell and Jeannette P. Ward. Dept. Psychol., MSU, Memphis, TN 38152

Striate cortex lesions were once thought to produce "cortical blindness", but destriate vision has now been demonstrated in many species, including man. Dual visual system hypotheses have suggested that such residual visual capacity is mediated through the tecto-cortical visual system, and while this hypothesis has not been tested directly, the effects of large occipital lobe lesions in tree shrew and monkey support this idea. The bushbaby is an ideal subject for a test of this hypothesis because its tecto-cortical projection is limited to a cytoarchitecturally distinct area in the temporal lobe (MT).

The present experiments were intended to determine the limits of destriate vision in the bushbaby and to evaluate the role of the MT area in this capacity. Bushbabies were trained on a variety of visual tasks, including two-choice discrimination problems, visuospatial localization and food localization tasks. After pretraining, six bushbabies were given extensive striate lesions and were retested. Then four animals received a second lesion, either of the MT area (17-MT) or of an intrinsic pulvinar projection area (17-VT), and were retested. A third group of animals with MT area lesions, which had been tested on similar tasks, received extensive striate cortex lesions and were retested (MT-17).

The results of these experiments were: (1) After extensive retraining, the final level of performance of five of the six striate lesioned animals was similar on most tasks to their preoperative performance. Acuity was decreased, however, and the animals could not learn a form discrimination. (2) The addition of a second lesion to the initial striate lesion did not increase the deficit on most tasks. (3) The 17-MT group was equivalent to the 17-VT group and both were better than the MT-17 group. (4) Although the MT-17 group had shown no deficit on any task before their striate lesions, they did poorly on most tasks attempted after the striate lesion. (5) The difference between the MT-17 group and the other groups could be explained on the basis of lesion size and by the fact that the groups receiving striate lesions first received more extensive training. (6) The hypothesis that the MT area is necessary for destriate visual capacity was not supported, rather the results of this experiment suggest that the striate lesion deficit depends on the extent of damage to circumstriate cortex and the amount of training the animals receive.

1978 PHOTORECEPTOR STRUCTURE AND FUNCTION EXHIBIT CIRCADIAN RHYTHMS IN THE *LIMULUS* EYE. Steven C. Chamberlain* and Robert B. Barlow, Jr. Institute for Sensory Research, Syracuse University, Syracuse, NY 13210.

Efferent fibers in the optic nerve trunk mediate circadian rhythms in the structure and response of the *Limulus* lateral eye. At night, synchronous bursts of efferent impulses increase the aperture between the cuticular cone and the light sensitive rhabdome, increase the area of photoreceptive membrane, and move the rhabdome closer to the cornea. The efferent input to the lateral eye at night also increases the electroretinographic and optic nerve responses, increases the acceptance angle of a single ommatidium, and decreases the spontaneous discharge of the optic nerve. During the day, these structural and functional effects can be produced by shocking the optic nerve or by perfusing the retina with serotonin.

The acceptance angle of a dark-adapted ommatidium increases from 6° during the day to about 13° at night. This is consistent with the observed changes in the structure of the ommatidium and the idea that the cuticular cones function primarily as light collectors and not as imaging lenses.

Visual sensitivity at night exceeds daytime levels by as much as 10^5. Intracellular records from single photoreceptor cells indicate that the endogenous circadian clock enhances visual sensitivity by elevating photoreceptor response (receptor potential) and lowering photoreceptor noise (spontaneous quantum bumps).

Photoreceptor rhabdome breaks down and renews daily. These transient structural changes appear to be controlled by efferent activity and light. Within 15 min after light onset at dawn the rhabdome is reduced in volume by at least 50%. 30 min after light onset the rhabdome is restored. This daily renewal may be analogous to disc shedding in vertebrates.

Photoreceptors are dynamic components of the *Limulus* visual system. They undergo circadian changes in structure and sensitivity presumably to compensate for diurnal changes in ambient illumination.

1979 RESPONSES OF RETINAL GANGLION CELLS IN SIAMESE CATS TO MOVING SLITS. Yuzo M. Chino*, Michael S. Shansky*, (SPON: E. Kicliter). Division of Visual Science, Illinois College of Optometry, Chicago, Ill. 60616, and D. I. Hamasaki, William L. McKnight Vision Research Center, Bascom Palmer Eye Institute, University of Miami, Miami, Fla. 33136.

It has been reported that optic tract recordings in Siamese cats reveal reduced encounter rates for Y-type retinal ganglion cells (Chino, Shansky, Hamasaki, Science, 197: 173-174, 1977) and this reduction is directly related to the degree of convergent squint exhibited by individual animals (Chino, Shansky, Hamasaki, Brain Res. 143: 459-473, 1978). In addition, responses to temporal and intensity variations in the stimulus as well as to a contrast reversal stimulus are significantly weaker than in common cats. These anomalies suggest that the receptive field organization of Siamese units may be different from that of common cats. In this study, we employed a moving slit (2^o/sec.) to investigate the interaction of center and surround in Siamese retinal ganglion cells.

We recorded optic tract responses from 96 units in 3 Siamese two of which exhibited a convergent squint, and 106 units in 3 common cats for purposes of comparison. Our results indicate that:

1) The significant reduction in Y-cell encounter rate is confirmed for this sample.
2) The RFC sizes of X-type units near the area centralis are significantly larger in Siamese.
3) Responses to moving slits are weaker among Siamese units.
4) Surround influences in Siamese neurons are notably weaker than in common cat units.

These results confirm the anomalous responses reported earlier and further imply an abnormal receptive field organization in Siamese retinal ganglion cells.

1980 **ULTRASTRUCTURAL EVIDENCE OF EARLY RETINAL GANGLION CELL DIFFERENTIATION IN XENOPUS LEAVIS.** **Charles Cima* and Philip Grant*(SPON: D. P. Kimble). Dept. of Biology, University of Oregon, Eugene, OR 97403.**

Ultrastructural evidence indicates that Xenopus retinal ganglion cell axons differentiate when retinal polarity is specified, that is between Stages 28 and 32. Light microscope studies indicated the presence of argyrophilic material in the ventral retina and optic stalk of early embryos. Ultrastructural analysis of this region confirmed the presence of axons in the stalk and interstices of ventral retinal cells. Axons containing aligned microtubules and neurofilaments and elongated mitochondria with a paucity of other cell inclusions are found with increasing frequency in the ventral retina from Stages 28 through 33/34. Central and dorsal regions of the retinae examined show little or no evidence of axons. A discrete, small bundle of axons is found in the optic stalk of Stage 28 embryos and by Stage 30/31 the number of axons in bundles has increased, suggesting early fasiculation.

Between Stages 28 and 33/34 (± 12 hours) extracellular space surrounding early axons diminishes and processes from neuroretinal cells in contact with axons 'wrap' developing axon bundles.

The evidence presented suggests that axon initiation occurs in stages much earlier than previously reported. Other investigators have failed to detect ganglion cell differentiation prior to Stage 32 possibly because they examined regions of the retina with few axons. The precocious differentiation of ganglion cell axons also suggests the appearance of fibers may be correlated with the events involved in stabilization of retinal positional information. Further, experiments which rotate the retina in the orbit may therefore have to be re-evaluated since regenerating axons may use previously established pathways to organize and 'home' in on tectal target cells.

1981 ROD-CONE INPUT TO LEMON SHARK GANGLION CELLS. Joel L. Cohen and Samuel H. Gruber. School of Marine and Atmospheric Sciences, University of Miami, Miami, Florida 33149.

Single unit responses were recorded from ganglion cells of the lemon shark, Negaprion brevirostris, retina, using the eyecup preparation suffused with 95% O_2 and 5% CO_2. Three cell types were distinguished: on, off, and on-off. Most responses were recorded from off-center cells. Receptive field center (RFC) diameters were found in the dark, using the area-summation method, with white light. RFC were found to be 1.25mm to 1.5mm in diameter. This corresponds to 7.5 to 9.0 degrees of visual angle. Spectral sensitivities were measured by recording a criterion response (1-2 spikes) to light of various wavelengths. After correcting for an equal quantum spectrum the data were plotted on a wavenumber basis. Three spectral inputs were found. Off-center cells receive a short (485nm) and medium (535nm) wavelength input. On-center cells receive an intermediate (506) and medium (535nm) wavelength input. Upon light adaptation with white light, the intermediate (506nm) wavelength component dissappears. We hypothesize that the short (485nm) and medium (535nm) wavelength spectral sensitivities arise from the cones, while the intermediate (506nm) wavelength peak arises from the rods. No color opponent cells were observed.

1982 RELATIVE USE OF VISUAL PATHWAYS IN ALBINO RAT: AUTORADIOGRAPHY WITH 14-C-DEOXYGLUCOSE COMPARED TO 14-C-PROLINE. Robert C. Collins, Torris V. Caston* and Edward F. Vastola*. Neurol., Wash. Univ. Med. Sch., St. Louis, Mo., 63130.

14-C-Proline was injected into the eye or visual cortex of albino rats. Autoradiography was performed on SB-5 X-ray film on 20 μm coronal slices of brains of animals killed 24-72 hours later. The relative distribution of retinal and corticofugal pathways was measured with a densitometer. Retinal projections to the superior colliculus were 2.5 times more dense than to the dorsal lateral geniculate nucleus, but the cortico-geniculate pathway was 2.3 times more prominent than the cortico-collicular pathway. These findings were compared with relative changes in 14-C-deoxyglucose utilization in visual pathways in additional groups of animals who were stimulated with strobe light, rotating vertical stripes, or bipolar electrical stimulation of the cortex. Compared to blind rats (enucleation), visual stimulation increased glucose utilization 68% in geniculate, 123% in superior colliculus, and 28% in visual cortex. The retinal influence on metabolism in the superior colliculus was thus 1.8 times greater than on the lateral geniculate. Electrical stimulation of visual cortex increased local cortical metabolism 100%, dorsal lateral geniculate 100%, and superior colliculus 58%. Thus the cortical influence on geniculate metabolism can be at least 1.7 times greater than on the superior collicus. These findings suggest that the differences in glucose metabolism at different sites in visual pathways in response to these stimuli are the result of differences in the distribution of first order retinal and corticofugal connections. The findings also indicate anatomical and metabolic differences between the tectal and geniculo-cortical systems that may be correlated with differences in their contribution to the animal's behaviour.

1983 CONGRUENT BINOCULAR PREFERRED DIRECTIONS IN THE SUPERIOR COLLICULUS OF KITTENS REARED WITH ONE EYE ROTATED. Max Cynader Colin Blakemore and R.C. Van Sluyters. Dalhousie University, Halifax, N. S.; Physiological Laboratory, Cambridge, England; U.C. Berkeley, Berkeley, California.

In the last decade several workers have shown that it is possible to bias the neuronal distribution of preferred orientations and/or directions in the visual system of specially-reared kittens. Alterations in the incidence of neurons with particular trigger properties have at least two possible causes: (1) atrophy (or death, or loss of responsivity) among unstimulated neurons so that only neurons which have been adequately stimulated during development are recorded (2) modification of the properties of individual neurons so that their trigger properties are now matched to their visual input. It has proved difficult to separate these two mechanisms with the deprivation procedures commonly employed.

One possible approach to this problem is to attempt to experimentally create a large number of neurons with trigger properties which do not occur in nature. The existance of such neurons would provide compelling evidence in favour of the modification hypothesis outlined above. We attempted to induce the formation of neurons with unusual response properties by surgically rotating one eye of five kittens through 90° while leaving the other eye unoperated. The kittens were then allowed at least 6 months of exposure with both eyes open in a normal environment before we recorded in the superior colliculus. We concentrated on the superior colliculus contralateral to the rotated eye, and furthermore on that part of the colliculus in which receptive fields from the two eyes were in rough topographic register in visual space despite the eye rotation. We searched for binocularly-driven collicular neurons and compared the preferred directions for these neurons as determined through each eye separately. Computer methods were used for stimulus presentation and data collection. In the absence of adaptive modification, one would expect that the preferred directions in visual space for a given cell would be separated by 90° when the stimulus was presented through either eye. Our results indicate however that the large majority of such binocularly-driven units show the same or similar preferred direction in visual space tested through either eye. This corresponds to orthogonal preferred directions on the two retinae. Since cells with these properties are not observed either in young kittens or in normally-reared adult cats, their existance provides evidence against the notion that atrophy of unstimulated cells underlies the effects of selected visual exposure.

1984 PERCEPTION OF MIRROR IMAGES BY CHILDREN. Nancy A. Dahl and Jean L. Pyfer*, Dept. Physiology & Cell Biology; Dept. Health, Physical Ed. & Recreation, U. Kansas, Lawrence, Ks. 66045.

Distinguishing mirror images from one another is impossible for most animals, difficult for some children, and even a problem for some adults. This confusion becomes critical in reading and writing and is believed to play a role in some dyslexia problems. Until perceptual strategies of identifying the difference between such letters as d and b can be ascertained, teaching techniques for helping children deal with reversal problems are, at best, based on guesswork. Left-right discrimination experiments that require symbolic responses could force left hemisphere participation and hence, confound results. This series of studies attempted to overcome that procedural weakness by requiring subjects to manually turn a hidden, raised arrow to match the visual stimulus of a tilted arrow. One hundred and ten children were tested from kindergarten (K), first (1st) and second (2nd) grades of local schools. During training and testing the subjects looked at a target circle on a screen as the stimulus was flashed for 200 msec. As a face appeared in the circle an arrow also appeared 5° to the right or left of the fixation point and tilted 45° from vertical (left or right, up or down). The arrow placement and tilt were in random order. The subject responded by imitating the face (with a smile, frown, or open mouth) and then rotating a hidden, raised arrow to match the stimulus arrow. The subject was required to turn the arrow with his/her right or left hand; the arrow was placed either to the right or left of his/her midline. Responses were classified as correct, mirror images across the vertical (m), reflect across the horizontal (i), or 180° different from the stimulus (p).

The K subjects made about twice (23%) as many total errors than did 1st (10%) or 2nd (9%). However, all subjects made more m errors than any other kind. To eliminate the random component of m errors that could have resulted from inattentiveness or confusion, the following formula was designed:

$$\text{Mirror Index (MI)} = \left[m - \frac{i+p}{2}\right]\frac{100}{n \text{ trials}}$$

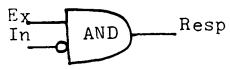
Ten subjects were found to have an MI greater than 20. Examination of the individual responses made by the high MI subjects revealed that their mirror responses were made at random. There were no differences between motor responses ipsilateral or contralateral to the visual field stimulated; there was no difference whether or not the hand crossed the midline of the body; left and right visual fields also elicited equal numbers of m errors implying that neither hemisphere was superior at this spatial perception task; and handedness conferred no advantage.

This work was partially supported by NIH Grant RR 07037.

1985 INHIBITION IN VISUAL CORTEX: A LOGIC PROCESSING MODEL TO ACCOUNT FOR SOME EXPERIMENTAL FINDINGS. J.D. Daniels. Div. of Engineering and Center for Neurosciences, Brown University, Providence, RI 02912.

A simple definition, shown by the truth table and logic gate below, is proposed for postsynaptic inhibition.

Ex	In	Resp
0	0	0
0	1	0
1	0	1
1	1	0



It is further proposed that logic processing, such as that for inhibition, may take place in the dendritic tree of a neuron. The outcome of the logic processing will regulate the spiking frequency of the neuron.

In order to incorporate inhibition realistically into a model,a connection rule, which specifies that that no afferent inhibition is allowed, is enforced.

Using the connection rule and inhibition definition a model for orientation specificity in visual cortical neurons is developed. No Inhibition from LGN fibers is allowed. In order to create a model with a minimum of connections an inhibitory neuron, the M-cell, is utilized to veto responses from afferent fibers to P- (pyramidal) cells which exceed pattern specifications for a particular orientation.

The M-cells themselves have non-specific responses, fan out to several neighboring P-cells, and have connectivity relationships similar to those of basket cells seen in cerebellar, hippocampal and cerebral cortex.

Aspects of the model as it relates to orientation specificity have recently been published (Biological Cybernetics, in press).

The logic processing model has now been extended to matters of binocular vision, including development under monocular occlusion. The responses of a binocular neuron are seen to be influenced by three factors--input from the left eye, from the right eye, and simultaneous input from both eyes. Effects of the third factor serve to create responses which,in binocular vision, are not the sum of the single-eye responses. Based on this, a model with modifiable inhibitory connections is presented.

1986 MICROCIRCUITRY OF LAYER IVab IN CAT AREA 17: NEURON TYPES AND PATTERNS OF INPUT. T.L.Davis* and P.Sterling (SPON: L.Palmer). Dept.Anat., Univ.Pa., Phila.19174.

Cell classes in cortex have been defined on the basis of differences in morphology which are believed to reflect differences in connectivity. Here we define classes by identifying directly differences in connectivity. From an animal whose lateral geniculate nucleus (lgn) had been destroyed (4 day survival), we reconstructed 32 adjacent neurons from electron micrographs of 150 serial sections through layer IVab. The cells were divided into seven classes based on differences in size, shape, dendritic branching pattern, and synaptic input.

Class I: pyramidal soma (at III-IV border); apical and basilar dendrites; dendritic spines; flat-vesicle terminals on soma (13/100μm^2); lgn terminals on basilar dendrites.

Class II: large stellate (20μm); dark cytoplasm; many flat-vesicle and round-vesicle terminals on soma (77/100μm^2, F/R=2); lgn terminals on cell body, primary, secondary, and tertiary dendrites.

Class III: stellate; varicose dendrites; medium distribution of terminals on soma (13/100μm^2); lgn and round-vesicle terminals almost completely restricted to secondary dendrites.

Class IV: radially-elongated soma; apical dendrites sharply tapered; dendritic spines; flat-vesicle terminals on soma (18/100μm^2); lgn terminals restricted to shafts of secondary dendrites.

Class V: multipolar soma; flat-vesicle terminals on soma (11/100μm^2); few lgn inputs on dendrites.

Class VI: small soma (7μm); dark cytoplasm; sparse distribution of flat-vesicle and round-vesicle terminals on soma (7/100μm^2, F/R=0.2); lgn terminals on soma.

Class VII: pyramidal soma; apical dendrites sharply tapered; dendritic spines; medium distribution of flat-vesicle and round-vesicle terminals on soma (14/100μm^2, F/R=2.1); no geniculate terminals.

No geniculate terminals were found on the spines or shafts of apical dendrites from deeper layers. We conclude that lgn input is distributed in specific patterns to at least 6 classes of neurons in layer IVab and anticipate that the classes defined here by their differences in connectivity will show corresponding physiological differences. (NIH EY00828)

1987 DENSITY AND CENTRAL PROJECTIONS OF RETINAL GANGLION CELLS IN THE TREE SHREW. Edward DeBruyn* and V. A. Casagrande. (SPON: Lucille H. Aulsebrook). Dept. Anat., Sch. Med., Vanderbilt Univ., Nashville, TN. 37232.

To investigate the normal morphological parameters of retinal ganglion cells in the tree shrew, adult retinae were isolated and whole-mounted on slides. Following staining with methylene blue, the numbers of ganglion cells were counted and relative densities measured. Results show a series of concentric elliptical isodensity lines with their long axes oriented approximately along the horizontal meridian. The ganglion cell densities ranged from 5,000 per mm^2 in the periphery to 13,000 per mm^2 in a central area. The central band of high density is reminiscent of the "visual streak" reported in a number of mammals.

Frequency histograms of cell areas indicate a skewed curve with the majority of cells (86%) ranging in size from 10μ^2-110μ^2, and the remaining large cells ranging in size from 110μ^2-302μ^2. A suggestion of bimodality was consistently observed, with a major peak occurring at 25μ^2 and a minor peak at 45μ^2. There is a progressive increase in the average cell area as eccentricity from the central area increases (from a mean of 32.8μ^2 at 28° eccentricity to a mean of 63μ^2 at 89°), and also an increase in the percentage of large cells (2.1% at 13° eccentricity, 14.2% at 77°).

Injections of horseradish peroxidase into either the dorsal lateral geniculate nucleus (LGN) or the superior colliculus (SC) resulted in slightly different distributions of labelled cells and a large group of small-sized unlabelled cells. Following the LGN injection (eccentricity = 40°), 55% of the cells (size range: 30-175μ^2) in the area of densest label contained reaction product. The frequency distribution appeared bimodal with a major peak at 75μ^2 and a minor peak at 115μ^2. The unlabelled cells (10-75μ^2) showed a unimodal curve with a peak at 25μ^2. The collicular injection (eccentricity = 45°) resulted in label in 52% of the cells (10-175μ^2), distributed with peak frequencies at 15μ^2, 90μ^2, and 115μ^2. Unlabelled cells (15-60μ^2) were again unimodally distributed with a peak at 25μ^2. In both cases, all large (>110μ^2) cells were labelled, indicating that this population contained cells whose axons innervated both the LGN and the SC. In contrast, the smallest cells (<20μ^2) contained label only after the SC injection. In both cases the majority of small cells were unlabelled indicating that they are either interneurons, or that they project to other visual centers, such as the ventral lateral geniculate nucleus or the pretectal nuclei. These results are consistent with earlier reports demonstrating differences in retinal distributions and central connections of ganglion cells based on size.

1988 LOCAL RATES OF BRAIN GLUCOSE CONSUMPTION IN PIGEON DURING REST, OPTOKINETIC STIMULATION AND UNILATERAL VISUAL DEPRIVATION. Dale G. Deutsch and Anton Reiner. Depts. of Biochem. and Psych. SUNY at Stony Brook, Stony Brook, N.Y. 11794.

The autoradiographic 2-[^{14}C]deoxyglucose (2-DG) technique (L. Sokoloff et.al., J. Neurochem 28, 897, 1977) was employed to qualitatively measure the local rates of glucose utilization in the White Carneaux pigeon brain. Pigeons received an injection of 25μCi 2-DG in the brachial vein. Following an hour in the home cage, birds were sacrificed and the brains rapidly removed and frozen in liquid Freon at -60°C. Ten micron sections were cut on a cryostat, picked up on cover slips, dried at 60°C for 5 min and placed in x-ray cassettes with Kodak X-Omat XR-1 film and exposed for 10 days. In these resting birds, high rates of glucose consumption were evident in a variety of regions, many of which have been anatomically shown to be components of avian central sensory lemniscal pathways. For example: the tectofugal visual pathway, the tectum to nucleus rotundus of the diencephalon to the ectostriatum of the telencephalon; the thalamofugal visual pathway, opticus principalis thalami of the diencephalon to the intercalated nucleus of the hyperstriatum accessorium of the telencephalon; and the auditory pathway, the cochlear nuclei and the superior olive to the nucleus mesencephali lateralis, pars dorsalis of the mesencephalon to nucleus ovalis of the diencephalon to neostriatal Field L of the telencephalon. Of these three systems, the components of the auditory pathway had the highest level of glucose consumption, with the tectofugal visual pathway having the second highest. Additional structures also showed higher than background levels of glucose uptake: the nucleus of the basal optic root, several pretectal nuclei, the vestibular nuclei, the anterior lobe of the cerebellum and the vestibulo-cerebellum. The results for resting birds are comparable to those for resting rats (Schwartz and Sharp., J. Comp.Neur. 177, 335, 1978).

Several experimental manipulations were attempted to determine whether glucose utilization could be altered by stimulation. With optokinetic stimulation for one hour, autoradiographs were not notably different from those of normal resting birds. However, with monocular occlusion 12 hours prior to 2-DG injection, and one hour survival, the tectum, nucleus rotundus and ectostriatum contralateral to the occluded eye showed somewhat decreased glucose consumption compared to the same structures on the normal side of the brain. We thank Harvey J. Karten and Melvin V. Simpson for their help and support during these studies. Supported by USPHS 1 F32 NS 05682-01(A.R) and New York State Health Research Council #855 (D.G.D)

1989 EFFECTS OF VISUAL DEPRIVATION ON THE DEVELOPMENTAL ANATOMY OF VISUAL CORTEX IN RATS. Timothy J. DeVoogd, James N. Cohn*, Mitchel Lichtenstein*, Thomas H. Burnstine*, and William T. Greenough. Dept. Psychology and Neural and Behavioral Biology Program, University of Illinois at Urbana-Champaign, IL 61820.

Valverde and others have shown that dark rearing in rodents results in reduced numbers of dendritic spines in visual cortex. These studies have generally not controlled either for the variance between litters of such anatomical measures or for the sensory deprivation imposed on the mother.

In the present study, litters of hooded rats were divided into three groups at birth. One group was raised in normal diurnal lighting, one group was raised in darkness, and one group was blinded. Tunnels allowed all mother rats to visit another cage which was in diurnal light. The rats were killed at 12, 15, 18, and 30 days of age. Their brains were removed, photographed, and stained by a rapid Golgi procedure. No consistent differences in gross brain dimensions (length and width) were associated with the dark rearing. Enucleated animals, however, had narrower posterior cortex than diurnal animals at 12 days and continued to grow more slowly than the diurnal animals. Cortical thickness was measured at precisely defined loci using a computer-assisted microscope. Cortex at the center of area 17 increased in thickness over time for all groups. Here, too, the enucleated rats were consistently lower than the diurnal rats and no consistent differences were seen between the diurnal and dark reared rats. This contrasts with the deficits in cortical dimensions obtained by Gyllensten and co-workers with dark rearing and may reflect differences in maternal cyclicity allowed by the access to diurnal lighting in this study. Spine counts in striate and parastriate cortex are in progress. Supported by Grant NSF BNS77-23660.

1990 CAT VISUAL CORTEX LACKS THE LUXOTONIC UNITS FOUND IN MONKEY. Edgar A. deYoe* and John R. Bartlett. Center for Brain Research, University of Rochester, Rochester, New York 14642.

The intensity of steady, diffuse, "background" illumination, determines the maintained discharge rate of at least 25% of the units in macaque and squirrel monkey striate cortex. (Proc. Intl. Union Physiol. Sci. 13: 55, 1977, J. Neurophysiol. 37: 421, 1974). Unlike the "sustained" units identified in cat visual system, these "luxotonic" units do not require that light be limited to the center of the receptive field and in fact, the "receptive field" of some such units appears to occupy all or most of the visual field. For luxotonic units, activity is either increased (photergic units) or decreased (scotergic units) by increasing light intensity and, again unlike the cat, such changes remain clearly identifiable for minutes or hours rather than seconds, even in the face of some adaptation. However, these long-duration effects are all but obliterated by low doses of either barbituates, nitrous oxide or even diazepam (Valium-Roche) and this could explain why diffuse illumination has long been considered an inadequate stimulus for cells of cat visual cortex. On the other hand, if cat visual cortex truly lacks luxotonic activity then, for cat vs monkey, there must exist a very basic and puzzling difference in the mechanism for visual analysis. To examine this possibility the activity of units in Areas 17, 18, 19 and Clare-Bishop of unanesthetized but painlessly immobilized cats is being recorded in relation to changes in diffuse illumination of the entire visual field. Of the over 90 units so far investigated, all of which responded to flashed or moving light, not one has exhibited anything approaching luxotonic activity although in a few cases increases or decreases in activity were "sustained" for 2-3 seconds. Most of the 90 units (66) have been from Area 17 and, while it is logically impossible to prove that this area is totally devoid of luxotonic activity, the statistical statement can now be made that the chances of as few as 5% of cat Area 17 units being luxotonic is less than 5 in 100. Whether the same will be true for the other areas under investigation remains to be seen but it now seems clear that in addition to the already known differences in binocular organization, Area 17 of cat and monkey also differ either 1), in their ability to differentiate between levels of ambient illumination or 2), in the mechanisms by which this is accomplished.

1991 ELECTRON MICROSCOPIC EVIDENCE OF REGIONAL VARIATION IN FIBER SIZE IN PIGEON OPTIC CHIASM AND TRACT. Thomas A. Duff, Grayson Scott* and Regina Mai*. Depts. of Surgery (Neurosurgery) and Anat., Univ. Wisc., Madison, WI 53706

Electron-micropic study of pigeon optic chiasm and tract revealed a regional variation in mean fiber size which closely parallels the gradient previously found in optic nerve (Soc. Neurosci. Absts: 3:558, 1977).

As fibers from one optic nerve enter the chiasm, they collect into a series of horizontal bands which interdigitate with similar bands containing axons from the other eye. Measurement of fiber size from sample electron-micrographs taken along bands located in dorsal, mid, and ventral chiasm revealed an overall mean axonal diameter value similar to that of optic nerve. Mean fiber size along each band formed a gradient, the dimension of which was related to band location in the dorsoventral axis. Uniform sampling of optic tract likewise demonstrated a gradient in mean fiber size, with relatively homogeneous, small axons located in the ventromedial region and more diversified fibers in the dorsolateral area. The overall fiber diameter spectrum in chiasm and tract appeared to be unimodal, but the histogram of samples possessing a large mean diameter value revealed a bimodal distribution similar to that found for the same population of fibers in optic nerve.

	Optic nerve	Optic chiasm	Optic tract
Modal diameter	0.75 μ	0.77 μ	0.77 μ
Mean diameter	1.04 μ	0.96 μ	1.06 μ
S.D.	0.44	0.48	0.53
Small mean diameter population (<0.99 μ)	temporal	ventromedial	ventromedial
Large mean diameter population (>1.24 μ)	nasal	dorsolateral	dorsolateral

These findings indicate that foveal and dorsotemporal retina convey impulses to anterior and mid optic tectum (McGill, et al., J. Anat. 100: 5, 1966) via a relatively homogeneous, small fiber system whereas the projection from nasal retina to dorsocaudal tectum is composed of fibers possessing a broader spectrum in size. These results also reveal that regional variation is a consistent feature of the retinotectal pathway, and, coupled with evidence of variation in both retinal and tectal ultrastructure, suggest regional specialization in processing of information arriving from different visual fields.

1992 EXPERIMENTAL AMBLYOPIA - PRODUCTION BY RANDOM MONOCULAR SHIFTS OF VISUAL INPUT. Frank H. Duffy, George D. Mower*, and James L. Burchfiel*. Seizure Unit and Neurophysiology Lab, Dept. of Neurology, Childrens Hosp. Med Ctr. & Harvard Med. Sch., Boston, Mass. 02115.

From the age of 4 to 12 weeks, kittens received 1 to 2 hours per day of specialized visual input but were otherwise raised in darkness. They wore goggles in which a 12 diopter wedge prism was placed before one eye. The prism was randomly rotated every 5 minutes producing unpredictable changes in the position of otherwise normal visual input. The other eye received normal visual stimulation.

Recordings in visual cortex revealed suppression of input from the treated eye. 60% of the cells had mappable receptive fields in the normal eye only, and these receptive fields had normal characteristics. 19% of the cells had binocular receptive fields. These receptive fields were abnormal in that they showed weak directional characteristics to both eyes and had larger receptive areas in the treated eye. 17% of the cells were mappable only from the treated eye. These cells had either simple or omnidirectional receptive field properties. 4% of the cells were visually unresponsive.

Thus, shifts in ocular dominance and other findings usually associated with the production of experimental amblyopia, were produced by unpredictable monocular shifts of visual input. Anatomical studies are in progress.

1993 CONTRAST SENSITIVITY OF THE FLY VISUAL SYSTEM. David Dvorak* (SPON. D.M. Snodderly) Dept. Neurobiology, Research School of Biological Sciences, Australian National University, Canberra, Australia.

Spatial contrast sensitivity functions were measured for the fly, Lucilia sericata, by recording extracellularly in the fourth optic ganglion the response of a wide field direction sensitive motion detecting neuron to a drifting sinewave grating displayed on a C.R.T. screen. At high light levels (0.1-4.0 cd/m^2) contrast sensitivity was maximal in the middle frequency range of 0.04-0.10 cycles/degree with marked high frequency attenuation and less steep but obvious low frequency roll off as well. As adaptation levels were lowered the high frequency cutoff point and peak sensitivity shifted towards lower frequencies. At the lowest light levels (10^{-2}-10^{-4} cd/m^2) low frequency attenuation disappeared altogether. A visual acuity curve (highest resolvable spatial frequency at different light levels) for the fly was compared with similar curves for the human derived from the psychophysical studies of Daitch and Green (1969) and DeValois, Morgan and Snodderly (1974). The variation in acuity with illumination in fly most closely follows that of the human peripheral retina. The results point to the notion that, as with the human, the retinal mosaic of the fly becomes functionally coarser as luminance drops. Possible physiological mechanisms underlying this behavior will be discussed.

1994 CORPUS CALLOSUM INFLUENCE ON DEVELOPING DEPTH PERCEPTION IN YOUNG CATS. Andrea J. Elberger* (SPON: J. M. Sprague). Department of Anatomy, School of Medicine, University of Pennsylvania, Philadelphia, PA 19104

The visual cliff apparatus (Walk and Gibson, 1961) was used to measure the development of depth perception in 4 normal cats (N), 4 cats that had received a surgical section of the posterior corpus callosum at 15-19 days old (E), and an older surgical subject, at 29 days old (E-29). Testing consisted of 10 - 2 minute trials per day starting at 20 and continuing through 40 days old. For each trial, the subject was placed on a red and white, 6 x 7mm checked centerboard and allowed to descend to one of two glass surfaces equidistant from the centerboard. One glass surface had the same checked pattern immediately underneath it (shallow, or safe, side), while the other glass surface had the checked pattern placed 25 inches below it (deep, or "cliff", side). Subjects were scored per trial as to whether they descended onto the deep side, the shallow side, or not at all.

The results show significant differences in the pattern of development of depth perception between the E and the N groups. The N group ceased almost all responses to the deep side by 28 days old, and after 33 days old, descended from the centerboard on every trial. The E group chose the deep side more often and persisted in doing so through 38 days old ($F=25.95$; $df=1,20$; $p< .001$). The E group also refused to descend from the centerboard more often and continued doing so through 39 days old ($F=7.08$; $df=1, 20$; $p< .025$). Examination of E-29's data indicate that these abnormalities occur even if the posterior callosum is sectioned at a time when depth perception is becoming accurate. The overall E group data suggest that there are two components to the development of depth perception of the visual cliff - avoidance of the deep side, and positive preference for the shallow side. For the N group, these two components develop simultaneously. Previous experiments have shown that cats in the E group have a tendency to have divergent strabismus and loss of binocular overlap of the visual field through at least 1 year old (Elberger, 1977). In view of this, early posterior corpus callosum section alters and retards the development of depth perception probably by altering early visual input so that depth cues that are present are ignored.

1995 COBALT LABELING OF THE GANGLION CELLS OF THE FROG FRONTAL ORGAN. William D. Eldred* and John F. Nolte. Dept. Anat., Univ. Colo. Sch. Med., Denver, CO 80262.

The frog's frontal organ is a photoreceptive system capable of discriminating between stimuli of different wavelengths. Previous physiological models have suggested that simple photoreceptor-ganglion cell interactions could account for these discriminations, but anatomical knowledge of the cell types involved, and their interconnections, is scanty. We examined the morphology and synaptic connections of the ganglion cells using axonal iontophoresis of $CoCl_2$. A suction electrode filled with 10% $CoCl_2$ solution was used to fill the frontal nerve axons, and the ganglion cells from which they originate, in the isolated frontal organ. The preparation was maintained in tissue culture medium during the 18-36 hours necessary for labeling. Subsequent fixation and precipitation with ammonium sulfide produced clear labeling of the ganglion cell bodies. The results indicate that, contrary to previous models, there is extensive synaptic interaction between ganglion cells. Small numbers of ganglion cells form clusters around areas of neuropil where some make ribbon-type synaptic contacts on each other. The pseudounipolar shape of the majority of labeled cell bodies corresponds to the shape of previously reported cells in the frontal organ of Rana esculenta stained to demonstrate acetylcholinesterase. The number of cells labeled with $CoCl_2$ varied from 40-105 which correlates well with our electron microscopic counts of axon numbers in the frontal nerve, and with previously published results from Rana esculenta. These results indicate that future physiological models should take into account the fact that synaptic interactions in addition to receptor-ganglion cell synapses occur in the frontal organ. In addition, the fact that at least some axons in the frontal nerve originate from cells which make ribbon-type synapses indicates that not all ganglion cells of the frontal organ are directly comparable to ganglion cells of the lateral eye retina.

1996 A COMPARISON OF THE HORIZONTAL AND VERTICAL OPTOKINETIC RESPONSES OF THE RABBIT. R. G. Erickson* and N. H. Barmack, (SPON: C. C. Bell). Neurological Sciences Inst., Good Samaritan Hosp. & Med. Cntr., Portland, OR.

Because of an otolithic input, the vertical vestibuloocular reflex (VVOR) of the rabbit has a higher gain (eye velocity/head velocity) and different phase characteristics than the horizontal vestibuloocular reflex (HVOR) for low angular accelerations. Since both vestibuloocular reflexes and optokinetic reflexes must combine to provide the rabbit with a relatively fixed spatial reference, it would appear that the optokinetic input would be of greater importance for providing this reference for the horizontal system. The present experiment examines this prediction by comparing the closed-loop gain (eye velocity/stimulus velocity) and open-loop gain (eye velocity/retinal slip velocity) for both horizontal and vertical systems. A random noise, optokinetic stimulus was presented monocularly to rabbits placed in front of a rear-projection tangent screen subtending 72 x 72 deg. Eye position of the non-stimulated eye was measured using an infra-red light projection technique. The closed-loop gain of optokinetically evoked horizontal eye movements evinced a directional selectivity, with a much higher gain for stimulation in the posterior —>anterior direction (P—>A), with reference to the stimulated eye. The P—>A gain was .8 at a stimulus velocity of .25 deg/sec, declined to .7 at 10 deg/sec and was .2 at 50 deg/sec. The A—>P gain was .55 at a stimulus velocity of .1 deg/sec declined to .02 at 10 deg/sec, and was 0 at 20 deg/sec. The vertical optokinetic gain was nearly equal for stimuli moving in either the vertical up or vertical down direction. At a stimulus velocity of .25 deg/sec the gain was .5, declined to .15 at 10 deg/sec, and was .02 at 50 deg/sec. The open-loop gain in the horizontal P—>A direction was 2.3 at a retinal slip velocity of .1 deg/sec, and declined to .15 at 50 deg/sec. The vertical open-loop gain at a retinal slip velocity of .1 deg/sec was 1.3, and declined to .03 at 50 deg/sec. The dynamics of eye movements evoked in the vertical and horizontal planes were also different. In the horizontal plane the eye never exceeded a deviation of 15 deg before being interrupted by a resetting saccade. Vertical deviations greater than 20 deg were often maintained for intervals exceeding 10 sec without resetting. These data suggest that the higher horizontal optokinetic gain may compensate for the reduced gain of the HVOR at lower angular accelerations of the head. An equivalent vertical optokinetic gain would be obviated by the contribution of the otoliths to the VVOR at these lower angular accelerations. 1997 THE GANGLION CELLS OF RABBIT RETINA. E.V.Famiglietti,Jr. and E.C.Siegfried*. Dept. Physiol. and Biophys., Wash. Univ. Sch. Med., St. Louis, MO 63110.

Retinal ganglion cells of rabbit, like those of cat, may be divided into 4 classes, based upon analysis of Golgi preparations. Class I cells have medium-to-large size cell bodies, thick axons and dendrites, "radiate" dendritic branching pattern (DBP), narrow dendritic stratification (DS), and large dendritic field diameter (DFD). Class II cells have small cell bodies, thin axons, a "tufted" DBP with a profusion of dendritic appendages, broad DS, and small DFDs. Class III cells have small-to-medium size cell bodies, relatively thin axons and dendrites, narrow DS, a variety of DBPs, and a wide range of DFDs at a single retinal locus. Class IV cells, with medium size cell bodies and either multistratified or diffuse dendritic branching, include at least 2 kinds of bistratified cell, and 2 kinds of "E-type" cell (Lettvin et al., 1961). Dendritic field, cell body and axonal diameters of all but a few ganglion cells of classes III and IV increase with increasing distance from the visual streak. Most class I and class III cells can easily be assigned to a or to b types, according to the level of the inner plexiform layer (IPL) at which their dendrites stratify. Class II cells are somewhat more heterogeneous than in cat and more difficult to type.

A fifth class of "intrinsic" ganglion cell has been identified. Its small-to-medium size cell body usually lies in the IPL, and it gives rise to long, wavy, somewhat spiny, and relatively unbranched dendrites which form a large dendritic field. Typically, 2 "axons" emerge from 1st or 2nd order dendritic branches as tapering "initial segments". Slender and beaded, the "axons" of class V cells ramify in rectilinear fashion, narrowly stratified together with the wavy dendrites of these cells in mid-IPL. These "axons", closely resembling the axons of Golgi type II neurons of the CNS, do not leave the IPL. (This work does not support the assertion of Marenghi, 1901, that some retinal ganglion cells have axon collaterals.) Neither in their overall morphology, nor in their "axonal" ramifications, do intrinsic ganglion cells of rabbit retina resemble the "giant associational nerve cells" of Gallego and Cruz, 1965. At present attempts are being made to relate the morphology and synaptic connections of rabbit ganglion cells to their neurophysiology and pharmacology.

1998 THE AXONAL ARBORIZATION WITHIN AREA 17 OF DIFFERENT CLASSES OF LATERAL GENICULATE NEURONS. David Ferster* and Simon LeVay, Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115

The cat's lateral geniculate nucleus (LGN) contains three morphological types of neurons: types 1,2 and 4 (Guillery, JCN 128:21). We have previously suggested that these correspond to the three physiological types: Y-, X- and W-cells (LeVay and Ferster, JCN 172:536).

Do the axons of each cell type have a distinctive pattern of arborization within area 17? To answer this question injections of horseradish peroxidase were made into a cut in the optic radiations of adult cats. Golgi-like staining of neurons in the LGN, and of axonal arborizations in the visual cortex were obtained. In laminae A, A1 and C, examples of type 1 and type 2 neurons were reconstructed and their axon diameters measured. Type 1 neurons possessed large diameter axons (2.0-3.3μm, exclusive of myelin) while type 2 neurons had medium sized axons (1.0-1.7μm). Both types gave off collaterals to the perigeniculate nucleus. In laminae C1-C3, neurons with very fine axons (0.5-1.0μm), probably type 4 neurons, were found. Identification of type 1 and type 2 neurons as Y- and X-cells is strengthened by the determination of their axon diameters, since these are appropriate for the conduction velocities reported for Y- and X-cells.

In the cortex, the terminals of filled axonal arborizations were restricted to 3 levels: (i) the upper half of layer I, (ii) a band extending from the bottom of layer III to the top of layer V and (iii) the upper half of layer VI. This distribution matches the distribution of geniculo-cortical afferents observed after ^{3}H-proline injections into the LGN (LeVay and Gilbert, Brain Res. 113:1) Camera lucida reconstructions of 30 complete axonal arborizations revealed 3 types. Axons of one type terminated primarily in layer IVab and the lower part of layer III. Their diameters, measured in the white matter, matched those of the type 1 geniculate relay cells. Their arborizations spread laterally for up to 2mm in layer IVab with their boutons grouped into several clumps, similar in size and arrangement to ocular dominance columns. Axons of the second type terminated primarily in layer IVc. Their diameters matched those of the type 2 geniculate relay cells. They had much smaller arborizations, usually with only a single clump of boutons. Most afferents of both these types gave off collaterals in the upper half of layer VI. The third type of afferent innervated the upper half of layer I. Their axon diameters matched those of the small cells in laminae C1-C3. They sometimes gave off collaterals to layer V or the lower half of layer III. We conclude that the different classes of relay cells, though partially intermixed in the LGN, have different laminar projections in area 17. (NIH grants R01 EY01960 and T01 EY00082)

1999 RETINAL AFFERENTS TO THE MIDBRAIN RAPHE OF THE CAT. Warren E. Foote and Elizabeth Taber-Pierce. Depts. of Psychiatry and Anatomy, Harvard Med. Sch.-Mass. Gen. Hosp., Boston, Mass. 02114.

During the course of recent work exploring the effects of midbrain raphe stimulation on principal cells in the dorsal lateral geniculate of the cat it was noted that a small number of optic tract fibers were antidromically driven by single shocks to this midbrain area. This observation suggested that ganglion cell axons might be traversing areas of the midbrain not known to receive visual information. In an attempt to provide anatomical verification of this possibility a series of animals were utilized in studies employing techniques of orthograde and retrograde transport.

Orthograde transport was accomplished by injecting a mixture of tritiated leucine and proline into one eye in each of five animals. After survival times ranging from 2 to 14 days, the animals were perfused with formalin and the tissue embedded, cut, and dipped in Kodak NTB-2 emulsion. Microscopic examination revealed the presence of light label in the nucleus raphe dorsalis and the central superior nucleus. Grain counts were performed to confirm this observation.

Retrograde transport was accomplished by iontophoretic application of a 4% solution of horseradish peroxidase (Sigma Type VI or Boehringer Grade I) dissolved in .05 M Tris-HCl buffer and 0.2 M KCl pH 8.6. Applications were made into either the dorsal raphe nucleus or the nucleus central superior. After 24 hours survival the animals were perfused with a 2.5% glutaraldehyde 0.5% paraformaldehyde mixture and the brains and retinas removed and reacted with Hanker-Yates solution. Under oil immersion reaction product was observed in the peripherally located, large ganglion cells of all retinas. These neurons appear to correspond to the alpha ganglion cells of Boycott and Wassle (J. Physiol. 240: 397, 1974). Since not all of the large ganglion cells contained reaction product and those that did were found in all retinal quadrants, these data coupled with autoradiographic material indicate a small binocular projection from peripheral retina to the midbrain.

2000 SURROUND ANTAGONISM AND OPPONENT PROCESSES IN DIRECTIONALLY SPECIFIC PIGEON TECTAL NEURONS. B.J. Frost, S.C.P. Wong*, and P.L. Brooks*, Dept. Psych., Queen's Univ., Kingston, Ontario, Canada.

It is now generally accepted that directional selectivity in neurons is produced by the asymmetrical propagation of inhibition in the null direction. We have confirmed these findings in directionally selective neurons in the pigeon tectum and have used a variety of techniques to reveal that these units also have a centre-surround structure where the directional characteristics of the surrounding region are the reverse of the central area. Conventional extracellular recording methods were used to study the motion characteristics of 126 neurons located in all tectal laminae of white Carneaux pigeons. A dual channel optical system permitted the independent manipulation of the size, direction, velocity and pattern of two stimuli.

Central Inhibition in the null direction was demonstrated when the normal excitatory response produced by movement of the test stimulus in the preferred direction through the centre of the receptive field, was inhibited by a second spot moving along the same path in the null direction. Additionally PSTHs produced by sweeping a single stimulus forward and back in the preferred and null direction of spontaneously active units directly shows inhibition in the null direction, which arises from the same area of the receptive field as excitation in the preferred direction. Surround inhibition has been demonstrated by increasing the size of a test stimulus past the optimal size, which results in a reduction and sometimes abolition of the response. Surround inhibition has been more directly revealed by moving a second stimulus synchronously (in same direction & velocity) with the test spot moving in the preferred direction through the centre of the receptive field. The excitatory response produced by the test spot alone is completely abolished when the second stimulus moves in the same direction through the surround. Finally surround facilitation has been demonstrated by moving a large textured pattern in the surround area only (centre-masked), in the opposite direction to the central test stimulus which is moved in the preferred direction. The receptive field structure of directionally specific neurons that emerges from these observations is a spatially organised, antagonistic centre-surround organisation, in which the central region exhibits excitation in the preferred direction and inhibition in the null direction, while the surround is arranged in an opponent fashion whereby "preferred" direction motion produced inhibition and "null" direction motion produces facilitation of the centrally generated response.

2001 THE ANATOMY OF THE OPTIC NERVE OF THE TURTLE, PSEUDEMYS SCRIPTA ELEGANS. J.E. Fulbrook and A.M. Granda. Inst. for Neuroscience, University of Delaware, Newark, DE 19711.

The optic nerve of the turtle was studied by both light and electron microscopy. The great majority (70-80%) of the fibers are myelinated. Myelinated fibers ranged in size from about 0.8 to 4.0 microns in diameter. Unmyelinated fibers ranged in size from 0.2 microns to about 1.0 microns in diameter. Fiber counts from different regions of optic nerve yielded a total estimate of 724,000 axons. The larger myelinated fibers were located more in the periphery of the optic nerve. Smaller myelinated fibers were located predominantly in the central region. Unmyelinated fibers were found throughout the nerve with no apparent differential distribution. Only one type of neuroglial cell was observed.

A well-defined neural groove was identified in the optic nerve preparations. The neural groove appeared as an invagination extending dorsally from the ventral surface halfway into the nerve. The groove originates at the optic disk and extends back to the chiasm where it disappears in the crossing fibers. The neural groove is bordered on both sides by discrete collagenous sheaths similar to the pial sheath surrounding the optic nerve. Blood vessels of varying sizes were found predominantly within the neural groove and pial sheath. Only a few blood vessels were found within the nerve proximal to additional small nerve invaginations and within regions of high neuroglial cell density. Comparative data on axon fibers and vascular organization will be discussed.

2002 RESPONSE LATENCIES IN CAT VISUAL CORTEX. Jill C. Gardner and Max S. Cynader. Dept. Psych., Dalhousie University, Halifax, N.S., Canada.

Responses to flashed stimuli were measured in a sample of over 500 neurons in cat areas 17 and 18. Unless otherwise indicated, the stimulus was a bright bar (2.74 cd/m^2 against a background of .086 cd/m^2) of 50 msec. duration.

Of the parameters which were examined, changes in stimulus luminance had the greatest effect on response latencies. Over a 2 log unit range, decreases in luminance resulted in latency increases of 40-50 msec. Other manipulations produced relatively small effects. Varying the orientation of the stimulus or its position on the receptive field caused changes of less than 8 msec. although these manipulations could produce substantial changes in firing rate. In general however, shorter latencies resulted from stimuli which evoked more spikes. An exception to this rule was seen with increases in stimulus size. Increasing the length or the width of the stimulus usually resulted in a decrease in the number of spikes and a decrease in latency. In part, this latency shift was attributable to the longer latency of surround inhibition.

The observations noted above held in both cortical areas. In other respects, responses in areas 17 and 18 showed marked differences.

Area 18 units were more responsive to flashed stimuli. Most cells responded well to even brief flashes (5 msec.) while this stimulus proved to be quite ineffective for area 17 units. With only rare exceptions, units in area 18 responded with a transient burst of impulses to a prolonged flash (250 msec.). Many area 17 cells gave sustained responses or showed both a sustained and transient component in their response. Within each area, simple and complex cells had similiar latencies. Responses in area 18 were very homogeneous, with almost all cells responding within a 20 msec. range, while area 17 showed a much broader latency spread. In area 17, a special class of hypercomplex cell found in the superficial layers was characterized by extremely long latencies. Response latencies averaged 10-15 msec. shorter in area 18 than in area 17.

The results indicate clear differences in the intracortical organization of areas 17 and 18. In area 17, strong inhibitory interactions and long latency responses contrast with the homogeneous area 18 response. Responses in area 18 reflect a simpler network, well designed to encode temporal information.

2003 PERIMETRIC DEFICITS ASSOCIATED WITH CHRONIC MONOCULAR PARALYSIS. P.E. Garraghty*, W.L. Salinger and M.G. MacAvoy*. Dept. Psych., University of North Carolina at Greensboro, Greensboro, NC 27412.

Single-unit recordings in adult cats which have undergone chronic monocular paralysis (14 days or more) reveal profound alterations in the cell populations of lateral geniculate nucleus and visual cortex (Salinger, W.L., Schwartz, M.A. and Wilkerson, P.R., Brain Research, 1977; Fiorentini, A. and Maffei, L., Vision Research, 1974). Little, however, is known regarding the behavioral significance of these physiological changes. In this study a behavioral perimetry technique was used to detect visual field deficiencies which may have developed concomitantly with the previously reported physiological changes. In this study a behavioral perimetry technique was used to detect visual field deficiencies which may have developed concomitantly with the previously reported physiological changes. Monocular paralysis was accomplished by surgical transection of cranial nerves III, IV, and VI. The width of the visual field for each eye was repeatedly measured before monocular paralysis surgery, and perimetric testing continued daily for a period of two weeks after surgery. Chronic monocular paralysis results in a peripheral visual field compression divided between nasal and temporal fields, and totaling slightly less than 20° in the paralyzed eye. A small part of the ultimate field compressions were present at the time of the first post-surgical tests, while the balance appeared progressively during the two weeks of monocular paralysis. The small initial compression could perhaps be accounted for by optical defects caused by transection of nerve III. The progressively appearing field compression, however, appears physiological in origin. The progressively appearing component of the perimetric deficit seems to be a behavioral correlate of the physiological changes which are found following monocular paralysis.

2004 RETINOTOPIC ORGANIZATION AND SINGLE UNIT RESPONSES IN THE PULVINAR OF THE CEBUS MONKEY. Ricardo Gattass*, Eduardo Oswaldo-Cruz* and Aglai P. B. Sousa* (SPON: Charles Gross) Institute of Biophysics, U.F.R.J., Rio de Janeiro, RJ 20.000, BRASIL.

Single and multi-unit recording from the pulvinar of 24 Cebus monkeys revealed two retinotopically organized areas. The largest was located in the ventro-lateral part of the pulvinar and included the pulvinar inferior and the ventral third of pulvinar lateralis. The second area was dorsal to the first, in the middle third of pulvinar lateralis. Both representations were restricted to the contralateral hemifield but had different magnification factors for the center of gaze. The ventro-lateral representation had a larger foveal representation than the dorsal representation.

The visual properties of single units in the ventro-lateral (N=134) and the dorsal areas (N=39) were similar. 74% gave clear time-locked responses to visual stimuli and had properties similar to those reported in the geniculo-striate system or the superior colliculus. Of these units, 76% were binocular, 75% preferred moving stimuli, 75% showed directional specificity and 47% showed orientation specificity. In addition, the activity of virtually all the units could be modified by somesthetic, auditory, olfactory or visual stimulation but the responses had long and variable latencies, habituated easily and often continued after the stimulus. A given unit often gave different patterns of responses to different modalities.

2005 THE PROJECTIONS OF THE LATERAL GENICULATE NUCLEUS TO AREAS 17 AND 18 IN THE CAT. E. E. Geisert, Jr. The Neuroscience Training Program and the Department of Anatomy, The University of Wisconsin, Madison, Wisconsin 53706.

Both areas 17 and 18 receive input from the lateral geniculate nucleus. The extent to which these two areas share the geniculate inputs is basic to an understanding of visual function. I have developed a new application of the retrograde transport method designed to demonstrate neurons which project to several cortical areas by axons that branch, and have applied this method to a study of the geniculo-cortical system of the cat. This method depends on the retrograde axonal transport of two markers, each of which is uniquely detectable by histological methods. In this study, horseradish peroxidase (detectable by the enzyme reaction product only) and tritiated proteins (either enzymatically inactivated tritiated horseradish peroxidase or tritiated bovine serum albumin, both of which are detectable by the tritium label only) were used. One of these markers was injected into area 17 and the other was injected into area 18. The animals were perfused with 4% glutaraldehyde. The tissue was sectioned at 200μm and processed to reveal the active horseradish peroxidase. Then these sections were embedded in methacrylate, resectioned at 4μm and processed by the autoradiographic method. In eight animals, individual neurons were seen which contained both the brown reaction product and the tritium label. These neurons project to both area 17 and area 18 by axons that branch. In layers A and A_1 of the lateral geniculate nucleus, 10% of the cells project to both areas 17 and 18, 70% of the cells project to area 17 only, less than 1% of the neurons project to area 18 only, and approximately 20% of the cells are interneurons. In the C laminae, 50% of the cells project to both areas 17 and 18, 20% of the neurons project to area 17 only, 10% of the cells project to area 18 only and 20% of the cells do not project to either area 17 or area 18. In the medial interlaminar nucleus, neurons also project to both area 17 and area 18 by axons that branch. (Supported by grants RO1 NS 06662 and RO1 EY 00962.)

2006 BIFURCATION OF THE CORTICOPONINTE PATHWAY IN THE CAT. Alan Gibson*, James Baker*, George Mower*, Farrel Robinson*, and Mitchell Glickstein. Dept. Psych., Brown University, Providence, RI 02912

There is a visual input to the rostro-medial pons which arises from layer V cells of several visual areas of the cerebral cortex. Layer V cells of the same cortical areas also provide an input to the superior colliculus. Do the axons of the corticopontine cells bifurcate and give off one branch to the superior colliculus and another to the pontine nuclei? To answer this question, we first recorded cells in the medial pontine visual area and then placed an array of stimulating electrodes at the same location. We next placed an array of stimulating electrodes in the superior colliculus. We recorded from cortical visual cells and tested to see if they could be activated antidromically from the pons. We then tested to see if such corticopontine cells could also be activated antidromically from the colliculus. Antidromic latencies from the stimulating sites and collision between collicular and pontine-elicited spikes were used to establish bifurcation.

68% (N=35) of the corticopontine cells in area 18 were activated from both the pons and colliculus. No consistent differences in antidromic latencies between the pons (mean latency= 3 ms) and colliculus (mean latency=3.2 ms) were seen. 54% (N=11) of lateral suprasylvian corticopontine cells had bifurcated axons (pons latency=3.4 ms, colliculus latency=2.6 ms). The posterior middle-suprasylvian area (MSS), a visual association area, has a heavy output to medial pons and superior colliculus. 42% (N=12) of MSS corticopontine cells bifurcated (MSS latency=5.5 ms, SC latency=6.4 ms). All of our estimates of the percentage of bifurcated axons must be minimal, since the exact location of the collicular stimulating electrodes would strongly affect the probability of detecting bifurcation.

We conclude that a high percentage of cortical fibers carrying visual information to the pons also sends a copy of that information to the superior colliculus. The cortex supplies visual input to the cerebellar hemispheres via the medial pontine nuclei, while the colliculus provides visual input to the vermis of the cerebellum via the dorsolateral pontine nuclei. The paravermian cortex and the cerebellar hemispheres have been associated with control of distal musculature, and the vermis with the control of proximal musculature (Chambers & Sprague, J. Comp. Neurol. 102: 105-129, 1955). Perhaps the cortical visual information carried by the bifurcated axons is useful for visuomotor coordination of both proximal and distal muscles.

2007 CLASSIFICATION OF CONCENTRIC CELLS IN THE RABBIT LGN AS X OR Y BASED UPON LINEARITY OF SPATIAL SUMMATION. David L. Glanzman* and Loraine G. Miller* (SPON: K. L. Chow). Dept. of Psychology, Stanford Univ. and Dept. of Neurology, Stanford Univ. Med. Sch., Stanford, CA 94305.

Recently, Hochstein and Shapley (J. Physiol. 262: 237, 1976) have argued that the fundamental basis for a distinction between X and Y cells in the cat visual system is reflected in the property of linearity of spatial summation; other classificatory criteria which have been employed in studies of X and Y cells, e.g., whether a cell gives a sustained or transient response to standing contrast, reflect non-essential properties. Thus, these latter criteria yield overlapping categories, whereas the criterion of linearity of spatial summation yields discrete categories of X and Y cells in the cat retina and LGN. We now report the first instance in which LGN cells in a mammal other than the cat have been classified as X or Y by means of the rigorous criterion of spatial summation linearity. Using sinusoidal grating stimuli similar to those employed by Hochstein and Shapley, we have found that concentric neurons in the rabbit LGN can be classified into two non-overlapping groups depending upon whether they exhibit linear or nonlinear spatial summation over their receptive fields. We have also found that properties such as size of receptive field center and type of response to standing contrast cannot be used to discretely classify rabbit LGN cells as X or Y.

The rabbit LGN, unlike that of the cat, contains a significant proportion of cells with uniform receptive fields. Uniform cells, like concentric cells, give either a sustained or transient response to standing contrast. We have tested uniform cells with sinusoidal grating patterns in order to determine whether they may also be grouped into X and Y categories. (Supported by NIH Grant EY 00691 and NASA Grant NGR 05-020-435.)

2008 NEURONAL ACTIVITY FROM MOTOR CORTEX IN VISUOBEHAVIORAL DEPRIVATION. Jay D. Glass. Dept. Pharmacol., U. of Pittsburgh, Sch. of Med., Pittsburgh, PA 15261

Visuobehavioral deprivation by monocular eyelid closure yields valuable insights into the development of the afferent visual pathways and into the relationship between the development of those pathways and the animal's capacity for visually guided behaviors. We have previously shown that the deprivation effects visually evoked activity not only from visual cortex as reported by others, but also from frontal cortex in man and motor cortex in cats. We now wish to report further observations on visually evoked activity recorded from motor cortex in chloralose anesthetized and awake cats following extended periods (11-18 months) of monocular closure.

In two cats under deep chloralose anesthesia, no differences were found between the single-unit or slow-wave response evoked from the deprived eye (DE) and nondeprived eye (NDE). However, as anesthesia level decreased, the response evoked from the NDE became robust whereas the response evoked from the DE retained its "depressed" form. In two cats with implanted electrodes studied during light, nonsurgical anesthesia, the slow-wave and single-unit response evoked from DE and NDE were dramatically different.

Four cats with implanted electrodes were studied while awake. A reliable sequence of slow waves was evoked from the NDE and an increase in unit activity usually occurred in phase with certain components of the slow wave. No reliable responses were evoked from the DE nor did an increase in unit activity occur. In addition, when only the DE was open the level of unit activity was lower than with the NDE, at times specific cells would cease firing.

In the chloralose anesthetized preparation, the response evoked from the DE always resembled the response evoked from a deeply anesthetized cat. In the awake cat utilizing only the DE, unit activity was at a lower rate than when utilizing only the NDE. A previous report about humans with visuobehavioral deprivation showed intense alpha rhythm which is not blocked by a photic stimulus to the DE, even though a response is recorded from visual cortex. Reports of behavioral impairments in deprived cats indicate a deficit in attentional mechanisms. These lines of evidence suggest that the deprivation has altered the relationship between visual input to the deprived eye and nonspecific arousal mechanisms.

2009 THE ROLE OF THE NUCLEUS ISTHMUS IN THE IPSILATERAL VISUAL PROJECTION TO THE FROG'S OPTIC TECTUM. Steven Glasser and David J. Ingle, Dept. Psych., Brandeis Univ., Waltham, MA. 02154.

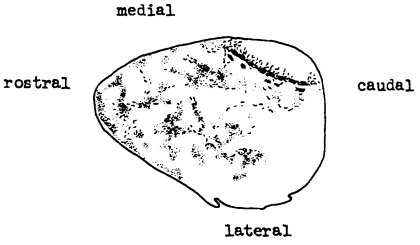
We investigated the effects of unilateral electrolytic lesions of nucleus isthmus in adult frogs (Rana pipiens), using single and multiple unit mapping of the optic tecta. While our lesions had no effect upon density or response properties of retinal fiber terminals activated from the contralateral eye, units of the ipsilateral projection could not be found over most of the dorsal tectum. No such loss was obtained in frogs where we intentionally missed the nucleus isthmus. Our data support the hypothesis (Gruberg, E.R. and Udin, S. E., J.C.N.179: 487, 1978) that the nucleus isthmi provide relay stations for the ipsilateral projection to frog tectum, and thereby provide one basis for binocular vision in Anuran amphibians. However, projections for nucleus isthmi to tectum may provide other functions besides binocular integration. Following large isthmus lesions, we often noticed two abnormal phenomena: 1) an increase in spontaneous activity throughout both tecta and 2) units in the superficial tectum which gave a prolonged discharge to the dimming of light. Thus, we suggest that removal of a modulating input from nucleus isthmus produces a kind of global disinhibition on both sides.

2010 The role of symmetrical and asymmetrical binocular input in the development of orientation specificity. Barbara Gordon, Joelle Presson*, James Packwood*, and Robert Scheer*. Department of Psychology, University of Oregon, Eugene, OR 97403.

In normal cats the orientation preferences of single units in the visual cortex are uniformly distributed. Previous investigations have used two procedures in attempts to alter this distribution. In some experiments kittens have been reared in striped drums which allow both eyes to see the same orientation (Blakemore and Cooper, 1970). Other workers have reared kittens wearing striped goggles so that the eyes receive asymmetrical binocular input; that is, one eye sees horizontal stripes and the other eye sees vertical stripes (Hirsch and Spinelli, 1971). While there is general agreement that the goggle procedure is effective, Stryker and Sherk (1975) failed to replicate the effect of drum rearing. In an attempt to resolve this controversy, we have reared kittens in four conditions that separate the drum vs. goggle variable from the symmetrical vs. asymmetrical binocular input variable. The conditions were: 1) drum reared, both eyes seeing horizontal (HH drum), 2) drum reared, left eye seeing horizontal, right eye seeing vertical (HV drum), 3) goggle reared, both eyes seeing horizontal (HH goggle), 4) goggle reared, left eye seeing horizontal, right eye seeing vertical (HV goggle). We recorded from at least 65 oriented cells from at least 2 cats in each condition. In contrast normal cats in which almost all visual cortex cells have orientation preferences, only 55% of the cells in drum and goggle reared cats showed orientation preferences. Of the remaining 45% of the cells, 21% were unoriented and 24% were visually unresponsive. For each condition we calculated the ratio of the number of cells preferring stimuli within 30° of the experienced orientation to the number preferring orientations within 30° of the perpendicular to the experienced orientation. In the HV goggle condition, which produced the most dramatic effect, this ratio was 9. For the other 3 conditions this ratio varied from 1.5 to 2.5. We conclude that, while both goggle and drum rearing are effective, the combination of goggles and asymmetrical orientations is the most effective way to alter the distribution of preferred orientations.

2011 PERIODICITY IN THE VISUAL COMMISSURAL PROJECTIONS OF THE GREY SQUIRREL. Harry J. Gould, III. Dept. Anat., University of Cincinnati College of Medicine, Cincinnati, Ohio 45267.

The topographic relationships of interhemispheric visual connections are demonstrated in the grey squirrel using the Fink-Heimer technique on tissue that was flattened by the method of Welker and Woolsey. Sectioning the corpus callosum reveals degeneration that is organized into three parallel bands on the lateral surface of the occipital cortex. Although cytoarchitectonic landmarks are difficult to determine on the flattened tissue, these bands apparently correspond to the 17-18 border, the 18-19 border and the 19-temporal border. As shown in the figure provided, the most prominent or major commissural band corresponds to the 17-18 border. It is characterized by alternating areas of dense and sparse degeneration. It continues rostromedially and caudally onto the medial wall of the hemisphere; these rostral and caudal extentions end before meeting. A second, narrow band of dense degeneration corresponds to the 18-19 border. Rostrally, on the lateral surface of the hemisphere, it is continuous with the major commissural band. It extends caudally to reach the medial wall of the hemisphere. A third, wide band of sparse degeneration corresponds to the 19-temporal border. Rostrally, this band is indistinguishable from the degeneration observed in the parietal cortex. Caudally, it ends before reaching the medial wall of the hemisphere. Both the second and third commissural bands are characterized by alternating regions that contain or are free of degeneration. The functional significance of the periodicity in these projections is unclear, yet the pattern is reminiscent of that observed for the geniculostriate contribution to ocular dominance columns in the cat and monkey. This suggests that ocular dominance may be important in interhemispheric integrative mechanisms. (Supported by URC 8-19101-1311-39)



2012 A LIGHTMICROSCOPIC AND ELECTRONMICROSCOPIC STUDY OF THE SUPERFICIAL LAYERS OF THE SUPERIOR COLLICULUS OF THE TREE SHREW (TUPAIA GLIS). J. Graham* and V.A. Casagrande. Depts. of Anat. and Psych., Vanderbilt Univ., Nashville, TN 37232.

Histochemical, Golgi and electronmicroscopic methods were used to study the superficial layers of the superior colliculus of tree shrews. Zones of retinal and cortical input were compared with the locations of efferent cells projecting to the dorsal lateral geniculate nucleus (dLGN) and the pulvinar (Pul). Following horseradish peroxidase injections of the dLGN and the Pul, retrogradely labeled cells were found in the upper 2/3rds and lower 1/3rd of the stratum griseum superficiale (sgs), respectively, as has been described by Albano, et al. (1977). The impression given by this material that the orientation of processes and size of the labeled cells varied according to their somata's location and extrinsic connections was born out by correlating this material with tissue prepared by various Golgi techniques. Cells located in the upper sgs had narrow dendritic fields, both the dendrites, often ascending to the sgs-stratum zonale border but confined to the upper sgs, and the somata being strikingly vertically oriented. By comparison, cells located in the lower sgs had larger somata and wider dendritic fields, both the dendrites, usually confined to the lower sgs, and the somata giving more of a multipolar appearance.

For electronmicroscopy, following enucleation and/or decortication (usually only of the striate cortex), the animals were allowed to survive from 2 days to several months. Differences between normal and lesioned material suggested that size of terminals and morphology of the (round) synaptic vesicles did not vary according to lesion type. However, pale mitochondria with irregularly organized cristae and scalloped profiles with multiple postsynaptic processes were associated with optic terminals, and dark mitochondria with more regularly organized cristae and profiles with fewer postsynaptic processes were associated with cortical terminals. Enucleation caused considerably greater number of terminals to degenerate than decortication. Although in both cases degenerating terminals were observed throughout the full depth of the sgs and into the upper stratum opticum, the majority of the degenerating optic terminals were located in the upper sgs, whereas degenerating cortical terminals were evenly distributed throughout the sgs. These results indicate that cells that project to the dLGN and those that project to the Pul differ in two ways, besides location and size. First, these cells exhibit different dendritic patterns. Second, the substrata in which their somata and dendrites lie receive different proportions of retinal and cortical afferents.

2013 EFFECTS OF CHOLINERGIC AGENTS ON RETINAL FIELD POTENTIALS IN NECTURUS. Steven Grant. Dept. Psych., Univ. of Georgia, Athens, GA 30602.

The effects of acetylcholine (ACh), eserine, nicotine, oxotremorine, atropine, and mecamylamine (0.25-10mM) were examined in the perfused mudpuppy eyecup. None of the agents abolished the ERG a-wave. ACh produced a reduction of all of the potentials; however, the b-wave and M-wave were abolished at lower concentrations than the PNR.

Eserine and nicotine enhanced the amplitudes of all of the potentials. Oxotremorine enhanced the PNR, reduced the M-wave, and had a weak and variable effect of the b-wave.

Atropine and mecamylamine reduced the b-wave over all concentrations. At low levels of illumination, atropine enhanced the off-response of the ERG. The effects of atropine and mecamylamine on the PNR were biphasic at high concentrations (5-10mM): a short period of enhancement preceded the eventual abolishment of the PNR. At lower concentrations (0.5-1.0mM), only the enhancing action was observed. The M-wave was reduced or abolished at all concentrations.

In conclusion, there are either seperate nicotinic and muscarinic receptors in this retina, or there is a single type of receptor with mixed pharmacological properties.

2014 THE DISTRIBUTION AND SHAPES OF TECTAL CELLS PROJECTING TO THE NUCLEUS ISTHMI IN FROGS. Edward R. Gruberg*and Jerome Y. Lettvin* (Spon: S.A. Raymond). M.I.T., Cambridge, Ma 02139

The path that carries information from one eye to the ipsilateral tectum goes in this way: The optic nerve is connected to the neurons of the contralateral tectum. These neurons in turn project topographically to the nucleus isthmi (NI) ipsilateral to them and are its exclusive input. Finally, the neurons of NI send axons to the tectal lobe contralateral to them (as well as ipsilateral). The receptive fields of NI units have small and large centers. The small centers are about 3-5° in diameter, about the size of a type II optic nerve fiber. Their response is to much the same geometric features of stimulus as excite type II fibers. The large centers are variable, but about 7-10° minimum, and respond to much the same features as excite types III and IV optic nerve fibers. This responsiveness is in strong contrast to that of tectal cells which have much larger receptive fields, show far less vivacious response, adapt extremely rapidly to repeated stimuli, and are hard to describe in terms of characteristic stimuli. It appears, by recording, that the cell firing of tectal neurons is a subset of the axonal firing, so that soma spike information does not represent properly the tectal output.

To find the location of tectal neurons projecting to NI, horseradish peroxidase was injected into NI by ionotophoresis and stained with the benzidine blue reaction after 1,2 or 4 days survival. The somata lie almost exclusively below layer G of Potter, i.e., below the tectal layers containing optic nerve fibers. A majority of the stained cells were in layer 6, while others were scattered through deeper layers. Many cells were colored throughout the extent of their dendrites into the fine rami, giving the appearance of a Golgi stain. Every type of cell previously described for frog tectum was seen, including ganglionic, pyramidal and bipolar varieties. Most common were cells in layer 6, of pyramidal type with a stout, unbranched apical dendrite of constant diameter extending up to layer A, to terminate there in a tight bush.

2015 ANATOMY AND PHYSIOLOGY OF OCULAR DOMINANCE IN THE STRIATE CORTEX OF MONOCULARLY DEPRIVED MACACA NEMESTRINA MONKEYS REARED WITH AND WITHOUT RETINAL LESIONS. Anita Hendrickson, James R. Wilson and John Boles. Dept. Ophthal., Univ. Washington, Seattle, WA 98195.

Ten monkeys were deprived of binocular vision by suturing shut the lids of one eye (EYE 1) prior to the 24th postnatal day. Between 10 & 12 mo of age EYE 1 was opened and EYE 2 closed (reverse suture) in all animals. The Early Lesion (EL,n=2) group had the central 10^{o} of EYE 2 retina ablated when EYE 1 was closed. Late Lesion (LL,n=4) animals had the same retinal lesion but at the time of reverse suture. No Lesion (NL,n=4) animals had only the initial and reverse sutures. At 6-12 mo after reverse suture the distribution and size of ocular dominance columns (ODC) in striate cortex was studied anatomically and electrophysiologically.

Electrophysiology was done in nitrous oxide anesthetized, paralyzed monkeys using standard techniques. Tungsten microelectrodes were passed tangentially to the cortical surface and the ocular dominance and orientation specificity of some single units and all multiunit background activity was determined. In all animals the deprived eye drove some cortical units. NL cortex showed an ODC repeat in layer IV of 350uEYE2/150uEYE1, but above or below IV only a few units and no background was driven by EYE 1. EYE 1 of EL drove the cells encountered in central cortex, but most were abnormal and often were widely separated ; no ODC could be found in IV. In peripheral cortex of EL, EYE 2 was dominant with recordings resembling NL animals.

The anatomy of ODC was studied using either transynaptic autoradiography (TrAr) after H^{3} proline&fucose injection into one eye which labeled dorsal lateral geniculate terminals in layer IV or C^{14}-deoxyglucose (dG) tracing after stimulation of EYE 1 which marks "active" ODC in all striate layers. TrAr in the NL group showed narrow ODC from EYE 1 and wide ODC from EYE 2; the dG activity from NL-EYE 1 was very light but some faint ODC extended from I to VI. The EL group after TrAr from EYE 1 showed clear narrowed ODC in peripheral cortex while central cortex had continuous label in IV; dG label from NL-EYE 1 had faint ODC in peripheral cortex but well labeled ODC from I to VI (1000u repeat) with a continuous label in IVC in central cortex. The LL-dG animal showed good labeling of ODC driven from EYE 1 in both central and peripheral cortex with central slightly more active than peripheral cortex.

We conclude that removing the EYE 2 central retina either during or after the critical period restores some functional capacity to central striate cortex as judged by both electrophysiology and dG marking. This effect seems to be due to changes above and below layer IV rather than within IV itself. Supported by EY01208, EY07013, RR00166 and RCDA EY39039 to A.H.

2016 MULTIPLICATIVE INTERACTION OF AFFERENT INFORMATION AT THE RETINO-GENICULATE SYNAPSE. R. Hess and B.B. Lee. Dept. of Neurobiology, Max-Planck-Institute for Biophysical Chemistry, P.O. Box 968, D-3400 Göttingen, GFR

Responses of retinal ganglion cells and of neurones in the lateral geniculate nucleus (LGN) of the cat to the velocity of moving visual stimuli were recorded with microelectrodes. The relationship between average response frequency and stimulus velocity were adequately described by power functions, and the slopes of the regression lines were extracted as characterizing parameter.

In the retina, the slopes varied between 0.2 and 0.55, with maxima for X-cells of 0.25-0.3, and for Y-cells of 0.35-0.4. In the LGN, the variability was larger ranging from 0.15 to 1.0. The maximum of the distribution was between 0.45 and 0.5. The difference of the slope distributions was significant at the 0.01 level. This average shift of the slopes indicates multiplicative interaction of inputs at the geniculate level.

The slopes found most frequently in X- and Y-cells in the retina occur relatively frequently in the distribution of slopes for LGN-neurones, and there is a conspicuously frequent occurence in the LGN of twice the slope of retinal Y-cells. This may indicate that in these cases there is a direct 1:1 transmission or a 2:1 excitatory convergence with multiplicative interaction. For the majority of cases, however, it seems more likely that the multiplication of the input functions is achieved through the lateral inhibitory network of the LGN. Further experiments to clarify the nature of this multiplicative interaction are in progress.

2017 LAMINAR ORIGINS OF TWO DESCENDING PATHWAYS FROM THE SUPERIOR COLLICULUS IN THE GREY SQUIRREL (Sciurus carolinensis). Virginia Holcombe* and William C. Hall. Departments of Anatomy and Psychology, Duke University, Durham, N.C. 27710.

While the superior colliculus is known to project to a variety of structures in the lower brainstem, the laminar distribution of the cells which project to these structures is not known. The goal of our experiments is to determine the distribution of these cells by labeling them with retrogradely transported horseradish peroxidase (HRP).

HRP (30% in saline) was injected electrophoretically into two major pathways from the superior colliculus: the predorsal bundle and the ipsilateral tectobulbar pathway. After survival times ranging from 24 to 48 hours, the brains were fixed by aldehyde perfusion, frozen-sectioned at 48μm, and processed according to modified LaVail and LaVail (DAB) and/or Mesulam (BDHC) protocols.

Following midline injections of HRP into the predorsal bundle as it crosses in the dorsal tegmental decussation, cells containing reaction product were found bilaterally in the superior colliculus. The vast majority of labeled cells (95%) were in stratum griseum intermediale while only a few scattered labeled cells (3%) were present in stratum griseum profundum.

Very small unilateral injections restricted to the target of the predorsal bundle in the medial reticular formation of the mid-pons resulted in labeled cells located predominantly (85-100%) in the contralateral superior colliculus. Once again, most of these cells (83-88%) were located in stratum griseum intermediale.

In contrast, an injection into the lateral reticular formation of the mid-pons resulted in labeled cells located predominantly (82%) in the ipsilateral superior colliculus. Most of these cells (86%) were located in stratum griseum profundum while only a few cells (3%) were present in stratum griseum intermediale.

We conclude from these experiments that the majority of axons in the predorsal bundle arise from cells located in stratum griseum intermediale of the contralateral superior colliculus, whereas the majority of axons in the ipsilateral tectobulbar pathway arise in the stratum griseum profundum. (Supported by NIH grant #NS-09623 and NIMH RSDA #MH-25734).

2018 DISTRIBUTION OF INPUTS FROM THE TWO EYES TO STRIATE CORTEX OF SQUIRREL MONKEYS D.H. Hubel and T.N. Wiesel. Department of Neurobiology, Harvard Medical School, Boston, Massachusetts 02115

In the macaque monkey the striate cortex is subdivided into well defined ocular dominance slabs, and input to layer IV c is correspondingly segregated into alternating left-eye and right-eye stripes. A similar segregation has recently been reported in the spider monkey (Florence and Casagrande, ARVO Abstracts, Inv. Ophthal. & Vis. Sci. suppl. April 1978, p. 291). In the squirrel monkey, following an injection of tritiated amino acid into one eye, the transneuronally transported label as seen in autoradiographs is distributed not in discrete stripes along IV c but uniformly (Hubel, Wiesel and LeVay 1976 Cold Spring Harbor Symp. XL, pp. 581-589); this has since been confirmed in several other laboratories. On searching carefully, however, one can see some suggestion of mild periodic variations in density of label, especially in the upper part of layer IV c (IV c α). Opposite the more densely labelled regions we found faint aggregations of label situated above the upper tier of label in IV a, occupying much of layer III.

In the squirrel monkey the lateral geniculate layers are less clearly demarcated than in old-world monkeys. There is thus a greater risk that label may diffuse from the layers corresponding to the injected eye to the other layers; this could tend to produce an apparent blurring of any segregation of left-eye and right-eye regions in the cortex. To check the autoradiographic findings we recorded responses in area 17 of several squirrel monkeys, in oblique and tangential microelectrode penetrations. Compared with macaque monkeys, squirrel monkeys indeed showed much less segregation of inputs from the two eyes. The upper layers had fewer monocular cells and more cells that could be driven about equally from the two eyes (dominance groups 3-5). As in the macaque, cells of layer IV c of squirrel monkey were difficult to resolve and there was no obvious orientation selectivity. In the macaque, multiunit activity at any point along IV c is almost entirely influenced from one eye, with abrupt alternations from one eye to the other roughly every 400 μm. In the squirrel monkey there was input from both eyes along the entire length of IV c that we explored except for occasional small patches with monocular input. Nevertheless both in IV c and in the upper layers there was a periodic fluctuation in dominance from one eye to the other at intervals of about 250 μm. The squirrel monkey thus seems to have ocular dominance columns, though they are probably narrower and certainly less well defined than those of the adult macaque.

2019 PATTERNS OF RETINAL TERMINATIONS AND LAMINAR ORGANIZATION IN THE LATERAL GENICULATE NUCLEUS OF PRIMATES. M.F. Huerta, J.H. Kaas, J.T. Weber and J.K. Harting. Dept. Anat., Univ. of Wisconsin, Madison, WI 53706 and Dept. Psychology, Vanderbilt Univ., Nashville, TN 37240.

Autoradiographic tracing procedures have been used to study the organization of retinogeniculate axons in seven primates, i.e. four species of New World monkeys, one species of Old World monkeys and two species of prosimians. These data suggest that the basic primate pattern of geniculate lamination consists of two parvocellular layers, two magnocellular layers, and two poorly developed, and highly variable, ventrally located superficial (S) layers. Ocular input to each member of the three pairs differs. In the macaque, the squirrel, and the saki monkey, the parvocellular layers subdivide and interdigitate into four leaflets so as to give the appearance of four parvocellular "layers". These leaflets are much less extensive in owl monkeys and marmosets. In some individual macaque monkeys there is further splitting of the parvocellular leaflets into subleaflets, giving the appearance of six parvocellular "layers" within this portion of the nucleus. The prosimians, galago and slow loris, have two additional layers that are not found in pithecoid primates, and only one superficial S layer is apparent. The additional layers are termed "koniocellular" since they consist of very small cells. Finally, New and Old World monkeys have both ipsilateral and contralateral retinal input to the interlaminar zones.

We conclude that the basic pattern of lateral geniculate organization is six layers, but not the traditional six. Prosimians have evolved two additional layers, the koniocellular layers, and have possibly lost one superficial layer. Both New World and Old World monkeys have elaborated the parvocellular layers by forming leaflets to varying extents. With the possible exception of the single S layer in prosimians, layers form pairs that are similar in cell types, but different in ocular input.

2020 MAPPING THE PRIMATE VISUAL SYSTEM WITH THE [^{14}C] 2-DEOXYGLUCOSE TECHNIQUE. C. D. Jarvis, M. Mishkin, M. Shinohara*, O. Sakurada*, M. Miyaoka* and C. Kennedy. NIMH, Bethesda, Maryland 20014.

Converging evidence from studies of lesion effects, anatomy, and single units indicates that, in the primate, the system for processing visual stimuli extends beyond the striate cortex to include the circumstriate and inferior temporal areas. From the inferior temporal area, in turn, visual information appears to be transmitted to subcortical structures in the temporal lobe. We attempted to map this functional system by means of the 2-deoxyglucose technique, an autoradiographic method for measuring local cerebral glucose utilization (Kennedy et. al., Science 187: 850, 1975). To achieve this, we prepared monkeys with a unilateral optic tract section combined with section of the forebrain commissures, thus visually deafferenting one hemisphere while leaving the other intact. This made it possible to compare values for local glucose utilization in a "seeing" and a "blind" hemisphere within the same animal, and thereby map the visually related areas. The studies were carried out in awake monkeys presented with visual patterns either in a rotating drum or in a discrimination apparatus. In the latter case, the animal performed the discrimination for water reward using the hand opposite the blind hemisphere.

In both situations, reduced glucose utilization in the blind as compared with the seeing hemisphere was seen cortically not only in the geniculostriate system, but throughout the entire expanse of circumstriate and inferior temporal cortex as far forward as the temporal pole. The functionally depressed zone included tissue adjacent to the inferior temporal cortex in the upper bank of the superior temporal sulcus and in the fusiform and perirhinal areas. Subcortically in the temporal lobe, side-to-side differences were seen in lateral and dorsal amygdala, ventral putamen, ventral claustrum, and tail of caudate. Outside this stimulus-processing system and its subcortical projections, asymmetries were also seen in the superior colliculus, inferior and lateral divisions of the pulvinar, and lower bank of intraparietal sulcus and exposed surface of the inferior parietal lobule. Performance on the discrimination task led to an asymmetrical increase of glucose utilization in structures associated with the active hand and to a symmetrical increase in structures associated with the act of drinking: within the visually related areas, however, the effects of the two different testing situations were substantially the same.

The results not only provide striking confirmation of an occipitotemporal stimulus-processing system, but also help to reveal its full extent and to localize its points of contact with the limbic and striatal systems.

2021 VISUAL FIELD DEFECTS AND MORPHOLOGICAL CHANGES RESULTING FROM MONOCULAR DEPRIVATION IN PROSIMIAN PRIMATES. Rhawn Joseph* and V. A. Casagrande (SPON: Oakley Ray). Departments of Psychology and Anatomy, Vanderbilt University, Nashville, TN. 37232

One normal galago senegalensis and 10 galago crassicaudatus, 7 of which were reared with monocular lid suture, served as either anatomical and/or behavioral subjects. We examined the visual field of 8 monocularly deprived and 2 normally reared subjects using a perimetry technique previously described (Sherman, Brain Res. 49: 25, 1973). When tested with the left (non-deprived) eye, all subjects exhibited 135° of vision, i.e., from 90° into the ipsilateral hemifield to 45° into the contralateral hemifield. When tested with the right (deprived) eye alone, the deprived subjects responded initially as if blind. After 1 week deprived subjects began to respond to stimuli presented from 45° - 60° within the ipsilateral monocular segment. Over the next 1 - 2 months, the vision in the deprived eye increased to 30° - 90° and stabilized. Thus, with the exception of the monocular-binocular borders, vision remained restricted to the monocular segment. With both eyes open the deprived and normal subjects responded to stimuli over the entire 180° of the visual field. Surprisingly, it was found that when stimuli were introduced simultaneously into both monocular segments at equal distance from each eye, 75% - 85% of the responses of deprived subjects favored the deprived right eye, whereas the responses of the 2 normal subjects favored both eyes about equally.

After testing was completed, 4 of the deprived behavioral galagos and 3 normally reared animals received an eye injection of ^{3}H proline. After survival periods of 2 days to 2 weeks the animals were sacrificed, their brains cut, and alternate sections through the lateral geniculate nucleus processed for autoradiography. This procedure aided in laminar and monocular segment identification of adjacent nissl-stained sections. One hundred-fifty cells from the binocular region of each LGN (25 cells per layer) and 25 cells from each monocular segment were measured according to previously described criteria (Guillery & Stelzner, J. Comp. Neur. 139: 413, 1970). Consistent with our earlier experiments (Casagrande et al., Soc. Neuroscience, III: 555, 1977) we found that mean cell areas in both the deprived binocular (except laminae 5) and monocular segments were significantly smaller than their non-deprived counterparts ($p<.001$), with the greater net change occurring in the binocular segment. As in cats (Sherman, '70), we conclude that the main effect of monocular deprivation can best be explained by some form of binocular competition.

(Supported by Grants EY 01778 and 1 K07 EY0061 from the National Eye Institute.)

2022 PROJECTION OF THE RETINA TO THE LATERAL GENICULATE NUCLEUS IN THE CAT FOLLOWING NEONATAL ABLATION OF VISUAL CORTEX. R.E. Kalil. Dept. Anat., Univ. Wis., Madison, Wis. 53706.

When visual cortex is damaged in the newborn cat, severe retrograde cell degeneration takes place in the dorsal lateral geniculate nucleus(LGN) within a few days. Despite the cell death which ensues, the basic laminar organization of the LGN is maintained, and many neurons survive in the nucleus. In particular, large isolated neurons can be seen scattered throughout laminae A and A1, and they are especially prominent ventral to A1 in the region of the C laminae.

Retrograde degeneration is not confined to the LGN, but also occurs transsynaptically in the retina. Thus in the ipsilateral temporal and contralateral nasal hemiretinae there is a marked loss of ganglion cells, especially those which are small and medium sized.

To study the projection of the retina to the LGN in cats that had received unilateral visual cortex damage on the day of birth, Fink-Heimer and autoradiographic methods for tracing axonal pathways were employed. Six months to 1 year after visual cortex removal, the cats were enucleated or injected intraocularly with tritium labelled proline. Following survival periods of 7 to 14 days, the animals were perfused with 10% formol-saline and frozen sections through the LGN were stained for degenerating axons or prepared as autoradiographs.

In the silver stained material, axonal debris in the LGN ipsilateral to the early visual cortex lesion is very dense, but does not show the clear organization of the normal retinogeniculate projection. Thus in the contralateral LGN degenerating optic axons tend to run along the lines of projection, but in the degenerate LGN axons from the retina form a feltwork which is largely disorganized, and contains many fibers which cross the lines of projection. In the autoradiographs, the normal retinogeniculate projection is characterized by an even distribution of silver grains in the appropriate lamina. By contrast, the projection to the degenerate LGN is marked by patches of label indicating a nonuniform pattern of innervation.

Taken together these results indicate that ganglion cells in the retina maintain a projection to the degenerate LGN. Although the projection is massive, it lacks the orderly arrangement of the normal retinogeniculate pathway, and suggests that axons from spared retinal ganglion cells may converge on surviving lateral geniculate neurons.

(Supported by N.I.H. grant EYO 1331)

2023 TRANSIENT RESPONSE ENHANCEMENT IN MUDPUPPY RETINA. Chester J. Karwoski and Luis M. Proenza. Dept. of Psychology, Univ. Georgia, Athens, GA 30602

A variety of responses in the retina of normal mudpuppy eyecup preparations show a transient response enhancement effect (TRE): that is, when series of small flashed spots are alternated with series of large flashed spots, the first small spot response following the large spot sequence is greater than the preceding small spot responses. TRE is strong in the proximal negative response and M-wave, the proximal K^{+}-increase, Müller cell responses obtained in the proximal retina, spike responses of OFF and ON/OFF ganglion cells, and intracellular responses of hyperpolarizing on/off neurons. TRE is weak or absent in responses of horizontal and bipolar cells, spike responses of ON ganglion cells, and the b-wave.

Psychophysically, it is known that threshold for detection of a small, centered, flashed spot is lower for up to several seconds after offset of a large adapting field, than after offset of a small adapting field (Teller et al, Vision Res., 11: 1445, 1971). The results presented here suggest that this phenomenon may have a component of retinal origin and that, like Werblin's windmill effect, it may arise from interactions in the proximal retina.

Supported by NIH Grant EY-00973 to LMP.

2024 A BEHAVIORAL ANALYSIS OF THREE VISUAL SYSTEMS IN THE LESSER BUSHBABY (GALAGO SENEGALENSIS). William Keys* (SPON: M. Wilson). Univ. Connecticut, Dept. Psych. U-20, Storrs, CT 06268.

Three regions of the bushbaby's visual cortex receive nonoverlapping projections from three thalamic nuclei which in turn receive different kinds of visual afferents (Glendenning, Hall, Diamond, and Hall, 1975). Earlier evidence has suggested that the geniculostriate, tectopulvinar-middle temporal area (MT) and superior pulvinar-extrastriate systems function in different ways, and resemble higher primates' systems for stimulus-feature analysis, visuospatial localization and visual learning, respectively.

In order to determine the degree to which these anatomically discrete systems are functionally independent, 12 bushbabies were divided equally among one normal control and three operated groups having bilateral cortical lesions in area 17 (S), MT, or areas 18 and 19 (XS). The performance of these groups on three tasks emphasizing different aspects of visual behavior was then measured for 9 months postoperatively. The first task consisted of a series of stripe orientation and size discriminations and provided measures of simple discrimination learning and sensory capacity. The second task required an animal to enter a tunnel and move to a goal box whose position in both horizontal and vertical planes was changed from trial to trial. This provided a measure of visuospatial behavior. The final task consisted of a series of stripe orientation discrimination reversals which tested the ability to learn complex visual tasks. Histological analyses were performed on all brains at the end of behavioral testing.

Group S showed major deficits in complex visual learning, yet was unimpaired in learning a simple visual discrimination and showed no long-lasting deficits in visuospatial localization. Group MT was impaired on all three visual problems, but had the most difficulty with the tasks requiring visuospatial localization and complex learning. Group XS was also impaired in the three tasks but showed less severe deficits in visual learning and sensory capacity than Group MT.

These results suggest that each of the three thalamocortical visual systems of the bushbaby play a major role in the mediation of different aspects of visual behavior. The geniculostriate system may function as a major source of visual information for advanced analyses in extrastriate cortices, while the tectopulvinar-middle temporal and superior pulvinar-extrastriate systems are important in both visual learning and visuospatial analyses.

2025 DEVELOPMENT OF KITTEN EYES AFTER MONOCULAR VISUAL DEPRIVATION: MYOPIC OR NOT? Albert W. Kirby and Harold Weiss*. Ophthalmology Dept., Kresge Eye Institute, Wayne State Univ. School of Medicine, Detroit, Michigan.

The effect of monocular deprivation on the central visual system of young cats and monkeys is well known, however the development of the non-neural elements is reportedly quite different. Wiesel & Raviola (1977) reported that neonatal lid fusion in the rhesus monkey resulted in considerable changes in the development of the sutured eye. Among those was elongation of up to 21% with resulting axial myopia (-13.5 diopters). Gollender et.al. (1976) reported that in the cat the eyes develop normally following lid suture with no axial elongation.

We followed the growth of the eyes on kittens whose eyes were sutured either before or just entering the critical period. A-scan ultra-sonography revealed a difference in axial length between the sutured and normal eye on each animal with the sutured eye ranging from 1.5 - 2.0 mm longer in the adult. Although the axial length of the deprived eye was greater, the eye was not myopic. In fact, the sutured eye was often hyperopic.

While the kitten study was in progress, we obtained a 4 month old rhesus monkey and immediately sutured one eye closed. Since our cat data was apparently differing from earlier reports, we wanted to use the monkey as a control and see if it also differed. Although the lid closure was not complete and the monkey was somewhat advanced in age at the time of suture, the partially deprived eye was 1.5 mm longer than the control in the adult and was in fact myopic (-3.5 diopters). Development of the deprived monkey eye therefore was in agreement with the report of Wiesel & Raviola.

To determine why the sutured eye of the cat was not myopic even though its axial length was greater than the control eye, keratometry was done to determine the refractive power of the cornea. It was found that the sutured eye in the cat had less refractive power in its cornea than the control eye. Our results indicate that the cornea of the sutured eye in the cat compensates for the increase in axial length so the eye does not become myopic. We do not know the mechanism for eye elongation in either the cat or the monkey or why the cornea apparently compensates for axial length differences in the cat.

2026 GOLGI STUDY OF THE TREE SHREW SUPERIOR COLLICULUS. Thomas P. Langer* and Thomas T. Norton, Dept. of Psychol., MIT, Cambridge, MA 02139 and Dept. of Psychol., Duke Univ., Durham, NC 27706.

The marked lamination and comparatively large volume of the tree shrew superior colliculus suggest that its neuronal elements may be well differentiated, strictly organized, and possibly specialized. Therefore, it is of interest to compare its detailed anatomy with that of other, apparently less differentiated, colliculi.

Neuron profiles were collected from a series of tree shrew superior colliculi stained by the Golgi-Rapid or Golgi-Kopsch methods, sectioned either transversely or parasagittally.

The tree shrew superior colliculus has a variety of well differentiated cell types in each of the broad classes of neurons characteristic of the superior colliculus. The cells of the various types appear to be confined to definite laminae.

Based on the Golgi impregnated profiles, the tree shrew superior colliculus is divisible into a superficial and a deep division, with a transitional region in the stratum opticum. The superficial division is characterized by a preponderance of neurons with their dendritic fields elongated or eccentric about the cell body while the neurons of the deep division are predominantly stellate cells.

The superficial division may be partitioned into at least three subdivisions. The superficial subdivision (0-250 μ below the surface) has marginal cells in its zonal portion, horizontal cells throughout and piriform cells along its deep margin. The middle subdivision (250-600 μ) contains predominantly narrow field vertical cells of a number of varieties along with wide field vertical cells in its deep portion. The deep subdivision (600-900 μ) contains a mixture of narrow field vertical cells and stellate cells with occasional wide field vertical cells.

The deep division may be resolved into several subdivisions based upon the cell types seen, but the cells throughout this region are predominantly small and intermediate sized stellate cells with thin, smooth dendrites which branch sparsely. Large spiny, densely arborized neurons and massive stellate cells occur in characteristic patterns in the superficial and deep portions of the deep division.

Comparison of the neurons in the tree shrew superior colliculus with data from other studies indicate that the tree shrew colliculus is probably more differentiated in that it contains a broader spectrum of well defined cell types somewhat more strictly ordered than is generally observed. At the same time its basic organization is the same as occurs in other superior colliculi.

2027 PHASE RELATIONSHIPS OF RESPONSES TO MOVING SINUSOIDAL GRATINGS OF SIMPLE CELLS IN CAT STRIATE CORTEX B.B.Lee, A.Elepfandt†, and V.Virsu.‡ Max Planck Institute for Biophysical Chemistry, D-3400 Göttingen, FRG

Sinusoidal gratings have often been used for the determination of the modulation transfer function and visual acuity of single cells in the cat visual system but little attention has been paid to phase relationships of responses in relation to receptive field location. We have studied these relationships by placing a photocell near a cell's receptive field and by recording unit responses in relation to photocell readings at various spatial and temporal frequencies and directions of movement. An estimate of the phase relation of the cell's response could then be made independent of photocell position. We have shown elsewhere (Lee, Elepfandt & Virsu, ENA meeting 1978) that retinal ganglion cell and lateral geniculate nucleus (LGN) neurone responses have the same phase relation to moving gratings irrespective of spatial frequency except for some deviations at low spatial frequencies in some LGN neurones. For on- and off-centre cells response peaks were about 40 to 50° ahead of the maximum and minimum luminances in the grating respectively (when latency is taken into account). We report here the application of this technique to simple cells in the striate cortex. Most simple cells show about the same phase relation to moving gratings irrespective of spatial frequency and could be divided into two groups responding 130° out of phase with one another. The one group displayed behaviour consistent with input from on-centre LGN neurones, the other with input from off-centre LGN neurones. This is consistent with the hypothesis that most simple cells receive input predominantly from on- or off-centre LGN neurones.

2028 SPATIAL AND TEMPORAL CONTRAST SENSITIVITY FUNCTIONS OF DORSAL LATERAL GENICULATE CELLS IN CATS RAISED WITH MONOCULAR LID SUTURE. Stephen Lehmkuhle*, Kenneth E. Kratz, Stuart C. Mangel*, and S. Murray Sherman. Dept. Physiol., Sch. Med., UVA, Charlottesville, VA 22901.

After neonate monocular lid-suture, the proportion of functional Y-cells in the cat's dorsal lateral geniculate nucleus appears dramatically reduced from normal. However, no effects of lid-suture have been reported for X-cells. We re-evaluated this by plotting spatial and temporal contrast sensitivity functions (CSFs) of geniculate cells in normal and monocularly deprived cats. Conventional single unit, extracellular recording methods were applied. The eyes were refracted and provided with 3 mm diameter artificial pupils to optimize the optics. CSFs were obtained with counterphased, sine-wave gratings for which contrast, spatial frequency, and temporal frequency (counterphase rate) were independently varied. The stimuli were generated on an oscilloscope and had a mean luminance of 33 cd/m^2. The CSFs plot contrast threshold for evoked neuronal discharge as a function of spatial and/or temporal frequency. Data were taken only from laminae A and A1 representing the central 25° of visual field.

No differences for X-cells were found among normal and non-deprived laminae A and A1; likewise, effects in deprived laminae A and A1 seemed identical. We found a significant reduction in spatial resolution of deprived X-cells (i.e., in deprived laminae). Whereas the highest spatial frequency which evoked responses from normal and nondeprived X-cells (at a contrast of 0.60) had a mean of 2.6 c/deg, the value for deprived X-cells was only 1.4 c/deg ($p<0.001$ on a Mann-Whitney U-test). At lower spatial frequencies, however, the CSFs of deprived X-cells were normal. For instance, at lower spatial frequencies, deprived, normal and nondeprived X-cells displayed equal sensitivity, and they all showed equivalent low frequency attenuation in contrast sensitivity. Although deficits appeared in spatial CSFs, the temporal CSFs of deprived X-cells seemed normal at spatial frequencies for which the cells were maximally sensitive.

As expected, few deprived Y-cells were found, but their CSFs were not obviously abnormal.

These data indicate that both X- and Y-cells are affected in deprived geniculate laminae, but that the effect on X-cells seems much less severe. Whereas few normal Y-cells can be found in deprived laminae, deprived X-cells seem to suffer only a reduction in sensitivity to high spatial frequencies.

2029 BEHAVIORAL DEMONSTRATION OF McCOLLOUGH EFFECT IN THE MONKEY.

William M. Maguire*, Glenn E. Meyer*, and Joan S. Baizer, Division of Neurobiology, Department of Physiology, School of Medicine, SUNY/BUFFALO.

In 1965 McCollough showed that if observers are exposed to red vertical stripes and green horizontal stripes, subsequently viewed white vertical stripes will appear greenish, and white horizontal stripes pinkish. The "McCollough Effect" is thus an aftereffect dependent on both color and orientation of the adapting stimuli.

There has been considerable speculation about the neural basis of this aftereffect. The most popular hypothesis is still that suggested by McCollough, that long term adaptation of cortical cells tuned for both color and orientation gives rise to the phenomenon. Cells tuned for orientation and color have been described in monkey striate cortex (Hubel and Wiesel, 1968). In order to test the hypothesis that changes in cells studied in monkey underlie a perceptual effect studied, until now, only in man, it is important to demonstrate that monkeys, like man, experience a McCollough effect.

We have obtained evidence that the monkey does show a McCollough effect. Monkeys were adapted by requiring them to fixate a spot moving slowly across alternating horizontal and vertical gratings of complementary color. Following adaptation a test grating whose color changed from red to green or green to red was presented. Animals were trained to release a response lever during the interval that the grating was white. After adaptation, there were orientation specific changes in the monkeys' responses as would be predicted if the animals were experiencing a McCollough effect. This work was supported by NIH grants 5 T32 EY 07019-03 and 1 R01 EY 02230-01 and NIH grant 5 SO7 RR 05400-16.

2030 CONTRIBUTIONS OF INDIVIDUAL LATERAL GENICULATE LAMINAE TO SINGLE CELL ACTIVITY IN THE CORTEX OF THE RHESUS MONKEY. Joseph G. Malpeli, Peter H. Schiller* and Stanley J. Schein. Dept. Psychol., M.I.T., Cambridge, MA 02139.

In this study we have made use of a technique of selective inactivation of precisely localized regions of brain tissue by means of microinjections of the local anesthetic lidocaine. Injections were made through a micropipette onto which had been plated a platinum recording surface for monitoring the extent and duration of the block. Injections of 20 nanoliters of 2% lidocaine into the lateral geniculate nucleus (LGN) reversibly inactivate a region approximately 300 microns in diameter for 3 to 8 minutes. By precise retinotopic alignment of an injection site in the LGN with a recording site in the visual cortex it was possible to block the input from a single LGN layer to cortex. Previous work has shown that parvocellular layers (3-6) are comprised mainly of color-opponent cells, while the magnocellular layers (1 and 2) are made up of broad-band cells. We have studied the effects of inactivation in a magnocellular layer (1), a parvocellular layer (4 or 6) and combined inactivations in magnocellular and parvocellular layers (1 and 6) on the visually driven activity of single cells in the parafoveal region of the monkey striate cortex. Control experiments demonstrated that the injections were restricted to the target lamina and did not interrupt retinal or geniculo-cortical fibers for the retinotopically corresponding parts of other laminae. The results are as follows:

1. Simple cells with a single edge subfield (S_1 cells of Schiller et al. J. Neurophysiol., 39:1281-1374, 1976) depend either on magnocellular input alone, or on parvocellular input alone.

2. Some complex cells are driven exclusively by either parvocellular or magnocellular input, while others receive excitatory input from both kinds of layers.

3. The effects of blocking individual parvocellular layers on the responses evoked by light and dark edges support the view that the upper and lower pairs of parvocellular laminae consist mainly of ON- and OFF-center cells, respectively.

Our results do not support the idea that some classes of LGN cells drive simple cells while other classes drive complex cells. We have seen no evidence that magnocellular input contributes selectively to orientation or direction specificity. (Supported by NSF grant #BNS76-82543, NIH grants #5 R01 EY00676 and NS05477-01A1, and NINCDS grant #5 P01 12336-03.)

2031 SPATIAL AND TEMPORAL CONTRAST SENSITIVITY OF X- AND Y-CELLS IN THE LATERAL GENICULATE NUCLEUS OF CATS. Stuart C. Mangel*, Kenneth E. Kratz, Stephen Lehmkuhle*, and S. Murray Sherman. Dept. Physiol., Sch. Med., UVA, Charlottesville, VA 22901.

We plotted the spatial and temporal contrast sensitivity functions (CSFs) for individual X- and Y-cells in the cat lateral geniculate nucleus. Standard single unit, extracellular recording techniques were used. The optics were optimized by refracting the eyes and providing them with 3 mm diameter artificial pupils. CSFs were derived with counterphased, sine-wave gratings for which contrast, spatial frequency, and temporal frequency (counterphase rate) were independently varied. The stimuli were generated on an oscilloscope and had a mean luminance of 33 cd/m^2. The CSFs represent contrast threshold for evoked neuronal discharge as a function of spatial or temporal frequency. Spatial CSFs were taken at a temporal frequency of 2 Hz, and temporal CSFs were taken at the spatial frequencies for which the cells were most sensitive. Data were limited to laminae A and A1 representing the central 25° of visual field.

Three differences between X- and Y-cells were seen in the spatial CSFs. First, at a contrast of 0.60, X-cells tended to respond to slightly higher frequencies than did Y-cells. The highest spatial frequencies to which X-cells responded ranged from 1.0-5.5 c/deg; for Y-cells, from 0.6-4.5 c/deg. Second, X-cells showed decreased sensitivity to low spatial frequencies whereas Y-cells did not. Finally, the receptive field center diameter of X-cells, as determined by hand plotting, was negatively correlated with the highest spatial frequency to which the cells responded. No such correlation was noted for Y-cells. Only one difference between X- and Y-cells was evident from the temporal CSFs. At 0.60 contrast, Y-cells clearly responded to higher temporal frequencies than did X-cells. The highest temporal frequencies to which Y-cells responded ranged from 10-27 Hz; for X-cells, from 3-18 Hz. Also, neither X- nor Y-cells displayed decreased sensitivity at low temporal frequencies. These findings indicate that X-cells, compared to Y-cells, on average are more sensitive to higher spatial frequencies and less sensitive to higher temporal frequencies. However, considerable overlap between the X- and Y-cell populations was seen both for spatial and temporal parameters.

2032 **NEURAL MECHANISM OF ORIENTATION-SPECIFIC ADAPTATION IN PRIMATE VISION.** **R. J. W. Mansfield and John G. Daugman* Psychology Department, Harvard University, Cambridge, Mass. 02138**

A central problem in determining the neural bases of vision is that of characterizing the relevant population of neurons activated by a stimulus. Attempts to relate perceptual processes to neural events have frequently relied upon apparent trigger features of single neurons. The simplified concept of a trigger feature is difficult to reconcile, for example, with the broad pattern of activation evoked by an oriented visual target in Area 17 of the macaque monkey as revealed by 2-deoxyglucose localization (Hubel, Wiesel and Stryker, J. Comp. Neurol., 177, 361-380, 1978) or by single unit recording. On the other hand, by examining the population response profile, we have identified a candidate neural mechanism for the orientation channels defined psychophysically in human vision using pattern-specific adaptation.

In separate experiments but under similar stimulus conditions, both the receptive field characteristics of striate neurons in the macaque monkey and human performance were determined. High contrast grating targets under computer control were superimposed upon otherwise stabilized retinal images to produce adaptation. Our neurophysiological results suggest that (1) the majority of orientation-selective neurons in the supragranular layers (II-IVb) of striate cortex adapt to repeated stimulation; (2) in general the degree of adaptation decreased with increasing angular difference from the optimal orientation for the cell; (3) the decrement in discharge frequency during adaptation followed an exponential time course with a mean time constant on the order of 10 sec.

Our analysis focused on the supragranular layers as they are known to contain the efferent neurons that form the initial segment of the cortical pathway subserving fine pattern discrimination. Reconstruction of the activation pattern of the efferent neurons was accomplished by means of a mathematical model incorporating the distribution of orientation tuning curves convolved with the function describing the decrement induced by adaptation. Orientation channels, defined by the elevation in threshold produced by adaptation for probe stimuli spanning 180° centered about the orientation of the adapting grating, were measured in human observers. Threshold elevation was found to be proportional, to a first approximation, to the calculated decrement in neural activation produced by adaptation.

2033 ROLES OF CENTRAL STRIATE CORTEX IN FORM DISCRIMINATION. Ronald R. Marcotte* and Jeannette P. Ward. Dept. Psych., Memphis State Univ., Memphis, TN 38152.

Bushbabies (Galago senegalensis), trained on a form discrimination task in a two-choice apparatus prior to disruption of the central representations of vision in striate cortex, were found to be protected from postoperative deficit. All animals were found to be deficient on novel form discriminations following partial central striate lesions. Pre- and postoperative testing of these same subjects on discriminations of fine stripe patterns and of small food objects revealed no evidence of deterioration of epicritic visual capacities. It is suggested that preoperative training allows the assignment of behavioral significance to a stimulus such that, during postoperative testing, the remaining parts of the visual field are capable of mediating recognition of the preoperatively learned form item.

Thus, there seem to be two levels of functioning within the central visual pathways: on one level central vision is involved in the sensory processing and extraction of features from visual stimuli; on another level, central vision seems to have an important and a unique role in the assignment of meaning to novel form stimuli. In this study it was shown that stimuli which acquire behavioral significance prior to central field disruption are readily recognized postoperatively while discrimination of novel stimuli which have acquired no behavioral significance prior to central field disruption is impaired.

2034 AUTORADIOGRAPHIC LOCALIZATION OF ACETYLCHOLINE IN THE RABBIT RETINA. Richard H. Masland and John W. Mills*, Massachusetts General Hospital and Harvard Medical School, Boston MA 02114.

We have attempted to locate the sites at which the rabbit retina incorporates extracellular choline into acetylcholine (ACh), and to distinguish them from sites where choline serves primarily as a lipid precursor. All retinas were incubated in vitro for 15 min in a medium containing 0.3 μM 3H-choline. Some were then incubated for a subsequent 1 h under conditions that promote the release of 3H-ACh and 3H-choline (flashing light, 1 mM unlabeled choline). Others were incubated under ACh-protecting conditions (20 mM Mg++, 0.2 mM Ca++, 30 μM eserine, 1 mM unlabeled choline). Half of each retina was analyzed chemically. A small piece was fixed with osmium tetroxide. The remainder was frozen and processed dry for autoradiography. The first group of retinas was found to contain radioactivity almost exclusively in the lipid pathway (phosphorylcholine and phosphatidylcholine, 93%). Radioactivity of the second group was distributed between ACh (28%) and the lipid pathway (67%).

All retinas showed silver grains over the photoreceptors and faint labeling of most ganglion cells. Radioactivity at these sites survived fixation with aqueous osmium tetroxide. The photoreceptor outer segments were progressively more labeled as the duration of incubation increased. Apparently the photoreceptor and ganglion cells are distinguished by a relatively great synthesis of membrane phosphatidylcholine.

The retinas that contained ACh showed dense grains, superimposed on the background described above, in two bands over the inner plexiform layer and over a few somas located at both of its margins. That the radioactivity responsible for these grains represented ACh was confirmed by its loss from freeze-dried sections exposed to water or from tissue initially fixed with aqueous osmium tetroxide. It was further confirmed by direct chemical analysis of the 3H-compounds eluted from sections divided at the level of the outer plexiform layer under visual control: more than 96% of the retina's total 3H-ACh was found in the proximal half-retina.

These results indicate that the inner plexiform layer contains cholinergic synapses, a finding consistent with conclusions reached earlier on the basis of chemical and electrophysiological experiments (J. Neurophysiol. 39:1210-1235, 1976). The inner nuclear layer cells that contain ACh have the size and position of conventional amacrine cells. Those of the ganglion cell layer could be either ganglion cells or displaced amacrines. Assuming that ganglion cells make no retinal synapses, this suggests that the only neurons of the rabbit retina to release ACh are a small group of amacrine cells.

2035 TOWARD A FUNCTIONAL ARCHITECTURE OF THE RETINA. B.A. McGuire*, J.K. Stevens and P. Sterling. (SPON: P. Liebman). Dept. Anat., Sch. of Med., Univ. of Pa., Philadelphia, PA 19104.

At least 12 classes of ganglion cells, 12 classes of amacrines, and 5 classes of bipolars can be distinguished in mammalian retina, according to Cajal, based on differences in size and dendritic morphology. Each cellular layer can be viewed as a mosaic of repeating subunits in which every cell class is represented at least once. In order to visualize such a subunit it would be necessary to accurately classify a substantial number of adjacent cells. As a start, we reconstructed from electron micrographs of 150 serial sections portions of 15 ganglion cells and 30 amacrine cells in a small patch (50 μm x 15 μm) of cat retina located 1-2° from the area centralis. We distinguished 5 classes of ganglion cells by differences in cell volume, dendritic morphology and pattern of synaptic contacts:

(I) Large soma (>45x10^3 μm^3); several thick primary dendrites to inner 1/3 of inner plexiform layer (IPL) (near the ganglion cells); proximal dendrites receive contacts (1 cell).

(II) Medium soma (14-19x10^3 μm^3); one or more dendrites to middle 1/3 of IPL; distal branches receive contacts (2 cells).

(III) Medium soma 14x10^3 μm^3); single stout dendrite to outer 1/3 of IPL (near the amacrine cells); distal branches receive contacts (3 cells).

(IV) Small soma (2-5x10^3 μm^3); single dendrite to middle IPL; distal branches receive contacts (2 cells).

(V) Small soma (1-2x10^3 μm^3); single fine dendrite in inner 1/3 of IPL; proximal dendrite receives contacts (2 cells).

The ganglion cells segregated by soma volume into 3 groups, but the ratios of surface area to volume (a measure related to input resistance) distributed unimodally.

Four classes of amacrines were distinguished in a similar manner and certain classes of both ganglion and amacrine cells were represented more than once. We anticipate that reconstructing a larger area will reveal additional classes and additional sublayers of the IPL. This should clarify the dimensions and full composition of the subunit, as well as the synaptic interconnections within it. (supported by NIH EY00828)

2036 UNITARY W-CELL SYNAPTIC ACTIONS IN THE CAT'S SUPERIOR COLLICULUS: EXTRACELLULAR MANIFESTATIONS. James T. McIlwain. Neuroscience Section, Div. Biol. & Med., Brown University, Providence, RI 02912.

The bulk of the cat's retino-collicular projection crosses in the chiasm and terminates just beneath the stratum zonale in the superficial gray layer. In this region, extracellular microelectrodes recorded .1-1 mV negative waves, 5-8 ms in duration, commonly occurring .3-.5 ms after a small biphasic prepotential. The large negative waves, observed only in a narrow zone just beneath the stratum zonale, were named juxtazonal potentials or JZPs. JZPs and their prepotentials were evoked by light stimulation of the contralateral but not the ipsilateral retina. The underlying projection was highly ordered retinotopically. Stimuli moving faster than 10-15°/s were ineffective but stimuli moving less than 1°/s evoked vigorous responses. Electrical stimulation of the optic tract evoked JZPs and their prepotentials in an all-or-none fashion. Shocks of increasing intensity recruited discrete JZPs of different latencies which summed to form the large negative field potential characteristic of this region of the colliculus. Prepotentials were driven reliably by optic tract stimulation of 100 Hz, whereas such stimulation produced a rapid but reversible decline in JZP amplitude. There was only a weak temporal correlation between JZPs and cellular action potentials recorded concurrently, but optic tract stimulation evoked JZPs at the same time that deeper cells were excited by the direct W-cell pathway to the colliculus. Individual JZPs and their prepotentials also exhibited latencies typical of the direct W-cell projection. Optic tract fibers conducting at W-cell velocities were found to mediate the negative field potential produced by summated JZPs. Extensive chronic ablation of occipital cortex, including areas 17, 18 and 19, produced no detectable effects on JZPs and prepotentials recorded ipsilateral to the ablated cortex.

These results, together with available morphological evidence, support the hypothesis that the prepotential arises when an action potential invades the elaborate terminal spray of a single W-cell axon. Extracellular currents, resulting from the subsequent synchronous activation of multiple excitatory contacts, produce the JZP. (Supported by PHS NS 09997 and EY 02505)

2037 DEVELOPMENT AND DISTRIBUTION OF A GANGLION CELL SUBPOPULATION IN THE CHICK RETINA. Steven C. McLoon and W. Franklin Hughes*. Dept's. Ophthal. and Anat., Rush Medical School, Chicago, Il. 60612

Unilateral destruction of the primordial optic tectum in the chick embryo at three days of incubation results in degeneration of a majority (>60%) of the retinal ganglion cells in the contralateral eye. This degeneration occurs largely between the 11th and 14th days of incubation. Those residual cells in the ganglion cell layer which do not degenerate are the topic of this report. These cells were studied in retinal whole mounts and in material sectioned for light and electron microscopy. At 15 days of incubation they were arranged in lines having a radial orientation. By 17 days they were more dispersed and showed a regular distribution throughout the retina. Measurements of these cells revealed large and amsll-size classes but an absence of the medium-size cells which are also present in the normal retina. The large cells were confined to the more peripheral retina. The small cells, however, showed a regular distribution throughout the retina. The residual cells showed the characteristics of neurons, and it was presumed that they had sustaining connections in non-tectal areas. To test this hypothesis, the eyes contralateral to tectal lesions were injected with 3H-proline at 17 days, and the central projections mapped by autoradiography. These retinas from experimental eyes showed projections to the non-tectal nuclei comparable to those in normal animals, e.g. lateral anterior nucleus, nucleus externus, and the ectomammillary nucleus. These results demonstrate that at least some of the cells which remain in the ganglion cell layer following tectal ablation have sustaining connections in the brain. Several characteristics of these cells will be presented in regard to their production and distribution in the ganglion cell mosaic.

2038 AN INTERESTING SYSTEM OF SMOOTH ENDOPLASMIC RETICULUM (ER) IN ROD CELLS.
Arthur M. Mercurio* and Eric Holtzman. Department of Biological Sciences, Columbia University, N.Y., N.Y. 10027

An extensive system of organized smooth ER is located at the base of the ellipsoid in rod cells of the frog retina. This system consists of sacs and tubules with a moderately electron dense content. In serial sections, it shows direct continuities with rough ER. Often it is located close to the plasma membrane. The sacs and tubules form elaborate stacked arrays oriented, in different cells, either parallel or perpendicular to the long axis of the myoid. Vesicles and tubules, similar in morphology to elements of this system, are found throughout the ellipsoid region. They are particularly prevalent in the filament-rich peripheral zones and at the tip of the inner segment near the basal body. Initial EM autoradiographic experiments utilizing isolated retinas have demonstrated the incorporation of ^{3}H-leucine into this subellipsoid smooth ER. This occurs at about the same time label appears in the Golgi apparatus but well before the outer segment discs are labelled.

This smooth membrane system is separate from and distinct from the Golgi apparatus which is often close by. It does not stain for the Golgi marker enzyme, thiamine pyrophosphatase. It is also distinct from the smooth-surfaced sacs and tubules, probably smooth ER, found in the myoid near the nucleus, in terminals, and in rod axons. This latter membrane can bind Pb^{++} when incubated in the appropriate cytochemical medium, a property it shares with the synaptic vesicles, of which it may be a source. The subellipsoid system differs from the ER of the paraboloid regions, prominent in some cones, in appearance and by the fact that no glycogen granules are associated with it.

Given the location and extent of the subellipsoid system, the relatively large amount of membrane it contains, and the reported abilities of ER to transport proteins and synthesize lipids, we advance the possibility that this smooth ER plays a role in the biogenesis of outer segment membrane. (Electron micrographs of this system have been published in Holtzman et al, Cell Surface Reviews IV, p. 192 and will appear in Holtzman et al, Biomembranes 10.)

2039 NEUROTOXIC AMBLYOPIA IN THE MACAQUE. William H. Merigan. Dept. Rad. Biol. & Biophysics., Univ. Rochester Med. Ctr., Rochester, N. Y. 14642.

Two pigtail macaques were exposed to low levels of methylmercuric chloride for extended periods without developing obvious clinical symptoms. Previous studies in our laboratory have shown that the distinctive pattern of cell loss in the calcarine fissure of the visual cortex which results from such exposures is very similar to that found in human poisoning. Of the two monkeys, the one exposed to the higher dose of methylmercury (blood level = 3ppm, 300 days) developed the visual field constriction typical of human methylmercury poisoning. The sensitivity of this monkey to sine wave flicker (temporal MTF) was tested behaviorally at three adapting luminances several months after termination of the exposure. At high luminance, the high frequency limb of the temporal MTF was shifted about 1/2 octave toward lower frequencies. Low luminance sensitivity to flicker was profoundly reduced (over 1/2 log unit) at all rates of flicker. In the minimally poisoned monkey (blood levels = 2ppm 1000 days) the visual field appeared normal and flicker thresholds were identical to those of normal macaques.

This syndrome of visual changes in experimental methylmercury poisoning is consistent with an impairment of the peripheral visual field. The constricted visual field seen in perimetry is one index of peripheral impairment. Loss of peripheral vision should also degrade sensitivity to high luminance-high frequency flicker and low luminance flicker since the periphery is especially sensitive to these stimuli. Since these are the changes we find, it is likely that the residual flicker sensitivity reported here represents the sensitivity of the intact central region of the visual field.

DOE report No. UR-3490-1386, supported by grants ES-01248, and ES-01885.

2040 SYNAPTIC ORGANIZATION OF THE INNER RETINA BASED ON GANGLION CELL PSP ANALYSIS AND PHARMACOLOGICAL STUDIES. Robert F. Miller, Thomas E. Frumkes, Ramon F. Dacheux,* and Malcolm Slaughter.* Dept. Physiol., SUNY at Buffalo, Buffalo, NY 14214.

A PSP analysis of retinal ganglion cells was carried out in the perfused retinal eyecup preparation of rabbit and mudpuppy. Intracellular current injection, conductance measurements and the selective blocking action of GABA-Glycine antagonists (bicuculline, picrotoxin, strychnine) were used to evaluate excitatory, inhibitory, and dysfacilitatory PSP components. Ganglion cells were classified according to the presence of "on," "off," or "on-off" EPSPs. Each of the 3 types were further classified according to the degree and type of inhibition received. Sustained on and sustained off cells show very little evidence of inhibition and resemble in waveform bipolar cell responses. Transient on and transient off cells show inhibitory inputs of 2 kinds. Type I on cells receive a sustained inhibitory input after an initial EPSP: Type I off cells receive a phasic IPSP at light off. Presumably, these responses reflect a strong inhibitory input from sustained type amacrine cells. Some evidence suggests that the sustained inhibition of on cells is GABA mediated, while that for off cells is Glycinergic. Type II on and type II off cells receive inhibition from on-off amacrine cells and show prominent on and off IPSPs. When the IPSPs are fully blocked with bicuculline or strychnine, both on and off EPSPs are observed in both types suggesting that they receive some excitatory input from both bipolar cell types, but under normal conditions, one of the EPSPs is obliterated by the powerful inhibitory action. On-off ganglion cells receive excitation from both bipolar cell types and are strongly inhibited by on-off amacrine cells. These on-off IPSPs are blocked by either bicuculline or strychnine. Very few cells show a selective block of the off IPSP with strychnine, suggesting that a small proportion of on-off cells receive inhibition from separate neurons at on and off.

These data suggest that there are 4 types of amacrine cells: an on sustained type releasing GABA, an off sustained type releasing Glycine, and on-off types releasing either GABA or Glycine. The complexity of a ganglion cell's receptive field is partially dependent on the amount and type of amacrine inhibition they receive. Sustained on and sustained off ganglion cells receive little if any direct inhibition, but other ganglion cell types receive inhibition from amacrine cells according to several somewhat stereotyped patterns.

2041 ROLE OF VISUAL CORTEX IN VISUAL FEEDBACK FOR POSTURAL CONTROL. Alar Mirka*, Richard E. Talbott and John M. Brookhart. Dept. of Physiology, Sch. of Med., UOHSC, Portland, OR 97201.

The participation of vision in the execution of a predictable postural control task by dogs was quantitatively evaluated before and after bilateral visual cortex lesions. The dogs maintained a trained stance during sinusoidal movement of the supporting platform, either alone or in combination with the striped central and /or peripheral visual scene. The frequency ratio of platform to visual field oscillation was fixed at 2.875. The conditions imposed on vision included: normal sight (N); blindfolding (B); vision restricted to central 70^0 of visual field only (CO); vision restricted to only peripheral visual field $>50^0$ (PO). The behavioral response was described in terms of Fourier coefficients for longitudinal pelvis movement at the forcing frequencies of platform and visual field movements. This permitted differentiation of behavioral response components induced by visual field movement from those induced by platform movement. Most or all of areas 17, 18 and 19 were ablated by subpial suction. At this time, complete data are available from three dogs; three others are under study.

Preoperatively, B increased the dog's body motion during platform oscillation alone. Thus, system performance is altered by the loss of visual input even in this predictable postural task. Postural responses were induced by visual field motion during CO, PO and N. Movement of the platform and peripheral visual scene during N provided conflicting visual input from the oscillated peripheral and stationary central visual scenes. Removal of the input from central visual field (PO) augmented the response induced by peripheral movement as compared to N. Thus, during N, the conflict between peripheral and central visual field inputs reduces peripheral field influences on postural control. These data indicate that postural control processes are subject to influences from both peripheral and central visual fields.

Postoperatively, the response to platform oscillation alone during N and B was unchanged. The differences between responses in the N and B conditions persisted in the absence of the visual cortex. Peripheral visual field movement induced a similar response during either N or PO; and no postural response could be induced by visual field movement during CO. Thus, postural influences from the central visual field are eliminated by ablation of the visual cortex. Conversely, the visual cortex is not essential for the influences on postural control that originate from the peripheral visual field. It follows that peripheral visual field feedback alone can support quantitatively unchanged postural responses to platform oscillation.

2042 INFLUENCE OF THE VISUAL CORTEX UPON RECEPTIVE FIELD ORGANIZATION OF LATERAL GENICULATE NUCLEUS NEURONS, IN RABBITS. S. Molotchnikoff, D. Richard and G. Baron. Dept des Sciences biologiques, Université de Montréal, Montréal, Qué., Canada H3C 3J7.

A previous report (Molotchnikoff and Lachapelle, Exp. Brain Res. 29: 1977) has shown that inactivating the Visual Cortex (V.C.) by an application of 3M KCl., produces suppression or enhancement of ON and/or OFF Lateral Geniculate cells discharges in response to diffuse light. These results led us to investigate receptive fields spatial organization following cortical depression. Experiments were performed on adult nembutal anesthetized and paralyzed rabbits. Eye movements were prevented surgically. The abolition of evoked potentials recorded from the V.C. indicated cortical inactivation. Receptive fields (R.F.) were mapped with spots onto a tangent screen at a distance of 57 cm. For the purpose of this study, cells (N = 41) were divided into two groups: 1) cells with center-surround organization 2) cells which presented an homogenous R.F. In the first group two subclasses were distinguished: ON-center (24%) and OFF-center (33%) neurons.

The most consistent effect of cortical depression, in all classes of cells, was a significant *reduction* of the responsive area in the periphery of the R.F. The outside diameter of the surround annulus dimished up to 50%. Rates of spontaneous activity were unmodified. This surround area from which no response could be elicited was identified as the distal periphery. ON and OFF responses were elicited from the intermediate area which then expanded centripetally in the majority of tested cells. Thus, the center area from which pure center response was evoked also declined in its surface. The excitatory center response remained unchanged or increased by cortical inactivation in all neurons analyzed but two ON-center cells, where the excitation has been replaced by an inhibitory pause.

These results demonstrate that cortex exerts a powerful action upon receptive field spatial organization. It is the surround which is mostly sensitive to corticofugal influences. It is suggested that cortical functions reduce center-surround inhibitory processes within the Lateral Geniculate Nucleus.

2043 A SPATIAL FOURIER ANALYZER BY ANY OTHER NAME IS AN EDGE DETECTOR. J. Anthony Movshon, Dept. Psychol., New York Univ., New York, NY 10003.

Models of pattern vision which postulate some form of spatial Fourier analysis have recently received considerable attention. The claim has been presented that descriptions of visual neuronal responses in terms of the spatial frequency and orientation of sinusoidal gratings are in some sense more powerful than other plausible characterizations, such as those based on spots, lines or edges. Since any spatially linear analyzing system should in principle be equally well described by any orthogonal set of basis functions, and since frequency analysis methods have no obvious a priori advantages in dealing with spatially nonlinear systems, I have examined the superiority of grating stimuli in experiments on single neurons recorded from the lateral geniculate nucleus and visual cortex of cats.

For LGN X cells and simple cortical cells, whose behavior is to a first approximation linear, quantitatively equivalent descriptions may be obtained using either grating or line stimuli. The results obtained using either kind of stimulus may be directly related to those obtained using the other by Fourier analysis. Moreover, both spatial frequency response and line weighting data can be used to make accurate predictions of neuronal responses to broad bars of rectangular or Gaussian luminance profile and to complex gratings.

For spatially nonlinear neurons, such as cortical complex cells, results from grating and line experiments may not be so easily related. Furthermore, neither set of data may be used alone to make accurate predictions of responses to broad bars and to complex gratings.

In no strong sense, then, may grating stimuli be considered "better" than other sorts of stimuli. Practical considerations do make some kinds of data easier to obtain and analyze when gratings are used, but the fact that these methods provide a convenient level of description does not provide strong evidence about their functional significance in visual processing. It is not possible on the basis of single neuron response data alone to define a unique "trigger feature" for a visual neuron, be it a bar, an edge, a spot -- or a spatial Fourier component.

2044 RAPID RECOVERY FROM VISUAL DEPRIVATION IN NEURONS OF CAT PARASTRIATE CORTEX. Michael J. Mustari and Max Cynader. Dalhousie University, Halifax, NS B3H 4J1.

Fourteen kittens were reared from birth until 4 months of age in total darkness, following which, visual responses of area 18 units were examined. Single units were recorded from cats at 2 weeks intervals up to 8 weeks and also at 3-6 months after removal from the dark. A total of 340 single units were studied in these experiments, about one half with computer methods for stimulus presentation and data collection. Particular attention was directed towards orientation and direction selectivity and peak firing rates of neurons. A unit was considered orientation biased (OB) or direction selective (DS) if the ratio between number of spikes in the best orientation or direction to number of spikes in the orthogonal orientation or opposite direction was 0.5 or less. Some OB cells were further classified as orientation selected (OS) if they failed to respond to stimuli oriented perpendicular to the optimal stimulus orientation.

Initially many cells in recently-deprived kittens were visually unresponsive; others proved difficult to drive, habituated rapidly and generally lacked specificity in receptivefield properties. Only 13% (N=120) of single units in these cats were OB and even less (2%) were OS, while 5% were DS. A considerable degree of recovery was observed in cats after 2 weeks out of the dark. Fifty-four percent (N=46) of neurons were OB, 11% OS, and 20% DS. There was no clear indication of different degree of specificity between simple and complex cells. The recovery process seemed to have asymptoted by 8 weeks and in the 3-6 month group 75% (N=84) of neurons were OB, 26% OS and 20% DS. The peak firing rates were intermediate in value between recently-deprived cats and normal cats.

The results of this study demonstrate that neurons in area 18 are very susceptible to dark rearing as are cells in area 17. The effects of dark rearing on single unit physiology are quite profound affecting not only orientation and direction selectivity but peak firing and latency of response as well. All types of cortical cells seem susceptible to dark rearing and recover to essentially the same degree. The rapid recovery of single unit trigger feature specificity with clear changes observable after only two weeks of recovery indicates that marked plasticity is still present in cortical circuitry of cats several months old.

2045 BLINDNESS IN MONKEYS AFTER LESIONS OF NONVISUAL CORTEX: NOT A VISUAL-MOTOR DISCONNECTION EFFECT. Richard K. Nakamura and Mortimer Mishkin. Lab. Neuropsychol., NIMH, Bethesda, MD 20014.

We previously reported that a large cortical lesion in the monkey outside the areas known to be necessary for visual discrimination learning resulted in behavioral blindness (Neurosci. Abs. 3: 571, 1977). The lesion, placed in one hemisphere, completely spared both the visual cortex (striate, prestriate, and inferior temporal) and the limbic cortex (medial temporal, ventral frontal, and cingulate) but included all other cortical areas: the other hemisphere was visually deafferented by optic tract section and forebrain commissurotomy. Histology and evoked potentials in several such preparations indicated that, in the hemisphere with the ablation, the geniculostriate pathway was intact as intended. Nevertheless, these animals behaved as though blind for periods ranging from 25 to over 400 days, showing partial recovery thereafter.

The present study asked whether the blindness was the result of a disconnection of the visual system in one hemisphere from the motor system in the other hemisphere. To test this, three animals were prepared as above but with the forebrain commissures left partly or completely intact. These animals thus had connections preserved between an intact visual system on one side and an intact output system on the other. Yet, they too were blind, in this case for a median period of 76 days. Subsequent division of the forebrain commissures did not result in a second period of blindness. The results demonstrate that the blindness is not a disconnection effect and suggest further that during blindness the visual signal is not processed beyond striate cortex, for otherwise the signal should have been transmitted across the preserved commissural channels (which start at the striate-prestriate border) to the motor system. This analysis implies that the territory ablated normally provides some activating input, direct or indirect, that is necessary for cortical visual processing.

In a further study, the original lesion was subdivided in an effort to localize the area supplying the activating input. It was found that a sensorimotor lesion (Brodmann's areas 1-6) failed to produce blindness in any of three monkeys. The complementary lesion, however, consisting of dorsal prefrontal, inferior parietal, insula, and superior temporal areas, did produce blindness in three monkeys for a median period of 27 days. These localization results provide additional evidence that the blindness is not a visual-motor disconnection effect, and suggest instead that it is a profound form of visual neglect, since parts of the lesion that produced blindness are known to produce neglect. Accordingly, the basis of neglect too could be impaired processing within the cortical visual system due to loss of activating input, though a less complete loss than that producing blindness.

2046 SELECTIVE UPTAKE OF [^{3}H]-γ-AMINOBUTYRIC ACID (GABA) AND [^{3}H]-GLYCINE BY NEURONS OF THE AMACRINE LAYER OF CAT RETINA. Y. Nakamura, B.A. McGuire* and P. Sterling. Dept. Anat., Sch. of Med., Univ. Pa., Philadelphia, PA 19104.

In reconstructing microcircuitry it is of considerable help to label neurons by means that may relate their morphology to their function. We injected eyes intravitreously with radioactive putative transmitters, GABA or glycine (100 μCi in 10 μl.) and perfused the animals one hour later. Series of 70-200 consecutive sections from regions near the area centralis were prepared as electron microscope autoradiograms. In the GABA experiments 2% of the cells in the amacrine cell layer were heavily labeled (34x background) and proved to be "interplexiform" cells (IPCs) whose reconstructed processes could be followed into both the outer plexiform layer and inner plexiform layer (IPL), where they made conventional synapses. There were about 90 IPCs/mm^2, but they were unevenly distributed, being closely spaced in some areas (20-45 μm apart) and absent in others (eliptical regions averaging 320x160 μm). An additional 20% of the amacrine layer cells were also labeled but less heavily (9x background). These were true amacrines, slightly larger and darker than the IPCs, with fine processes reconstructed through the outer 1/3 of the IPL. That GABA-labeled amacrine processes were also found diffusely through the IPL and particularly in the innermost region (near the ganglion cells) suggests that the GABA amacrines are of a "diffuse" or multistratified variety. In the glycine experiment, 15% of the amacrine layer cells were heavily labeled (16x background) and sent fine processes radially through at least the outer 1/3 of the IPL. An additional 33% of the amacrine layer cells were labeled, but less heavily (6.4x background). These sent one or more stout processes vertically through at least 3/4 the depth of the IPL. Large (2-3 μm), vesicle-filled varicosities arose from both cell bodies and the vertical processes and were also labeled. We conclude that amacrines showing selective uptake of GABA or glycine belong to distinct morphological classes and speculate that, when their synaptic connections are reconstructed, knowledge of their biochemical characteristics will provide clues to their physiological role. 2047 THE ROLE OF MÜLLER CELLS IN THE GENERATION OF THE RETINAL B-WAVE RESPONSE: A SOURCE DENSITY ANALYSIS. Eric A. Newman* (SPON: Daniel Kurtz). Research Lab of Electronics, Massachusetts Institute of Technology, Cambridge, MA. 02139

The origin of the electroretinogram b-wave response was investigated by determining its current source density distribution in the dark adapted eyecup of the frog, Rana pipiens. Local b-wave amplitude was measured as a function of depth within the choroid, retina and vitreous. B-wave current flow was determined by dividing incremental b-wave amplitude by the radial component of incremental tissue resistance. Current source density was calculated from the spatial derivative of the current distribution. These measurements show that the b-wave is generated by a proximal current source which is restricted to a narrow (∿10 μm) region bordering the retinal surface and a diffuse current sink, extending from approximately 10% to 80% retinal depth. The sink of b-wave current has two prominent peaks: near the outer nuclear layer and near the border of the inner plexiform and inner nuclear layers. This source density pattern suggests that the distribution of b-wave currents is determined by Müller cells, which are the only retinal elements extending from the retinal surface into the distal retina.

The two peaks of the b-wave current sink have similar retinal locations as the sources of the distal and proximal light-evoked increases in extracellular K^+ concentration ($[K^+]_o$) recently observed by Dick and Miller (Neuroscience Abstracts, 1977). The currents associated with the two portions of the b-wave sink have time courses similar to those of the two sources of K^+_o as well: the proximal current sink develops more slowly than the distal one. These observations support the model of b-wave generation based on passive Müller cell depolarization driven by increases in $[K^+]_o$. 2048 DESCRIPTIVE AND QUANTITATIVE EM STUDIES OF THE OPTIC TECTUM OF XENOPUS FOLLOWING ENUCLEATION. J. J. Norden, A.-J. C. Ostberg* and J. A. Freeman. Vanderbilt Univ., Nashville, TN and University College, London, England.

Using quantitative EM, 40,000 synapses have been counted in the superficial layers of control and denervated tecta in Xenopus from 12 hrs.-4 mos. following unilateral enucleation in an attempt to determine if sprouting of nearby fibers, which also innervate the superficial tectum, occurs after deafferentation. By 5 days, the total number of synapses on the denervated side drops to less than 50% of the synapses on the control side. This decrease in the number of synapses is still apparent 4 mos. following enucleation. Few vacated post-synaptic sites are seen at any time following enucleation. Most pre- and post-synaptic profiles are removed by gliosis while still in synaptic contact. Thus, we found no evidence for sprouting in the tectum of Xenopus at any time after deafferentation.

These results are in contrast to a report of collateral sprouting in the superior colliculus of the rat following unilateral enucleation (Lund and Lund, '71). In the latter study, there was a significant change in the number of flattened vesicle containing profiles making asymmetric contacts following enucleation. This indicated that remaining fibers had sprouted to occupy post-synaptic sites vacated by degenerating optic nerve terminals. In order to compare the results of the two studies, an additional 800 synapses in normal and denervated tecta in Xenopus were characterized according to a number of parameters with particular attention paid to vesicle morphology and type of synaptic contact. In Xenopus, however, the change in the number of flattened and spherical vesicle containing profiles and types of synaptic contacts could be accounted for in terms of the loss of retinal afferents alone.

We conclude that sprouting and reoccupation of synaptic sites does not occur after deafferentation in the tectum of Xenopus. And because post-synaptic sites are removed during degeneration, neither do vacated sites remain uninnervated. These findings have important implications for how synaptogenesis must occur during regeneration of the optic nerve in Xenopus. Optic nerve fibers must "induce", de novo, synthesis of post-synaptic densities rather than displace sprouted fibers or innervate vacated sites.

2049 SPATIO-TEMPORAL PROPERTIES OF SIMPLE AND COMPLEX CELLS IN THE CAT VISUAL CORTEX (AREA 17). H.C. Nothdurft* (SPON: K. M. Gottschaldt). Max Planck Institute for biophysical chemistry, Dept. Neurobiology, D 3400 Göttingen-Nikolausberg, West-Germany.

The temporal properties of spatial interaction were measured with pairs of visual stimuli (dots or lines) presented separately or in combination with various onset-intervals.

When stimulated with parallel lines, those complex neurons which were direction sensitive to a moving line responded also better to the corresponding sequence of line onset. The interaction was either facilitatory or suppressive (or both) and could last up to 600 ms. This sequence sensitivity was a uniform property within the receptive field and did not depend on stimulus position.

In contrast, the responses of simple cells did not show strong sequential sensitivity but revealed the spatial properties of excitatory and inhibitory regions in the receptive field. Commonly, the inhibition was more dominant and seemed to be longer lasting than in neurons of the lateral geniculate nucleus.

In relation to orientation specificity there was no clear example of facilitation along the optimal axis when tested with combinations of dots. The time course of suppression in the non-optimal orientation was not uniform though in some complex cells it was quite short.

The different spatial and dynamic properties of simple and complex cells are also revealed in their transfer of various complex pictures.

2050 PROPERTIES OF CORTICAL NEURONES ACROSS THE 17/18 BORDER: VELOCITY CHARACTERISTICS. Guy A. Orban, Henry Kennedy+ and Hugo Maes+. Laboratorium voor Neuro- en Psychofysiologie, K.U.L. Leuven, B-3000 Belgium.

Velocity influence on area 18 neurones with eccentric fields was described by Orban & Callens (EXBRAP 30: 125, 1977). The aim of the present experiments was to extent this study to the whole of area 18 and to examine whether or not the velocity response curves allow to distinguish between area 17 and area 18 neurones and to trace the 17/18 border. Oblique penetrations in a frontal plane (from medial to lateral) were made from area 17 towards area 18 in anesthetized (N_2O/O_2) and paralyzed cats. Neurones were studied both qualitatively on a plotting table and quantitatively with computer (PDP 11/40) controlled stimuli rear projected on a polacoat screen. The hand plotting allowed classification of units according to the criteria of Kato et al. (J. Neurophys., in press) and determination of receptive field (RF) location and of optimal stimulus parameters. The influence of stimulus velocity was investigated quantitatively with the multihistogram method. Velocity response (VR), velocity latency and velocity directionality curves were plotted. The two types of neurones : velocity sensitive (which have their latency changing with velocity) and velocity specific (or velocity tuned, which have a constant latency) are found in central and in peripheral regions of area 18. However the shape of the VR-curves of velocity sensitive neurones changes from a broad band curve to a high pass filter curve with increasing distance from the vertical meridian (VM). The velocity specific units are more numerous in central projections. There is an excellent correlation (within 100 μ) between changes in VR-curves and the retinotopy indicating the 17/18 border. The correlation between the electrophysiologic indication of the 17/18 border and the histology is much poorer. Indeed on Nissl sections the 17/18 border can only be indicated with a precision of the order of 1 mm. Three conclusions can be drawn from our study. (1) Velocity is a much more important parameter for area 18 than area 17. (2) Velocity specific neurones which belong to the movement analysing system (Orban, Perception 6: 501, 1977) are more common in central regions. (3) The current histological techniques are too coarse for an exact localization of the 17/18 border.

2051 STROBE REARING REDUCES SENSITIVITY TO SLOW MOTION. T. Pasternak, W.H. Merigan, J.L. Brown. Center for Visual Science, University of Rochester.

Cats were reared from birth to at least one year in a room illuminated by a short duration strobe flash (40/min). This illumination provided pattern visual stimulation but precluded the perception of motion. Earlier we reported (Pasternak, Merigan and Brown, Society for Neuroscience Annual Meeting, Anaheim, 1977) that cats reared in such conditions have greatly reduced spatial contrast sensitivity, especially to high spatial frequencies, and show a reduction in high frequency cutoff of over two octaves.

We report here data on the sensitivity of strobe reared animals to motion. Low velocity thresholds were measured using moving random dot patterns. In a two-alternative forced-choice procedure the cats were presented with moving vs stationary patterns. A correct nose pressing response toward the moving stimulus was rewarded with pureed beef. A modified method of constant stimuli was used and a threshold measured in each session.

All three strobe reared cats tested could discriminate moving from stationary dot patterns. However, the low velocity thresholds of these cats were greatly elevated compared to normal cats. While thresholds for normal animals were in the range of 1.1-2.7 deg/sec, thresholds for strobe reared cats were between 4.6-12.2 deg/sec.

The loss of sensitivity to low velocities of movement and the earlier finding of extreme loss of sensitivity to high spatial frequencies suggest that the sustained system is primarily affected by strobe rearing.

2052 VISUAL-MOTOR PROPERTIES OF UNITS IN THE SUPERIOR COLLICULUS OF THE ALERT CAT. Carol K. Peck and Madeleine Schlag-Rey, Dept. of Psych., Pomona College, Claremont, CA 91711, and Dept. of Anat., UCLA, Los Angeles, CA 90024.

Although the visual properties of cells in the superficial layers of the cat's superior colliculus (SC) have been studied in many laboratories, there is much less information on the intermediate and deep layers of the SC. In the monkey, these layers contain cells related to eye movements (EMs). We have studied the relationships between visual and eye movement properties of cells in the SC of the cat.

Single unit activity was recorded in both the SC of alert cats, with the head fixed during recording sessions. The cats had been trained to make voluntary saccades in anticipation of visual targets but were not trained to fixate the test stimulus (Schlag-Rey & Schlag, J. Neurophysiol., 1977). Receptive fields were mapped by computing the difference between the position of a visual target and the position of the eyes on trials when the eyes were stationary. In addition, presaccadic activity could be clearly separated from visually-evoked responses since the cats would often fixate a target with considerable delay.

Although movement was often the most effective stimulus for these units, all of them responded to stationary stimuli and many showed maintained activity, in contrast to previous reports in the paralyzed cat. Most units had some directional preference and some were very sensitive to changes in the direction of motion (e.g., the number of spikes in bursts decreased to 50% of maximum as the direction changed by 30^{o}-40^{o}).

One type of unit, frequently encountered, responded phasically to the onset of a visual stimulus and also discharged prior to a targeting EM, even if that EM occurred much later or after the stimulus was turned off, yet the same units would not discharge before EMs in complete darkness. Among tonically active units, two types could be contrasted. One type discharged from the onset of a stimulus until the cat made a targeting EM in the direction of the stimulus, while the other type became tonically active only if the cat fixated the stimulus. The absolute location of the stimulus (i.e., with respect to the head-body axis) was important for some units. This was observed both in units with phasic "on" responses to a stimulus distant from the point of fixation and also in units which responded during fixation.

The properties described above are consistent with the hypothesis that the SC is involved in coding appropriate EMs to visual stimuli.

Supported by NS-04955.

2053 REGIONAL SPECIALIZATIONS IN THE OPTIC TECTUM OF AN IGUANID LIZARD, DIPSOSAURUS DORSALIS. Ellengene H. Peterson, Department of Anatomy, University of Chicago, Chicago, Illinois.

In Dipsosaurus dorsalis, the optic tectum consists of: 1) the superficial strata, composed of seven alternating cell and fiber layers; 2) the middle strata; and 3) the deep strata, consisting of three monolayers of somata alternating with cell free zones. In addition to this pattern of lamination, the tectum in Dipsosaurus exhibits a series of regional specializations. Specifically, the tectum can be divided into at least three morphologically distinct regions on the basis of normal cytoarchitecture and the pattern of ganglion cell afferents as visualized in silver and autoradiographic material. These three areas are arranged as strips oriented approximately parallel to the rostrocaudal axis of the tectum. Seen in cross section they are: the mid-dorsal tectum, the lateral tectum, and the ventral rim. 1) In the mid-dorsal tectum, the laminae are relatively thick in the rostral half tectum. This expansion is most pronounced in the middle strata and reaches its maximum extent approximately midway along the rostrocaudal axis. In silver preparations, the mid-dorsal tectum contains a discrete patch of degeneration at the shortest survival times (5 days). In autoradiographic material, grains are concentrated over the three most superficial fiber layers and, at the shortest survival times, grain density is relatively high over the mid-dorsal expansion. 2) In the lateral tectum, the pattern of degeneration is different from that seen dorsally. At 5 and 10 days survival, little degeneration is evident, but at 15 days, three distinct bands of silver particles can be seen. At 21 days, degeneration in lateral and dorsal tectum are equally dense. In autoradiographic material, the laminar pattern of grain densities is similar to that seen dorsally but, at short survival times, it is less dense. 3) The ventral rim of the tectum can be distinguished in silver material by the presence, at all survival times, of two bands of large caliber fibers which enter the tectal layers parallel to the surface and run approximately 1/3 the way up the lateral wall of the tectum. They are accompanied by coarse argyrophilic debris, particularly over the deeper fiber layer. The three dense bands of silver particles seen in the lateral tectum do not extend into this ventral rim. In autoradiographic material, relatively few grains are seen in this region at the shortest survival times.

The optic tectum of Dipsosaurus thus exhibits a number of regional specializations. If the retina projects topographically onto the tectal surface, then these subdivisions of the tectum may reflect regional specializations in the ganglion cell layer of the retina. (Supported by A.P. Sloan Postdoctoral Fellowship and PHS Grant NS 12518)

2054 RETINAL MECHANISMS OF LIGHT ADAPTATION IN THE ALBINO RAT. Maureen K. Powers and Daniel G. Green. Vision Research Laboratory, University of Michigan, Ann Arbor, Michigan 48109.

In the isolated retina of the skate, sensitivity to light is regulated by two separate mechanisms, one located in the distal retina and the other in the proximal retina[1]. Light adaptation affects the two mechanisms differently. For example, dim background lights may depress sensitivity of proximal elements (e. g., ganglion cells) without influencing sensitivity of distal elements (e. g., receptors) at all. We have examined the relations between proximal and distal retina during light adaptation in the intact retina of the albino rat.

Using conventional techniques and diffuse illumination, we recorded the ERG b-wave, the isolated receptor potential (obtained by injecting aspartate into the vitreous) and single ganglion cell fibers in the optic tract. We measured two aspects of these responses: threshold (defined as 1 extra spike per stimulus presentation for ganglion cells, and as a 50 μV change of potential for the receptor potential and the b-wave) and the intensity-response function (number of spikes above nonstimulated levels elicited from ganglion cells, and μV change above noise for the receptor potential and the b-wave).

With no background present, the intensity needed to evoke a threshold response was about 100 times greater for the receptor potential than for either the b-wave or the ganglion cells. However, the intensity-response functions of all three measures were similar in shape when response was expressed as percent of maximum. Backgrounds that decreased b-wave threshold by 1 or 2 log units had the same or greater effect on ganglion cell threshold. The same background lights decreased the maximum amplitude of the b-wave's intensity-response function, but not of the ganglion cells'. The presence of background lights that increased ganglion cell and b-wave thresholds more than 50-fold had no effect on receptor potential threshold or intensity-response function.

We have shown that the receptor potential, b-wave and ganglion cells in the rat respond similarly in the absence of background lights, but differently in their presence. Our results are in good agreement with those of Green et al.[1] and with earlier work by Dowling[2] in the rat. We conclude that retinal mechanisms of light adaptation in the rat resemble those in the skate, and we suggest that they may be similar in other vertebrates as well. (Supported by EY00379 to D. G. G.)

2055 INVOLVEMENT OF SECONDARY COMMISSURES IN INTERHEMISPHERIC TRANSFER M. Ptito, G. Page, F. Lepore and M.C. Lassonde. Lab. de Neuropsychologie, Univ. du Quebec, Trois-Rivieres and Univ. de Montreal, Montreal, Canada.

Brain lesion studies have shown that interhemispheric transfer is present in animals bearing a transection of the corpus callosum and the optic chiasm. Such transfer is possible only if one postulates that visual information is conveyed across the midline via the secondary of subcortical commissures. The present experiment was undertaken to evaluate this hypothesis. Adult cats underwent a section of the left optic tract (LOT) and a destruction of the cortical visual areas (VA) in the contralateral hemisphere (17, 18, 19 and suprasylvian area). The intact directly deafferented hemisphere is thus only innervated via indirect subcortical commissures, such as the intratectal. After the LOT lesions, the animals learned a series of visual pattern discriminations in a Thompson box. The animals easily learned with either or both eyes the different pattern discriminations in a time comparable to controls or split-chiasm subjects. After undergoing the cortical resection (VA), they were retested in the previously learned tasks and taught new ones. Results showed that all subjects were able to achieve criterion on the previously learned discriminations. However, they were very slow at the beginning of the relearning period and required approximately twice as many trials to relearn the discrimination as after the LOT lesions. Initial performance on the new pattern discrimination was similar to that at the end of the relearning phase. However to achieve criterion the animals required about four to five times as many trials as after the LOT lesions. An additional lesion was then made at the level of the intratectal commissure (IC) to evaluate the importance of this commissure in supporting the residual vision demonstrated in the cats. The animals were tested on both the previous and on the new discrimination tasks. Preliminary results seem to indicate that IC cats have difficulty performing the previously learned discrimination problems. Data on new learning is still too sketchy to be evaluated. However, based on their ability to learn pattern discriminations following VA lesions and on the partially demonstrated relearning difficulties after IC sections, it may be tentatively concluded that the intratectal commissure is involved in the interhemispheric transfer of visual information.

2056 STRONG AND WEAK TRIADIC INPUT TO RELAY CELLS OF THE LATERAL GENICULATE. Salvatore C. Rapisardi* (Spon: J. H. LaVail) Dept. of Anatomy, Howard University, Washington, D. C. 20059

Nineteen terminal boutons of retinal fibers in the dorsal lateral geniculate of the cat have been examined throughout their extent in long series of uninterrupted, consecutive thin sections. The profiles postsynaptic to the retinal terminal (RT) fall into two categories. Both types show an electron lucent cytoplasm, but one (F profiles) contains loosely packed pleomorphic vesicles and no ribosomes. The second type (D profile) exhibits numerous ribosomal rosettes, but no vesicles. Triadic arrangements occur frequently. In such cases an F profile postsynaptic to an RT is presynaptic to a D profile which is postsynaptic to the same RT.

The RTs fall into two groups according to the extent to which they are involved in triads. In one group (9 RTs) over 95% of the total synaptic contacts made by the retinal afferent took part in triads. In the second group (10 RTs) less than 50% of the synapses made by the retinal afferent took part in triads. There are also differences between the triads found in each group. There is a great variability in the number of RT and F synapses received by any particular D element. Individual D processes which are part of triads in the high triad group of RTs receive about equal numbers of RT and F synapses, but D processes from triads in the low triad group receive about five times as many RT synapses relative to their F input. This suggests that a triad in the low triad group of RTs is less effective than a triad in the high triad group.

Reconstructions of D profiles postsynaptic to the RTs with high triadic involvement have grape-like appendages similar in appearance to those found on the dendrites of Guillery Class II cells. Models of D processes postsynaptic to RTs of low triadic involvement are relatively smooth, but show small appendages and resemble the dendrites of Guillery Class I cells.

The hypothesis that the function of the triad is a feed-forward inhibition upon relay cells is supported by Sterling and Davis'* finding that the F profiles accumulate DABA. Since the physiologically defined X and Y cells have been associated with Class II and Class I cells, respectively (Levay and Ferster, JCN, 172, 77; Kalil and Worden, JCN, 178, 78), the heavy triadic involvement of Class II cells suggested here is consistent with the Stevens and Gerstein* report of a retinally generated feed-forward inhibition (following an initial excitation) that is almost exclusively associated with X cells. *See abstracts this volume (supported by Grant #NS-11614)

2057 CELLS OF ORIGIN OF DESCENDING TECTOFUGAL PATHWAYS IN THE BIRD. A. Reiner and H.J. Karten. Dept. Psychiat. and Behav. Sci., S.U.N.Y. at Stony Brook, N.Y., 11794.

In birds, the tectum gives rise to two major descending systems, the ipsilateral tectopontine-tectoreticular pathway (ITP) and the crossed tectobulbar pathway (CTB). The ITP terminates within the lateral reticular formation (FRL) of the brainstem and within the lateral pontine nucleus (PL). The CTB decussates ventral to the oculomotor complex and terminates throughout the paramedian brainstem. These two major descending tectofugal pathways have been described in all vertebrates studied. The horseradish peroxidase technique was used in the present study to determine the laminar distribution of the cells of origin of these descending tectal systems in the pigeon.

Unilateral injections into the terminal field of the CTB at a variety of caudal pontine and rostral medullary sites resulted in labeled cells exclusivily in layer 13 of the contralateral ventral tectum. Unilateral injections into rostral pontine portions of the CTB yielded labeled cells in layers 13-15 of the contralateral dorsal tectum, as well as in layer 13 of the contralateral ventral tectum. These results suggest that rostrally terminating portions of the CTB arise from the deepest lamina of the dorsal tectum, while the more caudally terminating portions of the CTB arise from layer 13 of the ventral tectum. Unilateral injections into the ITP that included both PL and overlying FRL resulted in labeled cells in the ipsilateral tectum in layers 8 and 10-15. Injections confined to PL resulted in labeled cells in these same seven layers. All injections, both paramedian and lateral, resulted in labeled cells at two subventricular sites within the optic lobe, nucleus intercollicularis (ICo) and FRL. Label in ICO was predominantly ipsilateral to the injections, while label in FRL was predominantly ipsilateral to ITP injections but bilateral to CTB injections. These results suggest that both tectal and tegmental cell groups give rise to projections to paramedian and lateral zones of the brainstem.

The tectofugal projection upon nucleus rotundus of the diencephalon arises from layer 13. The present results indicate that lower brainstem regions may receive input similar to that received by nucleus rotundus since they also receive layer 13 input. Of particular interest is the observation that PL and possibly FRL are in receipt of input from tectal cells in layers 8 and 10. Cells of these layers characteristically extend their dendrites into tectal retino-recipient layers and have small visual receptive fields (1-10 degrees).

2058 SOME OBSERVATIONS ON THE ORGANIZATION OF THE CAUDAL POLE OF THE THALAMUS (LATERAL PULVINAR OR PLγ) IN THE MACAQUE MONKEY. Michael Rezak. Department of Anatomy, University of Illinois Medical Center, Chicago, Illinois 60612.

The organization of the caudal pole of the thalamus is poorly understood. Cytoarchitecturally it is comprised of extensions of the medial pulvinar and the lateral pulvinar. The lateral pulvinar has been shown to have three subdivisions and it is its most caudal subdivision or PLγ which forms the lateral part of the caudal pole of the thalamus. The connectional organization of this region was studied using retrograde (HRP) and anterograde (autoradiographic) tracing methods. Microinjections of tritiated amino acids into prestriate cortex (areas 18 and 19) revealed a highly convergent input to PLγ. Interestingly, discrete microinjections (0.1 µl) of tritiated amino acids in PLγ revealed no reciprocal projections to prestriate cortex. Instead PLγ was found to project to the temporal lobe. More specifically, PLγ has as its cortical target layers III, IV and I of inferotemporal cortex (areas 20 and 21). This projection to cortex follows a loose topographic organization such that ventral regions of PLγ project to posterior portions of inferotemporal cortex while dorsal PLγ projects to more anterior and ventral regions of inferotemporal cortex. No evidence for visuotopically organized connections of PLγ was found. It should be noted that recent physiological studies also have shown that inferotemporal cortex does not contain a detailed visuotopic map. The lack of reciprocity between PLγ and prestriate cortex was further underscored in our HRP studies where no peroxidase positive cells were found in PLγ after HRP injections in prestriate. Peroxidase positive cells were found in PLγ after HRP injections in areas 20 and 21. Thus, PLγ plays a heavy role in associating occipital cortex with inferotemporal cortex and thereby establishes a cortico-thalamocortical route which must operate in parallel with the well known cortico-cortical routes in the progressive relay of visual information.

2059 RETINAL INPUT TO THE HAMSTER'S SUPERIOR COLLICULUS: CONDUCTION VELOCITY DISTRIBUTION AND CORRELATION WITH RECEPTIVE FIELD PROPERTIES. Robert W. Rhoades and Leo M. Chalupa. Dept. of Psych. University of California, Davis, CA 95616.

In view of the current interest in the tripartate division of ganglion cell types in the mammalian retina and the role of these neurons in the organization of the receptive fields of cells in central visual structures, we sought, in the present study, to (1) determine the conduction velocity (CV) distribution of the retinal input to the hamster's superior colliculus (SC), and (2) to correlate afferent conduction velocities with the response properties of tectal cells. The experiments were accomplished by employing standard extracellular recording techniques in the SC and electrical shocks delivered to the contralateral optic nerve (ON) and optic chiasm (OX). In an additional series of animals we also attempted to delineate the nature of the retinal input to the ipsilateral SC. Here the ON electrode was positioned behind the eyeball ipsilateral to the SC from which we recorded.

Cells driven reliably by shocks delivered to the ON or OX were encountered throughout the depth of the tectum. However, as might be expected from the anatomical distribution of the retinal input to the SC (Chalupa and Rhoades, in preparation), the incidence of driven cells decreased markedly in the tectal laminae ventral to the stratum opticum. The distribution of CV's for the retinal afferents to the hamster's colliculus was quite broad (ranging from 1.7 to 25.5 m/sec) and clearly bimodal with a broad peak centered at 6 m/sec and another narrower peak at 12 m/sec. A few tectal cells were innervated by axons having conduction velocities in excess of 20 m/sec. These data, when combined with the distribution of ganglion cell sizes in the hamster's retina (Tiao and Blakemore, 1976, JCN, 168, 439-458), suggest that all retinal ganglion cell types in this species project to the colliculus.

Afferent conduction velocity was clearly correlated with directional selectivity. Ninety percent of the tectal neurons receiving inputs from axons having CV's of less than 5 m/sec were directionally selective while only 41% of those neurons having inputs from more rapidly conducting fibres (>5 m/sec) exhibited selectivity.

We tested 116 cells in the anterior portion of the colliculus for responsivity to photic stimulation delivered to the ipsilateral eye and electrical shocks applied to the ipsilateral ON. Of these 11% exhibited some degree of binocularity while only 6% were responsive to ON shocks. These electrophysiological findings correspond well with the limited nature of the retinal input to the ipsilateral SC (Chalupa and Rhoades, in preparation).

2060 VISUAL MASKING BY REMOTE STIMULI IN MONKEY SUPERIOR COLLICULUS NEURONS. Barry J. Richmond and Robert H.Wurtz, NIMH, Bethesda, Md. 20014

In the monkey superior colliculus some cells show a suppression of activity following saccadic eye movements due to a corollary discharge (Richmond and Wurtz, Neuroscience Abstracts, 1977) in contrast to a visual masking effect seen in the striate cortex (Judge and Wurtz, Neuroscience Abstracts, 1977). We have now studied visual responses of cells in the superficial layers of the superior colliculus to see if visual masking is also prominent in this structure.

Single cell responses were recorded in awake rhesus monkeys (Macaca mulatta) while the monkey fixated a spot of light on a tangent screen. All cells with either para-foveal or peripheral visual fields showed masking of 20 msec test spots of light by a preceding stationary "masking" spot (usually by 50 msec) when both stimuli were in the excitatory receptive field center. In addition, when a small spot placed far out of the excitatory visual field was used as a stationary masking stimulus, the response of the cell to the flashed test stimulus in the excitatory receptive field was attenuated, although not usually eliminated. The distant stimulus did not itself modify the low background rate of discharge of the cell. The effect was a visual interaction and did not require a saccade to the target as did the visual enhancement effect reported previously. The masking seems to be similar to previously reported distant interactions in cells of cat superior colliculus (Rizzolatti et al., J. Neurophysiol., 1974).

A visual interaction also modified the response to moving visual stimuli. Many cells in the superior colliculus have only a weak response to rapid stimulus movement such as occur during saccadic eye movements (900°/sec for the rhesus monkey). However, if the sweep was arranged to cross only the excitatory receptive field of the cell, the response to the sweep increased markedly. We have not determined whether the effect on the sweep response is due simply to the adjacent surround or to a more remote area such as described above.

Both the effects on stationary and on moving stimuli by stimuli outside the excitatory central receptive field area are visual interactions resulting from extended surround effects. These masking effects are likely to act in addition to the suppression resulting from a corollary discharge to reduce the response of a colliculus cell during eye movements.

2061 THE EFFECT OF ADAPTING TARGET LOCATION UPON THE GAIN OF THE SURROUND RESPONSE MECHANISM OF X CELLS IN CAT RETINA.
T.W. Robertson*, R.W. Winters*, W. Christen*, and H.I. Cohen* (SPON: Ronald G. Clark). Dept. of Psy., Univ. of Miami, Coral Gables, Florida.

The spatial distribution of the surround response mechanism (SM) of X cells was assessed with unmodulated adapting targets placed in different regions in the receptive field (RF). The adapting targets were a spot placed in the middle of the RF center and annuli concentric with this spot. The annuli had mean diameters varying from 0.57° to 2.0°; all adapting stimuli had the same flux. Two measures of the gain of the SM were used: the ability of a flashing annulus to reduce the on-response to a flashing spot in the RF center - the on-inhibition measure - and the magnitude of the off-discharge to an annulus flashed alone in the RF periphery - the off-excitation measure. The relationship between adapting target location and the gain of the SM was curvilinear for the on-inhibition measure but linear for the off-excitation measure. The greatest reduction in the gain of the SM was observed for the adapting annulus with a mean diameter of 0.96° when the on-inhibition measure was used and 1.75° when the off-excitation measure was used. The adapting spot (0.28°, 0.5°) was the least effective of the adapting targets in both experiments.

The results of the experiment using the on-inhibition measure support a RF model where the SM is very weak or non-existent in the middle of the RF center in X cells. The results from the experiment using the off-excitation measure do not support this model.

2062 COMPLEX PATTERN DISCRIMINATION IN THE ALBINO RAT: ROLE OF STRIATE CORTEX AND THE IPSILATERAL RETINO-CORTICAL PATHWAY.
LAWRENCE A. ROTHBLAT and MICHAEL L. SCHWARTZ. Dept. Psychol., GEORGE WASHINGTON UNIVERSITY, WASHINGTON, D.C. 20052

Monocular deprivation in the rat, as in the cat and monkey, produces a variety of morphologic and physiologic abnormalities which alter the development of normal behavior. A chief advantage of the rat as a model system is the fact that the optic nerve fibers, unlike those of the higher species, are almost totally crossed. Thus, the relationship between the neurologic alterations and behavior may be easier to assess. We were curious about the role of the small ipsilateral projection in visual performance; specifically, the ability of this pathway to mediate complex pattern discrimination. Earlier studies investigating this question have produced ambiguous results (Chang, Psychol. Abstr. 3491, 1937; Lashley, Psychol. Rev. 31:369,1924; Muntz and Sutherland, J. Comp. Neur. 122:69,1964).

Adult albino rats (N=10) were first trained to discriminate columns and rows of 5 mm squares in a fully automated discrimination apparatus. On completion of training, unilateral (left hemisphere) lesions were performed on all animals. Lesions were made in striate cortex (area 17 of Krieg) by thermocoagulation. The contralateral (right) eyelid was sutured in 4 of the rats, while in the remaining 6 animals the ipsilateral (left) eye was closed. Following a post-operative recovery period all animals were tested for retention.

Animals relearning the discrimination with the crossed fibers (left eye-right hemisphere) required a mean of 173 trials to regain criterion performance. The mean number of trials for the animals using the uncrossed projections (right eye-right hemisphere) reached 1520. In fact, 4 of the 6 animals using the ipsilateral projections failed to reach criterion within 1800 trials.

These results indicate that the uncrossed projections from retina to striate cortex are grossly deficient in mediating a complex pattern discrimination. Secondly, they show the importance of area 17 for successful performance on this task. Finally, they strengthen the assumption that subtle alterations in the morphology of striate cortex may be related to the decrements in behavior produced by visual deprivation.

2063 DIFFERENCES BETWEEN NASAL AND TEMPORAL RETINA IN SIAMESE AND NORMALLY PIGMENTED CATS.
Michael H. Rowe. Dept. Psych., Univ. Calif., Riverside, Calif. 92502.

It has been previously reported (Stone, Rowe & Campion, J. Comp. Neurol., in press) that there is commonly a reduction in ganglion cell density in siamese retinas which is particularly apparent in the area centralis and least apparent in the visual streak. This pattern of ganglion cell loss was interpreted as a selective loss of X- type ganglion cells, since it is well established that X-cells are the most frequent cell type in the area centralis, but that W-cells are most frequent in the visual streak (Rowe & Stone, J. Comp. Neurol., 169, 99-126.). These observations are here extended to a comparison between more peripheral regions of nasal and temporal retina. In normally pigmented cats the mean soma diameter of ganglion cells in temporal periphery is consistently larger than in nasal periphery (e.g. 15.6 μm vs 13.7 μm) and this is associated with a reduction, in nasal retina, of the number of ganglion cells in the 14-22 μm range. These cells typically constitute about 61% of the ganglion cell population in temporal periphery, but only about 46% in nasal periphery. In siamese retinas mean soma diameter is also greater in temporal than in nasal periphery (e.g. 14.3 μm vs 13.5 μm), but the difference is consistently less than seen in common cats. The number of cells in the 14-22 μm range is also consistently higher in temporal than in nasal retina in the siamese (40% vs 30%), but the increase is not as marked as that observed between corresponding regions of common cat retinas. Mean soma diameter is also consistently higher in temporal retina of common cats than in temporal retina of siamese (15.6 μm vs 14.3 μm), but such differences were not consistently seen in nasal regions. These data suggest that in normally pigmented cats, X-cells are relatively more frequent in temporal than in nasal retina. The differences between siamese and normally pigmented cats are consistent with a selective loss of X-cells in siamese retinas, since the differences between normally pigmented and siamese retinas are more pronounced in temporal than in nasal retina. Preliminary analysis of the retinas of newborn kittens indicates that these patterns of naso-temporal differences in ganglion cell composition are present at birth in both common and siamese cats.

2064 WHY DOES MONOCULAR PARALYSIS OF ADULTS YIELD X-CELL LOSSES WHILE VISUAL DEPRIVATION OF INFANTS YIELDS Y-CELL LOSSES?
W.L. Salinger, M.G. MacAvoy* and P.E. Garraghty. Dept. Psych., UNC-G, Greensboro, NC 27412.

In the adult cat, both binocular lid suture and monocular paralysis have been shown to reduce the encounter rate for X-cells (cells are characterized solely on the basis of response to optic chiasm shock-OX latency) in the lateral geniculate nucleus (LGN). In contrast, kitten onset eyelid suture produces a pattern of Y-cell losses. These contrasting results raise the possibility that the nature of the effects produced by environmental modification may in part be age dependent rather than simply a function of the type of visual deprivation. To evaluate this possibility the effects of monocular paralysis in infancy were examined.

The left eyes were paralyzed in kittens with no prior visual experience at 24 days of age. Following surgery the animals were reared to maturity in a normally illuminated colony. OX latencies for each of 395 cells encountered in the right LGN of these subjects were measured, and compared with those obtained from subjects with adult onset monocular paralysis.

Infant onset monocular paralysis resulted in a reduced encounter rate for both X- and Y-cells. These losses were evident in both the layer innervated by the mobile "nondeprived" eye (A_1) and in laminae subserved by the paralyzed eye (A and C). In contrast, infant onset lid suture produces no reported effects on the nondeprived laminae.

A parallel between the effects of monocular paralysis of infants and adults is seen in that the A_1 layer, innervated by the mobile eye, suffers a partial X-cell loss in both instances. In monocularly paralyzed kittens, however, the additional loss of Y-cells suggests that here, monocular paralysis has features typical of other infant onset perturbations.

Taken together, these results suggest that the age of onset of environmental modification constitutes an important determinant of the extent to which X- or Y-cells are affected. These data further indicate that the impact of sensory disruption is partially dependent on the nature of that disruption. To the extent that the age of onset of the disruption is itself a critical factor, one should be cautious in attempting to explain the effects of a particular type of environmental modification on the basis of its stimulus properties alone.

2065 TRANSIENT VARIABILITY CHANGES IN CAT RETINAL GANGLION CELLS DURING ADAPTATION TO DIFFUSE ILLUMINATION. Arthur C. Sanderson, Dan Schweitzer-Tong, and Wlodzimierz M. Kozak. Biomedical Engineering Program, Carnegie-Mellon University, Pittsburgh, PA 15213.

The spike discharge of cat retinal ganglion cells was recorded extracellularly from single optic tract axons, and the variability of the interspike intervals was studied during the transient period following a sudden step change in diffuse retinal illumination. Step changes of one log unit in the range 10^{-4} to 10^{+1} cd/m^2 with a fully dilated pupil (equivalent to a retinal luminance of about .026 to 2600 scotopic trolands) were utilized. 30 sec to 5 min adaptation time was allowed between steps.

Variability of the maintained discharge was described using the index of the best-fit gamma distribution of interspike intervals. The gamma index varied from 1 to 8. ON-cells tended to fire more regularly (higher index) at higher illumination levels, while OFF-cells tended to fire more regularly at lower illumination levels.

A nonstationary estimator of the gamma index was developed to characterize the variability during the transient adaptation period. This estimate is based on a moving window procedure which corrects for the inherent dispersion of interval lengths due to the changing spike rate. The corrected moving window estimate is smoothed in time, then ensemble averaged over a set of responses. The transient was analyzed for a period of 30 sec following the step change. During the transient, the gamma index started at a maximum of 1-3 times the steady-state value, then decayed with a time constant similar to that of the rate change.

Analysis of the transient variability data showed a power law relation between coefficient of variation and mean interval with a power between 0 and 1. This relation did not hold for steady-state values at different light intensities. Based on considerations of neuronal firing models, these results suggest that the principal source of variability occurs prior to the ganglion cell, and that fluctuations are scaled by the adaptation mechanism in the manner of a multiplicative gain control, for example, through cellular or local circuit mechanisms, rather than adjusted additively by network inhibition.

2066 A BIOCHEMICAL STUDY OF ISOLATED GLIAL (MÜLLER) CELLS FROM THE TURTLE RETINA. P. Vijay Sarthy* and Dominic Man-Kit Lam*. (Spon: D. D. Louie). Baylor College of Medicine, Houston, Texas 77030.

A method has been developed for the preparation of large numbers of glial (Müller) cells from the turtle retina. After proteolytic dissociation of the retina, Müller cells were separated from retinal neurons by velocity sedimentation at unit gravity. Fractions containing over 90% morphologically identifiable Müller cells were prepared by this procedure. Fractions containing only Müller cells were obtained by drawing selected cells individually into a micropipette under visual observation. Biochemical analyses of isolated Müller cells showed that 1) these cells did not synthesize and accumulate ACh, GABA, or catecholamines when incubated with appropriate radioactive precursors; 2) the specific activities of choline acetyltransferase (EC 2.3.1.6), glutamate decarboxylase (EC 4.1.1.15) and tyrosine hydroxylase (EC 1.14.16.2) in these cells were less than 2% of those found in the retina; 3) Müller cells, however, contained high activities of transmitter degrading enzymes - acetylcholinesterase (EC 3.1.1.7) and γ-aminobutyrate-transaminase (EC 2.6.1.19); and 4) the cells also possessed high levels of two presumably glial-specific enzymes - glutamine synthetase (EC 6.3.1.2) and carbonic anhydrase (EC 4.2.1.1). These results, together with other findings, suggest that Müller cells are not capable of neurotransmitter syntheses but possess the enzymes necessary for two important roles in the retina: 1) the inactivation of certain transmitters after synaptic transmission by uptake and degradation, and 2) the maintenance of acid-base balance and the provision of a stable micro-environment in the retina by removal of metabolic products such as carbon-dioxide and ammonia.

Supported by NIH grant EY 02423.

2067 CHANGES IN LGN CELL SIZE DO NOT NECESSARILY CORRELATE WITH CHANGES IN CORTICAL BINOCULARITY, IN CATS WITH MONOCULAR VISION. P.B. Schechter. U. of Chicago, Dept. of Ophthalmology, Chicago, Ill. 60637.

Cats raised with monocular vision have few visual cortical cells driven by the deprived eye. Also, cells in the LGN laminae receiving input from the deprived eye are smaller than those in the laminae receiving input from the experienced eye. Early work by Wiesel & Hubel (J. Neurophysiol. 26, 1963) suggested that the cortical ocular dominance change is caused by pattern deprivation, while the LGN cell size change is caused by light deprivation. Some recent studies have suggested, however, that changes in cortical binocularity and LGN cell size "...are produced by a common causal factor" (Movshon & Dursteler, J. Neurophysiol. 40, 1977), or that LGN changes are secondary to cortical changes (Cragg, Anker & Wan, J. Comp. Neur. 168, 1976). The present results address this controversey.

Four kittens were dark reared until their 30th day of life. One was given 3 hrs of monocular vision on day 30 (3 hr kitten), 2 were given 4 hrs per day on days 30, 31 and 32 (12 hr kittens), and one was given 5 hrs per day on days 30-33 (20 hr kitten). All kittens were then dark reared until day 42, when recordings were taken from their visual cortices. A fifth kitten was normally reared, with one eye sutured, until day 42 (MD). After the recordings, 100 cells were measured in the right and left laminae A of each kitten's LGN.

In the 3 hr kitten and one 12 hr kitten, about equal numbers of cells were monocularly driven by each eye. In the other 12 hr kitten, the 20 hr kitten, and the MD kitten, nearly all cells were monocularly responsive to the experienced eye. However, only in the MD kitten was there a significant difference between mean cell size of the two laminae A. These results do not support the speculations of Movshon & Dursteler (1977) or of Cragg et al. (1976), but are cnosistent with the suggestion of Wiesel & Hubel (1963), concerning the relationship between cortical and LGN changes resulting from monocular vision.

2068 PERMANENCE OF BEHAVIORAL AND DENDRITIC SPINE DEFICITS IN THE MONOCULARLY DEPRIVED ALBINO RAT. Michael L. Schwartz and Lawrence A. Rothblat. Dept. Psychol., George Washington University, Washington, D.C. 20052

Monocular deprivation in the rat significantly reduces the density of dendritic spines in visual cortex contralateral to the deprived eye (Fifkova, J. Comp. Neur. 140:431,1970). In addition, the ability of these animals to discriminate complex visual pattern is severely impaired (Schwartz and Rothblat, Neurosci. Abstr., 1976). We have recently found that the period during which spine density and behavior can be altered begins around the time of eye opening and extends approximately 30 days. Deprivation in adults leaves both measures unchanged. In the present study we attempted to determine whether these morphological and behavioral changes can be reversed by a period of normal experience.

All animals (N=34) were monocularly deprived for 30 days by suturing one of the lids just prior to normal eye opening. At 45 days of age, 20 of the animals were reverse-sutured. Ten of these rats (deprived group) began behavioral testing on the following day. The remaining 10 (recovery group) were allowed 30 days of normal experience prior to training. A third group was not reverse-sutured and performed behavioral tasks using the non-deprived eye (non-deprived group).

All animals were trained to discriminate columns and rows of 5 mm squares in a fully automated discrimination apparatus. Thirty trials were given each day until the rat met a criterion of 90% correct responses in a daily session or until 1800 trials were completed. The results revealed that both the deprived ($\bar{X}$=1524) and recovery ($\bar{X}$=1191) groups were significantly impaired ($p < .01$) relative to animals learning with the non-deprived eye ($\bar{X}$=721). Further analysis revealed no significant difference between the deprived and recovery groups on this task. Dendritic spine density was assessed by processing the brains according to the Rapid Golgi technique. Preliminary analysis of this material shows evidence of little, if any, recovery in spine density. The number of spines in the deprived hemisphere of recovery animals was reduced by 13% in comparison to a 16% reduction in the deprived hemisphere of rats examined immediately following 30 days of deprivation.

It can be concluded from these results that there is little evidence for recovery from either the behavioral or dendritic spine deficits that follow monocular deprivation in the rat. These results further support our previous finding of a sensitive period for visual system development in the rat.

(Supported by NIMH Grant MH R01-27424)

2069 PRENATAL DEVELOPMENT OF EFFERENT PROJECTIONS FROM THE VISUAL CORTEX OF THE RHESUS MONKEY. C.J. Shatz & P. Rakic. Dept. of Neuroscience, Children's Hosp. Med. Center, Boston, MA 02115 & Sect. of Neuroanatomy, Yale Univ. Sch. of Medicine, New Haven, CT 06510.

The time of neuron origin and the development of afferent connections in the rhesus monkey's visual system have been studied previously (Rakic,'77) but little is known about the formation of efferent projections from the visual cortex. We investigated the development of the cortical projections to the lateral geniculate nucleus (LGN), superior colliculus (SC) and pulvinar (Pul) by means of the orthograde axonal transport of radioactive tracers. Seven fetal monkeys, aged from embryonic day 63 (E63) to E95 were exteriorized by Cesarian section and 0.1 µl ^{3}H-proline (20-40 µCi) was injected into the occipital cortex. Each fetus was restored to the uterus and 24 hours later was removed, fixed by perfusion, and its brain was processed for autoradiography.

In the autoradiographs of the E63 fetus no radioactive label was seen in the corticothalamic radiations or within the LGN, SC, or Pul. In fetuses injected at E69, E71 and E78, label was present in the cell-poor zones surrounding the LGN. Within the LGN, label was confined to the lateral-most margin: the prospective magnocellular layers (Rakic, '77). The remainder of the nucleus was free of label. The large injection sites made it impossible to determine whether visuotopic order is present at these early ages. In fetuses injected at E83 and E85, the portion of the prospective parvocellular region of the LGN adjacent to the white matter also contained label. In the oldest monkey (E95), label extended throughout both the parvo- and magnocellular layers, as in the adult. By E83 the labelling pattern in the LGN appeared characteristically wedge-shaped and appropriately located with respect to the cortical injection, indicating that topographic order in the corticogeniculate projection is established.

The development of the cortical projection to the SC is similar in time course to that to the LGN. Between E69 and E78, label was confined to the stratum opticum; by E85 it extended into the superficial gray. In the Pul, substantial amounts of label were present as early as E69, indicating that the development of this projection may even precede those to the LGN and SC. Topographic order was present by E95 in SC and E83 in Pul.

The efferent pathways from the visual cortex in primates are therefore present by the middle of gestation. Their development is in rough synchrony with that of the afferent pathway: axons from the LGN are present within the occipital lobe by E78, but do not enter the cortical plate until about E90 (Rakic,'77). Moreover, the cortical efferent pathway is topographically ordered prior to the lamination of the LGN and before the segregation of afferents from the two eyes. Supported by N.I.H. grants NS 11233 and EY 05172.

2070 LIGHTING CONDITIONS DURING DISSECTION AFFECT PROPERTIES OF GANGLION CELLS. Jeremy M. Shefner and Michael W. Levine*. Psychology Dept., Univ. of Illinois at Chicago Circle.

The response properties of goldfish retinal ganglion cells in isolated retinae maintained with pure O_2 were compared for retinae dissected in dim red light and retinae dissected in normal room lights. Chromatic opponency was a regular feature of photopic ganglion cells in retinae dissected in dim red light, but ganglion cells from retinae dissected in room lights responded as though their only input was from the long wavelength sensitive ("red") chromatic mechanism. This deleterious effect of room lights did not have to be exerted during the dissection; cells from retinae dissected in dim red light, but then exposed to room lights, were also devoid of any input other than from the red mechanism. Thus, this effect is apparently due to the presence of the high luminance light itself, and not to photomechanical changes occurring during dissection.

In many other respects, ganglion cells observed in retinae dissected under the two lighting conditions display similar properties. Both spatially linear ("X-like") and non-linear ("$\bar{X}$") cells may be found in goldfish retinae independent of lighting conditions during dissection. Also, neither the mean nor the variance of the maintained discharge of ganglion cells in the dark differed as a function of which dissection was performed.

2071 A WIRING DIAGRAM FOR THE RECEPTIVE FIELDS OF BIPOLAR CELLS IN THE GENERALIZED VERTEBRATE RETINA. Robert Siminoff, BRI, UCLA, Los Angeles, CA 90024.

A model of the generalized vertebrate retina was developed based on a synthesis of the literature. The bipolar cells are organized into concentric receptive fields- the center excitatory area formed by direct inputs from photoreceptors and the surround inhibitory area formed by indirect inputs from photoreceptors via horizontal cells. A wiring diagram for the C-type bipolar cell is presented. The cones are organized into 2 alternating rows-- row A is formed by a red cone alternating with a green cone and row B is formed by a blue cone alternating with either a red or green cone. The direct cone input to the central region comes from a hexagon of 9 like-cones from 5 rows of cones in the mosaic. The surround region is formed by inputs from 6 C-type horizontal cells- each of which receives inputs from a hexagon of 9 opponent-color cones. Thus, if the central region is red-sensitive the surround region is green-sensitive. Electrical coupling of like-photoreceptors via high resistance " gap " junctions and stray light produce the added feature of the geometric center having the highest sensitivity (or weighted input) and the sensitivity decreases radially from the center. Additionaly, overlapping of the central and surround regions is produced. The horizontal cells act as inverters of variable gain. A L-type horizontal cell receives inputs from all cones within a given hexagon and produces a form of negative feedback to the cones. This results in a decrease in the effects of stray light and produces modifications in the receptive field organization of the bipolar cell. The L-type bipolar cell is similarly organized as the C-type except that the central region of each of the 6 horizontal cells receives inputs from a hexagon of 19 cones of the 3 spectral types of cones. Electrical coupling between like-horizontal cells produces spatial summation so that as the light intensity increases negative feedback via the L-type horizontal cell spreads laterally to minimize the lateral spread of light stimulus due to increased stray light. The ganglion cell reflects the organization of the bipolar cell. Two types of bipolar cells are present in parallel- the HPBC where direct inputs produce hyperpolarization and the DPBC where direct inputs produce depolarization. Thus each wiring diagram produces two types of bipolar cell - hyper/ dep and dep/ hyper.

2072 THE ACCESSORY OPTIC SYSTEM: A VISUAL SYSTEM IN VESTIBULAR COORDINATES. John I. Simpson and Robert E. Soodak*. Dept. Physiol. & Biophys., N.Y. Univ. Med. Ctr., 550 First Ave., New York, NY 10016

The accessory optic system in mammals is, in general, composed of three terminal nuclei (dorsal, lateral and medial) innervated by primary visual fibers. Response properties of cells of the medial terminal nucleus (MTN) were investigated using extracellular recording in anesthetized, paralyzed rabbits. MTN cells typically have a high background activity (25-50 spikes/sec.) and respond to chiasm stimulation with a latency of 2-2.5 msec. All cells influenced by moving patterns show both direction and speed selectivity. Effective stimuli are large (20-30° square), slowly moving textured patterns. Preferred directions are vertical with a posterior component; cells preferring upward movement are twice as numerous as those preferring downward movement. The preferred and null directions of MTN cells are not 180° apart. For example, if the preferred direction is up with a posterior component, the null direction is down with a posterior component. Best modulation occurs at about 0.5-1°/sec. Activity increases in a sustained manner 2-3 times over background for preferred direction movement and can be silenced for null direction movement. MTN cells respond primarily only at onset of illumination. The marked similarities between properties of MTN cells and of on, direction selective retinal ganglion cells in rabbit suggest that this ganglion cell class provides the primary visual input to MTN and is the major contributor to the accessory optic tract. Collectively, the direction preferences of on, direction selective ganglion cells define three directions in visual space: anterior, up and posterior, and down and posterior. Some cells in the nucleus of the optic tract (NOT) have response properties identical to those of MTN cells, except that the preferred direction is from posterior to anterior (Collewijn, Brain Res., 1975). These pretectal cells may, in fact, be part of the accessory optic system. Studies using HRP techniques show that MTN projects to the NOT region. This projection may act to synthesize an inhibitory signal for posterior movement. We propose that the three directions in visual space represented in the accessory optic system are derived from the orientation of the three semicircular canals of the vestibular system and that this organization allows for interaction of visual and vestibular signals in a single coordinate system. 2073 VISUAL ACUITY IN VISUALLY DEPRIVED CATS - BEHAVIORAL CORRELATES OF SINGLE-CELL ELECTROPHYSIOLOGY? Douglas C. Smith*, Randy Lorber*, Ann Kirk* and Michael S. Loop. Dept. Physiol., Univ. of Illinois, Urbana, Ill. 61801.

Visual deprivation through the first 3-4 mo. of a kittens life is known to produce profound changes in the responsivity and stimulus specificity of single cells in striate cortex. For example, following rearing with monocular deprivation (MD) only about 5% of area 17 cells respond to visual stimulation of the deprived eye (Wiesel & Hubel, '63; '65; Kratz et al., '76). In addition, other manipulations are associated with differences in the percentage of responsive cells. For instance, around 18% of striate cells are responsive to the intially-deprived eye following postcritical-period reverse suture (RS) (Smith et al., '78). Further, an average of 30% of the cells can be driven following postcritical-period enucleation of the nondeprived eye in a MD cat (MD-DE) (Kratz et al., '76; Smith et al., '78). Following binocular deprivation (BD) about 50% of the cells in striate cortex are responsive (Kratz & Spear, '76; Pettigrew, '74; Wiesel & Hubel, '65). Finally, in MD's with the other eye removed shortly after birth (MDE), about 68% of the cells are responsive which is less than the 78% found to be responsive to a single eye in normal cats (Kratz & Spear, '76). Moreover, while the percentages of cells displaying direction and/or orientation selectivity do not vary systematically across all of these groups, the actual numbers of selective cells do. This is due to differences in the percent responsive in each condition.

We have been measuring visual acuity in several of these deprivation conditions. Using the Mitchell et al., ('76) jumping stand we measured behavioral visual acuity for high contrast square wave gratings (luminance 13 cd/m^2). Thus far, we have established the visual acuity for 2 RS, 3 MD-DE, 2 BD and the nondeprived eye in 5 MD cats. The mean acuity for RS cats is 1.6 c/d, for MD-DE cats is 2.7 c/d, for BD cats is 3.5 c/d, and is 5.1 c/d for a nondeprived eye. Additional animals are currently being tested in each group as well as MD cats with the deprived eye opened and MDE cats. The results of these additional cats will be presented. Thus far, visual acuity appears to be highly correlated with the percentage of responsive cells and the number of cells displaying stimulus specificity.

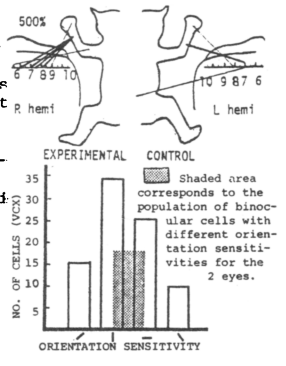
2074 RESPONSE OF FLY GIANT OPTIC NEURONS TO INTENSITY CHANGES AND MOVING PATTERNS. Spencer L. SooHoo and Lewis G. Bishop. University of Southern California, Los Angeles, CA 90007.

When a tethered flying insect sees relative angular motion, it will move so as to null out this relative motion. Goetz measured flying torque produced by a tethered fly and found that thrust response was maximum when a horizontally oriented striped pattern was moved vertically; the turning torque was maximum when a vertically oriented striped pattern was moved horizontally. Two functionally independent neural systems were suggested for the control of flight. Intracellular recording and staining showed that in the lobula plate there are anatomically and functionally distinct horizontal and vertical movement detectors. This report deals with the electrical responses of the large vertical cells. These cells respond to changes in light intensity with a graded response. The response consists of a depolarization upon which noise-like fluctuations are superimposed. These fluctuations are reduced by signal averaging; their power spectra density resembles that of random, band-limited noise. Relative to the monopolar neurons of the lamina or to the retinula cells, the vertical cells show a small dynamic range in their response to changes in light intensity. A striped pattern moving in the downward direction evokes a depolarization and increased fluctuations in the membrane potential; upward motion evokes a hyperpolarization and increased fluctuations in the membrane potential. A moving stimulus evokes a response whose magnitude is equal to that evoked by a stationary stimulus several orders of magnitude brighter. At low contrast frequencies the contrast frequency of a striped moving pattern appears in the response.

2075 EARLY EXPERIENCE AFFECTS BRAIN DEVELOPMENT IN NORMALLY REARED KITTENS. D.N. Spinelli and F. Jensen. Depts. of COINS and Psychology, University of Massachusetts, Amherst, MA 01003.

To elucidate the impact that early experience has on the developing brain in normally reared kittens, we experimented as follows. Kittens raised in a normal environment were trained for 8 min. a day to a simple task: vertical bars presented to one eye signalled an unsafe condition and the kitten had to lift the appropriate forearm or be shocked on it; on lifting, the unsafe stimulus was turned off and the safe one on in the other eye. Training began at 4 weeks of age, 5, and 11 in 3 groups. The kittens learned the task uneventfully. At 13 weeks of age, single cells were recorded from postcruciate gyrus (PC), primary visual cortex (VCX) and visual association cortex (VASCX). PC shows a greatly enlarged forearm locus for the trained forearm, up to 3 mm in diameter; whereas the locus for the untrained forearm has a diameter of .5 to 1 mm. Further, 70% of cells in the trained side respond to visual stimuli with orientation identical to the one used during training. In the untrained forearm locus, 30% of cells respond to visual stimuli and orientation sensitivity is randomly distributed. VASCX shows a preponderance of cells prefer orientations used during training and often respond to forearm stimuli. Surprisingly large effects (considering the brevity of visual training compared with total visual experience) are present in VCX: 1) a large shift toward monocularity; 2) orientations used during training are significantly more represented than others; 3) most important, the presence of cells sensitive to vertical bars for one eye and horizontal bars for the other. This shows, for the first time, that early experience can enlarge the cortical locus of a body part in PC and tune VCX cells to unusual stimuli in normally reared kittens. No atrophy from disuse can exist in these animals because they are not deprived and cells with these properties are not present in normal adults. We conclude that early experience in developing organisms powerfully affects the developing brain and impacts on concurrent experiences. These results are significant not only because of what they tell us concerning how experience is stored in the brain, but (as we believe that these changes once produced are permanent) because of the implications they carry concerning early experiences in human children.



2076 EFFECTS OF SELECTED LESIONS IN VISUAL CORTEX ON INTERHEMISPHERIC TRANSFER OF FORM DISCRIMINATIONS IN CATS. James M. Sprague, Giovanni Berlucchi*, Antonella Antonini* and Alfredo Simone*. Dept. Anat., Sch. Med., Univ. Pennsylvania, Phila., PA 19104 and Inst. Physiol., Univ. Pisa, 56100, Pisa Italy.

Suprasylvian lesions removing cortical areas 7 and 21, and portions of area 19 and of the lateral suprasylvian area (LSA) were placed unilaterally in split-chiasm cats. By comparison with the non-lesioned side and with cortically intact split-chiasm and split-brain cats, form discrimination learning with the eye on the lesioned side was severely retarded. This deficit cannot be attributed to an unintentional undercutting or damage of areas 17 and 18, since the laminae of the lateral geniculate nucleus (LGN) showed minimal retrograde atrophy; degeneration was found in NIM and in the inferior and lateral pulvinar nuclei. In addition, interhemispheric transfer of these discriminations to the lesioned side was absent or poor, while transfer in the opposite direction was normal. A cat with a suprasylvian lesion undercutting areas 17 and 18 (and severe atrophy of LGN as well as inferior and lateral pulvinar) was unable to learn from discriminations with the eye on the injured side, despite prolonged training with that eye and normal learning with the other eye. Another cat with a suprasylvian lesion selectively removing the anteromedial and posteromedial portions of LSA (Clare-Bishop area) showed no learning deficit using the eye on the injured side, but poor transfer to that side.

In contrast, split-chiasm cats with unilateral or bilateral lesions largely removing the commissurally connected portions of visual cortical areas 17, 18 and 19 showed good interhemispheric transfer of monocularly learned pattern discriminations. The capacity for interocular transfer in these cats was in fact little or no different from that of split-chiasm cats with an intact cortex.

The results support the hypothesis of a major involvement of cortical areas other than 17 and 18 in learning and interhemispheric transfer of form discriminations in the cat.

2077 LATERAL GENICULATE INTERNEURONS ACCUMULATE EXOGENOUS [^{3}H]-2,4- DIAMINOBUTYRIC ACID (DABA). Peter Sterling and Thomas L. Davis.* Dept. Anat., Sch. Med., Univ. Pa., Philadelphia, PA 19174.

Optic axons in the A-laminae of the cat lateral geniculate nucleus (LGN) contact directly the dendrites of relay cells (classes I, II) and also synaptic terminals containing flattened vesicles (F-terminals). The F-terminals in turn contact relay cell dendrites (Guillery, Z. Zellforsch. 96:1, 1969) and appear to be inhibitory. They arise as axons or presynaptic dendrites from interneurons (class III) which are the smallest neurons in the A-laminae and form about 25% of the population. We wanted to see whether the class III neurons or their processes had the ability to selectively accumulate gamma-aminobutyric acid (GABA) or its analog, DABA, since many neurons which appear to use GABA as a transmitter can accumulate these compounds. [^{3}H]-DABA was injected (50μCi in 2μl) into the A-laminae. One hour later the cat was perfused with buffered glutaraldehyde-paraformaldehyde and the geniculate prepared for light and electron microscope (EM) autoradiography. Neurons intensely labeled with silver grains were observed interspersed with unlabeled neurons for several millimeters around the injection site. We reconstructed from serial, one-micron autoradiograms 134 neurons in a patch of lamina A and found that the labeled cells formed about 25% of the population. They were the smallest cells, (12-18μm) and lacked the multilaminar body which is the hallmark of the somewhat larger (16-24μm) class II relay cell (LeVay and Ferster, J.C.N. 172:563, 1977). In EM autoradiograms the F-terminals were intensely labeled while optic terminals (RLP) and presumed cortico-geniculate terminals (RSD) were not. Astrocytes and oligodendrocytes were heavily labeled but not as intensely as the cell bodies and processes of the interneurons. These observations, plus the finding that the GABA synthetic enzyme, glutamic acid *decarboxylase, exists in certain neurons of the rat* LGN, suggest that GABA may be the transmitter for the inhibitory intrageniculate interneuron. (See also abstracts of Rapisardi and Stevens and Gerstein.) (Supported by NEI grant RO1EY00828)

2078 A SYNAPTIC TRIAD AS THE INPUT TO "X" LATERAL GENICULATE CELLS. John K. Stevens, George L. Gerstein, Dept. Physiology, Univ. of Penn., Phil, Pa.

Using single electrodes we have recorded from 26 unit-pairs in cat lateral geniculate nucleus (LGN). In each case these pairs consisted of a small monophasic positive action potential (AP), followed by a larger biphasic AP. The small AP has been identified via electrical stimulation as an optic tract (OT) fiber and, by exclusion we assume the large AP represents an LGN cell. Crosscorrelograms between these OT fibers and LGN cells revealed a very consistent relationship. After a single optic tract AP the probability of finding a LGN AP was enhanced for 1.0 to 1.5 msec (1st peak). This 1st peak in the correlogram was followed by a decrement in the firing probabiliy of the LGN cell for a 1.0 to 2.0 msec period (F period). The F period was followed in turn by a second increment in the firing probability of the LGN cell (2nd peak).

Special pattern crosscorrelograms demonstrate that these three components are contingent only upon a single AP from the OT fiber and not on the firing of the LGN cell. Thus, the F period and 2nd peak do not represent an intrinsic properity of the LGN cell itself (absolute refractory period), but rather must represent an external neural circuit. The simplest possible circuit consistent with these data would be a synaptic triad, where an OT fiber would excite both a LGN cell and an interneuron. The interneuron would in turn inhibit the LGN cell to produce the F period. The 2nd excitatory peak would represent a rebound effect.

We obtained response planes on 18 pairs. In 17 of these both the OT fiber and LGN cell had heterogeneous response planes ("X" cells). The remaining OT-LGN pair had homogeneous planes ("Y" cells). On six occasions cells recorded immediately preceeding or following an OT-LGN pair had homogeneous response planes. Thus, it is, unlikely that this "X" cell bias can be explained solely by electrode sampling errors.

The suggested circuit and its almost exclusive *association with "X" cells is attractively consistent* with the anatomical finding of Rapisardi that the LGN synaptic triad is associated with Guillery class II cells and supports the Sterling and Davis suggestion that the F terminals in the triad which accumulate DABA are derived from inhibitory interneurons. (See abstracts in this volume. Supported by NIH grants EY01832 and NS05606.)

2079 CODING OF TEMPORAL CONTRAST BY CAT RETINAL GANGLION CELLS. Vesna G. Sutija. Dept. Physiol. & Biophys., Univ. Miami Sch. of Med., Miami, FL 33152.

Responses from single ganglion cell fibers in the optic tract of cats were recorded extracellularly with laquer coated tungsten electrodes, and separated into X and Y using the linearity of spatial summation criteria. Subsequently a spot of light, frequency and amplitude modulated, was positioned concentrically with the receptive field center, while the periphery received steady background light. The background luminance level, the diameter of the spot and the waveform (sinusoidal or square) was also varied. The on-center X showed saturation with higher levels of background luminance and larger spot diameters. The waveform did not significantly influence their following rates at higher frequencies or the peak frequency response. The off-center X acquired properties similar to the off-center Y at lower background luminances (in terms of their high frequency following rates and the peak frequency response). Both on-center and off-center Y improved with higher background levels, larger spot diameters, and with squarewave stimulation (i.e. increased their bandwidths and their peak response shifted). For on-center X, the response to squarewave modulated stimulus could be predicted from the response to sinusoidally modulated light; all other subgroups showed marked nonlinearities. These findings are inconsistent with models of separate spatial and temporal information processing in the visual system. (Supported by N.I.H. post-doctoral fellowship Grant #5F32EY05021-02).

2080 THALAMIC PROJECTIONS TO ELECTROPHYSIOLOGICALLY DEFINED VISUAL AREAS IN THE CAT. Laura Symonds*, Alan Rosenquist, Stephen Edwards, Larry Palmer. Dept. Anat., Sch. Med., Univ., of Penna., Phila., PA 19104; and Dept. Anat., Sch. Med., Univ. of Virginia, Charlottesville, VA 22901.

Evidence from a number of different sources suggests that the posterior "visual" thalamus of the cat may be divided into at least three zones extending from medial to lateral in the dorso-medial to ventrolateral plane. Using the scheme and nomenclature of Updyke (J. Comp. Neurol., 173:81-122, 1977), we have made injections of tritiated amino acid into three extrageniculate thalamic subdivisions: lateral posterior interjacent (LPi), lateral posterior lateral (LPl), and pulvinar (P). LPi corresponds to the tecto-recipient zone, LPl to the cortico-recipient zone, and P to the pretecto-recipient zone. The patterns of cortical connectivity of these thalamic subdivisions were related to electrophysiologically and anatomically-defined visual areas of the cat cortex. In the suprasylvian cortex (Palmer, et. al., J. Comp. Neurol., 177:237-256, 1978), areas PMLS and VLS are labeled after LPl but not LPi or P injections. Areas DLS, PLLS, and PS (Heath and Jones, Ergebn. Anat. Entwickl.-Gesch., 45:1-64, 1971) are labeled after both LPi and LPl but not after P injections. Of the two rostral suprasylvian areas, ALLS appears to receive no thalamic input from the regions covered by our injections, and AMLS receives projections from the ventral but not the dorsal portions of LPl. Other data suggest that this latter finding may be explained by the existence of an extensive representation of the lower visual field in AMLS and the probability that lower fields are represented ventrally (and rostrally) in LPl. The "splenial visual area" of Kalia and Whitteridge (J. Physiol., 232:275-283, 1973) was labeled after injections into P and lateral portions of LPl but not after injections into LPi or medial portions of LPl. Area 7 is labeled after injections into P but not into LPl or LPi. Area 19 is labeled following injections into LPl and P, but not LPi. Area 20 appears on the basis of both electrophysiological recording and thalamic connectivity to consist of two subdivisions, and both of these are labeled after injections into LPi, LPl and P. We conclude that Updyke's division of the posterior thalamus into zones is largely supported by the uniqueness of their projections to identified cortical areas. 2081 ACTIVITY OF NEURONS IN VISUAL CORTEX OF THE ALERT MACAQUE EVOKED BY STATIONARY AND MOVING STIMULI IN THREE-DIMENSIONAL SPACE. William H. Talbot* and Gian F. Poggio, Dept. of Physiology Johns Hopkins School of Medicine, Baltimore, MD 21205

A previous study from this laboratory demonstrated sensitivity to depth of neurons in striate and prestriate cortex responding to stimuli moved in frontoparallel planes in front of and behind the plane of fixation. Two major groups of depth sensitive neurons were found: neurons that responded over a narrow range of depths centered near or at the fixation plane (*tuned excitatory, tuned inhibitory*) and neurons that responded over an extended range of depths on one or the other side of the fixation plane (*near, far*). We have now added to that study by separately analyzing binocular interaction during static and dynamic stereoscopic stimulation. Bar stimuli were presented against a background of dynamic random noise using a dichoptic dot matrix display. Trained monkeys fixated a small target during each stimulus presentation. The fixation target was shifted on the screens of the stimulator to a position that ensured that the response field for each neuron was centered on the display. Size and orientation of bar stimuli were usually adjusted for maximal response. Single cortical neurons were routinely tested with bars moving in frontoparallel planes (a dichoptic simulation of our earlier experiments), stationary bars at various apparent depths, and bars moving with constantly changing disparity that appeared to move toward and away from the monkey in various directions. Our results indicate that activity of most foveal cortical neurons is affected by stimuli moving in depth. For many cells classified as *tuned* from responses to moving bars of fixed disparity, tests with stationary bars and bars moving in depth confirm that these cells are primarily sensitive to positional disparity of retinal images. Neurons showing extended depth sensitivity when tested with stimuli of fixed disparity can be subdivided by dynamic disparity testing: some respond to stimuli that appear to move in depth with activity that is predictable from their responses to fixed disparity stimulation; others respond with activity that is opposite to prediction. Finally, a relatively large number of neurons that have little or no depth sensitivity when tested with fixed disparities are quite sensitive to the direction of apparent stimulus movement in depth. The characteristics of these neurons revealed when retinal image velocity and direction differ in the two eyes seems in some cases to be due to an ocular directional dominance that is not apparent in responses to monocular stimuli or to binocular stimuli that cause identical image movements in both eyes. (USPHS 5 PO1 6828)

2082 SEROTONIN-A NEUROTRANSMITTER OF THE BOVINE RETINA, Thomas N. Thomas, John W. Zemp and Dianna A. Redburn+, Department of Biochemistry, Medical University of S.C., Charleston, S.C. 29403 and +Department of Neurobiology and Anatomy, Univ. Texas Med. School, Houston, Tex. 77025

Serotonin (5-hydroxytryptamine, 5-HT) is an established neurotransmitter of the brain but very little information is available regarding its role as a retinal neurotransmitter. Some recent reports have demonstrated the presence of 5-HT and high affinity uptake systems for 5-HT in chick and rabbit retina. Our investigations indicate the possibility of 5-HT being a neurotransmitter of the bovine retina.

Slices of fresh bovine retina were incubated at 37°C in oxygenated Krebs-Ringer medium containing 50 µM pargyline and [^{3}H] 5-HT (10^{-8}M to 10^{-6}M). Low concentrations of [^{3}H] 5-HT were used so as to measure the high affinity uptake. These conditions favour uptake into serotonergic neurons. The uptake of [^{3}H] 5-HT by bovine retina is sodium and temperature dependent, ouabain sensitive, and it is saturable. A Michaelis-Menten plot of the uptake data gave an apparent Km of 4.3 x 10^{-7}M and a Vmax of 294.3 pmol/g/10 min. The uptake system also demonstrated a high degree of pharmacologic specificity. Reserpine (2 x 10^{-4}M) completely eliminated the uptake whereas chlorimipramine (10^{-4}M) produced 85% reduction in uptake. By using a technique that has been successfully used to study the release of neurotransmitters from brain and retina, we were also able to demonstrate K^+ stimulated, Ca^{2+} dependent release of [^{3}H] 5-HT from bovine retina. This is the first demonstration of evoked release of 5-HT from retina of any species. Spectrophotofluorimetric analysis of bovine retina demonstrated the presence of 5-HT and its major metabolite 5-HIAA.

This report demonstrates the presence of appreciable amounts of 5-HT and 5-HIAA in the retina, a high affinity uptake system, and K^+ stimulated Ca^{2+} dependent release. Evidence presented here supports the possibility of serotonin being a neurotransmitter of the bovine retina. Psychoactive and hallucinogenic drugs have been shown to alter serotonergic systems in the brain. The demonstration of serotonergic system in the retina would have profound pharmacological implications and would provide further insight into the mode of action of these drugs.

2083 EFFECTS OF MONOCULAR DEPRIVATION ON CELLS IN THE CAT'S LATERAL SUPRASYLVIAN VISUAL CORTEX. Lillian Tong* and Peter D. Spear. Dept. Psychol., Univ. of Wisconsin, Madison, WI 53706.

In experiment I, effects of rearing with monocular lid-suture (MD) on neurons in the lateral suprasylvian visual cortex (LS) were investigated. Nine MD cats were studied, and 239 cells were recorded in both the binocular and monocular segments of LS cortex. In normal cats, 65% of the binocular segment cells are driven by both eyes (Spear & Baumann, 1975). Following MD, however, nearly all cells (83%-90%) were driven exclusively by the experienced eye in the binocular segment of both hemispheres. The receptive field properties of these cells appeared normal: 75% were direction selective, 6% were movement sensitive, 10% responded best to stationary flashing stimuli, and 9% had indefinite receptive fields. In the monocular segment contralateral to the deprived eye, the deprived eye was able to drive many LS cortex cells. However, the receptive field properties of these cells were very abnormal; e.g., none of them were direction selective. Thus, both binocular competition and deprivation per se play a role in the effects of monocular lid-suture on LS cortex neurons.

Experiment II investigated whether these effects were due to abnormal visual cortex inputs (from areas 17, 18, and 19) or to changes in the thalamic-LS cortex pathways independent of the visual cortex. This was tested by recording from 159 cells in 9 MD cats which had areas 17, 18, and 19 removed bilaterally as adults. In the binocular segment contralateral to the deprived eye, the deprived eye drove 67% of the cells after visual cortex removal, compared to only 17% when visual cortex was intact. Thus, the visual cortex appears to suppress thalamic-LS cortex inputs from the contralateral deprived eye in MD cats. In addition, the ipsilateral experienced eye drove 69% of the LS cortex cells after visual cortex removal (36% were binocularly driven). This contrasts with normally reared cats, in which the ipsilateral eye drives only 14% of the LS cortex cells after visual cortex removal (Spear & Baumann, 1978). Thus, during rearing with MD, the ipsilateral experienced eye develops thalamic-LS cortex inputs which are not present in normally reared cats. The receptive field properties of cells driven by both the deprived and experienced eyes were abnormal following visual cortex removal in the MD cats; e.g., only 10% were direction selective. Thus, the visual cortex inputs provide direction selectivity to LS cortex cells in MD cats, just as in normally reared cats (Spear & Baumann, 1978). Taken together, the results of experiment II indicate that the effects of MD on LS cortex cells are produced both by an abnormal input from areas 17, 18, and 19 (which suppresses thalamic inputs from the deprived eye) and by changes in the thalamic-LS cortex pathway independent of the visual cortex (new inputs from the experienced eye).

2084 EFFECTS OF UNILATERAL AND BILATERAL LESIONS OF THE SUPRASYLVIAN AREA ON INTEROCULAR TRANSFER IN THE CAT. Michel Turcotte*, Maurice Ptito, Maryse C. Lassonde and Franco Lepore. Lab. de Neuropsychologie. Univ. du Québec, Trois-Rivières and Univ. de Montréal, Montréal, Canada.

The suprasylvian area (SSA) has been shown both anatomically and physiologically to be involved in visual processing. Recent studies (Berlucchi et al., Exp. Brain Res. 31, 1978) using visual cortical lesions excluding the suprasylvian area failed to abolish interhemispheric transfer. The authors concluded that transfer must depend on other cortical areas, such as the suprasylvian area. In the present experiment, eight adults cats underwent a section of the optic chiasm, followed by a unilateral destruction of the SSA. They were then tested monocularly on several pattern discrimination tasks both in a Thompson box and a Lashley type jumping stand. One group started with the eye ipsilateral (EI) in the cortical lesion the other with the eye contralateral (EC) to the SSA lesion. Animals in both groups learned the pattern discriminations equally well in an equivalent member of trials. The degree of interocular transfer was then assessed, that is, they were retested on the same patterns using the untrained eye. Partial results showed that interocular transfer was present in all subjects from both groups. However, more precise statistical analyses showed that transfer in the EI group was much better (index of interocular transfer derived from Murdock's formula: 0.93) than in the EC group (index of interocular transfer: 0.23). To further evaluate the importance of SSA in interocular transfer the SSA in the unlesioned hemisphere was next destroyed. The cats were first retested on the previously learned discriminations. No apparent deficits were noticed when testing was carried out using the hemisphere lesioned first. However performance decreased when testing with the eye connected to the newly lesioned hemisphere. Once criterion was achieved on all previously learned patterns, new pattern discriminations were given to one or the other eye. Again learning was comparable for both sides. However, when interocular transfer for the newly learned patterns was measured, it was found to be very poor in either direction (index of transfer: 0.20). These results support previous findings on the importance of the suprasylvian area in interhemispheric transfer of visual discriminations, although they also indicate that it is probably not the exclusive region for such a function.

2085 INTERACTIONS OF STRIATE AND POSTERIOR PARIETAL CORTEX IN SPATIAL VISION. Leslie G. Ungerleider and Mortimer Mishkin. Laboratory of Neuropsychology, NIMH, Bethesda, MD 20014.

This study investigated the contribution made by inputs from striate cortex to the visuospatial functions of posterior parietal cortex. In Exp. 1, monkeys received a three-stage operation intended to serially disconnect posterior parietal from striate cortex. At each stage they were tested for retention of the landmark task, a visual spatial discrimination sensitive to the effects of bilateral posterior parietal damage (Pohl, JCPP 82: 227, 1973). The results showed: no deficit after the initial unilateral posterior parietal lesion; severe deficit after the addition of a total contralateral striate lesion; and moderate deficit after disconnection of the intact posterior parietal and striate areas by section of the corpus callosum. Subsequent removal of the remaining posterior parietal cortex yielded no effect, indicating that tectofugal inputs to this cortex had played no significant role in the recovery following disconnection. Taken together, the results demonstrate that the visuospatial functions of posterior parietal cortex depend on corticocortical inputs from striate cortex. This parallels an earlier finding that corticocortical inputs from striate cortex are crucial for the pattern recognition functions of inferior temporal cortex. However, the relative effects of the striate and callosal lesions in the two studies were reversed, suggesting that posterior parietal cortex is more dependent on ipsilateral striate inputs than is inferior temporal cortex. In Exp. 2, monkeys received bilateral lesions of the striate areas representing either central vision (lateral striate) or peripheral vision (medial striate). They were tested both on a pattern discrimination task, to assess residual inferior temporal function, and on the landmark task, to assess residual posterior parietal function. On the former task, only the lateral striate lesion produced a deficit, whereas on the latter task, the two lesions produced equally severe deficits. Apparently, inputs from central vision are especially important for the pattern recognition functions of inferior temporal cortex, but inputs from central and peripheral vision are equally important for the visuospatial functions of posterior parietal cortex. Thus, although interactions with striate cortex are critical for both the parietal and temporal areas, the striate inputs to the two are organized differently: relative to inferior temporal cortex, posterior parietal cortex receives a greater contribution from inputs representing both the contralateral and the peripheral visual fields. These differences, which are seen in the receptive field properties of posterior parietal vs. inferior temporal neurons, may reflect differences in the cortical processing required for spatial vs. object vision.

2086 THE CLASS V CELL IN THE LATERAL GENICULATE COMPLEX AND LATERAL POSTERIOR COMPLEX OF THE CAT THALAMUS. B. V. Updyke. Dept. of Anat., L.S.U. Med. Ctr., New Orleans, LA 70112.

In 1970 Famiglietti (1) described an unusual cell type (class V cell) in Golgi impregnations of the cat lateral geniculate nucleus, and presented evidence suggesting that these cells possess both a myelinated axon and presynaptic dendrites. I have reexamined the morphological features of Golgi stained class V cells in the dorsal lateral geniculate complex (LGNd & MIN) and in the lateral posterior complex. Golgi staining was combined with Nissl counterstaining (2) in order to assess the distribution of class V dendrites relative to cytoarchitectural boundaries.

Class V cells are found within all layers of the LGNd, and within MIN and the lateral posterior complex. These cells have medium sized perikarya and smooth varicose or moniliform dendrites which branch dichotomously and usually taper to fine beaded terminal processes. Dendritic appendages are relatively sparse and typically occur as either single or serial swellings on threadlike processes.

Many of these cells have dendrites which are exceptionally long (500 - 700μm), resulting in large but sparse dendritic arbors. A striking feature of these arbors is the tendency for the dendrites to span both laminar and nuclear borders. Dendrites were seen to lie within and to cross the intralaminar zones of the LGNd; to extend medially beyond lamina A_1 into MIN, and dorsally beyond lamina A into the perigeniculate nucleus. Class V cells within the pulvinar send dendrites laterally into the external medullary lamina.

It was possible to recognize only the axon initial segments. Given the otherwise satisfactory quality of the impregnations, this consistent failure of the distal portions of the axons to stain is indicative of myelinated axons.

The anatomical evidence thus suggests that class V cells constitute a special class of thalamo-cortical relay cell. Work is now underway to reexamine Famiglietti's (1) suggestion that these cells also possess presynaptic dendrites; a feature which would imply additional "interneuron-like" functions.

Although one might speculate that cells with such striking morphology should respond differently from conventional relay cells, there seems to be no physiological confirmation for this notion. One is tempted to conclude that they have been overlooked in physiological studies of the cat LGNd.

2087 THE DISTRIBUTION OF CELLS PROJECTING INTERHEMISPHERICALLY IN EXTRASTRIATE VISUAL CORTEX OF THE MACAQUE. D.C. Van Essen* and J. L. Bixby* (SPON: J. Myerson). Division of Biology, California Institute of Technology, Pasadena CA 91125.

Axons in the corpus callosum that project to extrastriate visual cortex terminate preferentially in regions representing the vertical midline of the visual field. This characteristic pattern of connections provides a valuable anatomical method for assessing visual topography over large regions of cortex. We have extended this approach by comparing the distributions of the cells of origin and the terminal projections of the callosal fibers. The splenium of the corpus callosum was transected and a Gelfoam pad soaked with horseradish peroxidase (HRP) was applied to the cut surfaces of the callosum. After survival times of 3 or 6 days the brain was fixed, sectioned and reacted for HRP activity; in the 6-day survival animal additional sections were stained for degenerating terminals. The positions of HRP-labelled neurons were marked on drawings of individual sections and on two-dimensional, "unfolded" reconstructions of extrastriate occipital cortex (cf. Van Essen and Zeki, J.Physiol., 1978). The regional distributions of degeneration and HRP-labelled neurons were very similar throughout the occipital lobe. Thus, callosal-projection cells in one hemisphere terminate in a mirror-symmetric pattern in the opposite hemisphere. These experiments do not, however, reveal the degree to which the projections from any one locus are restricted to the exactly corresponding contralateral locus within the overall zone of terminations.

In most cortical regions all of the HRP-labelled cells were situated in layers II and III, and most labelled cells were obviously pyramidal in shape. An additional population of pyramidal cells in layers V and VI was labelled in several restricted portions of the anterior bank of the lunate sulcus, the prelunate gyrus, the posterior bank of the superior temporal sulcus, and the intraparietal sulcus. Whether these regions lie within topographically-defined visual areas V2, V3, V3A, or V4 is not yet known, but the existence of regional variations in the laminar distribution of callosal-projection neurons may provide a useful anatomical basis for distinguishing functionally significant visual cortical subdivisions. 2088 THE PROJECTION OF THE PRETECTUM UPON THE INFERIOR OLIVARY COMPLEX: AN AUTORADIOGRAPHIC AND HORSERADISH PEROXIDASE ANALYSIS IN THE TREE SHREW, THE RAT AND THE CAT. J.T. Weber, M.F. Huerta, M. Behan*, G.J. Royce and J.K. Harting. Department of Anatomy, University of Wisconsin, Madison, Wisconsin, 53706.

We have been studying the organization of visual inputs to the inferior olivary complex. Thus far, in several mammals, we have identified a substantial projection to the medial accessory olive which arises from the intermediate and deep layers of the superior colliculus. In the present communication, we present data which show that a second primary retinal recipient zone, i.e., the pretectum, also sends a substantial projection to the inferior olive.

We placed injections of ^{3}H-proline into the pretectal complex of tree shrews, rats and cats. In each of the three mammals, transported protein can be seen overlying the ipsilateral dorsal cap of Kooy. This projection is especially dense in the tree shrew and the rat. Two additional ipsilateral pretectal olivary projections were observed in rats and cats: one to the rostral portion of the dorsal accessory olive, and one to the beta nucleus. In the cat, sparse label overlies a portion of the ipsilateral medial accessory olive, which is outside the region we previously identified as receiving input from the superior colliculus.

In an attempt to identify the specific cells of origin of the pretecto-olivary pathway, we injected horseradish peroxidase (HRP) into the inferior olive of several cats and one rat. Following large olivary injections in the cat, backfilled neurons can be identified within the nucleus of the optic tract (NTO), the anterior (APN) and the posterior (PPN) pretectal nuclei. In contrast, subsequent to HRP injections confined to the caudal portions of the inferior olive, backfilled neurons are present only within the NTO and the PPN.

Injections of HRP into the inferior olive of the rat result in backfilled neurons being present only within the NTO and the APN. However, since the injection did not involve all olivary targets of the pretectum, it follows that additional pretectal cell groups in the rat might project to the inferior olive.

In summary, our findings reveal that there are species differences in the pattern of terminations of the pretecto-olivary pathway. Furthermore, it appears, at least in the cat, that the pretecto-olivary pathway arises from several pretectal cell groups.

2089 CONNECTIONS OF STRIATE CORTEX WITH THE POSTERIOR BANK OF THE SUPERIOR TEMPORAL SULCUS IN MACAQUE MONKEYS. R. E. Weller* and J. H. Kaas (Spon: R. A. Bombardieri). Depts. of Psychology and Anatomy, Vanderbilt University, Nashville, TN 37240.

In New World monkeys and prosimians, electrophysiological mapping methods have been used to reveal a topological representation of the visual hemifield in the temporal lobe that has been called the Middle Temporal Visual Area (MT). In these primates, MT is also characterized by having reciprocal connections with striate cortex (Area 17). MT has not been defined by mapping experiments in Old World monkeys, but a number of investigators have shown that a region of cortex on the posterior bank of the superior temporal sulcus (STS) in the temporal lobe receives projections from striate cortex. Furthermore, Ungerleider and Mishkin (Anat. Rec., '78) have recently reported that the patterns of projections from striate cortex to STS in macaque monkeys corresponds to the known retinotopic organization of MT, and they suggested that the receiving zone in the STS is the homologue of MT. The present results support that conclusion.

Connections of cortex on the banks of STS were determined by injecting ^{3}H-proline, horseradish peroxidase (HRP), or ^{3}H-proline plus HRP into various locations in striate cortex of 10 cerebral hemispheres in 7 macaque monkeys (Macaca fascicularis). The ^{3}H-proline experiments defined a region along the posterior bank of STS with input from striate cortex. Most of the label was concentrated in layer IV and the inner part of layer III. The location of the label in STS varied with the injection site, and multiple injection sites resulted in multiple zones of label in STS. HRP injections in striate cortex resulted in HRP-positive cells in the same region of STS that received projections from striate cortex. A large injection zone in striate cortex resulted in a large region of labeled cells in STS of about 10mm in width. Most of the labeled cells were in layer VI, and many of these cells could be identified as pyramidal neurons. Occasionally, HRP-positive neurons were also found in layer V, and a few labeled cells were encountered in layer III. In addition, a few scattered labeled neurons were sometimes seen outside of the STS. Labeled neurons were also found in Area 18 following the striate injections, and these neurons were largely in layer V. For comparison, large HRP injections were made in Area 17 (and extending partly into Area 18) in both hemispheres of one squirrel monkey, a New World monkey. As expected, a large number of cells in layer VI of MT were labeled.

The results show that a region of STS in macaque monkeys is reciprocally connected with striate cortex in a pattern very similar to that of MT in New World monkeys and prosimians. We conclude that a region of STS in Old World monkeys contains MT.

2090 ALBINISM & OPTIC NERVE DEFORMITIES: ALBINO VS. BLACK C57BL/6J-c^{2J} MICE. I.S. Westenberg. V.A. Hosp., Phoenix, AZ 85012.

The incidence of deformed optic nerves (ON) in albino rats of the Sprague Dawley strain has been reported as 70-97%, vs. 2% in pigmented rats of the Long-Evans strain. This is relevant to recent studies of abnormal retinal projections linked to albinism in rats, because most such reports have involved this albino strain. In the original report there were two independent variables, albinism (albino vs. pigmented) and strain (Sprague Dawley vs. Long-Evans). As in previous "between-strains" comparisons of Sprague Dawley rats vs. pigmented rats of other strains, there was no way to factor out the effects of albinism (genetic differences at the C locus) from the effects of strain (genetic differences at other loci); i.e., the variables of albinism and strain were confounded. The goal of the present experiment was to determine the role of one of these variables, albinism, in ON deformities.

In the present experiment albinism was the independent variable and strain was held constant. Specifically, the independent variable was 1 gene at the C locus, while genes at all other loci were held constant across all subjects; i.e., subjects were albino or pigmented but otherwise genetically identical (coisogenic). Such a "within-strain" comparison is possible with inbred pigmented and albino mice of the C57BL/6J-c^{2J} strain. Albino C57BL/6J-c^{2J} mice have 2 mutant c^{2J} genes at the C locus (c^{2J}/c^{2J}), while pigmented C57BL/6J-c^{2J} mice have 1 normal "+" gene and 1 mutant c^{2J} gene at the C locus ($+/c^{2J}$). Otherwise, pigmented and albino C57BL/6J-c^{2J} mice are genetically identical. Thus albinism can be varied while strain is held constant.

The ON of 109 albino C57BL/6J-c^{2J} males were compared to the ON of 113 black C57BL/6J-c^{2J} males; each of 63 litters provided at least 1 albino and 1 black male. All mice were bred in the Phoenix V.A. mouse colony from Jackson Laboratory stock. As part of another experiment the right eye of each mouse was removed at 100 days of age; later each was perfused with saline and fixative. Each left eye was removed, and each brain was removed with ON intact. Grossly abnormal ON were observed in 1 albino and 3 black males; a large kink occurred in the right ON of 1 albino and 2 black mice and in the left ON of 1 pigmented mouse. Each of the 4 mice was from a different litter and had albino and pigmented male littermates with normal ON. The deformity was not related to maternal genotype or pedigree. The incidence of deformed ON in C57BL/6J-c^{2J} mice corresponds to that of pigmented Long-Evans rats rather that that of Sprague Dawley albinos. It was lower for albino mice than for pigmented mice of the same inbred strain. Thus, when strain is held constant, albinism is not related to increased ON deformities, at least not in C57BL/6J-c^{2J} mice.

2091 QUANTITATIVE EM ANALYSIS OF THE DORSAL LATERAL GENICULATE NUCLEUS OF MACACA MONKEYS. James R. Wilson and Anita E. Hendrickson. Dept. of Ophthalmology, Univ. of Wash., Seattle, WA., 98195.

The number of vesicle-containing profiles and synaptic densities in the parvo- and magnocellular laminae and interlaminar zones of the dorsal lateral geniculate nucleus (dLGN) were counted and their relative frequencies determined in normal adolescent monkeys. Comparable counts were also made in the dLGN of adolescent monkeys deprived from 2 weeks postnatally by monocular lid-suture.

In the parvocellular laminae and in all of the interlaminar zones of the dLGN from normal Macaca, approximately 50% of the synaptic densities seen were from small profiles with closely-packed round vesicles (RSD; the majority most likely originating in cortex) ending on dendrites. About 20% of the synaptic densities were made by larger profiles with loosely-packed round vesicles (RLP; of retinal origin) ending on dendrites, and a similar number (~20%) were from flattened vesicle-containing profiles (F; probably intrageniculate origin) which also ended on dendrites. A small percentage (~10%) of the total synaptic densities were presynaptic to profiles containing flattened vesicles; these densities were formed by all three terminal types. Within the magnocellular laminae the relative number of F profiles and their synaptic densities was found to be higher than in the parvocellular or interlaminar zones. The profile number per unit area in the laminar and interlaminar zones was comparable; the lack of RLP terminals in the interlaminar zones was made up by increased numbers of RSD, F, and unclassified profiles. A Golgi analysis of the dLGN neurons indicated that the dendrites within the interlaminar zones were from a variety of neurons with cell bodies located both in the laminar and interlaminar zones. The only difference noted at the EM level for the counts made in the dLGN of deprived monkeys was an increase in the ratio of RSD to F profiles in the interlaminar zones - no quantitative differences were found between the deprived, non-deprived, or normal laminae of the dLGN in these counts.

We infer from the greater relative frequency of F terminals in the magnocellular laminae that there is probably more inhibition upon the proximal dendrites of these cells, which might relate to several electrophysiological aspects of Y-cell characteristics in the magnocellular laminae. These counts also demonstrate the importance of the interlaminar zones since these zones contain large numbers of synaptic densities and dendrites. The change noted in the deprived monkeys further emphasizes the possibility of significant interactions occurring in these interlaminar zones.

2092 CIRCLING FOLLOWING UNILATERAL LESIONS OF THE SUPERIOR COLLICULUS CORRELATED WITH CORTICAL NOREPINEPHRINE LEVELS. Jacqueline M.S. Winterkorn, Robert A. Ross and Thomas H. Meikle, Jr. Cornell Univ. Medical Coll., New York, N.Y. 10021

Unilateral lesions of the superior colliculus in cats have been reported to produce compulsive ipsiversive circling, which has been attributed to destruction of neurons in deeper layers of the colliculus which project through the tectospinal tract to the reticular formation and cervical spinal cord. Other reports have stressed that lesions interrupting ascending catecholamine pathways in the brainstem also are associated with post-operative circling. Because these catecholamine pathways ascend in the midbrain tegmentum subjacent to collicular neurons from which the tectospinal tract arises, and because lesions of the superior colliculus frequently encroach upon the tegmentum, the present study was designed to test the hypothesis that ipsiversive circling following unilateral ablation of the superior colliculus is due, not to interruption of tectospinal efferents from the colliculus, but rather to interruption of pathways ascending in the tegmentum ventral to the superior colliculus.

In each of 28 adult cats, one of the following unilateral brain lesions was made: superficial superior colliculus; deep superior colliculus; tectospinal tract; locus coeruleus; midbrain tegmental locus of dorsal adrenergic bundle. On each cat, behavioral tests, histological confirmation and biochemical assays of levels of activity in forebrain of the biosynthetic enzymes for dopamine and for norepinephrine were performed independently.

The results indicate that (1) superficial lesions of the superior colliculus do not produce circling and do not produce any change in the biochemical parameters studied; (2) lesions of the superior colliculus which include deep layers and encroach to varying degrees upon midbrain tegmentum produce varying degrees of ipsiversive circling highly correlated with decreased norepinephrine in ipsilateral cortex; (3) unilateral lesions of the tectospinal tract do not produce circling and do not produce any change in biochemical parameters; (4) lesions of the locus coeruleus produce significant decreases in cortical norepinephrine but do not produce ipsiversive circling; (5) discrete lesions of a small region of midbrain tegmentum can produce ipsiversive circling together with decreased cortical norepinephrine.

These results strongly suggest that circling after unilateral lesions of the superior colliculus is due not to interruption of the tectospinal tract but to damage of a critical region in the midbrain tegmentum, ventral to the superior colliculus. Although the dorsal adrenergic bundle passes through this critical region, ablation of the adrenergic cell bodies in the locus coeruleus does not produce ipsiversive circling.
